Development of three color variants of super-brilliant luciferase for multi-color, real time imaging of gene expression and dynamics of organelles and the cytoskeleton without external illumination.

A. Takai¹, R. Haruno², T. Nagai^{2,3}, Y. Okada¹;

¹RIKEN Quantitative Biology Center (QBiC), Osaka, Japan, ²Osaka Univ, Osaka, Japan, ³JST PRESTO, Tokyo, Japan

Since bioluminescence does not require excitation light, it is free from auto-fluorescence. Therefore, it has been used for quantitative analysis of gene expression and in vivo imaging. Furthermore, it is free from potential phototoxicity and is compatible with optogenetic tools. However application of bioluminescent imaging has been limited mainly by two drawbacks. Firstly, the light output from the bioluminescent protein or luciferase was much darker than fluorescent proteins (FPs), making it difficult to study fine structures such as cytoskeletal dynamics with luminescent imaging. Secondly, color variants of luciferase have been limited compared with FPs, precluding multicolor imaging.

In our recent study, we addressed the first limitation by developing a super brilliant yellow luminescent protein, Nano-lantern (Saito et al., *Nat. Commun.* 2012). In this study, we have overcome the second barrier. We report the development of cyan and orange variants of Nano-lantern, both of which are even brighter than the original yellow Nano-lantern by 1.5-2.3 times, and bright enough for observation with the naked eye or with a smartphone camera. Fusions of these multicolor Nano-lanterns with a variety of subcellular localization tags showed correct localization in both luminescent and fluorescent imaging, demonstrating their utility as imaging probes. In addition, expansion of the color palette of Nano-lanterns enabled not only multicolor luminescent imaging of subcellular structures, but also expression analysis of multiple genes at single cell level in embryonic stem cells, which are known to be very sensitive to phototoxicity. Furthermore, by combining split luciferase complementation with Ca²⁺-sensing peptide (CaM-M13), we demonstrated simultaneous measurement of Ca²⁺ dynamics in the nucleus and mitochondria.

Our multicolor Nano-lanterns are expected to be excellent imaging tools for gene-expression analysis, in vivo imaging, stem cell study and combinatorial analysis with optogenetics. Considering that the expanded color palette of FPs has driven wider application of fluorescent live imaging, we believe that

our multicolor Nano-lanterns should change the world of luminescent imaging from dim and monochrome to extremely bright and colorful.

Board Number: B101

Development of novel in situ and in vivo RNA detection methods based on FIT probes.

I. Gaspar¹, F. Hövelmann², A. Ephrussi¹, O. Seitz²;

¹EMBL, Heidelberg, Germany, ²Humboldt University, Berlin, Germany

We have been developing new tools based on fluorogenic forced intercalation (FIT) probes for RNA detection quantification and interference in biological samples. Upon duplex formation with target nucleic acids, the base surrogates TO dye increases its quantum yield and brightness substantially (>10 fold). We turned FIT probes brighter by including a second, brighter, slightly red shifted variant dye, JO, which is hardly responsive. In this setup TO acts as a light harvester that feeds JO - we showed that a single FIT probe is sufficient to allow detection of oskar mRNA in a rapid, wash free FISH setup using conventional wide-field microscopy, making it an ideal tool for RNA localization screens.

Locked nucleic acids (LNA) immediately adjacent to the TO base surrogate also enhance brightness – without significantly affecting responsiveness – by shortening the distance between stacked nucleotides in duplexes. This unique behavior of FIT probes allows synthesis of nuclease resistant oligos that are bright and contrasted enough for use in live imaging: as few as two LNA-containing FIT probes targeting different segments of oskar mRNA are sufficient to monitor oskar RNP motility in living oocytes. Motility data obtained by using 3-5 different probes in wild-type oocytes recapitulate what has been reported with the oskMS2-GFP system, indicating that this is a viable, non-transgenic alternative for studying mRNP biogenesis in vivo.

While normally the aim is to avoid interference with biological processes, nuclease-resistant oligos can also be targeted against RNA secondary structures and/or protein binding interfaces of interest. FIT probes, in addition, report successful hybridization, allowing the testing of the functional role of RNA segments. We find that a FIT probe targeting the 3' of the proximal stem of the spliced oskar localization element (SOLE) that is essential for efficient kinesin-dependent transport and oskar localization, causes motility defects nearly identical to those observed when mutating the SOLE sequence in transgenic oskar mRNAs.

Finally, we demonstrated that TO fluorescence reaches its maximum at stoichiometric probe-to-target ratio, and equipping FIT probes with a Cy7 presence reporter we could quantify oskar mRNA concentrations in situ. Although this qFIT method lacks single molecule sensitivity at the moment, it can measure high RNA concentration - even hundreds of RNA molecules within a confocal unit - providing a complementary approach to single molecule FISH studies.

P3**Board Number: B102****Co-opting fluorescent proteins for cell-specific gene manipulation.**C. Tang¹, T. Szikra², Y. Kozorovitskiy³, M. Teixeira², S. Lapan¹, B. Sabatini³, B. Roska², C. Cepko¹;¹Genetics and Ophthalmology, Harvard Medical School/HHMI, Boston, MA, ²Neural Circuit Laboratories, Friedrich Miescher Institute for Biomedical Research, Basel, Switzerland, ³Neurobiology, Harvard Medical School/HHMI, Boston, MA

Studies of the cell biology of multicellular organisms would be greatly facilitated by the ability to manipulate gene expression in any desired cell type. However, it remains a challenge to achieve cell-specific gene manipulation in many model systems, especially the mouse nervous system. Fluorescent proteins are commonly incorporated into transgenic organisms for labeling specific cell populations, but the unmodified forms cannot control biological activities. Using GFP-binding proteins derived from Camelid antibodies, we co-opted GFP as a scaffold for inducing formation of biologically active complexes, developing a library of hybrid transcription factors that control gene expression only in the presence of GFP or its derivatives. The modular design allows for variation in key properties such as DNA specificity, transcriptional potency, and drug dependency. Production of GFP controlled cell-specific gene expression and facilitated functional perturbations in the mouse retina. Further, retrofitting existing transgenic GFP mouse and zebrafish lines for GFP-dependent transcription enabled applications such as optogenetic probing of neural circuits. Current efforts to expand GFP-regulated activities, such as for GFP to directly control Cre recombination, will be discussed. This work establishes GFP as a multifunctional scaffold and opens the door to selective manipulation of diverse GFP-labeled cells across transgenic lines. This approach may also be extended to exploit other intracellular products as cell-specific scaffolds in multicellular organisms.

P4**Board Number: B103****“Decorating” cells with genetically encoded fluorescent proteins – what color suits you best?**J. Monbo¹, L. Tu², A. Joseph², O. Ospovat¹, A. Myers¹, D. Grunwald²;¹RNA Therapeutics Institute, University of Massachusetts Medical School, Worcester, MA, ²RNA Therapeutics Institute, University of Massachusetts Medical School, Worcester, MA

A key aspect of simultaneous multicolor single molecule real-time imaging in the living cell is choosing the appropriate combinations of fluorescent proteins. While ample information is available on molecular brightness, photo-stability, pH sensitivity and monomeric nature of most fluorescent proteins, interpolating the published data into performance in mammalian live cell experiments has been challenging. This leads to situations where the effort of testing new fluorescent proteins, combined with re-cloning of genetic constructs favor the use of suboptimal fluorescent protein combinations. The price paid is that less signal is collected using higher excitation power shortening the observation time of the

fluorescent protein. Additionally, higher excitation can also mean photo-damage to the cell thereby inducing a 'stress' reaction, potentially compromising results. Using a list of parameters, we tested 38 different fluorescent proteins for their suitability in live cell single molecule imaging. We refer to this set as a 'toolbox', and we have systematically evaluated all the fluorescent proteins for labeling of mobile (diffusing fluorescent protein & diffusive fusion protein) and immobile molecules (nuclear pore marker). We pay particular attention to the amount of fluorescence signal under low excitation power imaging conditions, sub-cellular (mis)-localization, cross excitation and cross emission at non-maximal photon output. This 'toolbox' will be of great use to the microscopy community.

A Live Cell Antifade Solution for GFP Imaging.

K.M. Chambers¹;

¹Thermo Fisher Scientific, Eugene, OR

Time-lapse, fluorescent imaging is a powerful tool in cell biology research. Photobleaching is one of the largest barriers for longer term imaging of fluorescent proteins and dyes. This phenomenon is caused by exposure to the intense light required to excite them. The loss of intensity of the fluorescent signal can leave researchers with incomplete or unclear data. Measures taken to minimize light exposure should be designed into each time-lapse experiment (Brown et al., 2009 and Waters, 2013). Factors to consider when designing these time-lapse, fluorescent experiments are light exposure time, the intensity of the light, and frequency of sampling (Brown et al., 2009) which can decrease the effects of photobleaching in an experiment. In addition, novel, oxygen-scavenging methods can also be used to reduce the amount of photobleaching observed in these types of experiments. Here is a study of a set of compounds analyzing their effectiveness at reducing photobleaching of fluorescent proteins and fluorophores. Results from a model system using GFP, RFP, and fluorescent dyes have led to a solution which reduces photobleaching in GFP, RFP, and several other dyes.

Board Number: B105

A palette of near-infrared fluorescent proteins.

D.M. Shcherbakova¹, M. Balaban², V.V. Verkhusha²;

¹Department of Anatomy and Structural Biology and Structural Biology and Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, ²Anatomy and Structural Biology and Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY

The genetically encoded near-infrared fluorescent probes are preferable for non-invasive in vivo imaging. In the near-infrared spectral region (650–900 nm) mammalian tissues are relatively transparent to light because the combined absorption by hemoglobin and water is minimal. Previously, we have

developed five spectrally distinct fluorescent proteins, such as iRFP670, iRFP682, iRFP702, iRFP713 (aka iRFP) and iRFP720, from bacterial phytochromes (1, 2). As a chromophore, iRFPs use a heme derivative, called biliverdin, abundant in mammalian cells. All iRFPs incorporate endogenous biliverdin efficiently and autocatalytically, do not require its exogenous supply and, therefore, can be used as easily as GFP-like proteins. iRFPs are dimers and can mainly serve for labeling of organelles and whole cells. iRFPs have enabled multicolor imaging of deep tissues in living animals.

Here, we report the development of monomeric iRFPs (miRFPs) suitable for protein tagging, which also do not require external biliverdin to fluoresce. To engineer miRFPs we applied a combination of the rational and random mutagenesis, followed by a high-throughput screening. As a result, we have obtained three spectrally different monomeric near-infrared proteins, named miRFP670, miRFP703 and miRFP708. miRFPs are characterized by a high effective brightness in mammalian cells, a high pH stability and a high photostability. We demonstrated that miRFPs perform well as fusion tags for cellular proteins. The set of miRFPs should enable imaging of several tagged proteins in living mammals, and thus will be useful in cell and developmental biology and biomedicine. The developed rational design should allow efficient engineering of future miRFPs with desirable spectral and biochemical properties.

Board Number: B106

Two-color imaging using spectral variants of iRFP670 and iRFP682 near-infrared fluorescent proteins.

M. Baloban¹, D.M. Shcherbakova², V.V. Verkhusha³;

¹Department of Anatomy and Structural Biology and Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, ²Department of Anatomy and Structural Biology and Structural Biology and Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, ³Anatomy and Structural Biology and Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY

The new class of fluorescent proteins (FPs) engineered from bacterial phytochromes (BphPs) [1] attracts much attention for in vivo imaging due to their near-infrared (NIR) fluorescence spectra. These FPs utilize widely available in mammalian cells biliverdin (BV), a product of heme degradation, as a chromophore and, therefore, are as easy to use as common GFP-like proteins. We recently reported five NIR FPs, called iRFPs, with different fluorescence and biochemical properties [2]. Interestingly, two of them, iRFP670 and iRFP682, exhibited the twice higher molecular brightness, as well as the blue-shifted absorbance (643 nm and 663 nm) and fluorescence (670 nm and 682 nm) compared to other iRFPs. Here we characterized the unusual properties of these NIR FPs in detail. Our biochemical and biophysical analysis showed that iRFP670 and iRFP682 incorporate the BV chromophore in two distinct confirmations. A single amino acid mutation resulted in a depletion of one BV confirmations in the protein binding pocket and, consequently, in 30 nm red-shifts of both absorbance and fluorescence. The

point mutation also caused a slight decrease in the molecular brightness and an increase in the pH stability of the obtained red-shifted variants, which we named iRFP670-red and iRFP682-red. The effective brightness of the iRFP670-red and iRFP682-red in live mammalian cells was comparable to that of the parental proteins, suggesting that the high efficiency and high specificity of the incorporation of endogenous BV chromophore was not affected. Spectrally resolvable fluorescence of the iRFP670 and iRFP670-red pair, as well as of the iRFP682 and iRFP682-red pair, allowed easy separation of two cellular populations using FACS cytometry and straightforward two-color fluorescence microscopy of live cells, thus making them the probes of choice for cell labeling in the NIR region. Our studies are also beneficial for a rational molecular design of future enhanced NIR FPs from a variety of natural BphPs.

Board Number: B107

Minimal tags for rapid dual-color live cell labeling and super-resolution microscopy.

I. Nikić¹, T. Plass¹, O. Schraidt¹, J. Szymański¹, J. Briggs¹, C. Schultz¹, E. Lemke²;

¹European Molecular Biology Laboratory (EMBL), Heidelberg, Germany, ²Structural and Computational Biology Unit, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

The choice of appropriate labeling technique is crucial for optimal super-resolution microscopy (SRM). Labeling density, probe size and photophysical properties are particularly important and to great extent determine the power of SRM. In addition, the probe should be attached as close as possible to the target protein as large linkers can induce artifacts and lower resolution. Many organic fluorophores offer small size and good photophysical characteristics, especially when compared to widely used GFP variants, but their direct linking to the target proteins remains challenging. We present a method that permits direct coupling- with virtually no linker- of SRM compatible dyes site-specifically to the target proteins by combining Amber codon suppression and click-chemistry technologies. To achieve this, host cells are modified to incorporate unnatural amino acids (UAAs) in response to a unique codon during translation. These UAAs carry chemical groups (strained alkynes and alkenes) that can be directly attached to tetrazine functionalized dyes in a special type of a fully biocompatible click-chemistry reaction named the inverse-electron-demand Diels-Alder cycloaddition (SPIEDAC). By testing different tetrazine derivatives of organic dyes, we tuned the SPIEDAC reaction in an orthogonal descendant for rapid dual-color protein labeling. These two reactions allowed labeling of distinct insulin receptor populations and Influenza VLPs (virus-like particles) with two different dyes in living mammalian cells, as shown by SRM. While we demonstrate the applicability of our tools for SRM, generic SPIEDAC ligation mechanism is transferrable to other techniques and could e.g. be used for making PET/MRI imaging tracers.

P9**Board Number: B108****Multicolor Fluorescence Photoactivation Localization Microscopy by Spectral Measurements.**M.J. Mlodzianoski¹, S. Gunewardene¹, N.M. Curthoys¹, S. Carter¹, S.T. Hess¹;¹Department of Physics and Astronomy, University of Maine, Orono, ME

The localization-based super resolution microscopy techniques Fluorescence Photoactivation Localization Microscopy (FPALM) (Hess et. al. 2006), Photoactivatable Localization Microscopy (PALM) (Betzig et. al. 2006), and Stochastic Optical Reconstruction Microscopy (STORM) (Rust et. al. 2006) circumvent the diffraction limit by measuring subsets of single molecules over a period of time. Spatially separated single molecules can then be localized with an uncertainty much smaller than the diffraction-limited resolution of the microscope. Reconstruction of images using localized single molecule positions can achieve a final image resolution on the order of tens of nanometers, a roughly ten-fold improvement over the diffraction limited resolution of ~250 nm.

Imaging single molecules records information that is lost in ensemble fluorescence microscopy techniques. This single molecule information has enabled additional imaging modalities and has led to three-dimensional super-resolution imaging (Huang et. al. 2008, Juetten et. al. 2008), dipole orientation (Gould et. al. 2008), and imaging of multiple fluorescent species (Huang et. al. 2007, Shroff et. al. 2008, Gunewardene et. al. 2011). Multicolor techniques are especially important in biological applications because they allow for the direct comparison of the spatial distribution of two or more differently labeled structures.

Here, we describe a novel multicolor imaging method that measures the emission spectrum of each single molecule directly. Fluorescence is split into two channels with a standard 50:50 beamsplitter; one channel measures the spatial distribution while the second channel is sent through a dispersive optic. Within the spectral channel, the molecular image is shifted and broadened according to its emission spectrum. Quantification of the emission spectrum allows for identification of the fluorescent species. Previously, ratiometric simultaneous multicolor images were limited to four or fewer different species if the collected number of photons was large and background noise low. Depending on the background noise, number of photons collected, and the width of the spectral window, our spectral method can distinguish a larger number of species simultaneously. Additionally, a large set of novel super-resolution imaging methodologies can be envisioned, based on changes in the emission spectra of fluorescent molecules as a function of pH, temperature, hydrophobicity, time, or any method which induces fluorescence emission spectra changes in the sample.

P10**Board Number: B109****Nanometer Resolution with the Time-resolved Confocal Microscope MicroTime 200.**

V. Buschmann¹, O. Schulz¹, M. Koenig¹, B. Kraemer¹, S. Tannert¹, M. Patting¹, F. Koberling¹, R. Erdmann¹;
¹PicoQuant GmbH, Berlin, Germany

Superresolution microscopy is about to evolve into a standard tool for biological research. Overcoming the diffraction limit for fluorescence imaging has been shown to be crucial for addressing various relevant biological questions. However, the resolution is practically limited to about 20 nm for STED, STORM or PALM. Optical resolution below 20 nm can be easily achieved by combining confocal detection with AFM tip induced local fluorescence modulation. With FRET, distances even below 10 nm are readily accessible.

As an open confocal microscopy platform, the MicroTime 200 is the ideal tool to combine sub diffraction spatial resolution with ultrasensitive time-resolved detection. Picosecond pulsed lasers and confocal detection together with time-correlated single photon counting (TCSPC) allow this system to add the full benefit of fluorescence lifetime based experiments to address highly specific biological questions.

We present combined Confocal+AFM measurements on the single molecule level with DNA Origami structures proving a resolution of even below 10 nm. We show fluorescence lifetime based FRET imaging (FLIM FRET) to be a superior approach in the case of concomitant FRET subpopulations enabling the extraction of accurate FRET efficiencies and donor acceptor distances in the nanometer range.

For multi species cell labeling we developed a pattern matching based approach which can take spectral as well as fluorescence decay information into account to improve the label recognition and separation especially in complex cellular environments. Finally the time-resolved single photon analysis is also applied to diffusion based FCS measurements in live cells to identify parasitic autofluorescence contributions on the nanosecond timescale which otherwise hamper the extraction of accurate local concentrations.

Keywords: confocal microscopy, TCSPC, FLIM, FCS, FRET, AFM, single molecule, pattern matching

P11**Board Number: B110****Video-rate super resolution microscopy in living cells.**F. Huang¹, C.E. Laplante², Y. Lin³, T.D. Pollard^{1,2,4}, J. Bewersdorf¹;¹Department of Cell Biology, Yale University School of Medicine, New Haven, CT, ²Department of Molecular, Cellular and Developmental Biology, Yale University School of Medicine, New Haven, CT,³Department of Biomedical Engineering, Yale University School of Medicine, New Haven, CT,⁴Department of Molecular Biophysics and Biochemistry, Yale University School of Medicine, New Haven, CT

Super resolution microscopy based on single molecule localization relies on precise and accurate localization of large numbers of single molecules. However, the necessity of accumulating large numbers of localization estimates limits the time resolution typically to seconds to minutes^{1,2}.

Two major limitations are the acquisition speed and the photon budget. An EMCCD camera is usually used in such experiments. Replacing it with a recently introduced sCMOS camera results in leaps in both acquisition speed and effective quantum efficiency. However, the intrinsic pixel-dependent Gaussian noise of the sCMOS cameras introduces localization artifacts and greatly reduces the reliability of the results.

Here, we present a set of specially designed statistics-based algorithms that characterize an sCMOS camera for the first time and allow for unbiased and precise localization analysis. Using this method we demonstrate Cramer-Rao lower bound-limited single molecule localization with an sCMOS camera. Combining the novel algorithm with a recently developed multi-emitter fitting algorithm³ and optimized imaging condition, we show that this technique shortens the typical acquisition time for fixed samples by up to two orders of magnitude without compromising the field of view. Furthermore, we demonstrate localization-based super-resolution microscopy in live cells by monitoring dynamics of protein clusters, vesicles and organelles at a temporal resolution from 2 to 30 frames per second⁴.

These methods allowed us to investigate cytokinetic apparatus in live fission yeast at 20-30 nm resolution. In general, the significantly improved temporal resolution allows super resolution imaging of a large range of dynamic events in living cells.

Ultrafast super-resolution fluorescence live imaging with spinning disk confocal microscope optics.

Y. Okada¹, S. Hayashi²;

¹RIKEN Quantitative Biology Center (QBiC), Osaka, Japan, ²Olympus, Tokyo, Japan

Most current super-resolution (SR) microscope techniques surpass the diffraction limit at the expense of temporal resolution, compromising their applications to live cell imaging. Here, we report a new SR method based on the spinning-disk confocal microscope that achieves a spatial resolution of about 120 nm, double that of conventional microscopy. Theoretically, our method is equivalent to the structured illumination microscopy (SIM), but it is 10 times faster. Conventional SIM reconstitute a SR image from 9-15 raw images. The SR signals are modulated as Moire patterns in the raw images, and are extracted by the digital processing. Our method recovers the SR signals by the optical demodulation through the stripe pattern of the disk, and only a single averaged image through the rotating disk is required for a single SR image. Thus, the frame rate of our method is only determined by the speed of the disk and the camera. Based on this theory, we have modified a commercial spinning disk confocal microscope. The improved resolution around 120 nm was confirmed with biological samples such as nuclear pores or microtubules. The rapid dynamics of EB1 at the growing ends of the microtubules were observed with 10 ms image acquisition time. Since our method requires only little optical modifications, it will enable an easy upgrade from existing spinning disk confocal to a SR microscope for live cell imaging.

Board Number: B112

Device for microwave-enhanced processing of cryo-substitution for light and electron microscopy.

D.W. Dorward¹, J. Raae-Nielsen¹, B.T. Hansen¹, V. Nair¹, E.R. Fischer¹;

¹RTB/Microscopy Unit, NIH/NIAID/Rocky Mountain Labs, Hamilton, MT

Cryo-substitution of frozen hydrated samples is the premier method for preserving native structure of specimens sectioned for light and electron microscopy. Also called freeze substitution, sample processing involves replacing ice with fixatives in organic solvents at or below -80 degrees C, followed by gradual warming to permissive temperatures for chemical cross-linking, typically over a 2-5 day period. In order to facilitate substitution and fixation, we developed and tested a cryo-thermal device for regulating sample temperature within standard laboratory microwave processors. The system consists of a microwave processor modified to accommodate a cryo-thermal sample platform and an external

programmable controller. Time, temperature, transition triggers, and ramping rates are user-defined between ± 100 degrees C, and recorded in spreadsheet format during processing. Using the system, we processed high-pressure frozen *Bacillus subtilis*, *Saccharomyces cerevisiae*, *Borrelia burgdorferi*, mixed pond water biota, Plasmodium-infected erythrocytes, and Chlamydia-infected HeLa cells in under 90 min. Embedding in acrylic resins in the platform at -20 or -40 degrees C added about another hour. Cooling and heating rates exceeded 20 and 10 deg/min, respectively. Recorded sample temperature plateaus varied less than 0.5 degree. Structure, contrast, tomography, and immune labeling were equivalent or superior to that achieved by traditional cryo-substitution or standard ambient-temperature fixation. Membrane contrast was reversible by adjusting the temperature at which samples were transferred from fixative mixtures to solvent only. Equivalent fixative mixtures produced negative contrast of mitochondrial cristae when transferred out of fixative at -20 degrees, and positive contrast when transferred at 20 degrees C. The system also enabled sequential use of three separate fixatives, with washing steps, in approximately 3 hours. These results indicate consistent, flexible, efficient, and effective methods for preparing and preserving diverse cryo-samples in near native state for light and electron microscopy.

Board Number: B113

Title: Permeabilization Activated Reduction in Fluorescence (PARF): a novel method to measure kinetics of protein interactions with intracellular structures.

P.P. Singh¹, J.L. Hawthorne¹, O.A. Quintero¹;

¹Department of Biology, University of Richmond, Richmond, VA

Understanding kinetic information is fundamental in understanding biological function. Advancement in imaging technologies have allowed for the development of assays for kinetic analysis. Fluorescence recovery after photobleaching (FRAP) is one such method that can be used to determine the diffusion rate of fluorescently labeled proteins in cellular environments and the kinetics describing interactions with intracellular structures. Through examination of the recovery kinetics of a photobleached region of interest, a researcher can determine the apparent exchange rate of the bleached fluor and half-life for recovery under equilibrium conditions. Like many of the other experimental approaches using biophotonic analysis to gain kinetic insight, FRAP requires a significant investment in specific equipment. We have developed a technique to measure kinetic information that does not require such a specialized imaging setup. Permeabilization Activated Reduction in Fluorescence (PARF) is an imaging-based kinetic analysis that allows the user to determine an apparent off-rate for a fluorescently-tagged protein of interest. To create conditions where the off-rate is observable, cells expressing a fluorescently-tagged protein are permeabilized with 25 μ M digitonin. The plasma membrane becomes permeable to molecules up to 200kD in size, allowing for the unbound pool of labeled protein in the cytosol to diffuse into the media. As the media volume is much larger than the cytosolic volume, the concentration of the unbound pool decreases drastically, shifting the system out of equilibrium and favoring the release of bound-protein from the structure with which it is interacting. The loss of bound protein is observed as a

loss of fluorescence from the intracellular structures. Because this change from bound to unbound is a first-order reaction, PARF kinetics can be fit to a single exponential decay, providing an apparent off-rate and half-life for loss of fluorescence. To test this approach, we compared PARF analysis of GFP, GFP-VASP, and GFP-Mito with previously published FRAP analyses of those constructs. FRAP exchange rates and PARF loss rates were similar. We then examined the PARF kinetics of a panel of actin-binding proteins in the presence and absence of jasplakinolide. As predicted, stabilization of the actin network resulted in slower loss of fluorescence. These results demonstrate that PARF analysis of non-equilibrium systems can reveal information about binding interactions without the infrastructure investment required for other quantitative fluorescence approaches.

Board Number: B114

Quantitative screening of antifade mounting media for fluorescence microscopy.

S. Sweeney¹, D. Cash¹, K. Jamil¹, E. Welch¹;

¹Thermo Fisher Scientific, Eugene, OR

Despite advancements in dye chemistry, the development of brighter and more stable fluorescent proteins and advances in the sensitivity of microscopes, photobleaching remains a significant challenge in the capture and analysis of cellular images. Advanced imaging techniques such as three-dimensional Z-stacking require multiple images of the same section to be collected with intense illumination. Retention of fluorescent signal throughout the experiment is critical not only for image quality, but also quantification of the results. The mechanism of the photobleaching of fluorescent dyes is hypothesized to be via a photo-oxidative pathway, wherein the long-lived triplet excited state of a fluorescent molecule irreversibly complexes with reactive oxygen species. To mitigate the effects of photobleaching, “antifade” reagents are often added to mounting media. These reagents slow the loss of signal from fluorescent dyes during imaging experiments through several possible routes, including acting as reducing agents, reactive oxygen scavengers or triplet-state quenchers. A number of protocols exist for the preparation of mounting media, often glycerol and polyvinyl alcohol-based, containing reducing agents (e.g. para-phenylene diamine). In many cases, however, commercial mounting media provides decreased variability in performance over time required for careful cellular analysis. Choice of mounting medium is largely dependent upon the type of sample and sample preparation, the type of imaging involved and the specific fluorophores used. Often, choice of mounting media is a compromise of photobleach resistance, initial intensity, signal to background, compatibility with fluorophores, refractive index and other factors.

In order to evaluate antifade mounting media we have developed methods for quantitative assessment of photobleaching, initial intensity and signal-to-background using a combination of both confocal and wide field microscopy. Using these methods, we systematically screened a series of 20 fluorescent dyes, nuclear stains and fluorescent proteins (including TagGFP, TagRFP and mCherry) in multiple cell lines (HeLa, U2OS, A541). Samples were mounted using commonly used commercially-available mounting media for comparison. Ideally, mounting media should protect the broadest range of dye classes (e.g.

cyanine- or rhodamine-based) from photobleaching, while retaining bright initial intensity. Our analyses show that the performance of mounting media is highly variable and most will protect one subset of dyes significantly better than others, diminish initial intensity or increase off-cell background.

Board Number: B115

Observation of Individual Secretory Granules in Living Mast Cells Using Confocal Microscopy.

S. Tanaka¹, Y. Takakuwa¹;

¹Department of Biochemistry, School of Medicine, Tokyo Women's Medical University, Tokyo, Japan

Mast cells, which are distributed in the mucous membranes and epithelial tissue of the body surface, cause various allergic symptoms by releasing inflammatory mediators such as histamine from their intracellular secretory granules (SGs) in response to allergic stimuli (degranulation). It is hoped that the development of treatments that inhibit degranulation will enable the mitigation of allergy symptoms. To do so, it is necessary to observe the intracellular dynamics of these SGs to elucidate the process of their maturation, intracellular transport, and degranulation. However, it has been difficult to observe individual and distinct SGs by the conventional microscopic methods (which is by tagging SG marker proteins with fluorescent proteins) since marked fluorescent dispersion makes the target outlines unclear. Here, to overcome this problem, we observed individual SGs by overexpressing green fluorescent protein (GFP) in the cytoplasm of mast cells and using confocal microscopy to photograph the “absence of GFP” representing SGs that arose as a result of GFP not penetrating the granular lumen. First, we demonstrated that the accuracy of this new method is higher than that of the conventional observation. To validate the principle, we observed polystyrene beads labeled with a red fluorescent dye in a GFP solution. When we constructed 3D images of the beads from sequential tomography images, the dispersion of light caused the images derived from the red fluorescence to be greatly distorted in the direction of the z-axis, while the images derived from the “absence of GFP” were spherical and corresponded to the theoretical volume of the beads. Next, in a similar manner, we overexpressed GFP in the cytoplasm of the rat mast cell line RBL-2H3 and constructed 3D images. From these images, we obtained information on the construction of individual SGs (number of particles, size, volume, and arrangement), as well as on the cell as a whole. We demonstrated that the cells in these images indeed showed SGs by co-localization of red fluorescent protein-fused SG marker proteins (Neuropeptide Y or VAMP7) co-expressed in the cells. Furthermore, by inducing degranulation, we obtained information on the structure of exocytotic SGs in the cells. In this presentation, based on the structural characteristics of the SGs that we have thus obtained, we will discuss the process of the maturation, intracellular transport, and degranulation of SGs.

P17**Board Number: B116****3D nano stiffness mapping of intracellular compartment using correlative light atomic force electron microscopy (CLAFEM).**M. Popoff¹, N. Barois², S. Janel², A. bongiovanni², E. Werkmeister², S. Divoux³, F. Perez³, F. Lafont¹;¹CNRS UMR 8204-CMIP, Institut Pasteur de Lille, Lille, France, ²BioImaging Center Lille, Institut Pasteur de Lille, Lille, France, ³CNRS UMR144, Institut Curie, Paris, France

Mechanical properties of biological material like cells and tissues are known to play a key role the cell differentiation, cell division, cancer, diseases and other processes. Atomic Force Microscopy is routinely used to gain access to the precise information on the sample's topography and physical properties. We propose here to unravel the elasticity of different identified organelles and microorganisms inside cells, at the nanoscale, with a novel technique combining stiffness mapping, super-resolution fluorescence and electronic microscopies, named CLAFEM (Correlative Light Atomic Electron Microscopies). We report herein the first results on bacteria, Golgi, actin tail comets and autophagosomes in both fixed and living cells.

P18**Board Number: B117****Continuous throughput and long-term observation of single-molecule FRET without immobilization.**S. Tyagi¹, V. Vandelinder², N. Banterle¹, G. Fuertes¹, S. Milles¹, M. Agez¹, E. Lemke¹;¹Structural and Computational Biology Unit, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany, ²Sandia National Laboratories, Albuquerque, NM

Single-molecule FRET (smFRET) studies through Total internal reflection fluorescence microscopy (TIRFM) is a powerful method to extract and reveal hidden heterogeneity in biological systems from long-term FRET trajectories of individual single molecules. TIRFM popularity also owes to the possibility of adding exogeneous reagent and following the biological processes over long-time. The high signal to noise (SNR) necessary for observing fluorescence from single emitters is achieved by tethering single molecules within the shallow evanescent field (less than 200 nm) generated at the interface of coverslip and buffer. This requirement of tethering molecules to coverslip restricts the applicability of TIRFM to a limited set of biomolecules as complex immobilization procedures cannot be generally applied and sometimes perturb the native state of the biological sample. Here we present a versatile technology, termed "SWIFT" (Single molecules Without Immobilization For TIRFM) that enables us to perform multisecond observation of freely diffusing single molecules with high SNR while bypassing the need for immobilization procedures. SWIFT is a microfluidic-nanofluidic hybrid platform where nanochannels are actively and reversibly generated by collapsing 1 µm deep flow channels using pressurized nitrogen gas in a control channel, which additionally increases photo stability of fluorophores by removing oxygen.

Biomolecules continuously flow through 12 parallel 100 nm deep channels, which keep them within the evanescent field. The microfluidic device is fabricated with soft lithography and molding techniques out of an elastomeric material, which enables to exploit the full potential of microfluidics including low-cost, ease of use and fast solution exchange. We show that several second long trajectories of thousands of molecules can be recorded with millisecond time resolution, illustrating the potential for long-term automated and high throughput experiments. We demonstrate the power of our method by studying a variety of complex nucleic acid and protein systems, including DNA, Holliday junctions, nucleosomes and human transglutaminase 2.

Video-enhanced polychromatic polarized light microscope (VEP polscope): bringing colors to the colorless world.

M. Shribak¹, E. Iourieva¹;

¹Marine Biological Laboratory, Woods Hole, MA

A conventional polarized light microscope, which is sometimes called a “polscope” for short, shows a two-dimensional image of birefringence due to structural or internal anisotropy of the specimen under investigation. The simplest polarizing setup, consisting of two crossed linear polars, produces pictures whose contrast is directionally sensitive. The image brightness varies proportionally with $\sin^2 2\alpha \sin^2(180^\circ - \delta/\lambda)$, where α is the specimen’s slow axis azimuth relatively to the direction of polarization of the illuminating light, δ is the specimen retardance and λ is the wavelength. If the slow axis and the light polarization are parallel, the brightness is zero. The brightness is highest if the slow axis is oriented at 45° and 135° respectively. Also the brightness is zero if the retardance equals to an integer number of wavelength. When the specimen under investigation is illuminated with white light and its retardance increases, then the brightness of all the wavelengths increases as well and the specimen appears grey. After the retardance has approached 400 nm, the blue part of the spectrum is suppressed and the specimen shifts to yellow and then red. Once the retardance reaches 600 nm, the red part of the spectrum has been blocked and the specimen turns blue and then green. The specimen exhibits Newton’s interference colors. In conventional polarized light microscopy, the color is solely determined by retardance and does not depend on the slow axis azimuth. The polarized light coloring is widely used in mineralogy and petrography. But this phenomenon could not be utilized in biology because most biological specimens exhibit a retardance of less than several tens of nanometers. Therefore, they are colorless. Even adding the first order red compensator, with a retardance of 575 nm does not help much. In this case, zero retardance corresponds to purple, and a slight color variation could be observed when the retardance change is at least 50 nm. Recently, we developed a new video-enhanced polychromatic polarized light microscope that produces interference colors at retardance

level of several nm. The polychromatic polscope employs a new principle of generating interference colors from white light. Here, color is determined by the orientation of the particle, not by its retardance. Thus, the full spectrum color can be achieved at a much lower retardance. The polychromatic polscope shows an orientation-independent birefringence image without requiring any digital computation. An eye or camera can directly see the colored polarization image in real time with a brightness corresponding to the retardance level and color corresponding to the slow axis azimuth. The previously colorless birefringent cell parts become vividly colored. We applied the new polychromatic polscope for imaging to a number of biological specimens including cancer tissue, malaria samples, mouse brain slices, various diatoms, zebrafish and sea urchins embryos, rotifer, paramecium, stentor, planaria, etc. Some of examples will be shown in the report.

Improving the imaging of unstained specimens in bright field microscopy.

C. Hernandez Candia¹, B. Gutierrez-Medina²;

¹Molecular Biology, IPICYT, San Luis Potosi, Mexico, ²Advanced Materials, IPICYT, San Luis Potosi, Mexico

Bright field is the simplest and most widespread light microscopy modality. However, its use in cellular biology has been limited due to lack of contrast in the imaging of thin, transparent samples such as cells. Instead, more evolved microscopy techniques (e. g. differential interference contrast, dark field, phase contrast, among others) have been used. An alternative to increase image contrast is deconvolution processing, a powerful method often used in fluorescence microscopy. However, application of deconvolution processing to bright field images has been scarce, mainly because acquisition of the corresponding point-spread function (PSF) has been difficult. In this work, we present direct measurement of the phase PSF of a high-aperture microscope operating in bright field. Polystyrene nanoparticles of 100 nm in diameter serve as the point objects that are imaged with high contrast and low noise using conventional microscopy plus digital image processing. To our knowledge, this is the first report that describes the experimental assessment of this function. The measured PSF allows us to demonstrate conventional deconvolution on the bright field images of living, unstained *Escherichia coli* cells, showing improved definition of cell boundaries and sub-cellular features. In addition, we were able to integrate the same digital imaging processing technique to an optical tweezers setup designed to perform single-molecule experiments. Using this setup, we were able to follow the stepping of the motor protein kinesin on clearly-imaged individual microtubules in real-time. In the context of optical manipulation, our microscopy approach using standard bright field eliminates the disadvantages of adding extra optical components that often constrain the properties of the optical trapping beam. Altogether, our studies provide a simple method to acquire the phase PSF, make possible the extension of deconvolution processing beyond fluorescence, and show that the improvement of bright field imaging via digital image processing can benefit single-molecule techniques such as optical tweezers.

P21**Board Number: B120****Exploring cellular ultrastructure in 3D by Array Tomography and SEM imaging: A case study on zebrafish immune cells isolated by FAC-sorting.**I.U. Wacker¹, C. Bartels¹, M. Thaler², C. Grabher³, R.R. Schroeder⁴;¹CAM/Cryo-EM, Universitaet Heidelberg, Heidelberg, Germany, ²Carl Zeiss Microscopy GmbH, Oberkochen, Germany, ³ITG, KIT, Karlsruhe, Germany, ⁴Cryo Electron Microscopy, Universitaet Heidelberg, Heidelberg, Germany

Array tomography (AT) has been introduced almost ten years ago, initially to characterize neurons by multiplexing antibody labeling on serial sections of brain slices adhering to glass slides (Micheva & Smith, 2007, *Neuron* 55, 26). Such arrays can also be imaged in a SEM when deposited on conductive substrates such as silicon wafers or metal-coated glass (Wacker & Schröder, 2013, *J Microsc*, 252, 93). Here AT is applied to unknown GFP-expressing populations of blood cells isolated from zebrafish by FAC-sorting. Contrary to human blood cells which can be identified and sorted after staining with different combinations of CD markers for zebrafish such an approach is not possible due to lack of suitable antibodies. Some blood cells, however, have typical ultrastructural features so we aimed at reconstructing whole cells in 3D. Sorted cell populations were chemically fixed and embedded in epoxide resin. Arrays of a few hundred serial sections were produced using an ultramicrotome and a custom-built handling device. Stacks of SEM images were recorded automatically with the newly developed Atlas-AT software (Carl Zeiss Microscopy), aligned and volume-rendered or segmented. We established organelle inventories of various cell populations of the lymphoid lineage isolated from three different hematopoietic organs: Whole kidney marrow (WKM), thymus, and spleen. We found two predominant phenotypes with similar organelle inventories but different surface morphologies. One phenotype, showing a ruffled surface represented the majority of cells in a sort from spleen, was present to a lesser degree in WKM and not at all in thymus. The other phenotype had a smooth surface and few longer processes, constituted the major population in the sort from thymus and proportionally smaller populations in spleen and WKM. These observations were confirmed quantitatively by classifying and counting all cell profiles present in one section – on several sections of an array far enough apart to ensure that no cell was counted twice. AT can also be used to identify rare events: In co-cultures of cell populations isolated from WKM or thymus with the human promyelocytic leukemia cell line HL60 we found a few cell couples consisting of fish cells attached to HL60 cells. Due to the close contact between the plasmamembranes of both cells and a concentration of secretory organelles towards the contact zone we concluded this to be immunological synapses, indicating cytotoxic activity for our unknown cells. This was proven by time-lapse light microscopy imaging of co-cultures. Taken together our case study demonstrates that AT can be extended from brain mapping to general imaging of exceedingly large volumes, such as whole cells, tissues and even small organisms at ultrastructural resolution.

P22**Board Number: B121****Measuring the distribution of taurine molecule inside biological tissue via intrinsic molecular vibrations using nonlinear Raman spectroscopy.**M. Kawagishi¹, Y. Obara², T. Suzuki², M. Hayashi³, K. Misawa², S. Terada¹;¹Dept Neuroanat Cell Neurobiol, Grad Sch Med Dent Sci, Tokyo Med Dent Univ (TMDU), Bunkyo, Tokyo, Japan, ²Dept Applied Physics, Tokyo Univ Agricul Technol (TUAT), Koganei, Tokyo, Japan, ³Wired Co., Ltd., Komae, Tokyo, Japan

Distributions of small organic molecule (less than 300 Da) compounds inside biological tissue have been obscure because of the lack of appropriate methods to measure them. Although fluorescence techniques are widely used to characterize the localization of large molecules such as proteins and nucleic acids, they cannot be easily applied to small molecule compounds: Fluorescent labels are relatively large compared to the target compounds and can change the properties of them. Raman spectroscopy is a technique to study vibrational information intrinsic to and characteristic of the chemical species of compounds. We used coherent anti-Stokes Raman scattering (CARS) spectroscopy to detect and identify a small molecule compound, taurine, without labeling. Molecular species could be uniquely identified from the spectral shape of the broadband vibrational spectra of target molecule. The local distribution of target molecule could be determined from the spectral intensity. We have developed a phase-sensitive CARS spectroscopy capable of simultaneous measurement of the broadband spectrum while maintaining a high frequency resolution. We utilized this technique to measure taurine inside mouse cornea tissue soaked in solution. We detected a Raman peak of taurine near 1000 wavenumber / cm inside cornea, and successfully characterized its depth profile in the tissue. Our CARS spectra measurement can be a promising method to measure and visualize the distribution of small bio-related compounds in biological background without using any labeling, paving the way for new cell biological analysis in various disciplines.

P23**Board Number: B122****In vivo tracking of label-free resident cells in murine tissues via third harmonic generation microscopy.**D. Malide¹;¹Light microscopy core facility, NIH/NHLBI, Bethesda, MD

Although fluorescent compounds and proteins have emerged as invaluable tools to mark cells and structures of interest for confocal and two-photon microscopy imaging, such probes can interfere with cellular functions. While it is possible to visualize naturally occurring signals via two-photon microscopy, imaging remains challenging and has been limited primarily to thin and transparent biological samples. We developed and validated a methodology for high resolution 3D harmonic imaging of intact murine

tissues that requires no fluorescent labeling, based on epi- third-harmonic generation (THG) imaging by pulsed near-infrared light in the 1200–1300 nm range. Visualizing THG in the epi- (backscattered) direction enabled high resolution depth-resolved imaging of whole mount, intact tissues without the need for physical sectioning. We demonstrated intrinsic THG interface signals, outlining cell membranes and tissue inhomogeneities, revealing subcellular resolution of 3D architecture in various murine tissues and organs. These included subcutaneous and perivisceral white and brown adipose tissue, with clearly demarcated lipid droplets, blood vessels and cells, and myelinated peripheral nerves. We also visually dissected intracellular lipid-rich granules in adrenal glands, mammary glands, sebaceous glands, pancreas, liver, and spleen. Characteristic patterns were also observed in the skeletal muscle, heart, bone, skin, lung, brain, and spinal cord. Using this methodology, we examined the intracellular lipid deposits in healthy or diseased mouse tissues, including fatty liver, ischemic cardiomyocytes, and in the atherosclerotic aortic wall. Moreover, multiharmonic, combined THG and second harmonic generation (SHG) images can be assessed qualitatively and quantitatively to evaluate 3D distribution of the cells in label-free tissues and organs in control and experimental conditions. In addition, we demonstrated the feasibility of multimodal imaging by combining simultaneously excited harmonic signals with fluorescence-excitation of red-shifted fluorescent proteins expressed in vivo. Finally, time-lapse 3D THG imaging, obtained with faster acquisition settings, enabled dynamic cellular tracking in intact undisturbed tissues. This methodology uses commercially available turn-key systems allowing easy implementation of a versatile tool to track resident label-free cells in their undisturbed surroundings, as a powerful alternative or complementary contrast mechanism to fluorescence-based techniques. THG imaging could especially facilitate development of noninvasive approaches for optical biopsies of various tissue-types in diagnostic medicine.

Molecular interrogation of single-cells using ion mobility separation mass spectrometry.

B. Shrestha¹, L. Zhang¹, A. Vertes¹;

¹The George Washington University, Washington, DC

Mass spectrometry (MS) with liquid chromatography (LC) is a standard analytical tool for analyzing small molecules in biological samples. Reduction of ion suppression due chromatography separation enhances detection of molecules. It also provides retention time values to increase identification confidence of molecules. However, due to their limited volume, analysis of single-cells with traditional chromatography methods is unviable. To overcome this limitation, we performed molecular analysis of single-cells using an on-the-fly approach, ion mobility separation (IMS). In situ sampling of cellular contents was achieved by laser ablation (laser ablation electrospray ionization or LAESI)¹ or capillary microsampling² prior to electrospray ionization. For this study, pollen tubes (*Lilium longiflorum*) and

hepatocyte (*Homo sapiens*) were used as model plant and animal cells, respectively. IMS improved signal-to-noise ratios of the ions from single-cells by discriminating them from isobaric ones found in the background. This led to an increase in the total number of molecular species detected from single-cells. In addition, the rotationally-averaged collision cross-sections (CCS) of ions were obtained from their drift times during IMS. The measured CCS of ions were used as additional parameters to increase the identification confidence of molecules from single-cells in combination with accurate mass-to-charge ratios and isotope distribution patterns. The reference CCS values were primarily obtained from existing literature and experiments with standards. When experimental values were unavailable, approximate CCS values were generated *in silico*. The identification of molecules of interest in single-cells was further confirmed by structural elucidation using tandem MS of the respective ions in bulk cell populations.

Board Number: B124

DEVELOPMENT OF CAPILLARY BASED VACUUM ASSISTED INSTRUMENTS FOR RAPID AND EFFICIENT COLLECTION OF SINGLE CELLS FROM CELL CULTURES AND MICRODISSECTION OF HETEROGENEOUS TISSUES.

S. Karsten¹, A. Zavala¹, Z. Ma¹, L.C. Kudo¹;

¹NeuroInDx, Inc., Signal Hill, CA

Cell specific studies are imperative for sound research in basic and translational cell biology. Collecting single or individual cells directly from cell cultures for downstream single cell analysis or recultivation purposes has remained challenging. Similarly, tissue heterogeneity poses significant challenge for retrieval of cell and region specific information. Existing approaches, such as flow sorting and laser assisted acquisition, are costly, sophisticated and often methodologically limited. We have developed two capillary-based vacuum-assisted cell and tissue acquisition instruments (Kuiqpick™ and Unipick™) with which individual fluorescently labeled and/or morphologically distinct cells can be acquired from any cultures grown in standard cell culture dishes. Moreover, the instruments are suitable for individual cell collection and region specific acquisition of cell clusters and subanatomical areas from complex heterogeneous tissues such as the brain. While Kuiqpick™ is integrated with a fluorescence compatible inverted microscope (Olympus CKX41), Unipick™ is a free standing instrument that may be mounted over any inverted microscope, providing additional flexibility in the laboratory. Both instruments demonstrate a wide range of cell and tissue acquisition parameters. They permit rapid collection of

individual cells from various cell cultures for various downstream applications including single cell analyses. Because small sample volume is incremental for single cell research, Kuiqpick/Unipick enables the collection of a single cell in as small as 12 nl. The current work demonstrates the efficiency of Kuiqpick™ for cell collection from adherent, suspended, and 3D cultures. Individual cells were collected from primary neural progenitor (NPC), SH-SY5Y, CHO and MDA-MB-435 cell cultures based on morphology or fluorescent label. Further, the collected cells were successfully recultured, demonstrating the minimal effect the process has on cellular viability (up to 95%). The clonal expansion of collected single SH-SY5Y and CHO cells was demonstrated within 6 and 25 days, respectively. In addition, applicability of the instruments for the collection of single cells grown in three-dimensional (3D) culture system was shown using MDA-MB-435 cells. To further demonstrate Kuiqpick/Unipick's capabilities for cell and region acquisition from complex heterogeneous tissues, single Purkinje cells and subanatomical regions (e.g. CA1-3, dentate gyrus) were efficiently collected from rat brain tissue sections. The instrument dissected brain sections with thickness from 10 to 500 μm. Native, fresh frozen, and sucrose treated tissues could be used. High quality RNA and proteins were isolated from the collected samples.

Board Number: B125

Development of single strand DNA aptamer for cell surface of human umbilical vein endothelial cell.

H. Terazono^{1,2}, H. Kim³, F. Nomura¹, Y. Wada⁴, Y. Kurihara⁴, H. Kurihara⁴, K. Yasuda^{2,5};

¹Tokyo Medical/Dental Univ, Tokyo, Japan, ²CAST, Kawasaki, Japan, ³Kanagawa Academy Sci/Technol, Kawasaki, Japan, ⁴Univ. Tokyo, Tokyo, Japan, ⁵Tokyo Medical and Dental Univ, Tokyo, Japan

Aptamer is a stranded molecular consisted of nucleic acid or amino acid that works as a ligand binding to targets such as protein, metal and organic small molecular. Aptamer is made by "Systematic Evolution of Ligands by EXponential enrichment" (SELEX) method from huge number of aptamers by repeating selection procedure. Aptamer is more useful than antibody for cell labeling and tissue engineering because it is easy to elaborate clones stable and be modified with genetic engineering procedures such as adding fluorescent material or biotin, or recombining the sequence to stronger affinity ligand. Furthermore, since aptamer is degradable by nuclease, it is easy to detach the aptamer labeling. Therefore, labeled cells with aptamer to perform fluorescence-activated cell sorting (FACS) or Magnetic-activated cell sorting (MACS) method is undoable to intact condition with nuclease, while antibody can't it. SELEX method can be applied to cell surface targets or tissue. This method is called Cell-SELEX and can also make aptamer against unknown targets of cell surface. Human umbilical vein endothelial cell is used for physiological, pharmacological investigations and tissue engineering. Therefore, aptamer against cell surface of HUVEC will be useful for these research fields. ssDNA aptamer library contained a central randomized sequence of 40 nucleotides flanked by primer hybridization sites. ssDNA aptamers against cell surface of HUVEC was obtained by a modified cell-SELEX method. In briefly, after aptamer library was incubated with cells, the unbound aptamer removed, and then, the bounded ssDNA was

exfoliated from cell surface by trypsinization not to leak cytosol materials of cell. After that, bound ssDNA was amplified by the PCR and ssDNA was made by alkaline treatment from dsDNA as the next round template. Totally 10 rounds of selection were performed. The selected aptamer sequences were read by a next generation sequence and classified the sequence by a bioinformatics. Each round aptamer was labeled with FITC or biotin, and binding affinity was analyzed by MACS or a fluorescence microscopy. In results, almost of HUVEC was collected by the selected aptamer-magnetic beads conjugates. Moreover, the affinity was increased with repeated selection. Moreover, FITC-labeled aptamer stained the surface of the cells. These results indicated that our modified cell-SELEX method allowed us to make ssDNA aptamer against cell surface of HUVEC as a ligand. Aptamer for HUVEC is expected to use for cell sorting, micropattern of cell, and many biotechniques. Furthermore, reading sequence of selected aptamers in full detail by next generation sequence method gives us many information and it is possible to select the sequence against the target cells even if there are a wide variety of cell types in same tube.

Reconstructing alveolar epithelial development using single-cell RNA-seq.

D.G. Brownfield^{1,2,3}, B. Treutlein⁴, M. Krasnow⁵, S. Quake⁴, H. Espinoza¹, T. Desai⁶, A. Wu⁴, N.F. Neff⁷, G. Mantalas⁴;

¹Biochemistry, Stanford University, Stanford, CA, ²Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, ³Department of Bioengineering, University of California, Berkeley, Berkeley, CA, ⁴Bioengineering, Stanford University, Stanford, CA, ⁵Stanford Univ Sch Med/HHMI, Stanford, CA, ⁶Internal Medicine, Stanford School of Medicine, Stanford, CA, ⁷Stanford Univ Sch Med, Stanford, CA

Although aspects of alveolar development have been studied by marker expression analysis and fate-mapping, the mechanisms that control the progression of lung progenitors along distinct lineages into mature alveolar cell types remain incompletely known, in part because of the limited number of lineage markers and the effects of ensemble averaging in conventional transcriptome analysis experiments on cell populations. With single-cell transcriptome analysis we were able to directly measure the various cell types and hierarchies in the developing lung. We used microfluidic single-cell RNA sequencing (RNA-seq) on 198 individual cells at four different stages encompassing alveolar differentiation to measure the transcriptional states which define the developmental and cellular hierarchy of the distal mouse lung epithelium. We empirically classified cells into distinct groups by using an unbiased genome-wide approach that did not require a priori knowledge of the underlying cell types or the previous purification of cell populations. The results confirmed the basic outlines of the classical model of epithelial cell-type diversity in the distal lung and led to the discovery of many previously unknown cell-type markers, including transcriptional regulators that discriminate between the different populations. We reconstructed the molecular steps during maturation of bipotential progenitors along both alveolar lineages and elucidated the full life cycle of the alveolar type 2 cell lineage. This single-cell genomics

approach is applicable to any developing or mature tissue to robustly delineate molecularly distinct cell types, define progenitors and lineage hierarchies, and identify lineage-specific regulatory factors.

Board Number: B127

Application of a live-cell RNA detection technology for use in cellular High Throughput Screening assays.

D. Weldon¹, A. Ko¹, Y. Williams¹, V. Koong¹;

¹EMD Millipore, Temecula, CA

High-throughput screening (HTS) approaches enable the systematic generation of vast amounts of experimental data through the automated processing and analysis of large numbers of biological samples¹. Many traditional biological experiments have been expanded and modified to take advantage of HTS technologies. Modern platforms contain internal systems to automatically control incubation temperature, exchange growth media, and maintain pH levels in sample plates, allowing researchers to perform large scale studies without compromising their demand for biological relevance. Gene expression analysis is an area of research that is widely pursued today using HTS approaches. Specifically, several HTS techniques exist today for the large-scale identification and analysis of RNA content, such as in the context of identifying gene responses to drug compounds. However, many of these techniques require cell lysis for subsequent PCR amplification steps, which compromises cell viability and integrity, and prohibits the use of the assayed cells for downstream characterization and functional studies. Further, these assays also lack the ability to discern gene expression differences within heterogeneous cell samples. Performing direct RNA detection in live cells would address these key issues, enabling the researcher to gain even more biologically relevant information from critical HTS experiments. Retaining overall cell viability and integrity yields more meaningful biological data. In addition, single-cell gene expression analysis is made possible when resolution of heterogeneous populations is needed. This approach also enables the use of the interrogated cells for further downstream functional assays. In this poster, we demonstrate the live-cell detection of ERBB2 mRNA using SmartFlare™ RNA detection probes in two breast cancer cell lines, which differ in their expression of this therapeutic marker and exhibit differential responses to drug treatments. These cells were cocultured in varying ratios, incubated with SmartFlare™ probes in normal culture conditions, and directly assayed for ERBB2 mRNA. We show that sensitivity in detection can be achieved at the single-cell level, enabling greater understanding of the inherent heterogeneity within mixed cell samples, while retaining the scalability and throughput commensurate with HTS approaches. Live cell RNA detection enables single-cell analysis, preserves cellular viability and integrity, and allows samples to be further utilized for downstream research. Researchers who seek to maximize data output, minimize sample preparation, and generate biologically-relevant data from HTS gene expression experiments can benefit from incorporating live cell RNA detection into their workflows.

P29**Board Number: B128****An automatable 3-dimensional cell invasion assay compatible with high content analysis.**J. Fronczak¹, S.I. Montanez-Sauri¹, M.S. Gajeski¹, B.R. Mader¹, T.G. Burland²;¹Platypus Technologies, LLC, Madison, WI, ²Platypus Technologies LLC, Madison, WI

Cell invasion is the movement of cells through extracellular matrix (ECM). Invasion is of particular concern in cancer, where invading tumor cells lead to metastasis, the deadliest aspect of the disease. High-throughput assays suitable for screening the impact of candidate anti-cancer drugs on cell invasion are therefore highly sought after. Traditionally, cell invasion is quantified through “transwell” assays in which movement of cells from one chamber to another chamber through a synthetic membrane and ECM layer is monitored. However, transwell assays do not readily facilitate automation or real-time monitoring of invasion, nor simultaneous microscopic analysis of cell phenotypes such as changes in overall morphology, nuclear structure, etc. Moreover, the use of a synthetic membrane to separate the two transwell chambers poorly simulates conditions found in vivo. Here we report development of a fully automatable cell invasion assay that is configured in an industry-standard 96-well format and that can be used to monitor cell movement in three dimensions through ECM. The new assay seeds cells around an “exclusion zone”. Following cell attachment, an overlay of collagen I is added. Cell movement into the exclusion zone is then monitored in real-time, and cell morphology and physiology may also be monitored simultaneously. We report data comparing the information content and multiplex capabilities of traditional transwell invasion assays with the new exclusion zone invasion assay. We conclude that the fully automatable invasion assay presented in this work delivers major improvements in efficiency and information content over transwell assays, and promises to facilitate high content screening of cancer drug candidates for their potential to inhibit metastasis.

P30**Board Number: B129****HC StratoMineR: A web-based data mining tool for the rapid analysis of high content data sets.**

W.A. Omta¹, R.G. van Heesbeen², R.J. Pagliero¹, D. Lelieveld¹, M. Kramer¹, M. Nellen¹, M. Yeong¹, P. Kemmeren³, R.H. Medema⁴, S. Brinkkemper⁵, J. Klumperman¹, D.A. Egan¹;

¹Center for Molecular Medicine, Department of Cell Biology, University Medical Center Utrecht, Utrecht, Netherlands, ²Division of Cell Biology, Netherlands Cancer Institute, Amsterdam, Netherlands, ³Center for Molecular Medicine, Department of Molecular Cancer Research, University Medical Center Utrecht, Utrecht, Netherlands, ⁴Division of Cell Biology, the Netherlands Cancer Institute, Amsterdam, Netherlands, ⁵Department of Information and Computing Sciences, University of Utrecht, Utrecht, Netherlands

High content screening combines high throughput screening, and automated fluorescence microscopy and image analysis. The field has long been supported by mature technologies for automated liquid handling and automated image acquisition and analysis, such that large scale high content screens are feasible. There are however, few tools available to aid in the analysis of the large multiparameter data sets that are produced by these screens.

We have developed a web-based tool called HC StratoMineR to aid the mining of high content screening datasets. This is a decision supportive data pipelining tool that assists even non-expert users in the efficient analysis of high content data sets. Our goal was to generate easy-to-read visualizations that make it possible to compare cellular morphological responses. Visualizations and other information provided are useful for the selection of useful parameters that have been generated by image analysis software. HC StratoMineR assists in the quality control of the screen and allows for the generation of a hit list based on cellular morphology. These hits are then classified using multivariate analysis techniques. Critically HC StratoMineR allows for a final report, where all decisions made are saved so that the next experiment can be analysed using the same methods.

We have validated HC StratoMineR using chemical and RNAi knock-down screens. Our work shows that HC StratoMineR greatly enhances and accelerates the analysis of high content data sets. We show that the software does indeed segregate samples according to the cellular morphology they induce. We demonstrate that HC StratoMineR can highlight structure-morphology relationships in compound screens and gene function-morphology relationships in RNAi screens. This allows researchers to extract the greatest benefit from high content data sets.

P31**Board Number: B130****Lipid nanoparticle delivery of RNA for loss-of-function and gain-of-function studies in primary neurons in vitro and in vivo.**D. Zwaenepoel¹, A. S. Ansari¹, A. Thomas¹, C. Walsh¹, T. Leaver¹, A. Wild¹, K. Ou¹, J. Taylor¹, E. Ramsay¹;¹Precision Nanosystems Inc., Vancouver, BC

A lipid nanoparticle (LNP) technology was developed to deliver mRNA and siRNA into neurons in vitro and in vivo with high efficiency and low toxicity. LNPs encapsulating RNA were prepared using the NanoAssemblr microfluidics platform. LNPs mimic low-density-lipoproteins (LDL) which are taken up by cells through the LDL-receptor in presence of Apolipoprotein E4.

In vitro - More than 95% of Primary E18 rat Cortical Neurons (13 days in vitro) mixed with glial cells (PCN) incubated 4h with siRNA-LNP (100 ng/ml) showed fluorescent LNP uptake (Flow Cytometry, Confocal Microscopy). PCN incubated with 100 ng/mL of PTEN siRNA-LNP (siPTEN-LNP) for 72h showed > 90% knockdown (RT-qPCR, Western Blot). PCN incubated with HPRT siRNA-LNP (siHPRT-LNP) showed sustained knockdown of > 70% for 21 days after a single dose treatment (100 ng/mL) on Day 0 (RT-qPCR). PCN treated with 100 ng/mL siPTEN-LNP alone, or 100 ng/mL siHPRT-LNP alone, or a combination of both nanoparticle preparations showed respective knockdown of PTEN and HPRT 72 hours post treatment (RT-qPCR). Comparison of Neuro9Kit to contemporary transfection kits showed significantly higher knockdown efficiency with 100 ng/mL sPTEN-LNP 72h post treatment (qPCR). Neuro9Kit showed no toxicity at 100 ng/ml siRNA-LNP 72 hours post treatment (LDH).

PCN incubated with 500 ng/mL GFP mRNA-LNP and/or 500 ng/ml mCherry mRNA-LNP for 72h showed GFP and/or mCherry expression (Flow cytometry, Confocal Microscopy).

In vivo - A somatosensory injection of siPTEN-LNP (500 nL at 5 mg/mL for 10 minutes) in Spargue-Dawley rats showed > 80 % knockdown in cortical slices up to 1 mm from the injection site 5 days post-injection (Western Blot).

Solid-core LNP manufactured using the NanoAssemblr demonstrated rapid uptake by neurons which mediated effective and sustained silencing/expression of a target genes in vitro and in vivo with no detectable toxicity. This technology offers a simple and flexible alternative to viral vectors, electroporation and lipofection for loss- and gain-of-function studies in neural development, injury and degeneration.

P32**Board Number: B131****Super-active TALEN with improved stability at 37 degree Celsius enables highly efficient and homogeneous gene knockout in mammalian embryos.**K. Ikeda¹, Y. Terahara¹, K. Sumiyama¹, N. Miyashita¹, Y. Okada¹;¹RIKEN Quantitative Biology Center (QBIC), Osaka, Japan

Gene editing *in vivo* has become possible by the development of artificial nucleases that can be designed to cut the genome DNA selectively at the target site in the genome. The DNA binding domain of a plant pathogen protein called Transcription Activator-Like Effector (TALE) has been used as the designable sequence specific DNA-binding domain. The fusion protein of TALE and the nuclease domain of Fok I endonuclease, called TALE nuclease or TALEN, has been proven to be useful for the genome editing in lower vertebrates such as zebrafish and *Xenopus*. In mammalian cells and embryos, however, TALEN often shows poor activity, which limited its applications. We have surmised that the TALE protein might not be stable at 37 °C, because the physiological temperature for the plant pathogen is around 25 °C. Through the analysis of the crystal structure of TALE protein, we have chosen two amino acid residues that might be pivotal for the stable alignment of the linear solenoid structure of TALE. Several mutations were introduced, and some successfully showed significantly higher activity at 37 °C both *in vitro* and *in vivo*. All-atom molecular dynamics simulations confirmed the stabilization of the conformation. The mutated residues apparently suppressed the intramolecular fluctuations. We have, therefore, named this mutant TALEN as “super-active” TALEN and examined its activity in mouse embryos. We have designed TALENs, both wild type and super-active mutant, for the mouse tyrosinase gene. The mRNAs for the TALENs were introduced to the pronuclear stage mouse embryos. The wild type TALENs failed to introduce mutations, and the coat color of the babies were agouti. Contrastingly, more than half of the babies were albino with super-active TALENs, which means both alleles of the tyrosinase gene were mutated throughout the body. Interestingly, CRISPR/Cas9 mediated gene editing of tyrosinase gene in mouse pronuclear stage embryo yielded even higher rate of coat color mutants. However, the babies were mostly mosaic of agouti and white, indicating that only some population of cells got biallelic mutation. Consistently, the genome analyses detected only less than four different alleles in each baby with super-active TALEN, while more than eight alleles were often detected in a single CRISPR/Cas9 baby. These results suggest that super-active TALEN shows its activity at two-cell stage, earlier than CRISPR/Cas9, suggesting that super-active TALEN might serve as an effective tool for the genome editing in mammalian cells and embryos.

P33**Board Number: B132****Establishment of an in vivo electroporation method into postnatal newborn neurons in the dentate gyrus.**H. Ito¹, R. Morishita¹, I. Ikuko¹, K. Nagata¹;¹Mol Neurobiol, Inst Developmental Res/Aichi Human Service Ctr, Kasugai, Japan

Electroporation-mediated gene transfer has been developed for the analysis of mammalian brain development in vivo. Indeed, in utero electroporation method is widely used for the investigation of the mouse embryonic cortical development while in vivo electroporation using neonatal mouse brain is employed for the analysis of the rostral migratory stream (RMS) and postnatal olfactory neurogenesis. In the present study, we established a stable gene-transfer method to dentate gyrus (DG) neurons by carefully determining the in vivo electroporation conditions, such as position and direction of electrode, voltage for electric pulses, and interval between electroporation and sample preparation. Consequently, GFP-positive cells in DG were observed to extend branched dendrites and long axons into the molecular layer and the hilus, respectively, 21 days after electroporation. They were morphologically identified as dentate granule neurons with many protrusions on dendrites, and some of them had wide head and thin neck that resembled matured mushroom spines. Expression of GFP in dentate neurons sustained for at least 9 months after electroporation under our experimental conditions. Taken together, the method developed here could be a powerful new tool for the analysis of the postnatal DG development.

P34**Board Number: B133****Development of Transgenic Chickens for Studies on Retinoic Acid Signaling.**J. Summers¹;¹Department of Cell Biology, University of Oklahoma Health Science Center, Oklahoma City, OK

Introduction. Despite the significance of retinoic acid (atRA) in the growth and development of many major organ systems, visualization of endogenous atRA has only been indirectly determined. Moreover, due to the fundamental importance of atRA in early development, studies aimed at understanding the function of atRA in late embryogenesis or postnatal development using conventional genetic approaches have been severely limited. Therefore, the goal of this project is to develop two lines of germline transgenic chickens that will allow, for the first time, visualization and modulation of endogenous atRA in embryonic and post-hatch chicks. **Methods.** The pminiTol2 backbone was used to generate two constructs in order to 1) visualize endogenous atRA gradients (GEPRA B) and 2) conditionally lower endogenous atRA concentrations (tet-RALDH2 shRNA). The GEPRA B construct was cloned into the pminiTol2 plasmid containing a pCAGGS promoter for optimal expression in the chicken. The tet-RALDH2 shRNA construct was modified from a third generation lentiviral vector, the pINDUCER series, that allows tetracycline-inducible knockdown of RALDH2 as well as the expression of eGFP and DS

red fluorescent proteins to monitor transfection and induction, respectively, using a single vector. The minitol2 transposon system was used to deliver each of these constructs to circulating primordial germ cells (PGCs) in chick embryos through a recently developed direct injection technique. Briefly, transfection complexes consisting of 0.6 ug of pMiniTol-GEPRA or tet-RALDH2 shRNA, 1.2 ug of a plasmid containing the transposase sequence under the control of the CMV IE promoter, and Lipfectamine 2000 were prepared. Chick embryos stage 14 – 16 HH (~72 – 74 hrs incubation) were injected with 1 – 2 ul of the transfection complex using a pulled glass capillary micropipette inserted into the caudal portion of the left dorsal aorta. Eggs were sealed with surgical tape and incubated normally. To estimate transfection efficiency, chick embryo gonads were dissected and examined for eGFP or YFP fluorescence at various stages. To confirm transfection of PGC's, gonads were immunolabeled using antibodies against the stem cell antigen, SSEA-1. **Results.** The tet-RALDH2 shRNA vector significantly reduced RALDH2 protein expression in vitro. Embryos between days 7 and 14 of incubation expressed eGFP (for tet-RALDH2 shRNA injected embryos) or YFP (for GEPRA injected embryos), preferentially in the gonads. Co-localization of YFP or eGFP with SSEA-1 confirmed the presence of transgenic PGC's in embryonic gonads. **Conclusions.** This approach provides a promising alternative to the use of standard transgenic model organisms, and will enable, for the first time, functional studies on retinoic acid signaling in embryonic and post-hatch chickens.

Functional Annotation for TCA and DNA Repair for Insects and Plants: A Survey.

D.M. Grogan¹, M. Castleman¹, L.E. Carson², E.C. Regisford³, J. Hu⁴;

¹Department of Agriculture, Prairie View AM University, Prairie View, TX, ²Cooperative Agricultural Research Center, Prairie View AM University, Prairie View, TX, ³Department of Biology, Prairie View AM University, Prairie View, TX, ⁴Department of Biochemistry and Biophysics, Texas AM University, College Station, TX

In the area of agriculture, plants and insects work in harmony or against each other to provide nourishment for the rest of the animal kingdom. These species are being studied by numerous scientists, hence it would be of deep interest to determine how well these works are collected, annotated and stored. Thus, a survey of functional annotations for agriculturally important plants and Insects was performed. We focused on two of the most common metabolic pathways amongst species, the Tricarboxylic Acid (TCA) Cycle and DNA Repair. The TCA cycle uses a sequence of chemical reactions to generate energy through the oxidation of acetate from carbohydrates, proteins and fats into carbon dioxide. DNA can be damaged by endogenous and exogenous agents, causing mutation and other serious conditions. DNA Repair is a series of enzymatic processes that correct the lethal changes that affect the sequence of a DNA molecule. We selected 39 Insects, 64 Plants and used QuickGO to find all annotations associated with each species using a taxonomy ID. Then, we filtered the annotations by using the GO Terms for the TCA cycle (GO:0006099) & DNA Repair (GO:0006281). Our results indicated that sixty-three percent of the selected species had annotations that were associated with the TCA cycle

or DNA Repair. Twenty-two percent of the selected species had annotations that were associated with both DNA Repair and the TCA cycle. Therefore, we conclude that more annotations of these biological processes species needs to be done.

Wild and Domestic Animals Surveyed for Functional Annotations of the TCA Cycle and Apoptosis.

M. Castleman¹, D. Grogan¹, L.E. Carson², E.C. Regisford³, J. Hu⁴;

¹Department of Agriculture, Prairie View AM University, Prairie View, TX, ²Cooperative Agricultural Research Center, Prairie View AM University, Prairie View, TX, ³Department of Biology, Prairie View AM University, Prairie View, TX, ⁴Department of Biochemistry and Biophysics, Texas AM University, College Station, TX

There is so much information from biological processes of all organisms that needs to be stored by bioinformatics databases. The European Biological Institute (EBI) hosts one of the databases that are used to store annotated information on all organisms. With this study, we focused on two very important biological processes, the Tricarboxylic Acid cycle (TCA) and the Apoptotic process. The TCA cycle uses a series of chemical reactions to generate energy through aerobic respiration. Apoptosis, described as cell suicide or programmed cell death, is essential to maintain appropriate cell numbers in organisms. Our objective was to determine the number of animals, both wild and domesticated, which the TCA Cycle and Apoptosis are annotated. It is hypothesized that all organisms studied will have annotations for these two very important biological pathways the TCA cycle and Apoptosis. On the EBI database, we used QuickGO to retrieve all annotations associated with the taxonomy ID of the selected animals. The annotation was then filtered by using the GO term for the Krebs cycle (GO:0006099) and Apoptotic process (GO:0006915). Out of 13 wild animals studied only 5 had annotations for the TCA cycle and Apoptosis. Only 4 out 19 domesticated animals had annotations for Apoptosis, while none of 19 had annotations for the TCA cycle alone. Our data indicate that more work needs to be done by biocurators for annotations of the TCA cycle and Apoptosis in wild and domesticated animals.

P37**Board Number: B136****Microsecond-Pulsed Dielectric Barrier Discharge Plasma Treatment Promotes Murine Ear Regeneration.**N. Chernets¹, D.S. Kurpad¹, Q. Zhang¹, Y. Song¹, T.A. Freeman²;¹Orthopaedic Surgery, Thomas Jefferson University, Philadelphia, PA, ²Orthopaedic Surgery, Thomas Jefferson University, Philadelphia, PA

The ability of mammals to regenerate damaged tissue is limited [1-3], and more commonly wound repair results in scar tissue formation. In this report, we describe the application of non-thermal atmospheric dielectric barrier discharge plasma (DBD-plasma) as a novel modality which can promote regeneration of new ear tissue in a non-regenerating mouse's ear after injury. It has been shown that intracellular reactive oxygen species (ROS) are elevated in response to DBD-plasma [4]. In our recent study of DBD-plasma treatment of mouse autopods, we reported that DBD-plasma generated ROS to activate signaling pathways and induced an increase of wnt activation in the distal apical epidermal ridge (AER) to enhance digit growth and elongation [4]. As parallels exist between the functionality of the AER in autopod development and the blastema in regeneration, we hypothesized that DBD-plasma could be applied to the wounded ear to induce enhanced epimorphic regeneration. To determine if DBD-plasma could promote regeneration, a through-and-through circular hole was punched in the center of the cartilaginous part the ear of non-regenerative C67BL6 mice using a 2 mm biopsy punch. A single 5 sec treatment of DBD-plasma each day for 5 days after the punch to one ear, while the other punched ear remained as an untreated control. Images of the ear holes were acquired for 32 days and the area of the hole was determined using image analysis. Histological staining and immunohistochemistry of ear regeneration samples were used to evaluate the structure of the wound epithelium and to determine the extent of tissue regeneration. DBD-plasma treated mouse ears showed accelerated wound closure, formation of blastema-like structures and replacement of cartilage, hair follicles and sebaceous glands as compared to bilateral controls. DBD-plasma treated mouse ears had a significantly higher closure rate on the 32nd day as compared to control ears (n=10, p

P38**Board Number: B137****Electrostimulation of Human Neural Stem Cells to Enhance Neuronal Differentiation.**F. Ghasemi Tahrir¹, G. Jin¹, W. Ma¹, W.H. Suh¹;¹Bioengineering, Temple University, Philadelphia, PA

Differentiation guiding techniques (chemical and non-chemical, all included) for directing the differentiation of stem cells (to a specific phenotype) are considered essential platform technologies that can one-day aid in the development of clinical treatments associated with nervous system diseases

(i.e., Alzheimer's disease, Parkinson's disease, spinal cord injury). In the present work, electrostimulation, in particular, has been utilized as an enabling technology that promoted the differentiation of neural stem cells to neurons. We will talk about a custom-designed current stimulation cell culture device that enhanced neuronal differentiation of human adult neural stem cells (hANSCs). The differentiation via electrostimulation was confirmed by live-cell (fluorescence and confocal) microscopy, immunocytochemistry (ICC) and reverse transcription quantitative PCR (RT-qPCR). Our results indicated that precisely controlled electrostimulation over few weeks significantly increased the expression of Tubulin beta-3, which is a neuronal marker.

Kinetics of Intracellular Nitric Oxide Production and Cytotoxicity in Lipopolysaccharide and Inteferon- γ -Induced Macrophage Activation.

K.T. Tran¹, K. Tyagarajan¹;

¹RD, EMDMillipore, Hayward, CA

Nitric oxide is a multi-functional biomolecule that can function as a bactericidal or tumoricidal mediator. The generation of nitric oxide plays a key role in several processes such as cellular proliferation, metastasis and apoptosis and has been suggested to modulate both tumorigenesis and tumor killing depending on its concentration, cell type and the oxidative milieu. It is well established that bacterial lipopolysaccharides (LPS) and interferon (IFN)- γ are potent inducers of nitric oxide production in murine macrophages which may contribute significantly to host defense mechanism against microbial pathogens. In this study we have systematically evaluated the mechanism and kinetics of nitric oxide production and subsequent cytotoxicity on lipopolysaccharide (LPS) and IFN- γ treatment of murine macrophage RAW264.7 cells. The cells were analyzed after treatment with a series of novel simplified assays on a compact microcapillary based flowcytometer including assay for intracellular nitric oxide detection, apoptotic assay for annexin V based detection along with cell death, caspase-3/7 activity and mitochondrial membrane depolarization. The kinetic studies clearly demonstrate the early production of nitric oxide observed at 6 hours and sustained levels through 48 hours of treatment. While annexin V based apoptosis and cell death were increasingly observed after 12 hours of treatment, no mitochondrial depolarization was observed throughout. Evaluation of caspase-3/7 activity in LPS-IFN γ treated cells showed a moderate caspase-3/7 activity after 6 hours and saturated at 24 hours with only 50% of the cells displaying caspase-3/7 activation which is another distinctive indicator of apoptosis. Our data suggest that nitric oxide production and subsequent NO-mediated induction of apoptosis proceeds through alternative cell death pathways that do not involve mitochondrial depolarization. These results thus provide interesting insights into the mechanism of cytotoxicity for intracellular nitric oxide production and allows for understanding characteristic of lipopolysaccharide and IFN γ -induced apoptosis of macrophage RAW264.7 cells.

P40**Board Number: B139****Directly observed membrane disruption and resealing during centrifugation of sea urchin eggs.**K. Miyake¹, M. Goda², S. Inoue³, N. Araki¹;¹Dep.Hist.Cell.Biol., Kagawa University, Faculty of Medicine, Kita-gun, Kagawa, Japan, ²Nagoya Univ, CeSPI, Nagoya, Japan, ³Marine Biological Lab, Woods Hole, MA

Large plasma membrane disruptions (PMDs) rapidly invoke a localized exocytotic reaction that adds a 'patch' of internal membrane to the plasma membrane at the PMD site, a calcium-dependent resealing mechanism. We have used sea urchin eggs as a model system to define the mechanistic basis of this fundamental cell survival response. Here we directly observed plasma membrane tears that occur in sea urchin eggs during centrifugation with a special centrifuge polarizing microscope (CPM). Dilute suspensions of unfertilized eggs were layered in a centrifuge chamber above an osmotically matched dense solution containing Percoll, forming a density gradient that allowed the eggs to slowly settle to an equilibrium position. Centrifugation at speeds of up to 8,000 rpm for 20 min, separated the eggs into two parts. One part was filled with yolk granules and internal vesicles, the second part was filled with clear cytoplasm. These membrane tears by shear forces did not show variously shaped surface projections involved in exocytosis at the PMDs. These cell separations depended on the presence of calcium. However, sea urchin eggs were broken by this centrifugation in the absence of calcium. The part filled with yolk granules and internal vesicles repaired the PMDs made by a two-photon laser, but the part of the eggs containing clear cytoplasm did not repair. We conclude that shear forces caused by centrifugation make small PMDs which can reseal in the presence of extracellular calcium, although large PMDs made by laser irradiation require a 'patch' of internal membrane by calcium-dependent exocytosis.

P41**Board Number: B140****Harness human iPS cell differentiation and reprogramming potential using an automated cell culture system.**T. Guo¹, M. Watson¹, N. Devaraju¹, L. Szpankowski¹, B. Fowler¹, M. Norris¹, M. Thu¹, M. Wong¹, D. Kemp¹, H. Choi¹, B. Clerkson¹, G. Harris¹, Y. Lu¹, C. Johnson¹, A. Leyrat¹, X. Wang¹, G. Sun¹, M. Unger¹, R.C. Jones², N. Li¹;¹Fluidigm Corp, South San Francisco, CA, ²Fluidigm Corporation, South San Francisco, CA

In vitro studies using pluripotent stem cells provide an essential tool for understanding hard-to-study in vivo developmental processes. Human iPSCs also holds great potential for disease modeling and cell-based therapies. A major challenge in the stem cell field, however, is to define the optimal condition for cell expansion, differentiation, and reprogramming. Since multiple intra- and extra-cellular signaling

pathways are involved in each cellular process, a combinatorial approach to screen multiple factors is highly desirable. To facilitate the exploratory processes, we have developed an automated cell culture system for cell manipulation and environmental control. The system consists of an integrated fluidic circuit (IFC), an electro-pneumatic controller instrument, experimental designer software, and automated run-time control software. Each IFC has 32 culture microchambers and 16 reagent inlets. Each microchamber can be dosed separately with different combinations and ratios of the 16 reagents at various predefined time points. Using this system, we have developed a novel nonintegrating method for direct conversion of human BJ fibroblasts to neurons at high efficiency and cell viability using microRNA mimics (miR-9, 9*, 124) and synthetic mRNAs (NeuroD2, Ascl1, and Myt1L). The system is compatible with multiple extracellular matrices including Matrigel[®], vitronectin, and fibronectin, It allows 3-day hands-off operation and long term cell culture (more than three weeks). We demonstrated that human iPSCs can differentiate to neural progenitor cells or nociceptor neurons on the IFC after treatment with small molecules. Furthermore, using combinations of small molecules and signaling proteins in chemically defined media, we demonstrated directing human iPSCs into primitive lineages of all three germ layers on one IFC within four days. Immunostaining of marker proteins and single-cell gene expression analysis were used to profile the cell types. The results were consistent with published reports and confirmed in large well-dish format. Finally, we have also developed protocol for RNA transfection that allows efficient delivery of exogenous mRNA such as nGFP into human iPSCs as well as successful siRNA knockdowns of either endogenous or exogenous genes. Using a siRNA against the pluripotent gene OCT4, we repeatedly demonstrated more than 50% knock-down in both RNA and protein levels of the gene, providing an easy approach for gene manipulation within human iPSCs. In summary, the automated microfluidic platform employs precise control of microenvironment of cells, facilitates studies of multifactorial combinations, and enables development of robust, reproducible, and chemically defined cell culture and manipulation.

Optical clearing of mouse skeletal muscle with the CLARITY method.

A. Milgroom¹, E. Ralston¹;

¹NIAMS, NIH, Bethesda, MD

Skeletal muscle has several levels of organization that may be specifically modified during development or in diseases, from the myofibrils to the whole muscle. It may be interesting, for example, to visualize the pattern of innervation or vascularization of a whole muscle. Fluorescent proteins conjugated to muscle proteins can be expressed in skeletal muscles and can be visualized in single dissociated fibers, in small bundles of fibers, or in vivo within a millimeter or less of the muscle surface. However, they cannot be localized in whole muscles, which are opaque to light. We now report that we have successfully applied the CLARITY method (Clear Lipid-exchanged Acrylamide-hybridized Rigid Imaging/Immunostaining/In situ hybridization-compatible Tissue-hydrogel; Chung et al., 2013, Nature 497, 332) to the clearing of the soleus and extensor digitorum longus (EDL) muscles of the mouse. The

CLARITY method we applied toward muscle tissue clarification is an adaptation of a technique originally used to clarify soft, lipid-rich brain tissue. In our application, the muscles were treated as described in the original technique, with small modifications: incubation in a solution containing a hydrogel monomer, paraformaldehyde, and a thermal initiator for 3 days at 4°C; followed by gelling at 37°C and clearing by electrophoresis at 23V for 8h. So far, attempts to label actin myofilaments in the whole muscle with fluorescent phalloidin, as well as neuromuscular junctions with Alexa-555-conjugated bungarotoxin, have failed. However, nuclei could be viewed after staining with Hoechst 33242 and myosin heavy chain bands could be imaged in 2-photon Second Harmonic Generation (SHG) imaging, albeit with reduced intensity compared to intact muscle. Thus it is possible to clarify a tissue like skeletal muscle, rich in connective tissue and filamentous proteins and low in fat. Furthermore basic muscle fiber organization and the myosin heavy chain organization responsible for SHG are maintained in the clarified muscle.

Monitoring perturbations in endoplasmic reticulum calcium homeostasis using a novel secreted reporter protein.

M.J. Henderson¹, E.S. Wires¹, K.A. Trychta¹, C.T. Richie¹, X. Yan¹, B.K. Harvey¹;

¹NIDA/NIH, Baltimore, MD

Calcium in the endoplasmic reticulum (ER) is maintained at a concentration approximately 10,000-fold greater than the cytoplasm. ER calcium homeostasis is critical for cellular functions and is disrupted in diverse pathologies including diabetes, cardiovascular diseases, and neurodegenerative diseases. Defining the relationship between disease progression and ER calcium imbalance, however, is challenging due to technological limitations. We have developed a tool that allows the examination of ER calcium fluctuations over extended times, which we have termed SERCaMPs, or secreted endoplasmic reticulum calcium monitoring proteins. Our studies identified a carboxy-terminal amino acid sequence (ASARTDL) that localizes a secreted protein to the ER and confers release of the protein specifically in response to ER calcium depletion. This sequence was appended to Gaussia luciferase (GLuc), a naturally secreted luciferase protein, to create GLuc-SERCaMP. Monitoring the secretion of GLuc-SERCaMP provides a simple method to assess ER calcium homeostasis *in vitro* or *in vivo* by collecting and measuring extracellular fluids such as culture medium or blood. GLuc-SERCaMP signal is robust, with detection of ER calcium depletion possible in as few as twenty cells in culture. We assessed the utility of GLuc-SERCaMPs in models of ER stress, including hyperthermia and glutamate toxicity, in rat primary neurons. Additionally, ER calcium homeostasis in rat liver was examined by measuring release of the reporter into blood. Our results suggest that SERCaMPs will have broad applications for the long term monitoring of ER calcium homeostasis and the development of therapeutic approaches to counteract ER calcium dysregulation.

An Alternative Mechanism for Actin Arc Formation at the Immunological Synapse of Jurkat T cells.

S. Murugesan¹, J. Yi¹, D. Li², L. Shao², E. Betzig², X. Wu³, J.A. Hammer¹;

¹NIH\NHLBI, Bethesda, MD, ²HHMI/Janelia Farm Research Campus, Ashburn, VA, ³NIH/NHLBI, Bethesda, MD

Actin cytoskeletal organization and dynamics play fundamental roles in T cell immunological synapse (IS) formation. The T cell's actin cytoskeleton undergoes striking rearrangements upon contact with an antigen presenting cell (APC) to form radially symmetric segregated domains named the distal, peripheral and central supramolecular activation clusters (dSMAC, pSMAC, and cSMAC). The outer dSMAC corresponds to a lamellipodial (LP) actin network composed of branched actin arrays that undergo robust, polymerization-driven actin retrograde flow. The central pSMAC corresponds to a lamellar (LM) actin network composed of concentric actin arcs that undergo actomyosin II-driven contraction. Finally, the inner cSMAC is largely devoid of actin. This bull's-eye pattern of SMACs generates a centripetal flow of actin that drives the inward movement of signaling and adhesion molecules to create a mature IS. Here we addressed how the concentric, linear actomyosin II arcs in the pSMAC are assembled. Current thinking would have it that the branched actin network in the dSMAC, which is created by Arp2/3-dependent nucleation, is converted by debranching and crosslinking into the concentric arcs. Using structured illumination microscopy, we identified for the first time linear actin filaments that are arranged perpendicular to the plasma membrane and that are embedded in the branched actin network in the dSMAC. As these filaments exit the inner aspect of the dSMAC, they splay out and reorient into concentric arcs with an inherent antiparallel organization required for myosin II-dependent contraction. The perpendicular actin filaments in the dSMAC are highlighted and accentuated by inhibiting Arp2/3-dependent actin polymerization using CK666, which collapses the branched actin array in between the perpendicular filaments. Importantly, inhibition of myosin II using blebbistatin results in loose, disorganized filaments in the pSMAC that fail to reorient into concentric arcs. These observations suggest that arc assembly can occur independently of Arp2/3-dependent nucleation, and that myosin II contractility is required for reorienting the perpendicular filaments emanating from the dSMAC into the concentric arcs in the pSMAC. We are now attempting to define the relative contributions of debranching/rearrangement of the branched actin network versus nucleation of linear filaments, possibly by the formin INF2 present on the plasma membrane at the tips of the perpendicular filaments, to the formation of the actin arcs in the pSMAC.

P45**Board Number: B145****A Coarse-Grained Model of Lamellipodium Protrusion and Retraction Driven by Fluctuations in Actin Polymerization.**G.L. Ryan¹, D. Vavylonis², N. Watanabe³;¹Department of Physics, Kettering University, Flint, MI, ²Department of Physics, Lehigh University, Bethlehem, PA, ³Tohoku Univ Grad Sch Life Scis, Sendai, Japan

Animal cells that spread onto a surface often rely on actin-rich cell extensions called lamellipodia to execute cell protrusion. XTC cells on a two-dimensional substrate exhibit regular protrusion and retraction of their lamellipodium, even though the cell is not translating. Travelling waves of protrusion have also been observed, similar to those observed in crawling cells. These periodic fluctuations in leading edge position have been linked to excitable actin dynamics near the cell edge using a one dimensional model of actin dynamics, as a function of arc-length along the cell. In this work we extend this earlier model of actin dynamics into two-dimensions (along the arc-length and radial directions of the cell) and include a model membrane that protrudes and retracts in response to the changing number of free barbed ends of actin filaments near the membrane. We show that if the polymerization rate of these barbed ends changes depending on their local concentration at the leading edge and the opposing force from the cell membrane, the model can reproduce the patterns of membrane protrusion and retraction seen in experiment. We investigate both Brownian ratchet and switch-like force-velocity relationships between the membrane load forces and actin polymerization rate.

P46**Board Number: B146****The role of filopodia in directed cancer cell migration in 2D and 3D.**A. Simon¹, S. Geraldo², P. Maiuri², a. funfak³, j. bibette³, m. piel¹, D. Vignjevic²;¹Inst Curie-Ctr De Recherche, Paris, France, ²Institut Curie, Paris, France, ³75005, ESPCI, PARIS, France

When cancer cells escape the primary tumor, they invade into the surrounding tissue and migrate through the extracellular matrix to reach the circulatory system. It is, therefore, conceivable that cancer cells migrate directionally towards the blood vessels. Directional guidance of cells following gradients of growth factors and chemokines are known to exist in vivo during embryonic development and immune response. Filopodia are thought to be the guidance organelles for directional migration through gradients. However, besides studies in neuronal and endothelial cells, there is no evidence confirming this hypothesis in other cell types, such as cancer cells. Using stable CT26 intestinal cancer cell line as a model for invasive tumorigenesis, we investigated if filopodia have a role in directed cancer cell migration in 2D and 3D substrates. The expression of proteins involved in filopodia formation and/or stabilization was inhibited in order to study the ability of depleted cells to move towards a source of growth factors. The different depleted cell lines were compared for their ability to perform chemotactic movements on a planar substrate towards a source of growth factors, using the Dunn's chamber. WT

cells were able to move directionally and persistently towards the attractants, whereas cells depleted for Fascin, mDia2 and MyosinX were not able to migrate directionally towards the gradient. These results show that filopodia are necessary for directional migration of cancer cells on 2D. To assess the role of filopodia in invasive migration of cancer cells through 3D environments, we embedded cancer cell spheroids in 3D matrices of collagen I. After 48 hours, WT cells present typical mesenchymal morphology, invading and migrating between the collagen fibers in a stellar pattern radiating from the spheroid periphery. Only Eps8 and MyoX depleted cells presented a round morphology in 3D and a dramatic decreased invasion of collagen 3D matrices. Finally, we are currently assessing if filopodia are guidance organelles for cancer cells migration in 3D matrices. For this study we are using a microfluidic 3D chemoinvasion chamber allowing the formation of long-term gradients of growth factors in a collagen matrix.

Retinomotor movements and the distribution of the visual enzyme, RPE65, in fish retinal pigment epithelial cells.

M. O'Donnell¹, C. King-Smith²;

¹Biology, Saint Joseph's University, Philadelphia, PA, ²Department of Biology, Saint Joseph's University, Philadelphia, PA

Eyes of lower vertebrates, including fish, lack a dilatable pupil to regulate light flux. Instead, dramatic retinomotor movements occur, which involve movement of melanin pigment granules in the retinal pigment epithelium (RPE) and elongation and contraction of photoreceptor inner and outer segments. When exposed to light, pigment granules create a moveable screen and disperse throughout the RPE elongated apical projections. Rods, responsible for dim light vision, elongate and are enveloped by pigment-filled RPE. Cones, which are responsible for color and bright- light vision, contract, putting them first in line to light entering the eye. In the dark, these retinomotor movements are reversed. RPE pigment granule migration and the positional rearrangements of photoreceptors are actin- and microtubule-dependent. A different type of light-dependent motility in RPE of mammalian eyes was reported in a recent study. RPE contains an isomerase, RPE65, which regenerates the all-trans retinal chromophore back to its cis-form, crucial for the visual cycle. RPE65 localizes towards the apical side of mouse RPE in the dark and redistributes to the basal side in the light. This motility appears to be an actin-myosin dependent process, requiring the motor protein, myosin VIIa (Lopes, et al. 2011, Hum Mol Gen, 20: 2560). Since pigment granule movement in fish RPE also requires actin and is much more extensive than in mammalian eyes, we are investigating whether RPE65 similarly undergoes light-dependent translocation in fish RPE. In dissociated, isolated fish RPE cells *in vitro*, RPE65 was identified in apical projections using immunofluorescence, however no change in RPE65 distribution was observed in cells triggered to aggregate or disperse pigment granules. To determine if RPE65 undergoes redistribution in light- and dark- adapted eyes *in situ*, we labeled cryosections of RPE plus retina. Although RPE65 labeling in the RPE was visible, melanin pigment quenched some fluorescence. We are

currently working with albino catfish RPE-retina to eliminate issues with pigment quenching and to characterize RPE65 distribution in fish RPE.

TRIM9 Regulates Filopodia During Cortical and Retinal Development.

N. Boyer¹, S. Gupton²;

¹Cell and Molecular Biology, University of North Carolina, Chapel Hill, NC, ²Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC

Early in neuronal development actin-rich filopodial protrusions are a critical prerequisite for neurite formation. Later, as nascent axons extend toward their postsynaptic partners, filopodia are central in growth cone response to extracellular axon guidance cues such as netrin-1. The netrin-1 receptor DCC localizes to axonal filopodia tips and mediates netrin-1 dependent filopodia formation and elongation as well as subsequent growth cone chemoattraction toward higher concentrations of netrin-1. We previously found that the E3 ubiquitin ligase TRIM9 binds DCC and is an important regulator in netrin-1 attractive signaling in murine cortical neurons. We show that TRIM9 interacts with actin regulatory proteins that promote filopodia formation, including members of the Ena/VASP family and Myo10, and that TRIM9 regulates filopodia number. Whereas the growth cones of cortical neurons typically have low basal numbers of filopodia that increase in response to netrin-1 stimulation, cortical neurons isolated from *TRIM9* knockout mice have elevated growth cone filopodia number that fail to respond to netrin-1. As such, *TRIM9*^{-/-} neurons morphologically resemble wild-type neurons treated with netrin-1 but lack sensitivity to netrin-1. Using high resolution time-lapse microscopy, we analyzed filopodia dynamics in cortical neurons; this revealed that loss of *TRIM9* increases the lifetime of individual filopodia, as does treatment of wild-type neurons with netrin-1. To determine if TRIM9-mediated regulation of filopodia lifetime and response to netrin-1 were conserved in other neuronal types, we investigated the role of *TRIM9* in retinal development. Retinal ganglion cells (RGCs) are another neuron type for which netrin-1 signaling is critical for axon guidance into the optic nerve. Cultured RGCs from *TRIM9*^{-/-} embryos again exhibited increased filopodia length compared to controls and failed to appropriately respond to netrin-1. Genetic loss of *TRIM9* results in a thinning of the RGC nuclear and nerve fiber layers in the adult murine retina as well as reduction in the number of RGC nuclei *in vivo*. Our findings suggest that TRIM9 is critical in the development of many neuronal types as well as in regulating filopodial responses to netrin-1 signaling. Current experiments are aimed to determine the mechanisms of TRIM9 mediation of pathways in netrin-1 signaling, as well as its relation to other neuronal guidance cues involved in retinal development such as Slits.

P49**Board Number: B149****Actin filaments are necessary for maintaining the normal structure of apical tubulobulbar complexes in the seminiferous epithelium.**K. Lyon¹, E. Bosseboeuf², A. Vogl¹;¹Cellular and Physiological Sciences, UBC, Vancouver, BC, ²Sciences Fondamentales et Appliquées, University de Poitiers, Poitiers, France

Here we explore the effects of actin perturbation on the morphology of tubulobulbar complexes in apical regions of the seminiferous epithelium. Tubulobulbar complexes are elongate subcellular machines responsible for the internalization of intercellular junctions during sperm release. Each tubulobulbar complex consists of a double membrane tubular core terminating in a clathrin coated pit. The membrane core is surrounded by a network of actin filaments and a distinct swelling or bulb develops in the distal third of the structure. Isolated testes were perfused for one hour with oxygenated Krebs Henseleit buffer (with BSA) at 33°C containing either cytochalasin D (10, 20 or 40 uM) or DMSO (control). They were then perfusion fixed either for fluorescence or electron microscopy. Quantification of fluorescently labeled actin at apical tubulobulbar complexes was done using thresholding techniques and demonstrated that the structures at stage VII of spermatogenesis were associated with lower levels of actin in experimental spermatids compared to controls. When evaluated at the electron microscopic level, the actin networks appeared patchy and expanded further away from the membrane cores than in controls. Ectopic bulb regions were also seen near the bases of the complexes in experimentally treated tissue. We conclude that the actin networks are necessary for maintaining the normal structure of apical tubulobulbar complexes. Supported by a NSERC Discovery Grant to AWV.

P50**Board Number: B150****Mutations in *Drosophila* crinkled/Myosin VIIA disrupt denticle morphogenesis.**J.L. Sallee¹, J. Crawford², V. Singh², D.P. Kiehart³;¹North Central College, Naperville, IL, ²Biology, Duke University, Durham, NC, ³Duke University, Durham, NC

Actin filament crosslinking, bundling and motor proteins are necessary for the assembly of epithelial projections such as microvilli, stereocilia, hairs, and bristles. Mutations in such proteins cause defects in the shape, structure, and function of these actin-based protrusions. One protein, Myosin VIIA, is an actin-based motor protein conserved throughout phylogeny. In *Drosophila melanogaster*, severe mutations in crinkled (ck) are “semi-lethal” with only a very small percentage of flies surviving to adulthood. Such survivors show morphological defects related to actin bundling in hairs and bristles and are deaf. To better understand ck/MyoVIIA’s function in bundled-actin structures, we used dominant female sterile approaches to analyze the loss of maternal and zygotic ck/MyoVIIA in the morphogenesis of denticles, small actin-based projections on the ventral epidermis of *Drosophila* embryos.

Maternal/zygotic ck/MyoVIIA mutants displayed severe defects in denticle morphology – actin filaments initiated in the correct location, but failed to elongate and bundle to form normal projections. Using deletion mutant constructs, we demonstrated that the motor domain and both of the C-terminal MyTH4 and FERM domains are necessary for proper denticle formation. Furthermore, we showed that ck/MyoVIIA interacts genetically with dusky-like (dyl), a member of the ZPD family of proteins that links the extracellular matrix to the plasma membrane. Loss of one protein does not alter the localization of the other; however, loss of the two proteins together dramatically perturbs denticle shape. Our data indicate that ck/MyoVIIA plays a key role in arranging actin filament bundles into biologically functional units, which drive proper shape of cellular projections. Dystroglycan depletion inhibits the functions of differentiated HL-60 cells.

A. Martínez-Zárate¹, I. Martínez-Vieyra^{1,2}, L. Alonso-Rangel¹, B. Cisneros³, S.J. Winder⁴, D. Cerecedo^{1,2}; ¹laboratorio de Hematobiología, Instituto Politécnico Nacional, Mexico DF, Mexico, ²laboratorio de Hematobiología, Instituto Politécnico Nacional, Mexico, Mexico, ³Genetics and Molecular Biology, CINVESTAV, Mexico, D.F., Mexico, ⁴Biomedical Science, University of Sheffield, Sheffield, United Kingdom

Haematopoiesis involves the coordination of several signal transduction pathways, which are induced by extracellular stimuli through cell–cell and cell–extracellular matrix (ECM) interactions. Interactions with the ECM binding partners represent the critical steps by which cells initiate cytoplasmic signaling essential for the regulation of their growth, differentiation, attachment and migration, and are important factors in the development and progression of many types of cancer. Dystroglycan (Dg) is an adhesion molecule responsible for crucial interactions between ECM and the cytoplasmic compartment. It is formed by two subunits, α -Dg (extracellular) and β -Dg (transmembrane), that bind respectively to laminin in the matrix and to one of several cytolinker proteins such as dystrophin with the cytoskeleton. As an integral part of the dystrophin glycoprotein complex (DGC) of skeletal muscle, dystroglycan is essential for signaling events mediated through this complex that may have a role as a mechanochemical, force-transducing system or shock-absorber and indirectly mediating other signaling pathways associated with the DGC. Dystroglycan has recently been characterized in blood tissue cells, as part of the dystrophin glycoprotein complex but to date nothing is known of its role in the differentiation process of neutrophils. We have investigated the role of dystroglycan in the human promyelocytic leukemic cell line HL-60 differentiated to neutrophils. Depletion of dystroglycan by RNAi resulted in altered morphology and reduced properties of differentiated HL-60 cells, including chemotaxis, respiratory burst, phagocytic activities and expression of markers of differentiation. These findings strongly implicate dystroglycan as a key membrane adhesion protein involved in the differentiation process in HL-60 cells and so is therefore of considerable functional importance.

P52**Board Number: B152****Discoidin domain receptor 1 controls linear invadosome formation.**

J. Di Martino¹, A. Juin², B. Leitinger³, L. Paysan¹, J. Bomo⁴, G. Baffet⁴, J. Rosenbaum¹, V. Moreau¹, F. Saltel¹;

¹INSERM U1053, Bordeaux, France, ²Cancer Research UK Beatson Institute, Glasgow, United Kingdom, ³Imperial college London, National Heart and Lung Institut, London, United Kingdom, ⁴INSERM U1085, Rennes, France

Accumulation of type I collagen fibrils in tumors is associated with an increased risk of metastasis. Invadosomes are F-actin structures able to degrade the extracellular matrix. We previously found that collagen I fibrils induced the formation of peculiar linear invadosomes in an unexpected integrin-independent manner, raising the question of the receptor involved. Here, we show that Discoidin Domain Receptor 1 (DDR1), a collagen receptor overexpressed in cancer, co-localizes with linear invadosomes in tumor cells and is required for their formation and matrix degradation ability. Unexpectedly, DDR1 kinase activity was not required for invadosome formation or activity, nor was Src tyrosine kinase. We show that the RhoGTPase Cdc42 localizes to linear invadosomes, is activated upon plating cells on collagen in a DDR1-dependent manner, and is required for linear invadosome formation. Finally, DDR1 depletion blocked cell invasion in a collagen gel. Altogether, our data uncover the important role of DDR1, acting through Cdc42, in proteolysis-based cell invasion in a collagen-rich environment.

P53**Board Number: B153****Metabolic filaments, the actin cytoskeleton, and orphan diseases.**

R.M. Broyer¹, J.E. Wilhelm²;

¹Biology, University of California, San Diego, La Jolla, CA, ²University of California, San Diego, La Jolla, CA

A core question in disease research is to determine how the cell is altered on a molecular level in affected individuals. In the case of diseases caused by inborn errors of metabolism, this means identifying the relationship between activity of the affected enzyme and the observed disease phenotypes. Recently, we uncovered nearly 50 previously unidentified, conserved filamentous structures including eight novel filament systems that are comprised of enzymes with previously described roles in cellular metabolism. Because these enzymes are implicated in intermediate metabolism, we have focused on answering two key questions. First, have these filaments acquired any cell biological or cytoskeletal role that is separable from the known function of the enzyme. Second, are there any inborn errors of metabolism whose phenotypes can be explained by understanding the function of these polymers. To answer these questions, we have focused our efforts on PRPP synthase, a metabolic enzyme that forms filaments that are conserved from yeast to humans. Interestingly,

Human PRPP synthase forms a novel nuclear filament. Since there are no known roles for PRPP in the nucleus, this suggested the filament might have a specific nuclear function. Furthermore, there are several classes of human disease mutations in PRPP synthase - overexpression mutations which cause gout, loss of function mutations that cause deafness and ataxia, and feedback resistance mutations that cause gout, deafness, and ataxia. The fact that feedback resistance mutations cause both gain and loss of function phenotypes also suggested that PRPP synthase filaments might have acquired a second function separable from its enzyme activity. Using fibroblasts from human patients, we have found that superactivity mutations cause PRPP synthase to polymerize in the cytoplasm where filaments are not normally found. These filaments are not nonfunctional aggregates since treatment with purine metabolites can cause reversible disassembly of the filaments. This suggests that superactivity mutations can generate dominant negative filaments in the cytoplasm leading to a loss of function phenotype. Additionally, we have identified a protein that co-localizes with PRPP synthase filaments that also appears to be required for *Drosophila* bristle formation, suggesting a link between purine metabolism and actin cytoskeleton regulation. This provides the first molecular explanation for how mutations in a purine biosynthetic enzyme can cause non-syndromic deafness in humans and opens the door for exploring how other metabolic polymers might explain the symptoms associated with many inborn errors of metabolism.

Actin Cytoskeletal Dynamics Regulate Adhesion and Force Generation in Airway Smooth Muscle Cells.

Y.M. Beckham^{1,2}, J. Solway³, M.L. Gardel⁴;

¹James Franck Institute, Institute for Biophysical Dynamics and Physics Department, University of Chicago, Chicago, IL, ²Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, ³Department of Medicine, University of Chicago, Chicago, IL, ⁴James Franck Institute, Institute for Biophysical Dynamics and Physics Department, University of Chicago, Chicago, IL

Actin dynamics in non-muscle cells have been well characterized and shown to play crucial roles in regulation of cell adhesion, migration and force generation. Despite this extensive knowledge, much less is known about the regulation of the actin cytoskeleton in smooth muscle cells. Adhesion and force generation by smooth muscle cells are crucial to many physiological functions and contribute to the pathology of numerous diseases, including asthma. Here we demonstrate that adherent human airway smooth muscle cells (hASM) have an actin cytoskeleton that is highly reminiscent to that of non-muscle cells. The cell periphery is dominated by an Arp 2/3-mediated lamellipodium while the cell center is characterized by a myosin-rich and formin-mediated lamella. Moreover, these actin-based organelles control cell adhesion and force generation in a similar fashion to their role in non-muscle cells. Arp2/3 inhibition eliminates the lamellipodium and results in abrogated nascent adhesion assembly and a reduction in hASM cell adhesion. Inhibition of formin-mediated actin assembly results in a decrease in lamellar actin by at least 25 percent. This formin-dependent decrease in lamellar actin results in a 60

percent decrease in contractility of hASM cells. This work suggests that models of non-muscle cell contractility may be useful in understanding the mechanics of airway smooth muscle cells.

Distinct Actin Filament Networks Modulate Different Cell Signalling Pathways Involved in Cell Proliferation and Senescence.

G. Schevzov¹, B. Wang¹, J.W. Hook¹, C. Tonthat¹, I. Pleines², B. Kile², E.C. Hardeman¹, P.W. Gunning¹; ¹School of Medical Sciences, UNSW, Sydney, Australia, ²Water and Eliza Hall Institute, Melbourne VIC, Australia

The spatial and temporal control of signalling pathways that regulate cellular processes, including proliferation and senescence, is orchestrated by a complex network of interactions involving scaffolding proteins and kinases. The actin cytoskeleton is known to play a critical role in integrating such signalling pathways. Within a cell functionally diverse actin filament networks are present. Currently, the molecular mechanism(s) by which these actin networks participate in signalling pathways is not well-understood principally due to a lack of tools that discriminate between them. Tropomyosins (Tm), a family of actin filament-associated proteins, can impart unique cellular functions to the actin cytoskeleton. Our investigations using mouse embryonic fibroblasts (MEFs) isolated from Tm isoform-specific knockout (KO) and transgenic mice have revealed significant alterations in cell proliferation and life span. Ablation of Tm5NM1 results in reduced cell proliferation in direct contrast to its overexpression. This result is Tm5NM1-specific since ablation of Tm4 shows no impact on proliferation. We show that Tm5NM1-mediated proliferation occurs via the MEK/ERK pathway. Furthermore we demonstrate that in the absence of Tm5NM1 the formation of pERK and its nuclear shuttling protein Importin 7 is reduced resulting in the observed impaired cell proliferation. In contrast, an in vitro life span assay demonstrates that Tm4 KO MEFs can readily escape senescence unlike the Tm5NM1 KO cells. The Tm4 KO MEFs show dysregulation of the PKC and JAK-STAT pathways. These studies provide the first evidence that specific Tm-containing actin filaments can influence signalling pathways. Taken together these findings allow us to begin to understand how signalling pathways are regulated within the cell in space and time via different actin filament networks marked by specific Tm isoforms.

P56**Board Number: B156****Zyxin mediated regulation of airway smooth muscle function may be involved in asthmatic airway hypercontractility.**

S.R. Rosner¹, C.D. Pascoe², E. Blankman³, C.C. Jensen³, R. Panganiban⁴, R. Krishnan⁵, C.Y. Seow², J. Park⁴, Q. Lu¹, M.C. Beckerle³, P.D. Pare², J.J. Fredberg⁴, M.A. Smith³;

¹Department of Environmental Health, Harvard School of Public Health, Boston, MA, ²St Paul's Hospital Center for Lung Innovation, University of British Columbia, Vancouver, BC, ³Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, ⁴Harvard School of Public Health, Boston, MA, ⁵Center for Vascular Biology Research, Beth Israel Deaconess Medical Center, Boston, MA

Morbidity and mortality due to asthma arise mainly from loss of airway patency as a result of airway hypercontractility. Airway hypercontractility is the result of excessive contraction of airway smooth muscle. Airway hypercontractility in the non-asthmatic lung is readily reversed by the taking of a deep breath, which results in bronchodilation. A deep breath stretches the contracted airway smooth muscle causing it to fluidize rapidly and then resolidify slowly. On the other hand, airway hypercontractility in the asthmatic lung is generally refractory to the dilative effect of a deep breath. In the asthmatic case, the airway smooth muscle enters what is called a latch state, wherein the parenchymal tissue lacks sufficient tethering force to stretch the airway smooth muscle. The molecular mechanisms of stretch induced airway smooth muscle fluidization and resolidification are unknown, as is the mechanism of its failure in asthmatics.

The LIM-domain scaffolding protein zyxin has been shown to be involved in repairing, remodeling and reinforcing actin stress fibers in response to mechanical strain. Thus, zyxin is essential for generation of peak traction forces. Zyxin is rapidly recruited to sites of stress fiber strain, where it enlists actin regulatory proteins to effect repair. Due to its role in regulation of the actin cytoskeleton's response to force, we hypothesized zyxin might be involved in the regulation of the airway smooth muscle response to stretch. In this work we show that zyxin plays a critical role in reinforcing the actin cytoskeleton of airway smooth muscle in response to stretch. We demonstrate that zyxin responds to physiologic levels of isotropic stretch through rapid recruitment to sites of acute strain on stress fibers, and in murine airway smooth muscle, loss of zyxin results in abrogated resolidification following single or multiple stretches. In precision cut lung slices from wild type or zyxin null mice, the airways from zyxin null mice dilate more rapidly in response to stretch. Furthermore, zyxin expression is increased in the lungs of humans who experienced fatal asthma attacks.

Together, these data show a role for zyxin in the regulation of airway smooth muscle response to stretch, and suggest a connection to airway hypercontractility in human asthmatics.

P57**Board Number: B157****Synthetic polyamines promote rapid lamellipodial growth by regulating actin dynamics.**D. Riveline¹;¹Laboratory of Cell Physics ISIS/IGBMC, Strasbourg, France

Cellular protrusions involved in motile processes are driven by site-directed assembly of actin filaments in response to Rho-GTPase signalling. So far, only chemical compounds depolymerizing actin or stabilizing filaments, inhibiting N-WASP, Arp2/3 or formins, have been used to eliminate the formation of protrusions, while Rho-GTPase-dominant positive strategies have been designed to stimulate protrusions. Here we describe the design of four polyamines (macrocyclic and branched acyclic), and show that they enter the cell and induce specific growth of actin-enriched lamellipodia within minutes. The largest increase in cell area is obtained with micromolar amounts of a branched polyamine harbouring an 8-carbon chain. These polyamines specifically target actin both in vitro and in vivo. Analysis of their effects on filament assembly dynamics and its regulation indicates that the polyamines act by slowing down filament dynamics and by enhancing actin nucleation. These compounds provide new opportunities to study the actin cytoskeleton in motile and morphogenetic processes.

P58**Board Number: B158****Biomechanical characterization of a new cellular model for Filamin C-related myofibrillar myopathy.**W.H. Goldmann¹, F. Chevessier-Tuennesen², L. Einsiedler^{1,2}, R. Schröder², B. Fabry¹;¹Friedrich-Alexander-Univ/Ctr Med Physics Technol, Erlangen, Germany, ²Institute of Neuropathology, University Hospital Erlangen, Erlangen, Germany

Mutations on chromosome 7q32 of the human filamin C gene (FLNC) are responsible for an autosomal dominant form of myofibrillar myopathy. The expression of mutant W2710X filamin C, the most common pathogenic mutation in humans, leads to the disruption of Z-discs of striated muscle sarcomeres and abnormal protein aggregates. We tested whether the expression of mutant filamin C protein changes the biomechanical properties and the intrinsic mechanical stress response of immortalized myogenic cells derived from heterozygous and homozygous filamin C knock-in mice bearing the human homologous W2711X mutation. Compared to wildtype cells, mutant filamin C myoblasts and myotubes showed increased cell death and substrate detachment in response to cyclic stretch on flexible membranes. Moreover, 2D force microscopy of murine myoblasts showed lower

tractions in mutated compared to wildtype cells. Our findings provide first evidence that altered mechanical properties may contribute to the progressive striated muscle pathology in filaminopathies. We postulate that the expression of mutant filamin C leads to altered biophysical properties making these mutated myogenic cells more vulnerable to mechanical stress.

Determining the impact of the actin cytoskeleton on the mechanical properties of cells.

I. Jalilian¹, G. Schevzov¹, T. Fath¹, C. Heu¹, L. Bischof², H. Vindin¹, J.R. Stehn¹, M. Knothe Tate³, E.C. Hardeman¹, P.W. Gunning¹;

¹School of Medical Sciences, UNSW, Sydney, Australia, ²Quantitative Imaging Group, CSIRO, Sydney, Australia, ³Graduate School of Biomedical Engineering, UNSW, Sydney, Australia

The influence of the actin cytoskeleton on the shape and mechanical properties of cells has been revealed extensively using anti-actin drugs. However, due to the lack of the specificity of these compounds for different actin filament populations it has been difficult to delineate the exact role of the actin cytoskeleton in these cellular features. Actin binding proteins largely affect the organisation and dynamics of actin in cells; however, the impact of these proteins on the mechanical properties of cells is still unknown. Tropomyosins (Tms) form a co-polymer with actin filaments and differentially regulate actin filament stability, function and organisation through their highly regulated expression and sorting to specific intracellular sites. Hence, Tm isoforms can be used as tools to identify and manipulate functionally distinct actin filament populations in a cell. In this study we investigated the impact of Tm-containing actin filaments on the organisation of the actin cytoskeleton and the mechanical properties of cells.

To investigate the role of different Tms, and hence different actin filaments, on cellular stiffness we examined rat neuroblastoma cells stably overexpressing TmBr3, Tm3, Tm4 or Tm5NM1 in comparison with control cells. Analysis of the number and length of actin cables per cell using a morphometric linear feature detection algorithm revealed significant differences in the length and number of actin cables per cell relative to that seen in the control cells. The mechanical measurements conducted by indentation-type atomic force microscopy (AFM) showed that TmBr3-, Tm4- and Tm5NM1-overexpressing cells were significantly stiffer than control cells. In contrast, cell stiffness did not change in Tm3-overexpressing cells indicating that the observed changes in cell elasticity are not a generic effect of accumulating more Tm. Moreover, siRNA knockdown of Tm5NM1 in Tm5NM1-overexpressing cells caused the elastic modulus to revert to that of control cells.

The results show that cell stiffness increases in TmBr3-, Tm4- and Tm5NM1-overexpressing cells. Since, the overexpression of Tm changes the numbers and length of the actin cables in an isoform-specific manner that is not directly related to cell stiffness, our data suggest that the mechanical properties of cells are more dependent on the organisation of the actin filaments than the number and length of actin

filaments. Therefore, we conclude that it is specific aspects of actin organisation which regulate the mechanical properties of the cell.

Dynamic actin filaments control the mechanical behavior of the human red blood cell membrane.

D.S. Gokhin¹, R.B. Nowak¹, N.E. Kim¹, J.A. Khoory², I.C. Ghiran², V.M. Fowler¹;

¹Department of Cell and Molecular Biology, The Scripps Research Institute, La Jolla, CA, ²Department of Medicine, Beth Israel Deaconess Medical Center, Boston, MA

The mammalian red blood cell (RBC) contains an underlying membrane skeleton that imparts the RBC with mechanical properties optimized for efficient passage through the microvasculature. The RBC membrane skeleton consists of nodes of short (~37-nm-long) actin filaments interconnected by long ($\alpha_1\beta_1$)₂-spectrin tetramer strands. RBC actin filaments are stabilized along their lengths by two tropomyosin isoforms, TM5NM1 and TM5b, and capped at their pointed and barbed ends by tropomodulin1 and $\alpha\beta$ -adducin, respectively. However, it remains unknown whether RBC actin filaments (or subsets or portions thereof) are dynamic during normal RBC homeostasis, and, if so, whether actin dynamics regulates RBC mechanical properties. To answer these questions, we first studied actin dynamics by rhodamine-actin (rho-actin) incorporation into RBC ghosts. We also treated RBCs or ghosts with three different actin-disrupting drugs: (i) cytochalasin-D (CytoD), which inhibits actin subunit association and dissociation at barbed ends; (ii) latrunculin-A (LatA), which destabilizes and depolymerizes dynamic actin filaments by binding to and sequestering actin monomers, driving the F:G-actin balance toward the G-actin state; (iii) jasplakinolide (Jasp), which stabilizes dynamic actin filaments, driving the F:G-actin balance toward the F-actin state. Results show that resealed RBC ghosts exhibit rho-actin subunit incorporation into discrete sites within the membrane skeleton, demonstrating that RBC actin filaments are indeed dynamic. Moreover, rho-actin subunit incorporation can be blocked via treatment with CytoD, demonstrating that dynamic subunit exchange occurs at barbed ends. Consistent with dynamic filaments, treatment of intact RBCs with LatA or Jasp induces a ~2-fold increase or a ~60% decrease, respectively, in soluble actin levels. Using total internal reflection fluorescence (TIRF) microscopy, we observed diffuse F-actin staining in DMSO-treated (control) RBCs, whereas LatA (but neither CytoD nor Jasp) treatment induced dramatic rearrangement of the RBC actin network, as indicated by gaps in the F-actin staining pattern. This result suggests the presence of a dynamic subpopulation of RBC actin filaments. LatA treatment and selective disassembly of this subset of RBC actin filaments had no effect on RBC osmotic fragility, but both membrane deformability and spontaneous membrane oscillations (“flickering”) were increased. Collectively, these results provide the first direct evidence for the existence of a dynamic subpopulation of RBC actin filaments, and that actin filament architecture directly controls the mechanics of the human RBC membrane.

P61**Board Number: B161****Localization of IQGAP1 mutants to retracting versus protruding cell areas.**J. Schober¹, M. Reimer¹;¹Pharmaceutical Sciences, Southern Illinois University Edwardsville, Edwardsville, IL

IQGAP1 interacts with numerous binding partners through a calponin homology domain (CHD), a WW motif, IQ repeats, a Ras GAP-related domain (GRD), and a conserved C-terminal (CT) domain. Among various biological and cellular functions, IQGAP1 plays a role in cell-matrix interactions and actin cytoskeleton dynamics during membrane ruffling and lamellipodium protrusion. Phosphorylation in the CT domain regulates intramolecular interaction and IQGAP1 cellular activity. In a recent study, we discovered that IQGAP1 localizes to actively retracting edges, instead of protruding areas, in B16F10 mouse melanoma cells and some other cells types. In these current studies we examined localization of IQGAP1 mutants to retracting versus protruding areas in B16F10 cells. Cells were cotransfected with GFP-IQGAP1 Full Length (GFP-IQGAP1-FL), as an internal control, and one of five Myc-tagged IQGAP1 constructs (FL, S1441E/S1443D, Δ CHD, Δ GRD or Δ CT). The cotransfected cells were plated onto laminin for 30 minutes, stained with anti-Myc and anti-WAVE antibodies, and normalized fluorescence measurements were made in retracting and protruding areas. Retracting cell areas were defined as GFP-IQGAP1-FL positive and WAVE negative, while protruding cell areas were defined as GFP-IQGAP1-FL negative and WAVE positive. In retracting areas there were large decreases in both Δ GRD and Δ CT localization, a slight decrease in Δ CHD localization, and normal localization of the S1441E/S1443D mutant. In areas of cell protrusion there were large increases in both Δ GRD and Δ CT localization, and normal localization of Δ CHD and S1441E/S1443D mutants. These results indicate that two domains, GRD and CT, are essential for normal localization of IQGAP1 to retracting cell areas. Furthermore, our results are consistent with a model in which IQGAP1 in the areas of cell retraction is in the open, phosphorylated, conformation.

P62**Board Number: B162****Role of Rho/Rock/Myosin in Senescence Induced Migration.**I. Aifuwa¹, N. Longe¹, S. An², D. Wirtz^{3,4};¹Johns Hopkins University, Baltimore, MD, ²School of Public Health, Johns Hopkins University, Baltimore, MD, ³Physical Sciences-Oncology Center, Johns Hopkins University, Baltimore, MD, ⁴Department of Pathology and Oncology and Sydney Kimmel Comprehensive Cancer Center, Johns Hopkins University School of Medicine, Baltimore, MD

Cells induced into senescence exhibit a marked increase in the secretion of pro-inflammatory cytokines termed senescence-associated secretory proteins (SASP). Here we report that SASP from senescent stromal fibroblasts promote spontaneous morphological changes accompanied by an aggressive migratory behavior in originally non-motile human breast cancer cells. This phenotypic switch is

coordinated, in space and time, by a dramatic reorganization of the actin and microtubule filament networks, a discrete polarization of EB1 comets, and an unconventional front-to-back inversion of nucleus-MTOC polarity. SASP-induced morphological/migratory changes are critically dependent on microtubule integrity and dynamics, and are largely cooperated via the inhibition of cell contractility. RhoA/ROCK inhibition reduces focal adhesions and traction forces, but promotes a gliding mode of migration.

Rapid Glucose Deprivation Immobilizes Active Myosin-V on Stabilized Actin Cables.

L. Xu¹, A.P. Bretscher²;

¹Weill Institute for Cell and Molecular Biology, Cornell University, Ithaca, NY, ²Cornell University, Ithaca, NY

Polarization of eukaryotic cells requires organelles and protein complexes to be transported to their proper destinations along the cytoskeleton. When nutrients are abundant, budding yeast grows rapidly transporting secretory vesicles for localized growth and actively segregating organelles. This is mediated by myosin-Vs transporting cargos along F-actin bundles known as actin cables. Actin cables are dynamic structures regulated by assembly, stabilization and disassembly. Polarized growth and actin filament dynamics consume energy. For most organisms, glucose is the preferred energy source and generally represses alternative carbon source usage. Thus upon abrupt glucose depletion, yeast shuts down pathways consuming large amounts of energy, including the vacuolar-ATPase, translation and phosphoinositide metabolism. Here we show that glucose withdrawal rapidly depletes ATP levels and the yeast myosin V, Myo2, responds by relocalizing to actin cables within 1 min, making it the fastest response documented. Myo2 immobilized on cables releases its secretory cargo, defining a new rigor-like state of a myosin-V in vivo. Only actively transporting Myo2 can be converted to the rigor-like state. Additionally, glucose depletion has differential effects on the actin cytoskeleton resulting in disassembly of actin patches with concomitant inhibition of endocytosis, and strong stabilization of actin cables, thereby revealing a selective and previously unappreciated ATP requirement for actin cable disassembly. A similar response is seen in HeLa cells to ATP depletion. These findings reveal a new fast-acting energy conservation strategy halting growth by immobilizing myosin-V in a newly described state on selectively stabilized actin cables.

P64**Board Number: B164****Tracking old and newly synthesized β -actin protein in three dimensional MDCK cyst cultures.**P. Vedula¹, A.J. Rodriguez¹;¹Federated Department of Biology, Rutgers University, Newark, NJ

In vivo, most simple epithelia are organized as a monolayer of cells surrounding a central lumen (e.g. intestinal epithelium, kidney tubules, mammary acini, alveolar sacs). *In vitro*, epithelial cells cultured in a 3-dimensional extra-cellular matrix develop into cysts and provide a model system to study epithelial morphogenesis and lumen formation. Previous studies have shown that several polarity proteins (apical and baso-lateral) along with components of the protein sorting machinery play a role in lumen initiation in MDCK cysts grown in matrigel. However the role of mRNA localization on protein synthesis and hence lumen formation and/or maintenance has yet to be determined. In this study, we use MDCK cysts in matrigel to address the role of β -actin mRNA zipcode on its protein synthesis. Utilizing the tetracysteine reporter system and biarsenical dyes – FIAsh and ReAsH, we were able to track β -actin protein synthesis temporally in the 3D cultures. This method provides valuable insight into the dynamic nature of actin based structures in a more physiologically relevant 3 dimensional culture system, thus opening the doors to how mRNA zipcode dependent protein synthesis regulates epithelial structure and function *in vivo*. In fact, we observe that newly synthesized β -actin protein labeled by ReAsH is localized predominantly at the lateral cell-cell junctions while the older protein labeled by FIAsh is distributed at the apical and lateral interfaces. This provides direct evidence for the long standing hypothesis that localized translation of β -actin does indeed dictate its preferential incorporation into different compartments in the cell controlling 3D epithelial morphogenesis.

P65**Board Number: B165****Investigating EB1 interactions with the actin cytoskeleton.**E. Alberico¹, H. Goodson¹;¹University of Notre Dame, Notre Dame, IN

Many cellular processes require coordination between the actin and microtubule cytoskeletons. Cell division and migration are two very important processes that require this type of coordination. Proteins such as mDIA1 and IQGAP1 are known to regulate these interactions. Our lab has found that EB1, a well characterized microtubule binding protein, can also directly interact with actin *in vitro*. Through bioinformatics and mutagenesis we have found that the EB1-actin binding site on EB1 partially overlaps the well characterized EB1-MT binding interface. We are currently investigating the role EB1 has in interacting with the actin cytoskeleton through characterization of EB1 mutants *in vivo*. Understanding the EB1-actin interaction *in vivo* will enhance our knowledge of cytoskeletal coordination and its role in a variety of cellular processes.

P66**Board Number: B166****Microtubule end-binding protein EB1 directly regulates collaborative actin assembly by APC and formins.**R. Jaiswal¹, H. Kim², D. Breitsprecher², B.L. Goode¹;¹Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA, ²Brandeis University, Waltham, MA

Tight coordination of the microtubule and actin cytoskeletons is essential for many biological processes, including directed cell migration, neuronal process formation, spindle rotation, and polarized cell adhesion. However, in few cases have the underlying mechanisms controlling microtubule-actin crosstalk been defined. Earlier studies identified EB1 as a binding partner of APC (adenomatous polyposis coli) and formins (Su et al., 1995; Wen et al., 2004), which prompted us here to investigate EB1's potential effects on APC-formin-mediated actin assembly. Using both TIRF microscopy and bulk actin assembly assays, we observed that purified full-length EB1 directly inhibits the actin nucleation activity of C-terminal fragments of APC, as well as collaborative actin assembly by APC and formins. EB1 specifically inhibited the nucleation of new actin filaments without affecting the elongation rate of existing filaments. Further, multi-wavelength single molecule TIRF experiments showed that EB1 inhibits actin nucleation by blocking the interactions of actin monomers with APC. Additionally, we show that APC directly links actin filaments to microtubule seeds, and that EB1 disrupts this linkage. Together, our results suggest that EB1 may coordinate microtubule plus end dynamics with APC-mediated actin assembly. We are now dissecting EB1-APC interactions to develop the tools required for testing this model in vivo.

P67**Board Number: B167****The formins FHOD-1 and INFT-1 are important for ovulation and localize to the somatic gonad of *C. elegans*.**A. Hegsted¹, D.W. Pruyne¹;¹Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Formins are actin nucleators, and many promote actin filament elongation. To determine the physiological role of each formin in the genetic model system *Caenorhabditis elegans*, single deletions of its non-essential formins were obtained. These deletions produced apparently healthy worms, which suggested redundant formin functions. We generated double formin mutants and found that worms doubly-mutated for the formin genes *fhod-1* and *inft-1* had smaller brood sizes (number of progeny) and movement defects. This project characterizes the effect of *fhod-1;inft-1* double mutation on brood size and the localization of FHOD-1 and INFT-1 within the somatic gonad. The worm gonad is composed of two symmetrical arms. Germ cells are produced in the distal gonad and migrate proximally. Myoepithelial sheath cells surround the distal and proximal gonad. The proximal sheath cells have contractile actin networks that move the developing oocytes towards the spermatheca. The spermatheca, an actin rich organ, is the site of fertilization. The developing embryo resides in the uterus until it is expelled through the vulva. FHOD-1 localizes to the vulval and uterine muscles, and the proximal sheath cells. INFT-1 is expressed at the spermatheca. An ovulation defect seen in the double mutant worms is endomitotic oocytes in the gonad arm (emo). This phenotype can be the result of a contractility defect in the proximal sheath cells and/or the spermathecae. We examined ovulation in the double mutant worms and saw that the maturing oocyte follows one of three paths: normal ovulation, engulfment by the spermatheca that breaks the oocyte, or no ovulation. This abnormal ovulation could be the reason for the smaller brood size. We hypothesize that FHOD-1 and INFT-1 are important for organizing actin in the myoepithelial sheath cells and the spermatheca to allow proper ovulation.

P68**Board Number: B168****Defining the roles of the formin Diaphanous in organizing the contractile ring and midbody ring during cytokinesis.**Y. Ruella Palm¹, D. d'Allard^{1,2}, G.R. Hickson^{1,2};¹UHC Ste-Justine, Montreal, QC, ²Universite de Montreal, Montreal, QC

Animal cells divide by the intricate process of cytokinesis. Initially, a Rho GTPase and actomyosin-dependent contractile ring (CR) drives the constriction at the cell equator until a stable midbody ring (MR) forms and matures to guide the separation of the two cells. The CR and MR are highly organized structures controlled by interactions among a network of Rho-dependent proteins. One such protein is Diaphanous (Dia), a formin that nucleates unbranched actin filaments, localizes to the CR and is essential

for cytokinesis. Nevertheless, it is unclear how Dia contributes to the organization of the CR and, potentially, to the subsequent formation of the MR.

We have examined the requirement for Dia and actin during cytokinesis by time-lapse video microscopy of *Drosophila* S2 cells expressing markers tagged with fluorescent proteins (FPs). Acute administration of the inhibitor of actin polymerization, Latrunculin A (LatA), defined a period of 20 minutes from closure of the CR during which the nascent MR requires dynamic actin: before this time, furrows regressed; after this time the MR remained stable in LatA. Moreover, a functional Dia-FP localized to the CR and nascent MR but not to the mature MR and the timing of its disappearance coincided with the transition to a LatA-insensitive MR structure. Depletion of Dia by RNAi slowed furrow ingression, enhanced furrow oscillations and prevented furrow completion. Live imaging of the F-actin probe, LifeAct-GFP, in Dia depleted cells revealed a marked decrease in equatorial F-actin at the time of normal CR formation, although a cortical flow of F-actin from the poles to the equator was subsequently observed. The CR components Myosin-FP and the scaffold protein Anillin-FP were still recruited to the equator of Dia-depleted cells but formed aberrant punctate structures, demonstrating a role for Dia in maintaining the normally uniform organization of the CR. Our prior truncation analysis has uncovered multiple mechanisms contributing to the localization of Anillin to the equatorial cortex (Kechad, El Amine). An N-terminal region of Anillin that contains both F-actin and myosin binding domains and that mediates the proper localization of Anillin to the CR, was no longer recruited to the cortex in Dia-depleted cells or in cells treated with LatA. Since the latter treatment did not prevent the recruitment of Dia-FP, this suggests that Dia-dependent F-actin polymerization is specifically required for the recruitment and retention of Anillin at the CR. This is likely an important role for Dia that provides clues as to the organization of the CR. Furthermore, our data are consistent with a model in which the regulated removal of Dia from the F-actin-dependent CR promotes the transition to the Anillin-dependent MR.

²Department of Internal Medicine, Division of Pulmonary, Allergy, Critical Care and Sleep Medicine, The Ohio State University, Columbus, OH, ³Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, ⁴Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, ⁵Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, ⁶Molecular and Cellular Developmental Biology Program, The Ohio State University, Columbus, OH

Actin Crosslinking Domain (ACD) is produced by pathogenic strains of *Vibrio cholerae*, *Vibrio vulnificus*, and *Aeromonas hydrophila*. Upon delivery to the cytoplasm of host cells via Type I or Type VI Secretion systems, ACD catalyzes the formation of an amide bond between K50 and E270 of actin monomers,

resulting in the formation of actin oligomers of varying sizes. According to the current view on the ACD pathogenesis, the ACD activity leads to a slow failure of the cytoskeleton due to the gradual accumulation of non-functional oligomers leading to depletion of both monomeric and filamentous actin pools. Instead, we propose that ACD employs a hitherto unprecedented toxicity mechanism by converting cytoplasmic actin into highly toxic oligomers that specifically target key steps of actin dynamics. Particularly, we demonstrate that the oligomers inhibit with sub-nanomolar affinity actin polymerization controlled by Diaphanous formins. TIRFM experiments reveal that the formin controlled elongation is blocked in a concentration dependent manner in the presence of nanomolar concentrations of the oligomers. Profilin plays a key role in the observed inhibition and mDia1 formin constructs with fewer proline-rich regions in their FH1 domains are inhibited by the oligomers less efficiently. Accordingly, we demonstrate that at least some vital functions of the cytoskeleton (e.g. integrity of epithelial barriers) are deeply impaired when only a small fraction of cytoplasmic actin is crosslinked into oligomers. The effects are reproduced by formin-, but not ARP2/3 complex-specific small molecule inhibitors. Intriguingly, the pool-down analysis of HeLa cell lysates using double-tagged actin demonstrates that the oligomers exhibit selectivity towards certain human formins, suggesting the possibility of creating specific ACD-based and/or ACD mechanism-inspired formin inhibitors. To conclude, we propose that delivery of only a few copies of ACD into the cytoplasm of the host cell enables this enzyme to produce actin oligomers that possess the unique combination of properties that is neither observed in G- nor F-actin. Specifically, a tandem organization of the ACD-crosslinked actin oligomers and their ability to interact with G-actin binding proteins (e.g. profilin) confers them an abnormally high affinity to tandem G-actin binding proteins (e.g. tandem proline-rich and WH2 domains of formins, VASP, and NPFs) and enables them to actively interfere with the specific nucleation and/or elongation activities of these proteins. Thereby, ACD initiates a toxicity cascade that employs actin oligomers as second messengers, whose novel, “gain-of-function” inhibitory properties potentially “poison” cellular functions orchestrated by formin-mediated actin polymerization.

Skeletal muscle loses the mass during the aging process. IGF-I, insulin like growth factor-I, stimulates several signaling pathways in the differentiation and hypertrophy of muscle cells, and prevents the skeletal muscle atrophy accompanying with aging. Small GTPase RhoA has been known to be essential for muscle development, but its precise role remains unknown. Here, we analyzed the activation and role of RhoA in an IGF-I-induced muscular hypertrophy model. To construct the IGF-I-induced muscle hypertrophy model, C2C12 cells were differentiated for 48 hours followed by further 48 hours in

differentiated media with or without IGF-I. With the addition of IGF-I, C2C12 cells showed prominent hypertrophic changes, and increased 1.3-fold in the maximum diameter of myotube by facilitating the fusion of myoblast. To determine the activation level of RhoA, we performed a pull-down assay for RhoA · GTP. After 24 hours of IGF-I treatment, RhoA activity increased 2.0-fold compared with 0 hour, and increased 62% relative to non-treatment cells. To confirm whether the activated RhoA contributes to the hypertrophy, we transfected RhoA dominant-negative mutant (RhoA-DN) into C2C12 cells to inhibit RhoA activation by IGF-I. The expression of RhoA-DN reduced the hypertrophy induced by IGF-I, and impaired the expression of differentiation marker (MHC and M-cadherin) and p38 MAP-kinase activation. These data suggests that IGF-I promotes the muscular hypertrophy via RhoA activation in this model. To identify the binding proteins of RhoA in IGF-I-induced hypertrophic signaling, we designed RhoA tagged with promiscuous biotin ligase BirA (Roux et al. 2012). This technique may provide novel insights into the role of RhoA in the signal networks during the muscular hypertrophy.

PIP2 is required for the stability of cleavage furrow-associated proteins during cytokinesis.

S. Yildirim¹, R. . Wong², H. Wei³, L.L. Fabian³, G. Polevoy⁴, J.A. Brill⁵;

¹cell biology, The hospital for sick children, Toronto, ON, ²Univ Toronto, Toronto, ON, ³Hospital for Sick Children, Toronto, ON, ⁴Cell Biology Program, Hospital for Sick Children, toronto, ON, ⁵Cell Biology Program, Hospital for Sick Children, Toronto, ON

Meiotic division during *Drosophila melanogaster* spermatogenesis serves as an excellent model for studying mechanisms of cytokinesis. Our previous studies showed that phosphatidylinositol phosphates (PIPs) act as regulators of this process. To define the role of phosphatidylinositol 4,5-bisphosphate (PIP2) in meiotic cytokinesis, we studied cleavage furrow-associated proteins such as Anillin, Sep2 (a septin) and Sqh (myosin regulatory light chain) in PIP2-depleted testes. Live imaging of spermatocytes depleted of PIP2 by ectopic expression of the Salmonella PIP2 phosphatase SigD revealed that Anillin, Sep2, and Sqh initially localize to the cleavage furrow, yet lose their cortical localization during furrow regression, leading to formation of multinucleate cells. Reduction in the abundance of these proteins in the furrow prior to furrow regression, as well as oscillations of GFP-Anillin and Sqh-GFP along the cortex, indicated a perturbation of cleavage furrow integrity. To confirm that these phenotypes resulted from PIP2 depletion, we examined the *Drosophila* PIP 5-kinase Skt1, which synthesizes PIP2. YFP-Skt1 localized to cleavage furrows of dividing spermatocytes. Male germ cells homozygous mutant for *skt1* were multinucleate, consistent with a role for Skt1 in cytokinesis. Moreover, dividing *skt1* mutant spermatocytes, like those expressing SigD, exhibited reduced levels of Anillin and Pnut (a septin) in the cleavage furrow. Taken together, our data suggest that PIP2 is synthesized at the cleavage furrow, where it serves to maintain association of furrow proteins with plasma membrane for successful completion of cytokinesis.

P72**Board Number: B172****The small GTPase Rap1 promotes cell movement rather than stabilizes adhesion in epithelial cells responding to insulin-like growth factor I.**M.A. Guvakova¹, I. Prabhakaran¹, W.S. Lee¹, D.K. Furstenau¹, D.C. Li¹, R. Hung¹, N. Kushnir¹;¹University of Pennsylvania, Philadelphia, PA

How the Ras-related GTPase Rap1 controls a fine balance between cell adhesion and cell migration remains puzzling. Here, we discovered a previously unidentified regulatory role of insulin-like growth factor type I receptor (IGF-IR) in CRK SH3-binding guanine nucleotide exchange factor (C3G)-Rap1-fascin-actin axis promoting cell movement. We demonstrate that a burst of Rap1 activity, rather than presumed hyperactivation is imperative for the onset of cell movement. We show that while autophosphorylated IGF-IR signals to C3G to activate Rap1, subsequent IGF-IR internalization promotes gradual inactivation of Rap1 by putative Rap1GTPase-activating protein (GAP). Additionally, IGF-IR signaling recruits active Rap1 at sites of cell motile protrusions. C3G depletion prevents IGF-I-induced accumulation of fascin at actin microspikes and blocks protrusions. In the absence of IGF-IR's activity, the wild type Rap1 and the constitutively active V12Rap1 mutant remain in cell-cell contacts. Forced inactivation of Rap1 signaling by overexpressing dominant negative N17Rap1, Rap1GAP, or by silencing C3G has a detrimental effect on F-actin and cell adhesion irrespective of IGF-IR signaling. We conclude that the basal levels of Rap1 activity hold up cell adhesion, whereas sequential regulation of C3G and GAP by IGF-IR reverses the labile Rap1 function from supporting adhesion to promoting migration. Furthermore, our findings support a role of C3G-Rap1 signaling in the IGF-IR-mediated regulation of an actin crosslinking protein fascin.

P73**Board Number: B173****Human formin-2 generates nuclear actin filaments in response to DNA damage.**B.J. Belin¹, T. Lee¹, R.D. Mullins²;¹Cellular Molecular Pharmacology, University of California, San Francisco, San Francisco, CA,²Department of Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

Compelling recent evidence has implicated nuclear actin filaments as regulators of cellular responses to certain environmental stresses, including serum stimulation, heat shock and cultured models of neurodegeneration (Baarlink et al., 2013; Bamburg et al. 2010). Using human tissue culture lines, we have observed that nuclear actin polymerization is stimulated by DNA damage induced by a variety of mechanisms, including telomere uncapping, UV exposure and MMS treatment. DNA damage-associated nuclear filaments can be visualized by phalloidin staining and are detected with high specificity using our nuclear actin-specific filament reporter, Utr230-EGFP-NLS. Using this tool, we identify several classes of

nuclear actin filaments after DNA damage: nucleolus-associated, nucleoplasmic and aggregate-like filament bodies. Unlike previously described nuclear actin filaments, DNA damage-induced filaments do not contain cofilin nor require mDia1/mDia2 for polymerization. Rather, we find that DNA damage-associated nuclear actin polymerization requires formin family actin nucleator formin-2 (FMN2). FMN2 accumulates in the nucleus in response to DNA damage, and FMN2 or importin-9 knockdowns implicate nuclear actin polymerization in efficient double strand break clearance and regulation of nuclear oxidation during the DNA damage response. These results suggest that regulation of nuclear actin assembly may be a common feature of cellular stress responses and reports the first characterized function for FMN2 in mammalian somatic cells.

Comparative analysis of tools for *in vivo* detection of actin filaments.

B.J. Belin¹, L.M. Goins², R.D. Mullins³;

¹Cellular Molecular Pharmacology, University of California, San Francisco, San Francisco, CA, ²University of California, San Francisco, San Francisco, CA, ³Department of Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

Several tools are now available for *in vivo* imaging of actin filaments, including Lifeact, variants of the utrophin actin-binding domain (Utr230 and Utr261), F-tractin and fluorescently labeled actin. Use of these filament reporters has become widespread and, despite growing evidence to the contrary, they are often regarded as comprehensive labels for actin filaments. To systematically evaluate their suitability for detecting commonly studied actin filament networks, we generated stable cell lines for each reporter in human, *Mus musculus*, *Xenopus laevis* and *Drosophila melanogaster* tissue culture cells. Within each line, we quantitatively compared reporter localization to phalloidin staining and used FRAP to determine how reporter binding and dynamics relate to filament turnover kinetics. Using this approach, we identified subtle reporter binding preferences that are qualitatively similar across organisms and provide reporter recommendations for studies of multiple filament networks, including cortical actin, lamellae, lamellipodia, filopodia and stress fibers. We find that F-tractin is the most broadly suitable filament reporter yet induces organism-specific morphological defects. Poor Lifeact binding and GFP-actin incorporation is common among formin-generated filaments, whereas Utr261 is often excluded from the Arp2/3-generated lamellipod. Utr230 is restricted to highly stable actin filaments and, surprisingly, detects Golgi-associated filaments in *D. melanogaster* S2 cells, which have previously been detected by immunofluorescence but cannot be seen with phalloidin. Overall our results underscore the need to test multiple visualization strategies to determine the most appropriate filament visualization tool for each desired application.

P75**Board Number: B175****Formin tails enhance processive elongation of actin filaments in addition to nucleation and filament bundling.**C.L. Vizcarra¹, B. Bor², M.E. Quinlan^{1,2};¹Chemistry and Biochemistry, University California-Los Angeles, Los Angeles, CA, ²Molecular Biology Institute, University California-Los Angeles, Los Angeles, CA

Formins are multi-domain proteins that assemble actin in a wide variety of biological processes. They both nucleate and remain processively associated with growing filaments, in some cases accelerating filament growth. The well-conserved Formin Homology 1 and 2 domains were originally thought to be solely responsible for these activities. Recently a role in nucleation was identified for the Diaphanous Autoinhibitory Domain (DAD), which is C-terminal to the Formin Homology-2 domain. The C-terminal tail of the *Drosophila* formin Cappuccino (Capu) is conserved among FMN formins but distinct from other formins. It does not have a DAD domain. Nevertheless, we find that Capu-tail plays a role in filament nucleation similar to that described for mDia1 and other formins. Building on this story, replacement of Capu-tail with DADs from other formins tunes nucleation activity. Capu-tail has low affinity interactions with both actin monomers and filaments. Removal of the Capu-tail reduces both actin filament binding and bundling. Further, when the tail is removed, we find that processivity is compromised. Despite decreased processivity, the elongation rate of filaments is unchanged. Again, replacement of Capu-tail with DADs from other formins tunes the processive association with the barbed end, indicating that enhancement of processivity is a general role for formin tails. Our data show a role for the Capu-tail domain in assembling the actin cytoskeleton, largely mediated by electrostatic interactions. Despite the absence of a DAD domain, the Capu-tail mimics all known functions of other DAD domains including autoinhibition. Finally, the role of formin tails in processivity was previously unrecognized.

P76**Board Number: B176****Mechanism of IRSp53 Inhibition by 14-3-3.**D.J. Kast¹, R. Dominguez¹;¹Physiology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

Filopodia are actin-rich, dynamic membrane protrusions that play essential roles in numerous cellular processes such as cell migration, phagocytosis, and axonal guidance. IRSp53 couples signaling pathways to membrane and cytoskeleton dynamics, acting as a potent inducer of filopodia. IRSp53 contains an N-terminal inverted BAR domain, followed by overlapping Cdc42/SH3-binding sites within a sequence known as the CRIB-PR domain, and an SH3 domain that recruits several cytoskeletal effectors. We have previously shown that activation of IRSp53 from an autoinhibited state requires the binding of Cdc42 to the CRIB-PR and/or effectors, such as Eps8, to the SH3 domain, which produce a conformational change in IRSp53. The sequence between the CRIB-PR and SH3 domains is rich in Ser and Thr residues, and

some of which bind 14-3-3 in a phosphorylation-dependent manner, providing an alternative route for IRSp53 regulation. Here we explore the phosphorylation-dependent mechanism of IRSp53 inhibition by 14-3-3. Using isothermal titration calorimetry we show that 14-3-3 binds weakly to single phosphorylated sites, but that binding is enhanced ~100-fold when specific pairs of sites are phosphorylated. Crystal structures show how the different phosphorylation sites of IRSp53 bind to 14-3-3, either as mono- or double-phosphorylated peptides. The results identify the most likely sites for inhibition by 14-3-3, and the kinases likely involved in phosphorylation of these sites. The data support a model of inhibition whereby asymmetric binding of 14-3-3 to two distinct phosphorylation sites inhibits activation by either Cdc42 or downstream effectors.

Disabled regulates Abelson nonreceptor tyrosine kinase localization and kinase activity in *Drosophila*.

L. Kotlyanskaya¹, E. Giniger², R. Kannan²;

¹Neurobiology Curriculum, UNC Chapel Hill, Bethesda, MD, ²NINDS institute, NIH, Bethesda, MD

Disabled (Dab) is a putative adaptor protein that is required for lamination of the cortex. In *Drosophila* it interacts with the Abelson (Abl) kinase signaling pathway to regulate epithelial structure and axon guidance. Previous evidence hints at Dab regulation of both Abl localization and Abl kinase activity. *Dab* mutant embryos show localized inhomogeneity in Abl localization during the midcellularization stage in early embryogenesis. Disabled structure, such as its polyproline domains which are potential SH3 binding regions, and the PTB domain, suggests that Dab may act as a scaffold and can potentially recruit Abl, by binding it directly or in a complex, may regulate its ability to bind to other proteins. We initiated a structure-function analysis to determine what domains of Dab may regulate Abl localization and activity using tagged Dab deletion constructs transiently transfected into S2 cells and subsequently assayed for Abl localization by immunofluorescence and confocal microscopy. To assay Abl activity, we took advantage of a FRET based Abl kinase reporter. We found that overexpression of Dab full length or Dab constructs containing the highly conserved central domain aggregate in puncta in S2 cells and these puncta colocalize with puncta of endogenous Abl, suggesting Dab recruitment of Abl in the cytoplasm. Under these conditions upon overexpression of Dab, we found increased Abl kinase activity as assayed by FRET, suggesting that Dab stimulates Abl kinase activity. We have further confirmed this increase in Abl kinase activity via FRET *in vivo* in cultured photoreceptors from *Drosophila* larvae overexpressing Dab. Conversely, *dab* mutant larvae have reduced Abl kinase activity as assayed by FRET. In conclusion, we have found that in S2 cell culture Dab adaptor protein regulates Abl kinase localization and activity. In the future we will make further refined deletions of Dab to determine what protein domains are responsible for these activities.

P78**Board Number: B178****Dendritic actin network growth in the absence of symmetry breaking.**P. Jreij¹, P. Bieling^{1,2}, T. Li¹, R.D. Mullins², D.A. Fletcher^{1,3,4};¹Department of Bioengineering, University of California, Berkeley, Berkeley, CA, ²Department of Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA, ³Biophysics Graduate Group, University of California, Berkeley, Berkeley, CA, ⁴Physical Biosciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA

At the leading edge of migrating cells, dendritic actin networks exert protrusive forces through the dynamic machinery of Arp2/3-mediated actin polymerization. Previous studies have shown that dendritic actin network assembly can be reconstituted on nucleation promoting factor (NPF)-coated surfaces from a minimal system of purified proteins including actin, profilin, Arp2/3, and capping protein. Variation in concentrations of these components has produced insight into their biochemical interplay and resulting network structure. However, in most studies to date, the requirement for actin networks growing around beads or bacteria to break symmetry before exhibiting steady-state growth introduces non-uniform stresses that could alter network structure and has limited the range of protein concentrations that could be explored. To investigate a broader range of protein concentrations and avoid stresses due to curved surfaces, we reconstituted dendritic actin networks on planar glass surfaces using silane-PEG-maleimide chemistry to pattern NPF APVCA domains on defined areas. In the presence of actin, profilin, Arp2/3, and capping protein, branched actin networks assembled on the patterns and grew out of plane at a constant rate. We followed the dynamic growth in real time using three-color spinning disk confocal microscopy for a range of NPF densities, Arp2/3 concentrations, and capping protein concentrations. Our findings show that the net rate of actin incorporation into the network is independent of changes in NPF density, Arp2/3 concentration, and capping protein concentration, even though network growth rates vary significantly in response to these changes. Our estimates of nucleation rates, filament lengths, and changes in number of free barbed ends across a range of Arp2/3 and capping protein concentrations are consistent with the Monomer Gating Model and help to constrain predictive models of dendritic actin network growth.

P79**Board Number: B179****Isoform-specific oligomerization of ZASP, a myofibrillar myopathy gene product, in vitro and in vivo.**R. Ohman¹, L. Brubaker¹, S. Kawakami-Schulz¹, X. Lin¹, K. Subedi¹, I. Chow¹, J. Kaufman², P. Wingfield², A.K. Mankodi¹;¹NINDS-NIH, Bethesda, MD, ²NIAMS-NIH, Bethesda, MD

BACKGROUND: Myofibrillar myopathies (MFM) present clinically as progressive muscle weakness that begins in early adulthood. Zaspopathy, a prototype MFM, is caused by heterozygous mutations in ZASP,

a Z-disc associated PDZ-LIM protein. The long and short ZASP isoforms are defined by the presence or absence of LIM domains, respectively. The mutated sZM domain is common to both isoforms. ZASP interacts with skeletal actin filaments via the sZM domain. The PDZ-LIM proteins are regulated by intramolecular association. However, oligomerization of ZASP has not yet been explored. OBJECTIVE: 1) To explore self-association of ZASP; 2) To identify oligomerization domains of ZASP; and 3) To investigate the role of ZASP self-association in normal skeletal muscle and in zaspopathy. DESIGN/METHODS: ZASP self-association was investigated with analytical sedimentation equilibrium assay of purified ZASP proteins as well as co-immunoprecipitation and chemical crosslinking assays in transfected cells and mouse and patient skeletal muscle. The domains involved in dimerization were identified with yeast two-hybrid assays. Actin-bundling ability of ZASP was explored using a low-speed co-sedimentation assay. Effects of different ZASP isoforms on actin stress fibers were examined in cultured mouse muscle (C2C12) cells. RESULTS: The long ZASP isoforms self-associate, whereas the short isoform does not. Wild type and mutant ZASP form homodimers and heterodimers. ZASP self-association occurs via interaction of the LIM domains. The mutated actin-binding domain is not involved in ZASP self-association. A low-speed co-sedimentation assay showed that GST or His6-tagged long ZASP isoform does not crosslink actin filaments. Expression of the mutated ZASP long but not short isoform caused F-actin disruption in cultured muscle cells. CONCLUSIONS: Wild-type and mutant ZASP form homodimers and heterodimers in zaspopathy, an autosomal dominant disease. Self-association of ZASP and F-actin disruptive properties of mutated ZASP are specific to the long isoform that is required for the integrity of the Z-discs in skeletal muscle. Future studies will explore the effects of post-translational modification on ZASP dimerization. Understanding ZASP associations within both the normal and disrupted cells of the Z-disc will lead to a better understanding of structural components of the Z-disc, and the contribution of disruption of ZASP-actin associations in MFM.

Counting actin molecules in cytoskeletal structures with Lifeact by quantitative fluorescence microscopy.

Q. Chen¹, N. Courtemanche^{2,3,4}, T.D. Pollard^{5,6,7};

¹Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT, ²Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT, ³Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, ⁴Department of Cell Biology, Yale University, New Haven, CT, ⁵Department of Molecular, Cellular and Developmental Biology, Yale University School of Medicine, New Haven, CT, ⁶Department of Molecular Biophysics and Biochemistry, Yale University School of Medicine, New Haven, CT, ⁷Department of Cell Biology, Yale University School of Medicine, New Haven, CT

Quantitative measurement of actin molecules in cytoskeletal structures is essential to understand many cellular processes, but counting actin directly using fluorescence microscopy has been challenging, because actin tagged with a fluorescent protein such as mGFP is not fully functional and cannot replace native actin. Here we present a method using Lifeact-mGFP to count actin molecules in contractile rings and actin patches in live fission yeast cells. Purified Lifeact-mCherry binds actin filaments stoichiometrically with a Kd of 16 μ M. To titrate actin filaments in fission yeast we drove the expression of Lifeact-mGFP with an inducible promoter 3nmt1 and obtained cells with a wide range of total fluorescence. We used quantitative fluorescence microscopy to measure the number of Lifeact-mGFP molecules in whole cells and actin patches and contractile rings in these cells. The total numbers of Lifeact-mGFP associated with both structures increased with the cytoplasmic concentration and plateaued at high concentrations giving an apparent Kd of about 20 μ M. From the plateaus of these binding curves we estimated a peak number of ~5,000 actin molecules in actin patches (similar to published values with actin-mGFP) and ~150,000 actin molecules in complete cytokinetic contractile rings.

In vivo system for identifying nuclear actin regulators.

C.M. Groen¹, T.N. Fagan¹, S. Sudhir¹, T.L. Tootle²;

¹Anatomy and Cell Biology, Univ Iowa-Carver Coll Med, Iowa City, IA, ²Department of Anatomy and Cell Biology, University of Iowa Carver College of Medicine, Iowa City, IA

Actin is not only a critical component of the cytoplasmic cytoskeleton, but plays key roles in the nucleus – including chromatin remodeling, transcription and nuclear organization. However, the structures,

functions, and how structure affects function of nuclear actin remain poorly understood. While nuclear actin does not typically form canonical filaments as observed by phalloidin staining, other unique structures have been observed. One of these structures is nuclear actin rods. Actin rods form in response to cellular stress (i.e. heat shock, starvation/re-feeding), and when cytoplasmic filamentous actin is disrupted. Nuclear actin rods are also observed during the progression of neurodegenerative diseases including Alzheimer's and Parkinson's disease. While nuclear actin rods have been implicated in contributing to cell survival, their functions and the mechanisms regulating their formation remain largely unclear. We have identified a new, in vivo, multicellular system to study nuclear actin rods. Ectopic expression of GFP-Actin results in nuclear actin rod formation within the nurse cells during stages 5-9 of *Drosophila* oogenesis. Rod formation depends on which of the six *Drosophila* actins is overexpressed and its level of expression. Notably, endogenous nuclear actin is observed in the same cells during these developmental stages, suggesting that nuclear actin plays a functional role during egg development. Thus, we can utilize the actin rods formed when GFP-actin is overexpressed as a system to uncover conserved means of regulating nuclear actin. Specifically, we are quantitatively assessing the prevalence and morphology of the actin rods formed by the different actins, and how those rod phenotypes are altered by cellular stress. We are also identifying novel mechanisms regulating nuclear actin rod formation and/or structure by genetically screening for phenotypic modifiers. These studies are expected to provide significant insight into the regulation and function of nuclear actin not only during development but also during neurodegeneration.

Tropomyosin 5a/b actin filaments collaborate with arp2/3 actin filaments to regulate cell motility.

S. Brayford¹, G. Schevzov¹, E.C. Hardeman¹, J.E. Bear², P.W. Gunning¹;

¹School of Medical Sciences, UNSW, Sydney, Australia, ²UNC Lineberger Comprehensive Cancer Center, Department of Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC

The mammalian actin cytoskeleton is differentially regulated by over 40 different isoforms of tropomyosin. Different isoforms sort to spatially distinct actin filaments within the cell where they perform isoform-specific regulatory roles. Using isoform-specific antibodies, we have demonstrated that of all known isoforms of tropomyosin, only Tm5a and 5b are enriched in the lamellipodium of mouse fibroblasts, indicating a role in the regulation of actin filament function within this structure. This led us to further investigate the functional role of these isoforms in the regulation of plasma membrane protrusions associated with cell motility. Using live-cell imaging, kymography and cell tracking we have shown that knockdown of Tm5a/b expression through RNA interference leads to a marked decrease in the persistence of membrane protrusions but no change in the level or location of arp2/3. This indicates that arp2/3 location is not dependent on Tm5a/b. A corresponding reduction in whole cell motility is observed in Tm5a/b knockdown cells which is paralleled by a reduction in the number of substratum adhesions. These findings suggest that the actin cytoskeleton within the lamellipodium contains two

types of actin filaments with different functional roles. One is the well-characterised branched filament network driven by arp2/3 which provides the protrusive force to generate dynamic membrane protrusions. The second is Tm5a/b-containing actin filaments, most likely unbranched, which stabilise arp2/3 protrusions by promoting the formation of adhesions to the substratum to gain traction. We propose that tropomyosin behaves as a discriminating factor that allows collaboration of different filament types to achieve a specific functional outcome for the cell.

Nucleation of Actin Filaments by the Arp2/3 Complex: New Mechanistic Insights from Kinetic Simulations.

S.B. Padrick^{1,2}, L.K. Doolittle^{1,2}, M.K. Rosen^{2,3};

¹Dept. of Biophysics, University of Texas Southwestern Medical Center, Dallas, TX, ²Howard Hughes Medical Institute, Dallas, TX, ³Department of Biophysics, University of Texas Southwestern Medical Center, Dallas, TX

The actin related protein 2/actin related protein 3 (Arp2/3) complex is a widely conserved actin nucleation factor. The Arp2/3 complex controls actin dynamics by nucleating new actin filaments in specific places, times and orientations in the cell, in response to stimulatory signals from nucleation promotion factors (NPFs) such as those of the WASP family. The fundamental signaling logic has been understood for several years; coincident signals from NPFs and pre-existing filaments combine to stimulate Arp2/3 complex to produce new filaments. Given the central role that Arp2/3 complex plays in many processes, there has been great interest in the detailed mechanism by which it nucleates new actin filaments. Here we use computational simulation of the kinetics of the nucleation process to explore a recent hypothesis that NPF release from the complex is required during nucleation.

While NPFs do promote high levels of activation, structures of actin in complex with a necessary actin binding NPF element, the WASP Homology 2 (WH2) region, indicate that their engagement with actin during delivery may prevent growth of the nucleated filament. This idea is consistent with recent single molecule studies. Here we incorporate this idea into a new kinetic mechanism that also enforces thermodynamic reversibility and allosteric coupling. By comparing the predicted behavior of this model to the global behavior of in vitro Arp2/3 complex nucleation activity, we find that agreement with the data is improved but requires additional kinetic steps for a complete description. Systematic exploration of parameter space for a series of successively more complex models has lead to a new kinetic model of Arp2/3 complex activation by NPFs. This new model will serve as a predictive template to guide further studies refining our understanding of this essential nucleation factor.

P84**Board Number: B184****Collapsin Response Mediator Protein-1 as a novel factor modulating Arp2/3-dependent actin structures.**H. Yu-Kemp¹, W.M. Brieher¹;¹Cell and Developmental Biology, University of Illinois-Urbana-Champaign, Urbana, IL

Listeria monocytogenes is a parasite that uses host proteins to assemble an Arp2/3-dependent actin comet tail for its propulsion. Comet tail assembly is more efficient in cytosol than in defined systems implying that unknown factors contribute to this reaction. We fractionated bovine brain cytosol and identified Collapsin Response Mediator Protein-1 (CRMP-1) as such a factor. CRMP-1 has long been studied as a factor for microtubule dynamics. Here, we show that CRMP-1 contributes to Arp2/3-dependent actin dynamics. Immunodepletion of CRMP-1 from brain cytosol reduced Arp2/3-dependent actin assembly around *Listeria*, and the defect could be successfully rescued with recombinant CRMP-1. In vitro assays confirmed that CRMP-1 enhanced Arp2/3-dependent branching and stimulated ActA- as well as VCA-activated Arp2/3-dependent actin polymerization. To test the contribution of CRMP-1 to Arp2/3-dependent polymerization inside cell, we examined the localization of CRMP-1 using immunostaining and GFP-CRMP-1 overexpression in epithelial cells. CRMP-1 localized to the leading edge of lamellipodia and cadherin-mediated cell-cell contacts, both of which are known to be Arp2/3-dependent structures. Knockdown and overexpression approaches revealed a positive correlation between the amount of CRMP-1 and the amount of F-actin inside the cell. In wound closure assays, CRMP-1-depleted cells had twice less protrusions at the wounded edge, with half actin intensity at the leading edge compared to control cells; while overexpression of CRMP-1 provided the opposite results. During wound closure, CRMP-1-depleted cells moved erratically and lost their directionality with unstable membrane protrusions. In contrast, GFP-CRMP-1 overexpressing cells moved unidirectionally, with the membrane at the leading edge stably protruding forward. Depletion of CRMP-1 also reduced the amount of cadherin and actin at cell-cell contacts, resulting in weaker cell adhesion for epithelial cells. Immunoblotting results indicated CRMP-1 present in the membrane fraction of cadherin enriched plasma membrane. This membrane had been shown to be able to assembly actin filaments in an Arp2/3-dependent manner. An antibody against CRMP-1 blocked this Arp2/3-dependent reaction, showing the role of CRMP-1 on regulating Arp2/3-dependent actin assembly at cadherin-mediated cell-cell contacts. In summary, our results identify CRMP-1 as a novel regulator of the actin cytoskeleton that specifically contributes to Arp2/3-dependent actin assembly. CRMP family proteins have been studied in regulating metastasis and neuronal growth cone guidance. Our data provide a mechanism for understating how CRMP proteins might modulate those biological events through their potential role in actin cytoskeletal organization.

P85**Board Number: B185****Isoform diversity modulates the ability of the Arp2/3 complex to stimulate actin polymerization.**J.V. Abella¹, C. Galloni¹, M. Howell², M. Way¹;¹Cell Motility Group, London Research Institute - Cancer Research UK, London, UK, ²High Throughput Screening Laboratory, London Research Institute, London, United Kingdom

The Arp2/3 complex is unique among actin nucleators in its ability to generate branched actin filament networks. These networks are critical in maintaining the architecture of the cell and regulating cell motility, invasion, endocytosis and phagocytosis. A number of intracellular pathogens, such as *Listeria*, *Shigella* and *Vaccinia* virus also use the Arp2/3 complex to stimulate actin polymerization to enhance their cell-to-cell spread. The Arp2/3 complex consists of 7 subunits (Arp2, Arp3 and ARPC1-5), which are evolutionary conserved from protozoa to mammals. Interestingly, in humans, Arp3, ArpC1 and ArpC5 have two isoforms that are 91, 67 and 67% identical respectively. This raises the possibility that Arp2/3 complexes with different properties may exist. We found that the each isoform of Arp3, ARPC1 and ARPC5 is incorporated into an Arp2/3 complex and recruited to vaccinia induced actin tails. However, specific combinations differentially regulate actin-based motility of the virus. Depletion of ARPC1A and ARPC5, individually or together, results in longer actin tails. Conversely, loss of ARPC1B and/or ARPC5L results in very short actin tails. Loss of Arp3 versus Arp3B also results in opposite actin-tail phenotypes. Importantly, we demonstrate that isoform-mediated differences in actin tail length are dependent on both the rates of actin polymerization and filament disassembly. FRAP analysis, however, reveals that recruitment and turnover of each isoform on the virus is identical. This suggests that the activity of the Arp2/3 complex depends on its subunit composition. These differences are not unique to vaccinia-induced actin polymerization. For example ARPC5L but not ARPC5 is essential for invadopodia formation and gelatin degradation. Moreover, Arp2/3 complex subunit composition also impacts on the rate of cell migration. Our observations now demonstrate that the Arp2/3 complex can no longer be considered as a unique functional assembly.

P86**Board Number: B186****Coronin 7 and its role in organizing the actin cytoskeleton.**K. Bhattacharya¹, K. Swaminathan², A. Noegel^{1,3,4,5}, R. Rastetter⁶;

¹Institute for Biochemistry, Medical Faculty, University of Cologne, Cologne, Germany, ²Beatson Institute for Cancer Research, University of Glasgow, Glasgow, Scotland, ³Cologne Center for Genomics (CCG), Cologne, Germany, ⁴Center for Molecular Medicine Cologne (CMMC), Cologne, Germany, ⁵Cluster of Excellence, Cellular Stress Responses in Aging-Associated Disease, Cologne, Germany, ⁶Department of Anatomy and Developmental Biology, Monash Univ, Melbourne, Australia

Coronins are F-actin binding proteins which belong to an evolutionary conserved family of WD40-repeat proteins. They are widely expressed in cells and tissues and are involved in signal transduction, transcriptional regulation, remodeling of the cytoskeleton and regulation of vesicular trafficking. Here, we focus on mammalian Coronin 7 (CRN7), the only 'long' coronin known in mammals, having two WD40-repeat domains which form a highly symmetrical tandem β -propeller. CRN7 localizes to the Golgi apparatus where it has a role in protein trafficking and maintenance of Golgi morphology. However, the role of CRN7 in cytoskeleton remodeling has not been addressed so far. Therefore, we have generated a CRN7 knockout (KO) mouse model and established primary fibroblast cultures to address the cellular functions and regulatory mechanisms involved with respect to the dynamics of the actin cytoskeleton.

Analysis of CRN7 KO cells in vitro revealed that primary CRN7 KO fibroblasts exhibited a disrupted Golgi architecture and altered Golgi-centrosome positioning compared to the wild type (WT) counterpart. Importantly, fibroblasts deficient of CRN7 exhibited a faster cell polarization, an increased cell migration and an accelerated wound closure. Additionally, we detected a higher F-actin content in the KO fibroblasts. Re-expression of CRN7 reversed the Golgi-related phenotypic deficits in the KO fibroblasts.

In line with the recently published data that a Cdc42- and Rac-interactive binding (CRIB) domain mediates functions of coronin (*corA*) in *Dictyostelium discoideum*, we likewise study here the significance of the CRIB motif present in CRN7 on both β -propellers. We found that CRN7 has a higher affinity for GDP-bound GTPases than for the corresponding GTP-bound GTPase and therefore, we draw our focus on investigating the downstream effectors of CRN7-mediated regulation of small RhoGTPases. Taken together, this study will provide an insight into the role of mammalian CRN7 as an organizer of actin-dependent cellular events.

Actin-dependant processes such as cell motility rely on the appropriate control and regulation of dynamic filamentous actin. Coronins are a conserved family of regulators found across all eukaryotes and are involved in the coordination of F-actin dynamics in motile cells. Different coronins display varying functions, including binding directly to F-actin and crosslinking filaments, modulating F-actin assembly and branching via interactions with the Arp2/3 complex, as well as by mediating F-actin disassembly by coordinating ADF/cofilins. Many eukaryotic genomes encode several types of coronins, while others such as *Plasmodium* encode only one. The entire actin regulatory network in *Plasmodium* is drastically reduced, consisting of only a handful of members, and strikingly no Arp2/3 complex. Here we determine the function of *Plasmodium* coronin in the human and murine malaria parasites *Plasmodium falciparum* and *P. berghei*. We demonstrate that *Plasmodium* coronin is able to bind and organize actin filaments in vitro into parallel-bundled actin cables and bind to the membrane phospholipid phosphatidylinositol (4,5) bisphosphate. In vivo *Plasmodium* coronin localises to the cell periphery and relocalizes during actin-dependent fast movement. Finally, knockout of coronin in *P. berghei* results in aberrant fast movement altering mosquito-stage sporozoite movement from circular to erratic. These combined data suggest *Plasmodium* coronin is a critical part of the organizing architecture of directional force generation required by malaria parasite motility.

P88**Board Number: B188****PI(3,5)P2 controls branched actin dynamics at late endosomes by regulating cortactin-actin interactions.**N. Hong¹, A.M. Weaver^{1,2};¹Department of Cancer Biology, Vanderbilt University Medical Center, Nashville, TN, ²Department of Pathology, Microbiology and Immunology, Vanderbilt University Medical Center, Nashville, TN

Branched actin critically contributes to membrane trafficking by regulating membrane curvature, dynamics, fission and transport. However, how actin dynamics are controlled at membranes is poorly understood. Here, we identify the branched actin regulator cortactin as a direct binding partner of the phosphoinositide (PI) PI(3,5)P2 and demonstrate that their interaction promotes turnover of late endosomal actin assemblies. In vitro biochemical studies indicate that cortactin binds PI(3,5)P2 via the actin filament-binding region of cortactin. Furthermore, actin filaments and PI(3,5)P2 compete for binding to purified cortactin, suggesting that formation of PI(3,5)P2 on endosomes may remove cortactin from endosome-associated branched actin networks. Indeed, inhibition of PI(3,5)P2 production led to accumulation of both cortactin and actin on Rab7-positive endosomes. Knockdown of cortactin reversed inhibitor-induced actin accumulation at Rab7-positive endosomes. These data suggest a model in which PI(3,5)P2 binding removes cortactin from late endosomal branched actin networks and thereby promotes net actin turnover.

P89**Board Number: B189****The small GTPase ARF1 regulates podosome assembly.**N.B.M. Rafiq^{1,2,3}, Z. Z. Lieu¹, C. Yu¹, A. Krishnasamy¹, G. E. Jones³, A.D. Bershadsky^{1,2,4}; ¹Mechanobiology Institute, National University of Singapore, Singapore 117411, Singapore; ²Department of Biological Sciences, National University of Singapore, Singapore; ³Randall Division of Cell & Molecular Biophysics, King's College London, London SE1 1UL, UK; ⁴Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot 76100, Israel**The small GTPase ARF1 regulates podosome assembly**Nisha Bte Mohd Rafiq^{1,2,3}, Zi Zhao Lieu¹, Cheng-han Yu¹, Anitha Krishnasamy¹, Gareth E. Jones³, Alexander D. Bershadsky^{1,2,4}¹Mechanobiology Institute, National University of Singapore, Singapore 117411, Singapore²Department of Biological Sciences, National University of Singapore, Singapore³Randall Division of Cell & Molecular Biophysics, King's College London, London SE1 1UL, UK

⁴Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot 76100, Israel

Podosomes are integrin-mediated adhesion structures often formed by cells of the monocytic lineage, as well as by other cell types, including Src-transformed fibroblasts, and play an important role in cell migration and matrix degradation. Podosomes are multiple micron-sized radially symmetrical structures consisting of a central actin core associated with an “adhesive ring” containing the integrins and associated plaque proteins. Actin polymerization mediated by Arp2/3 complex is critically important for podosome formation, while upstream signaling pathways involving Rho GTPases (in particular Cdc42), are known, otherwise they are poorly understood.

Here, we demonstrate that small GTPase ARF1, known to regulate the trafficking of COPI vesicles, is a potent regulator of podosome dynamics. We showed that down-regulation of ARF1 by siRNA led to a striking reduction in the number of podosomes in macrophage-like THP1 cells. In parallel, treatment of cells with Brefeldin A (BFA), a drug that targets a subset of Sec7-type GTP exchange factors (GEFs) of Arf1 led not only to dissociation of the Golgi apparatus but also to loss of podosomes in a dose-dependent manner. Podosome “rosettes” often observed in Src-transformed fibroblasts were also shown to undergo gradual disruption after addition of BFA. Furthermore, we found that inhibition of another subclass of ARF GEFs, cytohesins, by a small-molecule inhibitor SecinH3 led to disassembly of podosomes in both THP1 cells and Src-transformed fibroblasts. Accordingly, RNAi silencing of ARNO (Cytohesin-2), but not Cytohesin-1, led to a dramatic reduction in podosome number. Even though bulk of ARF1 is localized to Golgi apparatus, TIRF microscopy of fluorescently-tagged ARF1 revealed punctate structures localized to regions of podosome assembly; these ARF1 puncta were also co-localized with Rab11-positive vesicles. Remarkably, ARNO was found to co-localize with components of adhesive ring in individual podosomes. Finally, in immunoprecipitation experiments, ARF1 was found to interact with the Arp2/3-inhibitory protein, arpin, which in turn was shown to co-localize with the actin core of podosomes. We conclude that ARNO-ARF1 signaling is strongly involved in the regulation of podosome assembly, most probably via modulation of Arp2/3-dependent actin polymerization.

Solo plays regulatory role in astrocyte migration through activation of both Rac1 and RhoA.

K. Van Vlasselaer¹, G.E. Plopper²;

¹Rensselaer Polytechnic Inst, Troy, NY, ²Rensselaer Polytech Inst, Troy, NY

Astrocytic migration plays a crucial role both in normal fetal development as well as in abnormal astrogliosis and traumatic spinal cord injury. Rho GTPases, specifically Rac1 and RhoA, have been shown to be crucial to normal astrocyte migration though signaling nuances have yet to be elucidated. GTPase activity is spatiotemporally regulated through function of guanine nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs) to activate or inactivate GTPases respectively. One such GEF, Solo, has been described as a membrane associated Trio isoform involved in neurite elongation (Aoki,

2006) and has been shown to be upregulated during mouse astrocyte migration. While Trio, the rat and human isoform, contains both GEF1 (activates Rac1 and RhoG) and GEF2 domains (activates RhoA), Solo contains only the GEF1 domain. Preliminary data indicates that Solo preferentially co-localizes with Rac1, and that siRNA Solo knock down induces altered astrocyte migration and cellular morphology. The interaction of Solo with both Rac1 and RhoA could indicate a more complex role in astrocytic migratory signaling than previously thought.

Rho GTPase effector targeting during single cell wound healing.

A. Moe¹;

¹University of Wisconsin-Madison, Madison, WI

Wounding of single cells triggers formation and closure of an actomyosin ring around the wound. Formation of this ring reflects activation of the small GTPases, Rho and Cdc42, in concentric zones around the wound. However, the links between GTPase zones and the cytoskeleton are not well characterized. Here I have connected the Rho GTPases and cytoskeleton through analysis of the localization of Rho GTPase effectors at wounds. To determine the localization of effectors, *Xenopus laevis* oocytes were injected with mRNA encoding fluorescently labeled effectors and markers for active Rho/Cdc42 and were imaged using confocal microscopy and laser wounding. To analyze the localization patterns of effectors a new method was used to create circle scans, which are a modified line scan that encompasses 360 degrees of zone information. While some effectors such as P21 activated kinase 2 (Pak2) localize throughout the entire Cdc42 zone during wound healing, other effectors change localization over time towards the leading edge of the Cdc42 zone as healing progresses. Neural Wiskott-Aldrich syndrome protein (NWASP), which activates the Arp2/3 complex to nucleate branched actin filaments, and Transducer of Cdc42 dependent actin assembly 1 (Toca1), which is necessary for full activation of NWASP, show a slight change in localization over time towards the leading edge of the Cdc42 zone. Slingshot Phosphatase, which activates cofilin to sever actin filaments, localizes to the leading edge of the Cdc42 zone to a greater extent than NWASP or Toca1. Eliminating the ability of Toca1 to bind Cdc42 inverts the localization of Toca1 such that it localizes to the trailing edge and outside of the Cdc42 zone instead of the leading edge. Cofilin shows the most prominent shift in localization over time towards the leading edge of the Cdc42 zone. LIM kinase (LIMK1), a Rho and Cdc42 effector that inhibits cofilin, localizes throughout the Rho and Cdc42 zones with a peak in the Rho zone. Formin-like 1, an unbranched actin nucleator, localizes throughout the Cdc42 zone and in the Rho zone. Rho associated kinase (ROCK), a Rho effector that activates Myosin 2, localizes to the Rho zone. The fact that different effectors show different patterns of localization during wound healing suggests that there is subcompartmentalization within a Rho GTPase zone. This ultimately leads to the idea that similar to gradients of information leading to morphogenesis, a single cell is also capable of pattern formation using gradients of information to close a wound.

Mechanosensitivity of actin assembly maintains homeostasis in the stress fiber network.S. Wang¹, S. Thiyagarajan¹, M.A. Smith², E. Blankman², L.M. Chapin², M.C. Beckerle², B. O'Shaughnessy³;¹Department of Physics, Columbia University, New York, NY, ²Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, ³Department of Chemical Engineering, Columbia University, New York, NY

The cytoskeleton is a complex network subject to constant remodeling. A major component is the network of actomyosin stress fibers. Even in cells at rest subject to no external perturbations, the network undergoes continuous and apparently stochastic adjustments as stress fiber sarcomeres change length in an apparently random fashion. The origin of these fluctuations, and the mechanism that cells employ to continuously remodel actin to accommodate these length changes and maintain network homeostasis are unknown.

Here we systematically measured the statistics of stress fiber fluctuations in mouse embryonic fibroblasts stably expressing zyxin-GFP and other fluorescently tagged stress fiber components. These statistics are a constant of the network and define its stochastic dynamics, even though the network itself is in constant flux. Using zyxin-GFP to identify sarcomere boundaries from time-lapse confocal microscopy images, we measured the temporal statistics of sarcomere length over many sarcomeres and stress fibers, following individual sarcomeres for ~ 1000 s. Statistical analysis revealed an early phase (less than ~ 50 s), when sarcomere length changed randomly in time with an effective length 'diffusion constant' $D_{\text{early}} \sim 1000 \text{ nm}^2/\text{s}$, and a late phase (greater than ~ 50 s) with a smaller diffusion constant $D_{\text{late}} \sim 200 \text{ nm}^2/\text{s}$. This remarkable feature was reproducible over many cells and stress fibers.

To explain this behavior we developed a mathematical model attributing the stochasticity to myosin-II, the principal driving force for sarcomere length changes. Fluctuations in myosin-II force are inevitable due to turnover, variations in phosphorylation and the fraction of heads bound to actin, etc. We hypothesized that actin disassembly (assembly) is mechanosensitive, steered by elastic stresses which grow (decrease) when sarcomeres shorten (lengthen) and actin filaments are forced to overlap (pulled apart). This mechanism quantitatively reproduced the observed behavior: (i) The early phase emerged as the initial sliding of actin filaments at fixed length as a sarcomere shortens or lengthens. This resets the degree of overlap, and the net actin assembly rate that depends on this overlap. (ii) In the late phase, filaments continuously adjust length in phase with the changing sarcomere length. Both phases show linear time dependence of the mean square change in sarcomere length, as seen experimentally. Best fit model parameters were remarkably close to those obtained from our previous study of spontaneously severing stress fibers.

Thus, mechanosensitivity of actin assembly allows cells to continuously remodel the stress fiber network and to maintain network homeostasis.

P93**Board Number: B193** **α -Actinin modulates actomyosin network contractile response.**H. Ennomani*¹, G. Letort*¹, C. Guérin¹, R. Boujemaa-Paterski¹, F. Nédélec², E. De La Cruz³, M. Théry⁴, L. Blanchoin¹;¹iRTSV, CEA, Grenoble, France, ²EMBL, Heidelberg, Germany, ³Yale University, New Haven, CT, ⁴iRTSV, CEA, Paris, France

Cellular contractility – the internal generation of force or tension by a cell orchestrated by the actomyosin machinery – has emerged as a critical regulator of a wide range of processes during development. Tremendous efforts have deepened our understanding of the biochemical and mechanical properties of the actomyosin contractile units encountered in the complex cell environment. Yet, how the structural organization of actin filaments regulates myosin-driven contraction remains to be established.

We have recently developed a micropatterning method that enables the spatial control of actin nucleation sites for in vitro assays (Reymann et al., 2010). These actin templates were used to evaluate the response of oriented actin structures to myosin-induced contractility in presence of regulatory proteins. We demonstrated that crosslinking level modulates actin network deformation and/or disassembly upon myosin-induced tension. We showed also that crosslinkers are necessary to sustain myosin-driven deformation and force production of dynamic actin networks in the presence of disassembly factors (ADF/cofilin). In addition, we developed numerical simulation in order to relate the observed myosin-driven actin deformation with the underlying microscopic mechanism.

Because we are working with a reconstituted system for which we control the composition and the geometrical conditions, we are in a very good position to study the fundamental rules by which myosin-mediated contractility produce force.

P94**Board Number: B194****Mechanisms of actomyosin contraction during embryonic wound repair in *Drosophila*.**A. Kobb¹, R. Fernandez-Gonzalez^{1,2,3};¹Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, ²Department of Cell and Systems Biology, University of Toronto, Toronto, ON, ³Developmental and Stem Cell Biology Program, The Hospital for Sick Children, Toronto, ON

The coordination of cellular behaviors is critical during embryonic development, cancer metastasis and tissue repair. Coordinated cell movement is mediated by networks of actin and the motor protein non-muscle myosin II that span multiple cells. In particular, during embryonic wound repair, the cells

adjacent to the wound accumulate actin and myosin at the interface with the wounded cells. Actomyosin redistribution results in the assembly of a supracellular actomyosin cable around the wound whose contraction acts as a purse string and drives wound closure. However, the mechanisms of actomyosin recruitment to the wound margin and purse string contraction are not well understood.

The mechanisms of actomyosin contraction have been investigated during cytokinesis, the final step of cell division. During cytokinesis, a contractile actomyosin ring separates the daughter cells, and actin depolymerization, but not polymerization, plays a central role in the contraction of the ring. To investigate actomyosin dynamics during embryonic wound repair, we used a high-power ultraviolet laser to irradiate and create wounds in the epidermis of *Drosophila* embryos expressing fluorescently-tagged filamentous actin or myosin. We used Fluorescence Recovery After Photobleaching (FRAP) to quantify actomyosin dynamics at the wound margin and in cells far from the wound, during purse string assembly (2 min after wounding) and contraction (4 min after wounding). Our results showed that filamentous actin fluorescence rapidly recovered to 50% of its initial value within 22.5 ± 6.5 seconds during purse string assembly, and within 16 ± 4 seconds during contraction. Using image analysis we found that total actin levels at the purse string remained relatively constant throughout wound closure. Together, these data suggest that, unlike in cytokinesis, actin polymerization takes place during wound closure. Using FRAP, we found that myosin fluorescence at the purse string had a 1.5-fold greater mobile fraction compared to non-contractile myosin cables away from the wound, consistent with a mechanisms in which actomyosin filaments slide with respect to each other to promote contraction. We are currently integrating these data into a computational model to investigate actomyosin dynamics during purse string contraction. This model will allow us to make predictions about the role of different actomyosin regulators that we will then test experimentally to understand the molecular mechanisms by which cells coordinate their migration during embryonic wound repair.

Myosin light chain kinase activity regulates front-back polarity during cell migration by modulating protrusion lifetime.

S. Lou¹, J.A. Theriot^{2,3};

¹Chemical and Systems Biology, Stanford University, Stanford, CA, ²Department of Biochemistry, Stanford University School of Medicine, Stanford, CA, ³Howard Hughes Medical Institute, Stanford University School of Medicine, Stanford, CA

Rapidly motile cells such as neutrophils and keratocytes typically polarize to generate a single front and back in order to sustain productive forward movement. However, other less persistently motile cell types, such as fibroblasts and epithelial cells, frequently have multiple, apparently independent, protrusive fronts. The mechanisms that limit polarization to a single front and back for rapidly motile cells, and how those mechanisms differ for slow-moving cell types are not fully understood. Here we develop embryonic zebrafish keratocytes as a model system for keratocyte cell biology, and use these cells to investigate how a purely lamellipodial cytoskeleton self-organizes to regulate the number of

protrusive fronts and overall cell polarity. Specifically, we have observed that keratocytes isolated from 4 days post-fertilization (dpf) embryos often form multiple protrusive fronts, suggesting that the motility machinery in these cells polarizes differently from single-front keratocytes such as those found at 2dpf or in adults. Using a combination of genomic, genetic, and pharmacological approaches, we identify increased myosin light chain kinase (MLCK) expression in 4dpf keratocytes as a causative agent in enabling the formation of multiple protrusions. We show that MLCK activity influences cell polarity by increasing myosin accumulation in lamellipodia, which decreases protrusion lifetime, thus limiting their size. These results suggest that rapidly motile cells may be able to polarize to a single front and back because they normally have less myosin activity than many slow-moving cell types

CARMIL2 localizes to vimentin filaments and leading-edge membrane-ruffles in migrating cells.

M.H. Lanier¹, J.A. Cooper¹;

¹Cell Biology and Physiology, Washington University in St. Louis, Saint Louis, MO

Although recent studies have demonstrated that vimentin can regulate lamellipodia formation, the mechanisms through which vimentin influences actin assembly are not well understood. However, CARMIL2 is a strong candidate to play a key role. Previous studies have shown that CARMIL2 localizes to vimentin filaments in cells and regulates capping protein (CP), a key regulator of actin networks, in actin polymerization assays. Additionally, we have identified a membrane-localizing region near the C-terminus of CARMIL2 that is both necessary and sufficient for localization to leading-edge membrane-ruffles and the membrane surrounding macropinosomes. CARMIL2 knockdown cells exhibit migration defects, diminished lamellipodial ruffling and macropinocytosis, and possess a striking multi-protrusion phenotype. How the CARMIL2 localization pattern relates to CARMIL2 function and the importance of CP regulation by CARMIL2 for cell migration are not established. We hypothesize that CARMIL2 regulates polarity during cell motility by regulating CP and coordinating actin filament dynamics with the vimentin network. Here, we report live-cell dynamics of CARMIL2 on vimentin filaments and membrane-ruffles. Additionally, we have created CARMIL2 vimentin-localizing mutants and CARMIL2 membrane-binding mutants. In the future, we will test the ability of these mutants to rescue the CARMIL2 knockdown phenotype.

Structural determinants of myosin-I mechanosensing: the N-terminal region.

M.J. Greenberg^{1,2}, T. Lin^{1,2}, H. Shuman^{1,2}, E.M. Ostap^{1,2};

¹Pennsylvania Muscle Institute, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Myosins are actin-based motors that are mechanically and kinetically tuned to function in a wide range of cellular processes. The myosin-I family members Myosin-IB (Myo1b) and Myosin-IC (Myo1c) have similar structures and ATPase kinetics. However, when mechanical loads are placed on the motors, they display very different behaviors. The ATP-dependent, actin-detachment kinetics of Myo1c are relatively unchanged when the myosin powerstroke is resisted by loads of less than 2 pN, so it is able to generate power and act as a molecular transporter. However, the ATP-dependent, actin-detachment kinetics of Myo1b slow dramatically under similar loads, enabling it to act as a tension-sensing anchor. We recently determined the high-resolution structure of the Myo1b motor domain and found the N-terminal region (NTR) in a conformation that has not yet been observed in other myosins. Because the NTR sequence is highly variable and alternatively spliced within the myosin-I family, we investigated whether the NTR plays a role in tuning the mechanochemical properties of myosin-I motors. We generated recombinant constructs of Myo1b and Myo1c in which their NTRs were deleted or swapped, and we characterized their kinetic and mechanochemical properties using stopped-flow techniques, single molecule optical trapping techniques, and in vitro actin-gliding assays. Our results show that the NTR does indeed play an important role in tuning the mechanochemical properties of Myo1b and Myo1c. Moreover, our results demonstrate differences in how the NTR tunes Myo1b and Myo1c, suggesting that the sequence diversity and alternative splicing of this region may play an important role in generating diversity of myosin-I function in the cell. This work was supported by a grant to EMO from NIH (GM057247).

Functional analysis of disease-associated mutations in myosin I using fission yeast as a model system.

J. Bi¹, R.T. Carroll¹, M.L. James¹, J.L. Ouderkirk¹, M. Krendel¹, V. Sirotkin¹;

¹Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Myosin 1e (myo1e) is a mammalian non-muscle myosin, which is expressed in the renal filtration unit (the glomerulus) in humans and mice. We have previously shown that Myo1e knockout mice have defects in renal filtration and glomerular ultrastructure that are similar to those observed in patients

with kidney disease called focal segmental glomerulosclerosis (FSGS). Recent genetic studies have also identified point mutations in the *MYO1E* gene in patients with FSGS. However, the precise relationship between the point mutations found in FSGS patients and the functional activity of myosin I remains to be determined. Using fission yeast *S. Pombe* as a versatile tool for analyzing myosin functions, we were able to directly test the effects of FSGS-associated mutations on myosin activity. Fission yeast have a single myosin I, Myo1p, which is associated with yeast actin patches, which are branched actin networks assembling at the sites of endocytosis. In the absence of Myo1p, yeast exhibit defects in cell growth under high salt and high temperature conditions and severe endocytosis defects. Taking advantage of the conservation of motor domains between human Myo1e and *S. pombe* Myo1p, we generated mutations in the Myo1p motor domain that were equivalent to FSGS-associated mutations in Myo1e. We found that these mutations in Myo1p resulted in the defects in yeast growth and endocytosis similar to those observed in the Δ myo1p strain. Fluorescently tagged Myo1p was used to examine myosin localization relative to actin patch marker, fimbrin. Mutations in Myo1p disrupted its localization to actin patches and resulted in relocation of Myo1p to membrane-associated protein complexes known as eisosomes. Finally, to assess the stability and folding of Myo1p mutants, we compared the localization of Myo1p to that of Rng3p, a member of UCS family proteins that acts as a myosin chaperone. Earlier studies have demonstrated that mutations in the Myo1p motor domain can promote recruitment of Rng3p to Myo1p, likely due to the decreased stability of the Myo1p. We hypothesized that Myo1p mutants that are nonfunctional due to defective folding would also interact with Rng3p and recruit it to Myo1p mutant containing structures.

Role of Myo1 C-terminal domains in Myo1 localization and regulation of actin patch dynamics.

R.T. Carroll¹, E. Oakes², M.L. James¹, V. Sirotkin¹;

¹Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY,

²LeMoyne College, Syracuse, NY

Myosin-1 (Myo1), the sole type 1 myosin in *Schizosaccharomyces pombe*, is recruited to sites of endocytosis and its arrival is followed by Arp2/3 complex mediated branched actin assembly into structures known as actin patches. Myo1 has an N-terminal motor domain, a lever arm with two light chain binding motifs (IQ1 and IQ2), and a C-terminal cargo binding tail. The Myo1 tail consists of a phospholipid binding TH1 domain, a proline-rich TH2 domain, an SH3 protein interaction domain and a CA domain, which binds Arp2/3 complex. Previously, we found that disruption of IQ motifs led to decreased recruitment of Myo1 to endocytic sites and endocytosis defects, the severity of which correlated with the reduction in the amount of Myo1 at the endocytic site. To investigate the role of the Myo1 C-terminal domains in Myo1 localization and regulation of actin patch dynamics, we created a series of GFP-tagged and untagged myo1 mutants with increasingly long deletions starting from the C-terminus. Using genetic crosses we combined these mutants with mCherry-tagged fimbrin Fim1. We

found that deletion of CA did not have any effect on Myo1 localization and actin patch dynamics. Deletion of CA and SH3 domains resulted in a 30% reduction in peak levels of myosin compared to wild type, increased assembly time for fimbrin and a decreased efficiency of internalization. Deletion of CA, SH3 and TH2 domains further reduced myosin levels at the patch (60% reduction) with similar actin assembly and internalization defects as in SH3-CA deletion mutant. The TH2-SH3-CA deletion mutant accumulated to the same peak levels as the Myo1 mutant with an internal deletion of TH2, suggesting that the TH2 domain is a major contributor to Myo1 patch localization. Deletion of CA, SH3, TH2 and TH1 domains resulted in the loss of Myo1 localization to actin patches and endocytic internalization defects similar to those in cells with a complete myo1 deletion, suggesting that TH1 is required for Myo1 localization at the endocytic site. By crossing untagged C-terminal truncation myo1 mutants with GFP-tagged ARPC5 subunit of the Arp2/3 complex, we observed trends in patch dynamics defects that were similar to defects observed with fimbrin. However, the defects were more severe since GFP-tagged Arp2/3 complex is only partially functional and is synthetically lethal with TH1-TH2-SH3-CA truncation or complete myo1 deletion. In myo1 tail truncation mutants, similar to cells depleted for Myo1 or yeast WASp homolog Wsp1, Arp2/3 complex accumulated at the slower rate but reached the same peak levels as in wild type. Since depletion of Myo1 also reduced accumulation of Wsp1 in endocytic patches, we propose that Myo1 plays a role in recruiting Wsp1, directly or indirectly, to the endocytic sites.

Characterization of kidney disease associated mutations in myosin 1e.

J. Bi¹, C.D. Pellenz¹, M. Krendel¹;

¹Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Focal segmental glomerulosclerosis (FSGS) is one of the most common primary glomerular disorders that may lead to end-stage kidney disease. One of the pathological features of FSGS is the presence of massive proteinuria (protein excretion in the urine), which results from defects in protein filtration by the renal filtration unit, the glomerulus. Pathogenesis of FSGS involves impaired function of glomerular podocytes, specialized epithelial cells that cover the surface of the glomerular capillaries. Myosin 1e (Myo1e) is a non-muscle myosin, which is expressed in kidney podocytes in humans and mice. We have previously found that Myo1e is a component of the specialized junctional complexes associated with cell-cell contacts between podocytes, and that mice lacking Myo1e develop proteinuria. Mutations in the *MYO1E* gene have also been found in patients with childhood familial FSGS. Based on these findings, recent sequencing studies focused on identifying FSGS-associated mutations have included *MYO1E* as one of the genes of interest. This resulted in identification of novel mutations in Myo1e whose effects on protein localization and function have not been determined. Using immortalized Myo1e-null cultured podocytes that were isolated from knockout mouse kidneys, we were able to examine localization and activity of the mutant Myo1e constructs. We introduced GFP-tagged Myo1e constructs into cultured podocytes using adenoviral vectors and studied their localization in live cells. We have also utilized live-cell imaging to visualize the recruitment of junctional components during cell-

cell contact assembly. Using this approach, we were able to directly demonstrate the pathogenic nature of some of these mutations, which result in mislocalization of Myo1e and defects in cell-cell junction assembly. The observed junctional defects may lead to the formation of “leaky” glomeruli *in vivo*.

Myosin 1e role in regulation of breast cancer cell migration and invasion.

J.L. Ouderkirk¹, N.O. Deakin¹, G.J. Goreczny¹, C.E. Turner¹, M. Krendel¹;

¹Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Cell migration contributes to many normal physiological processes such as embryogenesis and the immune response, but can also be pathological as seen with cancer cell invasion and metastasis. The actin cytoskeleton and its associated proteins, including myosin motors, play an important role in cancer cell migration. The aim of this study was to dissect how class I myosin 1e (Myo1e) regulates cancer cell migration. Myo1e includes a motor domain that interacts with actin filaments and a tail domain that contains membrane-binding and protein interaction motifs. Thus, it may act as a scaffold connecting actin filaments to the plasma membrane. Using an invasive breast cancer cell line MDA-MB-231 as a model, we found that shRNA-mediated knockdown of Myo1e reduced cell migration in a transwell assay compared to cells treated with scrambled shRNA. Myo1e knockdown also impaired cell invasion through Matrigel, a thin layer of matrix proteins coating a transwell filter. Observation of cells migrating towards EGF under a layer of agarose showed that control cells migrated further than Myo1e knockdown cells. Overall, these findings show that Myo1e is involved in cancer cell migration, especially in the settings where cells have to undergo complex shape changes, such as transwell migration and movement under a layer of viscous media. GFP-Myo1e localized to the outermost portion of the leading edge in migrating cells, and we are currently investigating whether it contributes to formation of protrusions at the leading edge. Based on our observations *in vitro*, we predict that Myo1e may also promote tumor cell migration *in vivo*. To test this hypothesis, we have generated Myo1e knockout mice expressing MMTV-PyMT oncogene. The MMTV-PyMT transgenic mouse is a well characterized mouse model of invasive breast cancer. We will use this model to examine how deletion of Myo1e affects breast cancer progression *in vivo*.

P102**Board Number: B207****Controlling Initiation and Termination of Kinesin-1-Driven Transport with Myosin-Ic and Non-Muscle Tropomyosin.**B.B. McIntosh^{1,2}, E.L. Holzbaur¹, E.M. Ostap^{1,3};¹Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA,²Pennsylvania Muscle Institute, Philadelphia, PA, ³Pennsylvania Muscle Institute, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Intracellular transport is largely driven by processive actin- and microtubule-based molecular motors. Non-processive motors have also been localized to trafficking cargos, but their respective roles during transport are not well understood. Myosin-Ic (Myo1c) is a non-processive actin motor that functions in a variety of exocytic events, yet the molecular roles of this motor during trafficking are unclear. To investigate the interplay between myosin-I motors and the canonical long distance transport motor kinesin-1, we attached both Myo1c and kinesin-1 motors to lipid-coated bead cargo. This is a more physiological cargo-motor attachment strategy that allows motors to actively reorganize within the membrane and respond to the cytoskeletal environment. We compared the motility of these cargos in the absence and presence of Myo1c motors at engineered actin filament-microtubule intersections attached to the surface of a coverslip. We found that Myo1c influences kinesin-1 run initiation by significantly increasing the frequency of microtubule-based runs that begin at actin filament-microtubule intersections. Myo1c also regulates run termination. Beads with both motors bound consistently pause at actin-microtubule intersections, remaining tethered for an average of 20 seconds, with pauses longer than 200 seconds also observed. Actin-binding proteins such as non-muscle tropomyosin have been proposed to positively or negatively regulate the interactions between specific myosin motors and actin filament populations *in vivo*. *In vitro*, we found that non-muscle tropomyosin-2 (Tm2) abrogates Myo1c-driven actin filament gliding. In the crossed filament assay, we found that Tm2 abolishes Myo1c-specific effects on run initiation and run termination. Together these observations suggest that within the cell, Myo1c is important for the selective initiation and termination of kinesin-driven runs along microtubules at actin filament intersections. The regulation of Myo1c by tropomyosin provides a mechanism for regional specificity, preventing inappropriate pausing during long distance transport, while also enabling targeted delivery of cargo to highly exocytic, dynamic actin populations, beneath the plasma membrane.

P103**Board Number: B208****Conserved Binding Partner of Vertebrate and Invertebrate Class III Myosins.**M. Raval¹, K. Mecklenburg², S. Freed³, O.A. Quintero⁴, J.E. O'Tousa^{2,3}, C.M. Yengo⁵;¹Pennstate College of Medicine, Hershey, PA, ²Indiana University, South Bend, IN, ³Biology, University of Notre Dame, Notre Dame, IN, ⁴Department of Biology, University of Richmond, Richmond, VA,⁵Pennsylvania State Univ Coll Med, Hershey, PA

Class III myosins (MYO3A and MYO3B) are actin-based myosin motors which are proposed to function as transporters in actin rich structures such as the stereocilia of inner ear hair cells and calycal processes of photoreceptors (PRs). The first member of the MYO3 family was identified in *Drosophila* photoreceptors and called NINAC (Neither inactivation nor afterpotential C) based on its role in phototransduction. It was observed that NINAC null mutant flies undergo light and age dependent retinal degeneration. Previous work demonstrated that NINAC is found in a complex with a protein called retinophilin (RTP). In our current work we demonstrate that NINAC interacts with RTP via the proximal region of the tail domain, a region conserved in invertebrates. We also show that NINAC localization in the rhabdomere requires the presence of RTP. We find that the vertebrate homologue of RTP, membrane occupation nexus repeat protein (MORN4), interacts with MYO3A. We demonstrate that MORN4 gets transported to the filopodial tips of Cos7 cells in a MYO3A dependent manner. The presence of MORN4 enhances the MYO3A-induced elongation of filopodia. The domain structure of the MYO3A tail is encoded by 6 exons (30-35). Using tail exon deletion constructs we demonstrate that MYO3A tail exons 30-31 are the probable sites for MORN4 interaction. We also demonstrate that MYO3B which has a shorter tail (and lacks sequence similar to exon 30-31 of MYO3A tail) is unable to bind MORN4. We used expressed and purified GST labelled MORN4 to demonstrate that MORN4 specifically interacts with the MYO3A tail domain in GST pull down assays. The MYO3A tail domain exon 30 contains a proposed calmodulin (CaM)-binding IQ motif (IQ3) of unknown function. Thus, we hypothesized that Ca²⁺ may play a regulatory role in the MYO3A-MORN4 interaction. We observed a 30% increase in MORN4 tip localization in ionomycin treated Cos7 cells which were co-transfected with GFP-MYO3AΔK and mCherry-MORN4 as compared to control conditions. No significant change was observed in the MYO3A tip localization. Overall, our results suggest that the Retinophilin/NINAC interaction is conserved in vertebrate orthologs MORN4/MYO3A. In vertebrates we propose that MORN4 stabilizes MYO3A by tethering it to the membrane, thus allowing MYO3A to generate membrane tension and contribute to the process of elongation of actin rich protrusions.

P104**Board Number: B209****The TAP-MYO5A mouse: a Tandem Affinity Purification tag knockin mouse for the isolation and identification of proteins that interact with myosin Va.**C.J. Alexander*¹, W. Wagner*², N.A. Copeland³, N.A. Jenkins³, J.A. Hammer⁴;¹NHLBI, NIH, Bethesda, MD, ²ZMNH/UKE, Hamburg, Germany, ³The Methodist Hospital Research Institute, Houston, TX, ⁴LCB, NIH/NHLBI, Bethesda, MD

Myosin Va, a processive class V motor, is involved in the transport of diverse cargos, including melanosomes, endoplasmic reticulum (ER), and mRNAs. The creation of tools to identify proteins that interact with myosin Va should increase our understanding of the cellular processes supported by this myosin. Towards that end, we report here the generation of a tandem affinity purification (TAP) tag knockin mouse at the *MYO5A* locus. A recombineering-based approach was used to insert via homologous recombination a TAP-tag composed of the IgG binding domain of Protein A, a TEV cleavage site, and the FLAG epitope tag into *MYO5A* locus immediately after the initiation codon. Mice homozygous for the knockin allele, which express the TAP-tagged version of myosin Va (TAP-MyoVa) exclusively and under the control of the endogenous *MYO5A* promoter, exhibit normal coat color and no evidence of ataxia, arguing that TAP-MyoVa functions normally. Consistently, the dendritic spines of Purkinje neurons isolated from this mouse are fully loaded with ER, in contrast to the spines of Purkinje neurons from dilute (myosin Va null) mice, which are devoid of ER. Similarly, melanosomes are distributed normally in melanocytes from the TAP-MyoVa mouse, in contrast to melanocytes from dilute mice, where the organelles are concentrated in the cell center. Moreover, introduction of a CMV promoter-driven TAP-MyoVa construct into dilute melanocytes rescues melanosome distribution. Given this clear evidence that TAP-MyoVa is fully functional, we purified TAP-MyoVa and associated proteins directly from juvenile mouse cerebella excised from TAP-tagged mice and subjected the samples to mass spectroscopic analyses. Importantly, elutes contained several known myosin Va binding partners (Dynein light chain 1 and Neurofilament light chain), further verifying that TAP-MyoVa is fully functional. Moreover, we found numerous novel interacting proteins, including Annexin A2 and Elongation Factor 1A. The mouse model created here should facilitate the identification of novel myosin Va binding partners, which in turn should advance our understanding of the roles played by this myosin *in vivo*. *Authors contributed equally to this study

P105**Board Number: B210****Filopod Extension in Dictyostelium Requires MyTH4-FERM Myosin Motor Activity.**K.J. Petersen¹, G.G. Luxton², M.A. Titus²;¹Biochemistry, Molecular Biology and Biophysics, University of Minnesota, Minneapolis, MN, ²Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN

Filopodia are cellular protrusions composed of bundled parallel actin filaments that initiate from the cortex with roles in cell adhesion and signaling during directed cell migration. MyTH4-FERM myosins (including Myosin 7, 10 and 15) localize to the distal tips of filopodia, stereocilia, and microvilli. Myo10 is required for filopod growth in mammalian cells while Myo7 is essential for filopod growth in Dictyostelium. We performed live cell imaging using GFP-tagged Myo7 in null cells. Myo7 rescued filopod formation and localized to filopodia tips and actin-based pseudopods. In pseudopods, enrichment at the leading edge near the cell membrane preceded the growth of filopodia. Tip extension velocity remained constant throughout the growing phase independent of Myo7 accumulation at the tip. A construct lacking MyTH4-FERM domains but including the putative SAH domain (Myo7 Motor) failed to rescue filopodia and did not co-localize with cortical actin. Neither of the two FERM domains were essential for rescue of filopod formation. Deletion of FERM2 led to increased production of substrate-adhered filopodia suggesting FERM2 might negatively regulate Myo7 activity in vivo. We tested this by identifying conserved residues implicated in auto-inhibition of Myo10 and expressing a mutated Myo7 (KK2333,2336AA) that also showed increased production of filopodia relative to wild type Myo7. A mutant lacking the motor domain (Myo7 Tail) was enriched near the cell membrane but failed to rescue filopod formation. Neither FERM domain was essential for localization, although a mutant lacking both domains failed to localize. These results suggest that normal formation of filopodia requires membrane-localized Myo7 with precisely regulated motor activity. (This work is supported by an NSF grant to MAT)

P106**Board Number: B211****Myosin X Reveals Dynamics and Function of Basal Filopodia.**D. Courson¹, K. Liu¹, A. Fanning¹, R. Cheney¹;¹Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC

Though often depicted as simple and flat, the basal surface of monolayers of polarized epithelial cells is actually seething with protrusive activity. Using live-cell, time-lapse TIRF microscopy we visualize the dynamics of the basal surface of stable and migrating mammalian epithelial monolayers. Previous work showed that epithelial cells in migrating sheets extend cryptic lamellipodia, in the direction of migration. In this report we show that polarized mammalian epithelial cells (MDCK and Caco2) also have filopodia on their basal surface. Basal filopodia are numerous during monolayer formation and maturation, and probe ahead of the lamellipodia during migration.

Basal filopodia have gone largely unnoticed, however we demonstrate that myosin X (Myo10) marks the tips of epithelial filopodia of cells in isolation and basal filopodia of cells in polarized sheets. In wound healing assays Myo10 puncta are planar polarized at the leading edge of cells found throughout the monolayer, from deep within the sheet out to the leading edge. Basal filopodia and Myo10 puncta become less prominent as the monolayer becomes quiescent but reappear within minutes of wounding.

Myo10 and filopodia have both recently been shown to play roles in cancer metastasis. Our findings demonstrate that Myo10 and basal filopodia both directly affect cellular motility. We show that knocking down Myo10 results in the loss of basal filopodia and ~40% reduction in the rate of collective migration. A similar decrease in motility is observed by inhibition of filopodia via low dose cytochalasin. Interestingly, the difference in motility between wild type and Myo10 knockdown cells is lost upon treatment with low dose cytochalasin, consistent with the hypothesis that the loss of filopodia, rather than some other Myo10 function, is responsible for the observed motility defect in the knockdown cells. Ongoing work is examining the mechanism behind Myo10 recruitment, filopodia formation, and their roles in collective migration.

Myosin 18A Co-assembles with Myosin II to Drive the Functional Diversity of Myosin II Bipolar Filaments.

J.R. Beach¹, N. Billington², K. Remmert¹, M. Barzik³, S.M. Heissler², L. Shao⁴, D. Li⁴, T.B. Friedman⁵, E. Betzig⁴, J.R. Sellers⁶, J.A. Hammer¹;

¹LCB, NIH/NHLBI, Bethesda, MD, ²NIH/NHLBI, Bethesda, MD, ³NIH/NIDCD, Bethesda, MD, ⁴HHMI/Janelia Farm Research Campus, Ashburn, VA, ⁵NIH/NIDCD, Rockville, MD, ⁶LMP, NIH/NHLBI, Bethesda, MD

Bipolar filaments of nonmuscle myosin II (NMII) power myriad cellular and developmental processes. Here we provide evidence that myosin 18A α (M18A α) and myosin 18A β (M18A β), two M18A splice variants, co-assemble with NMII, opening the door to novel mechanisms of bipolar filament regulation. Structurally, M18A α and M18A β resemble NMII with extra domains at their N- and C-termini. Specifically, both isoforms possess a non-helical tailpiece that contains interaction sites for SH3 and PDZ domain-containing proteins, while M18A α also possesses a ~300 residue N-terminal extension containing a KE-rich region, a nucleotide-insensitive actin-binding site, and a PDZ domain. Importantly, both isoforms contain numerous substitutions in their active site and lack actin-activated ATPase activity, arguing that they are not motor proteins (Guzik-Lendrum et al., JBC, 2013). Using a combination of TIRF and structured-illumination microscopy (TIRF-SIM), which we used recently to show that NMIIA, IIB and IIC co-assemble into heterotypic bipolar filaments in live cells (Beach et al., Current Biology, 2014), we find clear evidence that M18A α and M18A β (both expressed and endogenous molecules) co-assemble with NMII in live cells in a variety of structures, including sub-nuclear stress fibers (SNSFs). Consistently, sedimentation, EM and single-molecule imaging show that purified M18A co-assembles with NMII *in vitro*. Incorporation of M18A into NMII bipolar filaments could serve to regulate filament assembly/disassembly. Indeed, excess M18A disrupts NMII filament assembly both *in vitro* and in live

cells. M18A levels *in vivo* are, however, markedly sub-stoichiometric to NMII (ranging from ~1:10 to ~1:100), and preliminary FRAP studies do not show an obvious effect of M18A depletion on NMII filament turnover. These results favor the idea that small numbers of M18A molecules dope NMII filaments to serve, via their extra N- and C-terminal domains, as adaptors to link the filament to cellular structures. Consistently, the targeting of M18A α to SNSFs depends on its PDZ domain, suggesting that this domain links SNSFs to the nuclear envelope. M18A could also serve to recruit molecules to the NMII filament. Consistent with this idea, we show M18A's non-helical tailpiece binds β PPIX, a Rac GEF with roles in adhesion and protrusion, via β PPIX's SH3 domain. Finally, we identify two additional M18A splice variants (M18A δ and M18A γ) that possess unique N- and C-terminal domains. Collectively, our data argue that diversity of NMII function in higher eukaryotes is driven in part by co-assembly with various spliced isoforms of M18A, which serve as adaptors to link the filaments to different cellular structures and signaling molecules without interfering with NMII motor activity.

Myosin 18A localizes with myosin II at cell: cell junctions in epithelial cells and tissues.

K. Remmert¹, J.R. Beach¹, N. Porat-Shliom², R. Weigert², Y. Yang³, J.R. Sellers⁴, J.A. Hammer¹;
¹LCB, NIH/NHLBI, Bethesda, MD, ²NIDCR, NIH, Bethesda, MD, ³Hunan Agricultural University, Changsha, China, ⁴LMP, NIH/NHLBI, Bethesda, MD

Class 18A myosins (M18A) are a poorly understood subclass of myosin with a domain architecture similar to that of myosin II (MII). Specifically, both M18A α and M18A β , two M18A isoforms generated by alternative splicing, consist of a "motor" domain followed by a short neck region, an extended coiled-coil domain, and a C-terminal non-helical tailpiece harboring binding sites for SH3 and PDZ domain-containing proteins. Myosin 18A α also possesses an N-terminal extension containing a KE-rich region, an ATP-insensitive actin-binding site, and a PDZ domain. Knockout of myosin 18A results in embryonic lethality in both mice and flies, suggesting a fundamental role in development. Despite their structural similarity to MII, M18A isoforms have no actin-activated ATPase activity and do not translocate actin filaments *in vitro*, suggesting that their functions do not require motor activity. Importantly, M18A and MII co-assemble via their extended coiled-coil domains into individual mixed bipolar filaments both *in vitro* and *in vivo*. This critical finding suggests that myosin 18A may serve to regulate MII filament turnover and/or act as an adaptor to link the filaments to different cellular structures/signaling molecules via its extra N- and C-terminal domains, all without interfering with MII motor activity. M18A is ubiquitously expressed across mammalian tissues, with elevated expression and isoform-specific expression in numerous cell types, including epithelia. In this study we determined the subcellular localization of M18A in polarized MDCK cell sheets and in cryo-sections of various mouse epithelia using a M18A-specific antibody. We find that M18A is concentrated at cell-cell junctions at the apical surface of polarized MDCK cells, a site where MII is known to be critical for maintaining the integrity of adherens junctions. Similarly, M18A is enriched in kidney proximal tubules and in intestinal brush border microvilli

specifically at cell: cell junctions where MII is also enriched. Finally, we find in secretory tissues such as the pancreas and salivary gland that M18A localizes along with MII onto the secretory granules after their fusion with the plasma membrane. Functional studies are underway to determine if M18A, like MII (Masedunskas et al, PNAS 2011), is required to facilitate the integration of the granular membranes into the apical plasma membrane, thereby completing the exocytic process. Together, our data suggest that M18A may be working together with MII to maintain the integrity of epithelia and to drive secretion in specialized tissues such as the pancreas and salivary gland.

MYO19 ensures symmetric partitioning of mitochondria and coupling of mitochondrial segregation to cell division.

J.L. Rohn¹, J.V. Patel², O.A. Quintero³, B. Baum²;

¹Centre for Clinical Science and Technology, University College London, London, United Kingdom,

²Laboratory for Molecular Cell Biology, University College London, London, United Kingdom,

³Department of Biology, University of Richmond, Richmond, VA

During animal cell division, an actin-based ring cleaves the entire cell into two. Defects in this process can lead to chromosome mis-segregation, a hallmark of cancer, as well as to defects in cytoplasmic inheritance and the partitioning of organelles. Although a great deal is known about how chromosome segregation is coupled to the process of cell division, the way organelles coordinate their inheritance during partitioning to daughter cells is less well understood. Here, using a high-content live-imaging siRNA screen, we identify myosin-XIX (MYO19) as a novel regulator of cell division. Previously this actin-based motor was shown to control the interphase movement of mitochondria. Using live-cell imaging, our analysis shows that MYO19 is indeed localised to mitochondria, and that its silencing leads to asymmetric segregation of mitochondria during anaphase and telophase, as well as to defects in mitochondrial partitioning at cytokinesis. Moreover, MYO19 RNAi cells frequently fail to complete division. This cell division failure phenotype persists in cell lines stably expressing shRNA against MYO19, as these cell lines display a higher percentage of multinucleate cells, compared to controls. This phenotype appears to be due to the physical interference of cytokinesis machinery by mitochondria, as the phenotype can be mimicked using a treatment that blocks mitochondrial fission and rescued by decreasing mitochondrial fusion. The phenotype can also be rescued by exogenous expression of GFP-MYO19 refractory to RNAi treatment. Taken together, these data support a model whereby the actin-based myosin motor, MYO19, is responsible for the faithful segregation of mitochondria during cell division, and highlights the importance of coupling organelle inheritance to cytokinesis.

P110**Board Number: B215****Myosin XIX (Myo19) regulates actin-based mitochondrial dynamics.**X. Hu¹;¹Department of biology, Institute of Molecular Cell Biology, Münster, Germany

Mitochondria are highly mobile and dynamic organelles. They are involved in several important cellular functions, including energy production, metabolism, calcium buffering and apoptosis. Defects in their localization and dynamics lead to human disease. Myosin-XIX (Myo19) is a novel myosin in vertebrates that has been reported to function as an actin-based motor that associates with mitochondria. Myosins generally consist of a motor, neck and tail region. The tail region of Myo19 is necessary and sufficient for mitochondrial localization. However, at present it is not known how Myo19 associates with mitochondria and how it affects mitochondrial dynamics. We found that overexpression in HeLa cells of either the full length Myo19 or the Myo19 tail region resulted in dramatic alterations in mitochondria distribution, morphology and movement. Overexpression of Myo19 typically resulted in a collapse of mitochondria around the nucleus. Live cell imaging revealed that overexpression of Myo 19 induced in many continuously moving mitochondria a tadpole-like shape. Overexpression of the tail region of Myo19 caused a similar collapse of the mitochondria to the perinuclear region and the movement of individual mitochondria was hard to discern. The transport of mitochondria in dendrites and axons of neurons is particularly vital to meet local cellular energy demands and for buffering intracellular calcium. We found that mitochondrial length was significantly decreased in Myo19 overexpressing hippocampal neurons. No other differences were found between neurons transfected with RFP-Mito alone or RFP-Mito together with EGFP-Myo19 or EGFP-Myo19 tail regarding mitochondria density, velocity, run length, directionality etc. These results suggest that Myo19 is involved in regulating mitochondria morphology in neurons, but not transport. In conclusion, Myo19 regulates actin-based mitochondrial dynamics.

P111**Board Number: B216****Positively Charged Residues are Essential for Proper Localization of the MYO19 MyMOMA Domain to the Mitochondrial Outer Membrane.**P.R. Mehta¹, P.P. Singh¹, J.L. Hawthorne¹, N.Q. Wong¹, O.A. Quintero¹;¹Department of Biology, University of Richmond, Richmond, VA

Myosins are well characterized for their roles as molecular motors that convert the chemical energy of ATP hydrolysis into the mechanical force essential for cellular processes such as muscle contraction, cytokinesis, and intracellular transport. Class XIX myosin (MYO19) is an unconventional myosin found in organisms ranging from unicellular holozoans to mammals that contains a unique tail domain responsible for its interaction with mitochondria. The **Myo19 mitochondria outer membrane association domain (MyMOMA)** contains approximately 150 amino acids with a pI ~ 9, and is sufficient for

localization to the mitochondrial outer membrane. However, the minimal sequence required for mitochondrial binding and the specific amino acid residues required for mitochondrial targeting have not been identified. Here we report that a stretch of approximately 83 residues in the human MyMOMA domain is sufficient for mitochondrial outer membrane localization, and that two positively charged residues are essential for recognition of the mitochondrial outer membrane. We generated a suite of MyMOMA truncations based on sequence analysis of 13 vertebrate MYO19 orthologs, establishing the boundaries for truncations based on lack of sequence homology. The 83-amino acid minimal binding region is enriched for positively charged amino acids has a $pI \sim 10.5$. Endogenous MYO19 copurifies with mitochondria-enriched fractions via differential centrifugation, and can be released from those fractions by incubation in high pH buffer, suggesting that positively-charged residues may be involved in the MYO19 binding mechanism. We sequentially replaced positively charged residues in the minimal binding domain with uncharged residues via mutagenesis, identifying the specific residues required for interactions with the mitochondrial outer membrane, RK872-873. Interestingly, constructs containing the RK872-873AA mutation localized to the endoplasmic reticulum. To determine if ER-bound mutant MYO19 tail and mitochondria-bound wild type MYO19 tail display differences in strength of membrane interaction, we performed kinetic studies using permeabilization activated reduction in fluorescence (PARF) analysis. These studies indicated that both constructs display similar apparent off-rates. Taken together these data support the hypothesis that the MyMOMA domain contains a membrane-binding activity, and that membrane targeting is mediated through a yet-to-be determined mechanism requiring amino acids RK872-873.

Characterizing the proximal protein interactions of Myosin-XIX (MYO19) via promiscuous biotin ligase.

E.L. Schinski¹, F. Yan², M.B. Major², O.A. Quintero¹;

¹Department of Biology, University of Richmond, Richmond, VA, ²Department of Cell Biology Physiology, University of North Carolina, Chapel Hill, NC

Myosin XIX (MYO19) is a motor protein that binds to mitochondria, and plays a role in the organization and dynamics of mitochondria. MYO19 consists of a motor domain, a 3 IQ motif-containing neck region, and a short tail. In conjunction with filamentous actin, the motor converts the energy released by ATP hydrolysis into useful force that is transmitted through the neck region to act upon the cargo-binding tail domain, thereby imparting force on the cargo. According to this model, there are multiple instances where interaction with other proteins is likely for MYO19 function, separate from the interaction with actin. We aim to elucidate the protein interactions of MYO19 by identifying proximal components and potential binding partners. To identify such interactors, we have created fusion constructs capable of tagging nearby proteins. By tagging MYO19 truncations with the promiscuous *E. coli* biotin ligase, BirA*/BioID, we are able to induce biotinylation of proximal cellular proteins. We hypothesize that the IQ motifs in the neck region bind EF-hand regulatory proteins such as calmodulin, and that the tail

domain interacts with proteins on the mitochondrial outer membrane. We first transfected HeLa cells with the BioID-MYO19 constructs, and incubated the cells in media containing biotin. We were able to observe expression of the MYO19/BioID constructs via fluorescence immunohistochemistry. Biotinylation was observed via immunostaining and anti-streptavidin blotting of HeLa cell lysates. Biotinylated proteins were isolated from lysates using magnetic strepavidin-coated beads, and the bound proteins processed via mass spectrometry. Through the analysis of these MYO19 associated proteins, we hope to better understand the cellular function of MYO19 by identifying proteins with which it may interact.

Investigating the role of myosin 7b in intramicrovillar transport.

M.L. Weck¹, S.W. Crawley¹, M.J. Tyska¹;

¹Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

The intestinal brush border serves as the sole site of nutrient absorption within the body and also acts as an important barrier against luminal pathogens. The brush border is comprised of membrane protrusions called microvilli that are found on the apical surface of enterocytes. These protrusions are supported by a core bundle of 20 to 30 parallel actin filaments with the plus ends oriented towards the lumen. Recently, our lab showed that two protocadherins, protocadherin-24 and mucin-like protocadherin, play a key role in the organization of the brush border during its assembly. These protocadherins interact to form a *trans*-heterophilic adhesion complex that physically connects the distal tips of microvilli and regulates the tight packing of the brush border. However, the mechanism of how these complexes are targeted to the tips of microvilli remains unknown. The microvillar protocadherins interact with two cytoplasmic binding partners, harmonin, a scaffolding protein, and myosin 7b (*myo7b*), an unconventional myosin. We hypothesize that the motor protein *myo7b* is responsible for transporting these complexes to the plus end of microvillar actin bundles. To test this hypothesis, we generated an shRNA-mediated knockdown of *myo7b* in CACO-2_{BBE} intestinal epithelial cells. Knockdown of *myo7b* results in reduced distal tip localization of the intermicrovillar adhesion complex (IMAC) components, as well as perturbations in microvillar clustering and brush border morphology. To further characterize the potential of *myo7b* as a transporter, we created a *myo7b* stable cell line using brush border-expressing LLC-PK1-CL4 kidney epithelial cells. Robust targeting of *myo7b* to the tips of microvilli occurs after several days of polarization. This localization is dependent on the tail domain as deletion of this region results in a loss of distal tip targeting. Previous studies of other myosins have indicated that cargo binding to the tail domain may promote motor processivity by inducing dimerization. To explore this possibility for *myo7b*, we engineered forced dimer constructs of the motor domain (MD) and full length *myo7b* using a GCN4 leucine zipper motif. The MD forced dimer targets in fully polarized LLC-PK1-CL4 cells, indicating that dimerization is sufficient for targeting and likely mediated by the tail domain through cargo binding. Additionally, we also examined how point mutations that disrupt motor domain function impact the distal tip targeting of *myo7b*. These data

suggest that active cycling and force generation are required for microvillar tip targeting. Taken together, these data indicate a role for myo7b in brush border formation through the localization of the IMAC to the tips of microvilli.

Computational and experimental FRAP analyses of myosin XI-dependent vesicular transport show coupling with F-actin in polarized cell growth.

J.P. Bibeau¹, J.L. Kingsley², F. Furt³, E. Tuzel², L. Vidali³;

¹Biology and Biotechnology, Worcester Polytechnic Institute, Worcester, MA, ²Physics, Worcester Polytechnic Institute, Worcester, MA, ³Biology/ Biotechnology, Worcester Polytechnic Institute, Worcester, MA

Plant polarized cell growth is driven by the trafficking of secretory vesicles to the site of cellular expansion. Although the actin cytoskeleton and its associated motor myosin XI are heavily implicated in this process, little is known about their relative dynamics and binding properties *in vivo*. Here we applied fluorescent recovery after photo-bleaching (FRAP) techniques to the tip-growing cells of the moss *Physcomitrella patens* to investigate myosin XI dynamics and its relation to secretory vesicles. To complement our FRAP experiments, a three-dimensional Brownian motion simulation of FRAP was used to gain further insight into the dynamic behavior of myosin XI and vesicles. Our results clearly indicate that the dynamics of myosin XI at the cell apex differ significantly from those measured at the sub-apical region. Specifically, the rate of fluorescent recovery was found to be more rapid at the sub-apical region, indicating that a fraction of myosin XI is less mobile at the tip. To evaluate if the reduction on motility is dependent on F-actin, we depolymerized the actin using latrunculin B. This treatment significantly increased the mobile fraction of myosin XI at the cell apex, but not to the levels of the sub-apical region. To clarify this we used computer simulations that indicate that this discrepancy can be fully explained by cell boundary effects on the fluorescent recovery. In addition, our computer simulations have allowed us to estimate diffusion coefficients for myosin XI and vesicles, and at the same time estimate the fraction of myosin XI molecules associated with vesicles at the tip of the cell. Taken together our experimental results and simulation data support a model where myosin XI, secretory vesicles, and F-actin act cooperatively to drive polarized secretion and growth.

P115**Board Number: B220****Biochemical characterization of the interaction between Rab proteins and myosin XI in the moss *P. patens*.**S. Kaptur¹, J. Garbarino¹, M.L. Dubuke², F. Furt¹, E. Armstrong¹, M. Munson², L. Vidali¹;¹Biology/ Biotechnology, Worcester Polytechnic Institute, Worcester, MA, ²Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA

Actin-mediated trafficking plays an essential role in intracellular transport in all studied eukaryotic cells, including the moss, *Physcomitrella patens*. *P. patens* is an excellent model organism for studying actin-mediated trafficking because of its genetic tractability and simple cytology. Actin-mediated trafficking in *P. patens* is essential for polarized growth of its tip cells. The actin-associated motor, myosin XI, has been identified as an important protein for this process. Myosin XI is most similar to the class V myosins from yeast and animal cells. Similar to myosin V, *P. patens* myosin XI functions as a dimer with a head, neck, coiled-coil, and cargo binding domains. Myosin XI is hypothesized to function as a molecular motor carrying exocytotic vesicles along actin filaments to the plasma membrane. In mammalian and yeast cells, the association between myosin and its vesicle cargo is mediated by Rab-GTPases, such as Rab11 and Ypt31/32 respectively. We hypothesize that, in plants, a similar Rab-myosin interaction is necessary for vesicle transport. To evaluate this, we selected three classes of plant Rab proteins based on homology to Rab11 and Ypt31/32 and we are developing an in vitro binding assay to determine if these candidate Rab proteins have myosin XI binding activity.

Previous work in our laboratory also identified mutations in the myosin XI cargo-binding domain that failed to complement the RNAi-based knockdown of myosin XI. In this study, we aim to determine the structural consequences of the most severe mutations. We used PCR mutagenesis to generate protein expression constructs for three mutants of the myosin XI cargo-binding domain. We are purifying the wild type and mutant proteins, and plan to compare their folding and stability by circular dichroism, thermal denaturation, and potential for aggregation. Finally, using the Rab proteins identified as potential binding partners, we will determine if the loss-of-complementation in the RNAi screen was due to a binding defect between myosin XI and its cognate Rab. In this study, we use biochemical methods to determine the cause of the failure-to-complement of the myosin XI mutants and to determine if a subclass of Rab proteins is important for myosin XI binding to vesicles in plant cells.

Effect of Tyrosine 18 Phosphorylation on the Conformation and Dynamics of Tau.

J. Stern¹, G. Morfini², C. Berger³;

¹Cellular, Molecular and Biomedical Sciences Program, University of Vermont, Burlington, VT,

²Department of Cell and Molecular Biology, Univ Illinois-Chicago, Chicago, IL, ³Department of Molecular Physiology and Biophysics, University of Vermont, Burlington, VT

Tau is a neuronal microtubule (MT) associated protein that performs numerous functions including stabilizing MTs, participating in signaling cascades and directly inhibiting kinesin-1 motility *in vitro*, but the relationship between Tau structure and function has yet to be fully elucidated. Recent single molecule experiments have shown that in addition to forming a conventional static complex, Tau can diffuse in an ATP-independent manner while bound to MTs, and the equilibrium between these populations differs with both Tau isoform and MT lattice structure. Furthermore, Tau can adopt a dynamic folded conformation in solution, stabilized through interactions between the N- and C-terminal regions of the molecule. In light of these findings, we hypothesize that the folded conformation of Tau represents the diffusive state and that the equilibrium between the diffusive and static states is mediated by post translational modifications that affect the stabilizing interactions of the N- and C-termini. We further hypothesize that phosphorylation at tyrosine 18 (Y18) in Tau's N-terminus helps stabilize the folded conformation and promotes the diffusive behavior of Tau on the MT surface. Correspondingly, dephosphorylation of Y18 leads to a shift from the diffusive to the static state on the MT surface. To test these hypotheses, phosphomimetic and unphosphorylatable control constructs of 3RS-Tau were made by substituting glutamic acid and alanine, respectively, at and around Y18. TIRF microscopy was used to examine the dynamic behavior of these Tau constructs on the MT surface, as well as their ability to inhibit kinesin motility.

Down-regulation of stathmin is required for the phenotypic changes and classical activation of macrophages.

K. Xu¹, R.E. Harrison²;

¹University of Toronto, Toronto, ON, ²Department of Biological Sciences, University of Toronto Scarborough, Toronto, ON

Macrophages are major effector cells of the innate immune response with specialized capacity for recognition and elimination of pathogens, and present antigens to lymphocytes for adaptive immunity. Macrophages become activated upon exposure to pro-inflammatory cytokines and pathogenic stimuli.

Classical activation of macrophages with interferon- γ (IFN γ) and lipopolysaccharide (LPS) triggers a wide range of protein signalling events and morphological changes to induce the immune response. Our previous microtubule (MT) proteomic work revealed that stathmin association with MTs is considerably reduced in activated macrophages, which exhibit significantly enriched stabilized MTs. Here we show that there is a global decrease in the MT catastrophe protein stathmin level in activated macrophages using both immunoblotting and immunofluorescent microscopy. Our results suggested this is an LPS-specific response that induces proteasome-mediated degradation of stathmin. Furthermore, we explored the functions of stathmin down-regulation in activated macrophages by generating of a stable cell line overexpressing stathmin-GFP. We show that stathmin-GFP overexpression impacts cytoskeletal stability by reducing MT stabilization and acetylation, which significantly diminishes morphological changes associated with cell activation. In addition, we found that stathmin overexpression severely impaired immune functions such as complement receptor 3 (CR3) - mediated particle binding and macrophage activation. Overall, our results implicating a pivotal inhibitory role for stathmin in classically activated macrophages.

Doublecortin bends growing microtubules.

S. Bechstedt¹, J. Hsu¹, G.J. Brouhard¹;

¹McGill University, Montreal, QC

Microtubules are the stiffest members of the eukaryotic cytoskeleton. Despite their high persistence length, microtubules are highly bent in many cellular contexts, such as the neuronal growth cone. Here we show that Doublecortin (DCX), a microtubule-associated protein (MAP) expressed in developing neurons, bends growing microtubules in vitro. We measured the curvature, k , of microtubules bent by DCX using B-splines and show that DCX induces a characteristic bend in growing microtubules, whose curvature depends on DCX concentration. Our results demonstrate for the first time, that a MAP can directly modulate microtubule curvature.

P119

Board Number: B225

CP190-microtubule association is mediated by a novel N-terminal region that requires dimerization mediated by a flanking BTB domain.

K.M. Plevock^{1,2}, R.X. Guillen², B.J. Galletta², K.C. Slep³, N.M. Rusan²;

¹University North Carolina, Chapel Hill, NC, ²National Heart Lung, and Blood Institute, NIH, Bethesda, MD, ³Department of Biology, University of North Carolina, Chapel Hill, NC

CP190 is a large, multi-domain protein, first identified as a centrosome protein with striking oscillatory localization over the course of the cell cycle. During interphase it has a well-established role within the

nucleus as a chromatin insulator. Upon nuclear envelope breakdown, there is a redistribution of CP190 to centrosomes and the mitotic spindle, with a population remaining associated with chromosomes. Previous work described a central CP190 region important for centrosome localization and microtubule (MT) binding. However, a detailed analysis of the CP190 N-terminal region has not been fully described. Here, we investigate CP190 in detail by performing domain analysis in cultured *Drosophila* S2 cells combined with protein structure determination by x-ray crystallography and *in vitro* biochemical characterization.

Our analysis of CP190 identified a novel centrosome targeting and microtubule (MT) interacting region. This previously uncharacterized CP190 N-terminal region robustly localizes to interphase MTs and is enriched at the growing MT plus ends. This region consists of a highly conserved BTB domain and a linker region that directly interacts with taxol-stabilized MTs *in vitro*. We present the 2.6 Å resolution structure of the CP190 N-terminal 126 amino acids, which adopts a canonical BTB domain fold and exists as a stable dimer in solution. The CP190 BTB domain is important for robust MT localization. The ability of the linker region to colocalize with MTs in cell culture requires BTB-domain mediated dimerization, though MT colocalization can be rescued via artificial dimerization, replacing the BTB domain with either GST or the GCN4 coiled-coil. These data suggest a possible regulatory role for the BTB domain in modulating CP190 association with the MT network. Finally, in live cells, we see that this N-terminal region and the artificially dimerized linker localize to the kinetochore.

The Microtubule tip is a central node for amplification of calcium signals.

M. Geyer¹, F. Huang¹, S. Vogel¹, A.B. Malik^{1,2}, Y. Komarova¹;

¹Pharmacology, Univ Illinois-Chicago, Chicago, IL, ²Univ Illinois Coll Med, Chicago, IL

Growing microtubule (MT) tips establish a transient interaction with endoplasmic reticulum (ER), the main Ca²⁺ store in the cell, but the functional outcome of these events are poorly understood. Here we demonstrate that growing MTs serve as the binding platform for the inositol 1,4,5-trisphosphate receptors (IP₃Rs), the Ca²⁺ gating channel on the ER membrane. End binding protein 3 (EB3), a core element of plus end tracking protein (+TIP) complex, interacts with the IP₃R channel and triggers its clustering. This interaction provides the molecular basis for spatio-temporal organization of Ca²⁺ signals and determines the overall outcome of the complex cellular response. Targeting EB3-IP₃R interactions in endothelial cells stabilizes Vascular Endothelial (VE)-cadherin adhesions and suppresses vascular inflammation suggesting that MT-dependent amplification of Ca²⁺ signaling is a significant pathological component that can be targeted therapeutically. These findings establish the primacy of the EB3-IP₃R complex as a central signaling node in vascular pathophysiology.

P121**Board Number: B227****An elastic shield coupled to rigid interface provides mechanical integrity to myonuclei.**S. Wang¹, T. Volk¹;¹Department of Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel

Differ from most other cell types, striated muscle cells contain high number of nuclei distributed evenly on the surface of the myotube and are subjected to variable mechanical stress during muscle contraction.

The characteristic oval myonuclear shape and positioning have been linked to transcriptional regulation, as well as to correct export of mRNAs and proteins. Thus, correct nuclear shape and position are critical for proper muscle function. Consistently, numerous muscular dystrophies and (cardio-)myopathies exhibit nuclear mis-positioning and aggregation.

Previously, we revealed the essential role and molecular interaction between the two *Drosophila* KASH-domain proteins Klar and MSP-300/Nesprin in promoting the even distribution of myonuclei and their anchorage to the acto-myosin in striated muscle fibers. Recently, by performing muscle-specific RNAi screen, we identified additional proteins involved in the core mechanism for myonuclear shaping and distribution process. We demonstrate that the Spectraplakkin Shortstop (Shot) is a crucial stabilizing component of a microtubule (MT)-based network that surrounds the myonucleus. Moreover, Shot and MSP-300 interact genetically with each other and their stable attachment to the nuclear envelope requires their mutual existence.

Furthermore, both Shot and EB1 display a perinuclear localization pattern like MSP-300, and their knockdown leads to severe disruption of myonuclear shape, supporting a cooperative and reciprocal activity between MSP-300, Shot and EB1 in organizing the perinuclear MT network. Additionally, knockdown of Shot or EB1 perturbs nuclear shape and meanwhile induce ectopic perinuclear F-actin accumulation, indicating a potential involvement in the negative regulation of F-actin polymerization. Finally, our experiments demonstrate that MSP-300, Shot, and EB1 are essential to protect and maintain myonuclear architecture during mechanical stress implicated during muscle contraction.

Together, all these components form a perinuclear flexible shield essential for protecting myonuclei from intrinsic or extrinsic forces. The loss of this scaffold resulted in significantly aberrant nuclear morphology and a subsequent abnormal distribution of factors essential to maintain proper nuclear architecture. Overall, we propose a novel mechanism for protecting myonuclear morphology and reveal its critical link to correct distribution of nuclear factors in differentiated muscle fibres. These findings may shed light on the cause of various muscular dystrophies.

P122**Board Number: B228****Induced changes in the dynamics of EB1-mNeonGreen and microtubules in *Chlamydomonas*.**Y. Liu¹, K.F. Lehtreck², P. Yang¹;¹Department of Biological Sciences, Marquette University, Milwaukee, WI, ²Cellular Biology, University of Georgia, Athens, GA

EB1 is a master plus end tracker central to microtubule-based processes. It appears like comets near the plus end of only growing microtubules where GTP in tubulin is stochastically hydrolyzed to GDP. At this position EB1 could recruit effectors that modulate microtubule dynamics or harness cellular structures to plus ends. Yet EB1 is also localized outside plus ends, such as basal bodies and the centrosome. The molecular basis for the distinct locations remains to be resolved. To investigate the factors affecting EB1's locations, we express fluorescing EB1 as endogenous EB1 in *Chlamydomonas* that generate a few types of microtubules. Both EB1-GFP and EB1-mNeonGreen decorated basal bodies and microtubule plus ends at the flagellar tip. However, contrary to EB1-GFP that was entirely obscured by intense autofluorescence from photosynthesis pigments, EB1-mNeonGreen exhibited comet-like patterns typical of EB1 at the plus end of profuse growing microtubules in the cell body. Therefore like EB1-GFP, EB1-mNeonGreen could report the behaviors of EB1 and mNeonGreen is conducive for live imaging of photosynthetic cells. In some preparations - depending on media content, cell density and illumination for microscopy – the comets vanished, perhaps due to diminished growing microtubules; or, unexpectedly, EB1-mNeonGreen appeared like static fibers, some of which resembles the rootlets comprised with characteristic bundles of 2 or 4 microtubules. We are currently defining the conditions that induce changes in the dynamics and interplay of microtubules and EB1.

P123**Board Number: B229****The dynamics of EB1 in *Chlamydomonas* flagella.**Y. Liu¹, A. Harris², K.F. Lehtreck², P. Yang¹;¹Department of Biological Sciences, Marquette University, Milwaukee, WI, ²Cellular Biology, University of Georgia, Athens, GA

The motor-driven intraflagellar transport (IFT) has been considered as the principle trafficking modality for gated lengthy flagella except for small particles that rely on passive diffusion. Although EB1 is best known for binding to the plus end of growing microtubules, immunolocalization revealed EB1 at basal bodies near the entrance and the tip of *Chlamydomonas* flagella regardless growing, full length or shrinking. To reveal how EB1 molecules travel to and remain at the tip, we expressed EB1-GFP as endogenous EB1 in a few *Chlamydomonas* strains, including temperature sensitive IFT mutant *fla10*, in which anterograde IFT could be switched off at 32°C. In all strains and temperatures examined, EB1-GFP is present at the tip and basal bodies as well as the flagellar shaft, albeit dimmer. Fluorescence recovery

after photobleaching (FRAP) analysis showed that EB1-GFP moves directionally but far faster than IFT. The tip population in steady-state flagella fully recovers within 2-3 min post bleaching. Further analysis suggests that EB1 forms a stable pool at the flagellar tip which slowly exchanges with the population in the shaft. EB1-GFP is expected to form a dimer of about 120 kDa. Our data suggests that IFT-independent movement is sufficient to rapidly translocate cytoplasmic proteins of more than 100 kD in size to the flagellar tip. We are currently investigating the nature of IFT-independent directional rapid movement of EB1 and whether the non-canonical behavior of EB1 at the flagellar tip is linked to the dynamics of the axonemal microtubules.

TIP150 regulation in cell migration and functional relevance interaction with the cytoskeleton.

G. Adams¹, P. Xia², D. Cao², Z. Wang³, T. Zhu^{1,2}, H. Duane², X. Yao⁴;

¹Morehouse School of Medicine, Atlanta, GA, ²Univ Sci/Technol China, Hefei, China, ³Univ Science/Technol-China, Hefei, China, ⁴Cellular Dynamics, University of Science Technology of China, Hefei, China

The regulation of cell migration is a highly complex process that is often compromised when cancer cells become metastatic, migrating from primary-to-secondary locations. The microtubule cytoskeleton is necessary for cell migration, but how microtubules and microtubule-associated proteins regulate multiple pathways promoting cell migration remains unclear. Microtubule plus-end binding proteins (+TIPs) are emerging as important players in many cellular functions, including cell migration. Here we identify a +TIP, TIP150, that promotes cell migration. TIP150 accumulates at growing microtubule plus ends through interaction with the EB1. The EB1-dependent +TIP activity of TIP150 is required for cell migration, as well as for interactions with both actin and microtubule. Here we describe the characterization and functional identification of TIP150 and its association in cellular migration. We hypothesize that TIP150 helps regulate cell migration and links actin to microtubules. To this end, we used a series of biochemical and biophotonic experiments to show TIP150 is necessary for directional cell migration and potentially links to microtubules and actin, further offering additional evidence of the importance of microtubule dynamics in the cell migration process.

P125**Board Number: B231****The role of +TIPs in the remodelling of microtubules during intestinal epithelial differentiation.**

D. Goldspink¹, J. Perkins¹, Z. Matthews², B. Tyrrell¹, P. Powell², T. Wileman², E. Lund¹, N. Galjart³, M. Mogensen¹;

¹School of Biological Sciences, University of East Anglia, Norwich, United Kingdom, ²School of Medicine, University of East Anglia, Norwich, United Kingdom, ³Erasmus MC, Rotterdam, Netherlands

Microtubule dynamics and organisation play a key role in determining cellular function in differentiated epithelial cells. The intestine contains a hierarchy of epithelial development and provides an ideal model to study microtubule organisation. Stem cells located at the base of the crypt give rise to transit-amplifying cells that divide, differentiate and migrate up the crypt and into the villus in the small intestine or the surface epithelium in the colon.

Here we show that epithelial cells located at the bottom of intestinal crypts contain an umbrella-like microtubule array with minus-ends anchored at apical centrosomes. However, in the villus centrosomal anchorage is lost and a stabilised apico-basal microtubule array forms with minus-ends anchored at apical non-centrosomal sites. Interestingly, some of the microtubule plus-end tracking proteins (+TIPs) show distinct expression patterns in the intestine. For example, the end-binding protein EB2 is highly expressed at the bottom of crypts but downregulated in the transit amplifying and differentiated enterocytes. EB2 reduction in intestinal epithelial cells leads to microtubule stabilisation and crosslinking to actin filaments, suggesting that EB2 downregulation plays an important role in apico-basal array formation. EB1 is expressed throughout the intestine but a shift from comet only to microtubule lattice association is evident in differentiating cells with distinct apico-basal bundles.

Loss of microtubule centrosomal anchorage coincides with the redeployment of the centrosomal anchoring protein ninein to apical junctional sites. Interestingly, the +TIPs CLIP-170 and p150 are also found at these anchoring sites. Analysis of intestinal villus and surface epithelium of CLIP-170/115 knockout mice reveal a loss of ninein from these anchoring sites. Furthermore, functional inhibition in epithelial cell lines suggests that CLIP-170 along with active Rac1 and IQGAP1 ensures efficient redeployment of ninein by facilitating microtubule plus-end cortical capture at adherens junctions. Using recent advancements in intestinal organoid cultures we have further investigated the role of these +TIP proteins in epithelial differentiation. Our data suggest tight regulation of both expression and localisation of EBs and CLIP-170 during intestinal differentiation and show that these +TIPs are critical for microtubule reorganisation and epithelial differentiation.

P126**Board Number: B232****Microtubule +TIP protein EB1 binds to GTP and undergoes dissociation from dimer to monomers upon binding with GTP.**K. K. Gireesh¹, J. S. Sreeja¹, S. Chakraborti², P. Singh¹, G. E. Thomas¹, H. Gupta¹, T. Manna¹;¹School of Biology, Indian Institute of Science Education and Research Thiruvananthapuram, Kerala, India, ²Department of Neurobiology signalling and Cancer, Institut Curie, Orsay Cedex, France

Dynamic properties of microtubules predominantly rely on the conformational status of their growing plus end. The process of conformational arrangement is tightly regulated by a wide range of proteins localized at the ends. One of the highly abundant proteins localized at the plus end is EB1, which autonomously tracks the growing end and regulates the plus end dynamics. The mechanism through which EB1 recognizes the plus ends has been under intense scrutiny in recent years. Previous studies have indicated that EB1 can recognize the GTP-bound tubulin structures at the plus ends and it localizes on the microtubule surface at a site close to the exchangeable GTP-binding site of tubulin. Furthermore, its binding has been shown to promote maturation of the plus end and accelerate the GTP hydrolysis cycle at the end. Although the GTP-dependent structural change in tubulin has been demonstrated as a critical determinant for recognition of the plus ends by EB1, the effect of GTP on the structure of EB1 has remained unclear. In this study, we have used spectroscopic, calorimetric and biochemical methods to analyze the effect of GTP on EB1 *in vitro*. Isothermal titration calorimetry and tryptophan fluorescence quenching experiments demonstrated that EB1 binds to GTP with a dissociation constant $\sim 30 \mu\text{M}$. Circular dichroism measurements showed that EB1 undergoes changes in its secondary structure upon binding with GTP. Size exclusion chromatography and the urea-induced unfolding analyses revealed that GTP-binding induces dissociation of the EB1 dimer to its monomers. Size exclusion chromatography followed by biochemical analysis determined that EB1-GTP binding involves association of approximately one molecule of GTP per EB1 monomer. We also found that GTP did not affect the stability of the dimer formed by the C-terminus (191-268) of EB1. Detailed analysis further revealed that the GTP specifically binds to the N-terminus (1-130) of EB1 and induces conformational changes in the N-terminus, suggesting that the GTP-induced conformational change in the N-terminus destabilizes the monomer-monomer interaction in the full length EB1 dimer. The results reveal a hitherto unknown GTP-dependent mechanism of dimer to monomer transition in EB1 and further implicate its possible role in regulation of EB1 dimer vs. monomer stability and the plus end regulation in cells.

P127**Board Number: B233****Drosophila melanogaster Msps TOG3 utilizes unique structural elements to promote domain stability and maintain an integral tubulin-binding surface.**A.E. Howard^{1,2}, K.C. Slep³;¹Biochemistry and Biophysics, University of North Carolina, Chapel Hill, NC, ²Molecular and Cellular Biophysics Program, University of North Carolina, Chapel Hill, NC, ³Department of Biology, University of North Carolina, Chapel Hill, NC

XMAP215 family members are potent plus-end microtubule (MT) polymerases. Mutation or depletion of XMAP215 decreases MT polymerization rates and contributes to abnormal spindle phenotypes. The XMAP215 family utilizes an array of tumor overexpressed gene (TOG) domains, consisting of six (A-F) helix-turn-helix HEAT motifs, to bind tubulin. Recently, we showed that XMAP215 family TOG domains have differential, positionally conserved architectures across the array, highlighted by the similar architectures of TOG1 and TOG2, and the differential, comparative architecture of TOG4. Differential TOG domain architectures have the potential to contribute to unique TOG-tubulin interactions, with implications for position-dependent TOG domain tubulin-binding activities and function within the XMAP215 MT polymerization mechanism. Although structures of TOG domains 1, 2, and 4 are well-described, structural and mechanistic information characterizing TOG domains 3 and 5 are outstanding. Here we present the crystal structure of *Drosophila melanogaster* Msps TOG3 to 2.3 Å resolution. Msps TOG3 has two unique features; the first is a unique C-terminal tail that interlocks and stabilizes the ultimate four HEAT repeats, the second is a unique architecture in HEAT repeat B. The Msps TOG3 C-terminal tail has conserved determinants, including an arginine (R816), that form multiple contacts with HEAT repeats C-F. Mutational and circular dichroism studies demonstrate that the TOG3 C-terminal tail promotes TOG3 domain stability. Pairwise structural alignments of TOG3 with other TOG domain structures determined to date show that TOG3 is most similar to TOG domains 1 and 2, with rmsd values of 2.4 and 3.0 Å, respectively. In contrast, TOG3 diverges from the architecture of TOG4 with a rmsd of 4.6 Å. Docking TOG3 onto recently solved Stu2 TOG1- and TOG2-tubulin structures suggests that TOG3 uses similar, conserved tubulin-binding intra-HEAT loop residues to interact with tubulin. This suggests that TOG3 has maintained a TOG1- and TOG2-like TOG-tubulin binding mode despite structural divergence in the second HEAT repeat. The similarity of TOGs 1-3 and the divergence of TOG4 suggest that a polarized, differential TOG architecture may play a key mechanistic role in XMAP215-dependent MT polymerization activity.

P128**Board Number: B234****STU2/XMAP215 interacts with SUMO and the sumoylation machinery.**A. Alonso¹, M. Greenlee¹, R.K. Miller¹;¹Biochemistry and Molecular Biology, Oklahoma State University, Stillwater, OK

Sumoylation is a ubiquitin-like modification that regulates a wide variety of fundamental cellular processes, including DNA repair, transcription, and cell-cycle transitions. However, it is currently not known how sumoylation regulates microtubules. Microtubules perform important roles in the structure of the mitotic spindle as well as serving as tracks for transportation of cargo to various destinations in the cell. Sumoylation has only recently been shown to regulate spindle positioning. Our lab has previously shown that the LIS1 homologue Pac1 is modified *in vivo* by SUMO and ubiquitin. Pac1 is important for recruiting dynein to the plus end of the microtubule. Dynein is subsequently “off-loaded” to the cortex where it pulls on cytoplasmic microtubules to move the mitotic spindle across the bud neck, a key step in positioning the mitotic spindle. Using two-hybrid analysis, we show that PAC1 interacts with STU2. The C-terminus of Stu2 is sufficient for this interaction. Stu2 is the yeast homologue of XMAP215 and stabilizes microtubules by facilitating the loading of tubulin dimers onto microtubule ends. Stu2 can also de-stabilize microtubules by sterically interfering with tubulin addition. Here we show by two-hybrid analysis that Stu2 interacts with Smt3/SUMO. Stu2 also interacts with the E2 Ubc9, and the E3 Nfi1 of the sumoylation pathway. Stu2/XMAP215 also interacts with SUMO *in vitro* and *in vivo*. Using an *in vitro* sumoylation assay, four shifted bands of Stu2p can be observed. Using a temperature sensitive allele of the ubiquitin like protease, Ulp1, Stu2 displays a higher molecular weight band *in vivo* that cross reacts with SUMO by immunoblotting. In whole cell extracts, Pac1 shifts more extensively than Stu2 by western blotting. Considering that Stu2 is the eighth class of MAP shown to interact with SUMO, we suggest that sumoylation may be a general mechanism for regulating microtubule-associated proteins.

P129**Board Number: B235****Stu2, the budding yeast XMAP215/DIS1 homolog, is a microtubule polymerase with higher activity on yeast tubulin than on mammalian-brain tubulin.**M. Podolski¹, J. Howard¹;¹Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

Stu2 is the budding yeast member of the XMAP215/Dis1 family of microtubule polymerases. It is essential in cell division, allowing proper spindle orientation and metaphase chromosome alignment, as well as spindle elongation during anaphase. Despite Stu2 having a phenotype that suggests it promotes microtubule growth, like the other members of XMAP215/Dis1 family, studies till now with purified Stu2 indicate only that it antagonizes microtubule growth. One potential explanation for these contradictory findings is that the assays were performed with mammalian brain tubulin, which may not be the right

substrate to test the activity of Stu2, given that yeast and brain tubulins are quite divergent in sequence, and that the vertebrate tubulins are subject to many post-translational modifications. To test this possibility, we reconstituted the activity of Stu2 with purified budding yeast tubulin. We found that Stu2 accelerates microtubule growth in yeast tubulin several fold, similar to the acceleration reported for XMAP215 in porcine brain tubulin. Furthermore, Stu2 accelerates polymerization in yeast tubulin to a much greater extent than it does in porcine brain tubulin, and the concentration of Stu2 required to reach 50% maximum activity in yeast tubulin was nearly two orders of magnitude lower than in porcine brain tubulin. We conclude that Stu2 is a microtubule polymerase, like its relatives, and that its activity is considerably higher in yeast tubulin compared to mammalian brain tubulin. These studies highlight significant differences between tubulins from different sources and the importance of using conspecific tubulin when studying microtubule associated proteins.

Board Number: B236

Alcohol metabolism by Cytochrome P450 2E1 does not contribute to hepatocellular defects associated with tubulin acetylation, but does impair STAT5 nuclear translocation.

E. Doody¹, D. Tuma², P. Tuma¹;

¹Department of Biology, Catholic Univ America, Washington, DC, ²Department of Internal Medicine, University of Nebraska, Omaha, NE

Although alcoholic liver disease has been clinically well described, the molecular mechanisms that promote hepatotoxicity are not yet fully understood. The liver metabolizes alcohol using two enzymes, alcohol dehydrogenase (ADH) and cytochrome P450 2E1 (CYP 2E1). Both ADH and CYP 2E1 metabolize alcohol into acetaldehyde, but CYP 2E1 activity also results in the production of reactive oxygen species (ROS) that lead to oxidative stress. We have previously shown that microtubules are more highly acetylated in alcohol-treated polarized hepatic WIF-B cells and livers from alcohol fed rats. We further determined that alcohol metabolism to acetaldehyde by ADH is required for enhanced acetylation. However the role of CYP2E1-mediated metabolites and ROS in tubulin acetylation was not examined. To determine if CYP 2E1-mediated alcohol metabolism is required for enhanced acetylation, we treated cells with 100 μ M diallyl sulfide (DAS), a CYP 2E1 inhibitor, or 5 mM N-Acetyl Cysteine (NAC), an antioxidant that decreases ROS, in the presence of 50 mM alcohol. Alcohol-treated cells revealed that inhibition of CYP 2E1 with DAS did not alter enhanced tubulin acetylation, supporting that its activity does not mediate the effect. Consistent with this result is the finding that DAS treatment failed to rescue the impaired ASGP-R internalization observed in alcohol-treated cells. However, inhibition of CYP 2E1 did reverse the STAT5B nuclear translocation impairment that has been previously observed in alcohol-treated cells. It is believed that this is caused by a defect in STAT5B activation by Jak2 kinase, which is independent of the microtubule network, further supporting that CYP 2E1 alcohol metabolism does not affect microtubule hyperacetylation.

P131**Board Number: B237****Alcohol-induced tubulin acetylation sites identified by mass spectrometry.**J. Groebner¹, D. Tuma², P. Tuma¹;¹Department of Biology, Catholic Univ America, Washington, DC, ²Department of Internal Medicine, University of Nebraska, Omaha, NE

Although the progression of alcoholic liver disease is clinically well-described, the mechanisms leading to alcohol-induced liver damage remain elusive. Previously, we determined that microtubules are hyperacetylated and more stable in ethanol-treated WIF-B cells, liver slices and in livers from ethanol-fed rats. Our focus is to determine whether tubulin hyperacetylation can explain alcohol-induced defects in microtubule-dependent protein trafficking. Previously, we determined that transport of newly synthesized proteins from the Golgi to the basolateral surface and STAT5B nuclear translocation are impaired by alcohol metabolism. Recently, we confirmed that delivery of apical proteins from the basolateral-to-apical membrane via transcytosis is also impaired in ethanol-treated WIF-B cells. Unlike in control cells, transcytosing proteins accumulated sub-apically and aligned along acetylated microtubules in ethanol-treated cells. Both dynein and dynactin colocalized with transcytosing proteins, but only dynein (not dynactin), more tightly associated with microtubules from ethanol-treated cells. Thus, we conclude that enhanced dynein binding to microtubules in ethanol-treated cells leads to decreased motor processivity resulting in vesicle stalling and impaired delivery. A common feature of these delivery routes is regulation by microtubule-based motors. The “tubulin code” hypothesis proposes that microtubule-based motor trafficking for specific cellular functions may be regulated by tubulin isotype composition and post-translation modifications. To more directly examine microtubule hyperacetylation in alcohol-treated cells, we have analyzed purified taxol-stabilized microtubules from control, trichostatin A (TSA - leads to global protein acetylation)- and ethanol-treated WIF-B cells by mass spectrometry. In preliminary studies, we have successfully recovered both α - and β -tubulin with ~60% coverage in both control, TSA- and ethanol-treated cells. As predicted, Lys40 (the known α -tubulin acetylated site) was fully acetylated in ethanol-treated cells with all recovered fragments being acetylated. In contrast, no acetylated Lys40 containing peptides were recovered from control tubulin. We also identified novel acetylated lysines in the C-terminal half of α -tubulin (in ethanol-treated cells) and β -tubulin (in both control, TSA- and ethanol-treated cells). One site was more highly acetylated in ethanol-treated cells. We are currently generating site specific lysine mutants to directly identify which residues contribute to impaired motor properties and defects in protein trafficking.

P132**Board Number: B238** **α -Tubulin Acetyltransferase α TAT1 Preferentially Targets Tapered Microtubule Ends with Exposed Lys40 Acetylation Sites.**C.E. Coombes¹, A. Yamamoto¹, T. Reid¹, M. McClellan¹, G.G. Luxton², J. Alper³, M. Gardner¹;¹Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN, ²Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN, ³Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

Microtubules are structural polymers inside of cells that are subject to post-translational modifications. These post-translational modifications help to create functionally distinct subsets of microtubule networks in the cell. Acetylation is unique from other post-translational modifications in that it is the only modification which takes place in the hollow lumen of the microtubule. While it is known that the α -tubulin acetyltransferase α TAT1 is responsible for the majority of the microtubule acetylation that is observed in cells, the mechanism for how α TAT1 accesses the Lys40 acetylation site inside of the microtubule lumen is not fully understood, and remains an important topic of investigation. To examine how α TAT1 accesses the luminal acetylation site, we performed a combination of biochemical assays, fluorescence and electron microscopy experiments, and simulations. We found that the microtubule α -tubulin acetylation rate is limited by accessibility of the enzyme to the lumen, and that α TAT1 preferentially targets tapered microtubule ends with exposed Lys40 acetylation sites. This preference for tapered microtubule ends may play a role in the specific targeting of α TAT1 to subsets of cellular microtubules. These results provide important insights into the mechanism for α TAT1 microtubule acetylation and its dependence on the microtubule structure.

P133**Board Number: B239****Mouse Sperm Associate Antigen 6 Regulates Cell Growth, Cell Migration And Ciliogenesis Through Activation of Acetylated Tubulin In Mouse Embryonic Fibroblast Cells.**Z. Zhang¹;¹Obstetrics/Gynecology, Virginia Commonwealth University, Richmond, VA

Mammalian Spag6 is the orthologue of Chlamydomonas PF16, which encodes a protein localized in the axoneme central apparatus of flagella and regulates flagellar/cilia motility. Most Spag6-deficient mice are smaller in size than their littermates, suggesting that mouse SPAG6 might also play roles other than regulating flagellar/cilia motility. When mouse embryonic fibroblasts (MEFs) were cultured from Spag6-deficient mice and their littermates, it was found that both primary and immortalized Spag6-deficient MEFs proliferated at a much slower rate than the wild-type MEFs of the same passages. Spag6-deficient MEFs also had enlarged cell size, and they appeared to be more flattened and had more cytoplasmic

vesicles than the wild-type MEFs. Transwell chambers and wound-healing assays demonstrated that the Spag6-deficient MEFs had dramatically reduced migration ability. During migration, polarized distribution of α -tubulin, a subunit of microtubule, and F-actin, another cytoskeleton component observed in the wild-type MEFs was never seen in the Spag6-deficient MEFs. Abnormally dividing cells were observed in the Spag6-deficient MEFs as demonstrated by multiple centrioles illustrated by γ -tubulin staining. Spag6-deficient MEFs also demonstrated ciliogenesis defects; the percentage of cells with primary cilia was significantly reduced compared to the wild-type MEFs, and some Spag6-deficient MEFs had multiple cilia. The expression level of acetylated tubulin, a marker for cilia, and also an indicator for microtubule stability, was dramatically reduced in the Spag6-deficient MEFs. In contrast, overexpressing SPAG6 in multiple cultured mammalian cells significantly increased acetylated tubulin expression level, and SPAG6 co-localized with acetylated tubulin. Our studies have revealed unexpected roles of mouse SPAG6; it not only regulates flagellar/cilia motility, it also regulates cell proliferation, cell migration, cell division, and ciliogenesis, perhaps through influencing acetylated tubulin expression and microtubule stability. Given F-actin distribution is also changed in the Spag6-deficient MEFs, SPAG6 might also influence functions of other cytoskeleton systems.

Not just charged strings: binding of Tubulin's disordered tails to VDAC is regulated by small sequence changes and by posttranslational modification.

K.L. Sheldon¹, S.M. Bezrukov¹, D.L. Sackett¹;

¹Program in Physical Biology, NIH/NICHHD, Bethesda, MD

The tubulin alpha-beta heterodimer is the subunit of microtubules (MT) but is also a freely diffusing cytoplasmic protein in its own right which can find binding partners distinct from those for MT. One of these partners is the mitochondrial outer membrane protein VDAC (Voltage Dependent Anion Channel), which mediates small molecule traffic into and out of the mitochondria. We previously showed that tubulin binding to VDAC blocks channel traffic and reduces oxidative metabolism, and that this requires the unstructured anionic tail peptides found on both the alpha- and beta-tubulin subunits. But those studies left unclear if the tubulin body per se is required, whether the alpha- and beta-tails contribute equally to VDAC blockade, and the role, if any, of tubulin posttranslational modifications (PTM), which mostly occur on the tails. These intrinsically disordered tails contain only ~3% of the mass but ~40% of the net charge on the tubulin heterodimer. Earlier studies showed that anionic polymers could cause VDAC blockade, but gave no indication of sequence sensitivity. Here we use single molecule binding studies to show that channel closure is due to the tails alone, since grafting them to albumin gives the same VDAC closure as tubulin. We show that the beta-tail is ~100-fold more potent than the alpha-tail, and that this difference is largely due to the presence or absence of a terminal tyrosine. The activation of the alpha-tail by detyrosination is reversed by subsequent removal of the next residue. We also show that nitration of tyrosine reverses the tyrosine inhibition of binding and even induces prolonged VDAC closures. Our results demonstrate that small changes in sequence or PTM of the disordered tails of

tubulin result in substantial changes in VDAC closure. We expect that this pattern may be repeated when comparing the numerous isotypes of alpha- and beta-tubulin, as well as other PTMs. These results also provide a sensitive system to study biology of disordered protein sequences, and their sensitivity to small chemical changes.

Zeta-tubulin Orients Cilia in Multiciliated Epithelial Cells.

E. Turk¹, A. Wills², J.B. Wallingford², T. Stearns^{1,3};

¹Department of Biology, Stanford University, Stanford, CA, ²Molecular Biosciences, University of Texas at Austin, Austin, TX, ³Department of Genetics, Stanford School of Medicine, Stanford, CA

Tubulins are a conserved superfamily of proteins that are important in the structure and function of the microtubule cytoskeleton. Members of the alpha-tubulin, beta-tubulin, and gamma-tubulin families are found in all eukaryotes, and are the structural elements of the microtubule polymer, and the main nucleator of that polymer, respectively. Members of the delta-tubulin and epsilon-tubulin families are present in many, but not all, eukaryotes and are associated with centrioles. We have characterized in vertebrates a member of another tubulin family, which most closely resembles tubulins previously named eta-tubulin or zeta-tubulin. Based on an assessment of the entire tubulin superfamily we will refer to this as the zeta-tubulin family. Zeta-tubulin is present in many single-celled eukaryotes, chordates, and marsupial mammals, but is absent in *Drosophila*, *C. elegans*, zebrafish, and placental mammals. Analysis of genome sequences indicates that zeta-tubulin is the last remaining tubulin family member to be characterized in vertebrates. Zeta-tubulin is the least well-conserved of the tubulin families, both in terms of the number of lineages that have lost the gene and in the divergence of the protein within branches that have retained it. We have characterized *Xenopus laevis* zeta-tubulin in a variety of cell lines and developmental stages. In the multiciliated skin cells of the frog embryo, zeta-tubulin is a basal body component, with a pattern of localization consistent with it being a part of the basal foot. Remarkably, *Xenopus* zeta-tubulin is able to localize to basal bodies in multiciliated cells of mouse, which has lost the gene for this tubulin. This suggests that the module of function, perhaps the basal foot, is conserved and that another tubulin family member might take the place of zeta-tubulin in species in which it is lost. Depletion of zeta-tubulin results in disorganization of basal body distribution and polarity in multiciliated cells, but no apparent phenotypes in other cell types. In contrast with multiciliated cells, zeta-tubulin in cycling cells does not localize to centrioles and instead is associated with the TRiC-CCT complex, a large cytoplasmic chaperone that is responsible for folding actin, tubulin, and other proteins. We conclude that zeta-tubulin performs a specialized function in basal bodies of differentiated cells, most likely in the function of the basal foot appendage that orients basal bodies with respect to the cell and tissue axes.

P136**Board Number: B242****Intragenic complementation reveals that γ -tubulin has at least three functions important for growth of *Aspergillus nidulans*.**M.A. Hervás-Aguilar¹, K.J. Bichsel¹, B.R. Oakley¹;¹Molecular Biosciences, University of Kansas, Lawrence, KS

γ -tubulin plays a key role in microtubule nucleation at microtubule-organizing centers of both fungal and animal cells, but data from a number of organisms indicate that it has additional important, although less clearly defined, functions. Previously, we created temperature-sensitive mutations through alanine-scanning mutagenesis of the *mipA* (γ -tubulin) gene of *Aspergillus nidulans* and one of these mutations reveals a role for γ -tubulin in inactivating the anaphase promoting complex coupled with Cdh1 at G₁/S. These mutants display a range of phenotypes and we were interested in how many distinct functions were defective in our alleles. One approach to answering this question is through intragenic complementation. The principle underlying intragenic complementation is that if two alleles of a gene that are defective for different functions are co-expressed in the same cell, the protein products of the two alleles will, between them, carry out all the required functions of the protein. Cells in which both alleles are expressed will, thus, grow better than cells in which either of the two alleles is expressed. If the two alleles are defective for the same function, all protein molecules will be defective for that function and there will be little or no improvement in growth. We tested eight conditionally growth inhibited alleles for intragenic complementation by creating strains in which one mutant allele was present at the endogenous *mipA* locus and the same or another mutant allele was inserted at the *wA* locus. All alleles were recessive to the wild-type *mipA* allele. For four alleles, expression of a second copy of the same allele, surprisingly, resulted in improved growth at restrictive temperatures. Several allele pairs exhibited intragenic complementation (defined as a growth advantage compared to two copies of either of the two alleles). The alleles fell into three intragenic complementation groups indicating that γ -tubulin has at least three functions important for growth. To determine if the functions of γ -tubulin could correlate with functional domains in the γ -tubulin, we modeled the structure of *A. nidulans* γ -tubulin and γ -tubulin complex proteins based on the structure of human TUBG1 and GCP4. The results indicate that the two-copy-suppressed alleles cluster together as do each of the intragenic complementation groups. These data indicate that γ -tubulin has at least three functions important for growth that may correlate with functional domains of the protein. Supported by the NIH and the Irving S. Johnson Fund of the KU Endowment. Kyle J. Bichsel is supported by an IRACDA fellowship.*

P137**Board Number: B243****Interaction of Colchicine-Site Drugs with β VI-Isotype of Tubulin.**M. Loew¹, D.L. Sackett², S.L. Bane¹;¹Chemistry, SUNY-Binghamton, Binghamton, NY, ²Program in Physical Biology, NIH/NICHD, Bethesda, MD

Tubulin, the main component of microtubules, exists as multiple isoforms. Although these isoforms are highly conserved, the β VI isoform is significantly divergent in amino acid sequence. This isoform is found in hematologic cells and is recognized as playing a role in platelet biogenesis. Tubulin from the erythrocytes of *Gallus gallus* (Chicken erythrocyte Tubulin, CeTb) contains roughly 95% β VI tubulin. This form of tubulin has been found to lack interaction with colchicine, a feature previously thought to be ubiquitous of tubulin from higher-order eukaryotes. In this study, we sought to gain a better understanding of the structure-activity relationship of the colchicine site of this divergent isoform. We developed a fluorescence-based assay to detect binding of drugs to CeTb and used it to screen known colchicine-site drugs with CeTb. Drugs that showed good affinity for CeTb include podophyllotoxin, combretastatin A2 and A4, and MDL-27048. Colchicine derivatives had poor affinity with the exception of one allocolchicine derivative. Because the colchicine site of human β VI is very similar to that of chicken β VI, these results may have relevance to the action of microtubule-targeting drugs on hematopoietic tissues in humans.

P138**Board Number: B244****Using *Drosophila melanogaster* as a Model Organism to Study Reproductive Toxicants.**K. Hernandez¹, I. Cepin¹, C. Juarez¹, S. Lovell¹, A. Nicholas¹, R. Wint¹, K. . Boekelheide², J. Rollins³;¹Division of Natural Sciences, College of Mount Saint Vincent, Bronx, NY, ²Brown University, Providence, RI, ³College of Mount Saint Vincent, Bronx, NY

There is a growing international movement to make use of the ongoing revolution in biology to revise longstanding approaches to toxicity testing and risk assessment of environmental chemicals, pharmaceuticals, and consumer products. At its core, this new approach will measure molecular changes in model organisms and cells in vitro to develop a mechanistic understanding of chemically-induced alterations in the function of biological pathways. Model organisms, such as *Drosophila melanogaster*, provide the unique advantage of "simplified complexity," portraying complex organismal processes, such as spermatogenesis, without the many redundant proteins and pathways characteristic of mammals. Six different toxicants (pharmaceutical and environmental) were studied: 2,5-hexanedione, carbendazim, taxol, di (2-ethylhexyl) phthalate, colchicine and dibromochloropropane. Three different dosing methods were tested: 1. Adult flies laid eggs in toxicant laced food in order to mimic exposure in young animal, 2. Adult flies were starved and given the toxicant directly by dissolving the toxicant in

sugar water, 3. Embryos were permeabilized and treated with the toxicant directly. Method 1 was the only method that was not lethal and the effect of the toxicant on sperm development was assessed by phase contrast squashes of wild type and β tubulin-GFP flies. Many defects, such as transition to meiosis, meiotic cytokinesis, and sperm elongation and maturation can easily be quantified using this simple assay. DEHP, di (2-ethylhexyl) phthalate showed little effect on sperm development in all three-dose groups. 2,5-hexanedione was lethal at high doses and effected. Flies overexpressing β tubulin by carrying a trans gene of β tubulin-GFP were more sensitive to this toxicant. The wild type exposed to the toxicant had some motile sperm but also showed signs of degenerative spermatocyte cysts. Taxol exposure yielded less motile sperm and shorter sperm tails. Wild type flies exposed to CBZ were more sensitive to the toxicant than β tubulin-GFP flies however little or no effect on sperm development. Future work on this project will be to maximize the efficiency of dosing so lethality will not be an issue and sperm development can be properly assessed using microscopy, fertility and sperm viability assays.

Board Number: B245

Intravital microscopy suggests that induction of mitotic arrest by antimitotic cancer drugs does not predict their efficacy in fibrosarcoma mouse xenograft tumors.

S. Florian¹, D.R. Chittajallu², R.H. Kohler³, J.D. Orth⁴, R. Weissleder^{1,3}, G. Danuser⁵, T.J. Mitchison¹;
¹Department of Systems Biology, Harvard Medical School, Boston, MA, ²Department of Cell Biology, Harvard Medical School, Boston, MA, ³Center for Systems Biology, Massachusetts General Hospital, Boston, MA, ⁴MCD Biology, University of Colorado Boulder, Boulder, CO, ⁵Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX

Despite immense progress in targeted cancer drug design, to date, the most important drugs in chemotherapy remain traditional cytotoxic drugs which are thought to kill proliferating cells, no matter if malignant or not. This "antiproliferative" hypothesis is based on results from the 1970s coming from mouse leukemia models or cell culture experiments.

Microtubule binding drugs are clinically important antiproliferative drugs which arrest cultured cancer cells in mitosis through activation of the spindle assembly checkpoint (SAC). As opposed to empirically found microtubule binding drugs, newer drugs designed to more specifically induce mitotic arrest have repeatedly failed in clinical trials, suggesting that the antitumor effect of microtubule binding drugs is still not well understood. Alas, tissue culture assays are not predictive of their respective clinical success, suggesting that more realistic models are needed to understand why there are such huge differences in antitumor efficacy.

Therefore, we developed an integrated in vivo microscopy and image analysis pipeline of mouse xenografts to compare the cell cycle effects of microtubule drugs to those of newer, targeted antimitotic drugs in the form Ispinesib, an inhibitor of the mitotic kinesin Eg5. Image analysis with a custom developed software for automated three dimensional segmentation and cell cycle classification revealed

that the microtubule interacting drugs Paclitaxel and Eribulin which are in wide clinical use induce similar mitotic arrest as the Eg5 inhibitor Ispinesib which failed clinical trials. Nevertheless, similar to the clinical situation, they seem to be more effective in reducing tumor cell density than Ispinesib in our system. This suggests that, rather than mitotic arrest, a different mechanism, intrinsically coupled to microtubule binding, may be responsible for the antitumor effect of microtubule drugs in vivo.

Characterization of a novel microtubule-associated protein in *Toxoplasma gondii*, a human parasite.

Y. He¹, J. Liu¹, K. Hu¹;

¹Department of Biology, Indiana University Bloomington, Bloomington, IN

Toxoplasma gondii is a widespread protozoan parasite that can infect nearly all warm-blooded animals. It can cause toxoplasmosis in humans. Infections in immunocompromised individuals and unprotected fetus have devastating consequences, including the development of lethal *Toxoplasma* encephalitis. *T. gondii* is also a model for its relatives in the phylum Apicomplexa, which includes the malarial parasites. These parasites have a highly organized cytoskeleton that is essential to their replication and infection in the host. Furthermore, the cytoskeleton of the parasite has many properties distinct from that in the host cell and therefore an ideal target for anti-parasitic measures. One prominent component of the *T. gondii* cytoskeleton is its set of 22 cortical microtubules. Compared with microtubules found in mammalian cells, the cortical microtubules are highly ordered and exceptionally stable. It is believed that these special properties of the cortical microtubules are due to novel microtubule associated proteins, because the major tubulin subunits in *T. gondii* are essentially identical with those in mammalian cells. In our effort to search for the proteins that regulate the function of the cortical microtubules, we identified a group of proteins that coat the microtubules, including TLAP3 (for TrxL associated protein 3). TLAP3 has no close homolog in the sequenced genomes of mammals, thus is a potential drug target. We have constructed a transgenic line through homologous recombination. In this line, fluorescently tagged TLAP3 is expressed from its endogenous locus. Interestingly, we found that the localization of TLAP3 is restricted to an apical region close to the presumed organizing center of the cortical microtubules. This may suggest an organization role of TLAP3 in the initial construction of the cortical microtubules. Consistent with this hypothesis, TLAP3 is found close to the apex of developing daughter cells. To further test this possibility, we are creating TLAP3 knockout parasite to probe its function using Cre-LoxP mediated excision.

P141**Board Number: B247****What is tubulin glutamylation good for?.**D. Chawla¹, R. Shah¹, J. Lee¹, Z. Barth¹, N. Peel¹;¹Department of Biology, The College of New Jersey, Ewing, NJ

Microtubules are dynamic polymers that play essential structural roles in cell division, vesicle trafficking, and cilia function. Much is known about the regulation of microtubule dynamics by interacting proteins, but the post-translational modification of tubulin as a regulatory mechanism remains relatively unexplored. Tubulin glutamylation is the covalent attachment of glutamic acid to tubulin in the polymerized microtubule. This modification is enriched on long-lived microtubules, and it is proposed that tubulin glutamylation contributes to centriole stability, cilia motility and axon function.

Comprehensive in vivo analyses of the function of tubulin glutamylation have proved challenging because of the existence of a large family of glutamylating enzymes. *C. elegans*, however, has only 5 glutamylating (tubulin tyrosine ligase like; TLL) enzymes making their combinatorial analysis feasible. We have obtained deletion mutations in all five TLL enzymes, non of which display overt phenotypes. To test for redundancy we have combined the mutations and are currently analysing two mutant combinations. First, a triple mutant that shows reduced male fecundity. Second, a quint mutant lacking all glutamylating enzymes. By closely examining the phenotypes of these worms we hope to definitively determine the in vivo function of tubulin glutamylation.

P142**Board Number: B248****Did acetylation of α -tubulin play a role in the evolution of microtubules from filaments?.**R.F. Luduena¹;¹Biochemistry, Univ Texas Hlth Sci Ctr-San Antonio, San Antonio, TX

There is considerable evidence that the first tubulin molecules formed filaments rather than cylindrical microtubules (MTs) (McIntosh et al, Cell 135, 322, 2008; Ludueña, Int. Rev. Cell Mol. Biol. 302, 41, 2013). How could this filament become a microtubule (MT)? There are three factors to consider: 1) Addition of the C-terminus could have favored MT formation; removal of the C-terminus prevents incorporation into MTs (Joe et al, J. Biol. Chem. 284, 4283, 2009). This may be too fortuitous, however. 2) Lateral joining of the protofilaments (PFs) would allow them to exert more force on heavier cargo (McIntosh et al, J. Cell Sci. 123, 3425, 2010). Although this is very likely to have been a factor, it does not explain why a cylinder rather than, say, a triple helix, was favored. 3) Perhaps a more compelling rationale, however, arises from acetylation. This is a very widespread and therefore probably ancient modification of lys40 in α -tubulin that is associated with increased MT stability and intra-luminal structures as well as binding to mitochondria and Golgi (Friedman et al, J. Cell Biol. 190, 363, 2010; Deakin & Turner, J. Cell Biol. 206, 395, 2014). The modified lys40 is in the lumen of the MT. Recent findings suggest that acetylation does

not affect overall MT structure but that it mediates binding to some intra-luminal protein (Howes et al, Mol. Biol. Cell 25, 257, 2014). It is very difficult to imagine the modifying enzyme, the modification, and the associated intra-luminal protein evolving after the MT appeared. These are more likely to have evolved when tubulin formed only PFs and the lumen did not exist. The acetylation could have mediated binding to an ancestor of a present-day intra-luminal protein, or perhaps a protein linking to mitochondria or Golgi. If so, and if that protein was itself a filamentous polymer (Linck et al, J. Biol. Chem. 289, 17427, 2014) then if adjacent tubulin PFs associated with each other at an angle, so as to form a curved rather than a flat ribbon, then it would have been a stronger structure if at least two of the tubulin PFs bound to the ancestral intra-luminal protein. For this the PFs would have had to associate laterally at an angle. At this point, it would have been easy for more PFs to have added laterally until a cylinder appeared. It is unlikely that a cylinder that evolved this way would have been symmetrical, so it is not surprising that there is a seam at the join. It is not necessary for the intra-luminal protein to fill the entire lumen and indeed, once the MT evolved, there was no universal need for an intra-luminal protein at all or even for an acetylated lys40, so these features could have been retained only for specific functions involving intra-luminal proteins.

Reconstitution of the human augmin complex provides insights into its architecture and function.

K. Hsia¹, E.M. Wilson-Kubalek², A. Dottore¹, Q. Hao¹, K. Tsai², S. Forth³, Y. Shimamoto¹, R.A. Milligan², T.M. Kapoor¹;

¹Rockefeller University, New York, NY, ²Scripps Res Inst, La Jolla, CA, ³Rockefeller Univ, New York, NY

Proper microtubule nucleation during cell division requires augmin, a microtubule-associated hetero-octameric protein complex. In current models, augmin recruits γ -tubulin, via its hDgt6 subunit's C-terminus, to nucleate microtubules within spindles. However, augmin's biochemical complexity has restricted analysis of its structural organization and function. Here, we reconstitute human augmin and show it is a Y-shaped complex that can adopt multiple conformations. Further, we find that a dimeric sub-complex retains in vitro microtubule binding properties of octameric complexes, but not proper metaphase spindle localization. Addition of octameric augmin complexes to *Xenopus* egg extracts promotes microtubule aster formation, an activity enhanced by Ran-GTP. This activity requires microtubule binding, but not the characterized hDgt6 γ -tubulin-recruitment domain. Tetrameric sub-complexes also induce asters, but activity and microtubule bundling within asters are reduced compared to octameric complexes. Together, our findings shed light on augmin's structural organization, microtubule binding properties and define subunits required for its function in organizing microtubule-based structures.

P144**Board Number: B250****Characterization of human gamma-tubulin isotypes and their differential expression during neuritogenesis.**E. Draberova¹, S. Vinopal¹, V. Sulimenko¹, T. Sulimenko¹, V. Sladkova¹, L. D'Agostino², C.D. Katsetos², L. Kren³, P. Draber¹;¹Biology of Cytoskeleton, Institute of Molecular Genetics AS CR, Prague 4, Czech Republic, ²Pathology Laboratory Medicine, Drexel University College of Medicine, Philadelphia, PA, ³Faculty Hospital Brno, Brno, Czech Republic

Gamma-tubulin is a highly conserved member of the tubulin superfamily essential for microtubule nucleation. Many organisms including humans possess two genes encoding gamma-tubulin, and their coding sequences share a high sequence similarity. It is thought that in mammalian tissues gamma-tubulin 1 represents ubiquitous form of gamma-tubulin, while gamma-tubulin 2 is found predominantly in brain where it is neuron associated. It was suggested that gamma-tubulin 2 could also have some other functions. The molecular basis of the purported functional differences between gamma-tubulins is unknown. Here we have demonstrated that human gamma-tubulins can be discriminated according to their electrophoretic properties and have unraveled through in vitro mutagenesis that the differences originate in the C-terminal regions of the gamma-tubulin molecules. Using epitope mapping we identified an antigenic determinant recognized by an anti-peptide monoclonal antibody that is specific for human gamma-tubulin 1. We have shown both at the mRNA and protein levels, using RT-qPCR and 2D-PAGE, that gamma-tubulin 1 is the predominant isotype in primary neurons derived from human fetal cerebral cortex (ScienCell Research Laboratories). Comparable amounts of both gamma-tubulin isotypes were found in autopsy samples from non-pathologic cerebral cortex of human adults. Localization of gamma-tubulin 1 in mature cortical neurons was confirmed by immunohistochemistry performed on surgically resected clinical samples containing non-lesional cerebral neocortex. Depletion of gamma-tubulin 1 by shRNAi in the human neuroblastoma SH-SY5Y cells resulted in impaired microtubule nucleation and metaphase arrest. A wild-type phenotype in gamma-tubulin 1-depleted cells was restored by expression of exogenous human gamma-tubulin 2. During all-trans retinoic acid-induced neuritogenesis in SH-SY5Y cells, expression of human TUBG2 was upregulated, while the expression of TUBG1 was basically unchanged. Our data suggest that while both human gamma-tubulins are nucleation competent, differences in their properties and accumulation of gamma-tubulin 2 in mature neurons, in the face of a predominant gamma-tubulin 1 expression in these cells, may reflect additional gamma-tubulin 2 function(s) in neurons. Assembly and Disassembly of Cilia/Flagella 1

P145

Board Number: B252

Identification of the molecular ruler that defines the 96-nm repeats of cilia/flagella.

T. Oda¹, H. Yanagisawa¹, R. Kamiya², M. Kikkawa¹;

¹Dept Cell Biology, The University of Tokyo, Tokyo, Japan, ²Dept Life Science, Gakushuin University, Tokyo, Japan

Primary ciliary dyskinesia (PCD) is an inherited disease caused by abnormal ciliary motility. Majority of PCD cases associated with axonemal disorganization result from mutations in CCDC39 and CCDC40 genes. However, their localizations and functions in cilia/flagella are not clearly resolved. In this study, we revealed the molecular mechanism how FAP59 and FAP172, the *Chlamydomonas* homologues of CCDC39 and CCDC40, govern the assembly of axonemal ultrastructures. Using biochemical pull-down assay and cryo-electron tomography, we showed that FAP59 and FAP172 form a complex, and the absence of the two proteins disrupts 96-nm repeats of axonemes. Structural labeling revealed that FAP59 and FAP172 take 96-nm long extended conformations along outer doublet microtubules, suggesting their possible role as a molecular ruler. To test this hypothesis, we elongated the amino acid sequences of FAP59 and FAP172 by duplicating their coiled-coil domains. Surprisingly, the repeat length became ~128-nm long, and axonemal components such as radial spokes, inner dynein arms, and dynein regulatory complexes were duplicated. These results strongly suggest that the FAP59/172 complex is the molecular ruler that determines the 96-nm repeats in cilia/flagella by regularly recruiting axonemal components to the correct binding sites.

TTC26/DYF13/IFT56 transports a potential length sensor as a cargo for controlling the ciliary length.

H. Ishikawa¹, W. Marshall²;

¹University of California, San Francisco, San Francisco, CA, ²Biochemistry and Biophysics Dept., University of California, San Francisco, San Francisco, CA

Cilia/flagella are microtubule-based organelles that protrude from the surface of most cells, are important to sense extracellular signals and make a driving force for fluid flow. Because the length of cilia/flagella is correlated with their function, cells must have cilia/flagella of adequate length in order to perform their function properly. However, the regulation mechanism of ciliary length is mostly unknown. To control the length of cilia, cells seem to sense ciliary length and to have a feedback pathway to adjust the amount of cargo transport into cilia. The assembly and maintenance of cilia/flagella are dependent on intraflagellar transport (IFT). IFT is an active transport process within cilia

mediated by a bidirectional movement of multiprotein complexes, known as IFT particles. We identified an IFT mutant *Chlamydomonas* strain, *dyf13*, which exhibits short flagella and motility defects. To identify the causes of short flagella, we measured the accumulation of an IFT protein at basal bodies in wild-type and *dyf13* mutant cells. Wild-type cells showed accumulation of IFT at basal bodies that depends on the length of cilia during regeneration. However, the IFT accumulation in *dyf13* mutant cells was always higher than that of wild-type cells and was independent of ciliary length. This observation suggests that DYF13 itself, or its cargo, is related to the feedback pathway and length sensor for ciliary length control.

Board Number: B254

Cilia autonomous regulation of tubulin transport by IFT.

J.M. Craft¹, K.F. Lechtreck¹;

¹Cellular Biology, University of Georgia, Athens, GA

Microtubules are the major structural elements of cilia and eukaryotic flagella. During ciliary assembly, large amounts of tubulin must be transported into the organelle. Intraflagellar transport (IFT) is the major protein transport system in cilia and IFT has been implicated in tubulin transport. The IFT proteins IFT81 and IFT72, for example, form a module that binds tubulin dimers *in vitro* indicating that IFT particles interact directly with tubulin [1]. Direct *in vivo* imaging of tubulin during transport, however, has proved challenging [2]. To analyze ciliary tubulin transport and its regulation, we expressed GFP- α -tubulin in wild-type *Chlamydomonas reinhardtii*. GFP- α -tubulin was incorporated into cytoplasmic and ciliary microtubules [3]; it was posttranslationally modified and formed heterodimers with β -tubulin suggesting that GFP-tagged and endogenous α -tubulin behave largely similar. Total internal reflection fluorescence (TIRF) microscopy revealed that GFP- α -tubulin entered flagella by active transport and by diffusion. Two-color *in vivo* imaging showed that GFP- α -tubulin moved on IFT trains inside cilia; thus, IFT functions as a tubulin transporter. Without of IFT, GFP- α -tubulin continued to enter cilia by diffusion. To assess how tubulin interacts with IFT, we expressed modified α - and β - GFP-tubulins; this ongoing project revealed C-terminally truncated GFP- α -tubulin is still transported by IFT and assembled into the axoneme. During ciliary growth, IFT-based transport of GFP- α -tubulin was increased $\sim 15x$ over steady-state frequencies and, in growing cilia, the occupancy rate (% of IFT particles carrying GFP- α -tubulin as a cargo) increased from $\sim 10\%$ to $\sim 80\%$ indicating that tubulin transport by IFT is regulated. Fluorescence recovery after photobleaching (FRAP) analysis and western blotting revealed a strong increase in the concentration of soluble GFP- α -tubulin in regenerating over steady-state cilia. In cells possessing both growing and non-growing cilia, tubulin transport via IFT was elevated only in the growing cilia; likewise, the concentration of tubulin was increased solely in the matrix of the growing cilia. Thus, cells can direct tubulin flux specifically into growing cilia and established distinct concentrations of soluble tubulin within different cilia of a given cell. Our data suggest that tubulin transport via IFT is regulated locally in a flagella autonomous manner, likely within the basal body-cilium entity. We propose a model in which IFT functions as a tubulin pump to increase the concentration of soluble tubulin inside cilia, which will

promote the elongation of axonemal microtubules and thereby ciliary growth. 1Bhogaraju et al. 2013. Science 41:1009. 2Hao et al. 2011. Nat Cell Biol 13:790. 3Rasala et al. 2013. Plant J 74:545.

A novel *Chlamydomonas* IFT81 mutant reveals that the IFT81 tubulin-binding domain is not crucial for tubulin transport and flagellar assembly.

T. Kubo¹, J.M. Brown¹, G.B. Witman¹;

¹Department of Cell and Developmental Biology, Univ Massachusetts Med Sch, Worcester, MA

Intraflagellar transport (IFT) is a bidirectional motility of IFT complexes A and B along cilia/flagella, driven by the anterograde motor kinesin-II and the retrograde motor cytoplasmic dynein 1b. IFT is important for the assembly and maintenance of cilia/flagella. Here, we report a novel *Chlamydomonas* insertional mutant *ift81-1* in which the hygromycin-resistance gene used for introducing and identifying the mutation has inserted into exon 7 of *IFT81*, resulting in an apparently null mutant. Cells of *ift81-1* fail to assemble flagella; this phenotype is similar to that of *ift74-2*, a null mutation for IFT74, which interacts with IFT81 in IFT complex B (Brown et al., in preparation). Transformation of *ift81-1* with the wild-type IFT81 gene rescued flagellar assembly and function, confirming that the phenotype is due to loss of IFT81. Recently, it was proposed, based primarily on in vitro experiments, that the calponin-homology domain of IFT81 together with the highly basic N-terminal domain of IFT74 forms a tubulin-binding module that is the basis for tubulin transport within cilia (Bhogaraju et al., 2013). The *ift81-1* mutant has provided an opportunity to test this hypothesis in vivo. Within its calponin-homology domain, IFT81 has five highly conserved residues (K73, R75, R85, K112, and R113 in *Chlamydomonas*) which have been implicated in tubulin binding (Bhogaraju et al., 2013). To assess their importance in tubulin transport and flagellar assembly, we rescued *ift81-1* with constructs expressing versions of IFT81 with one or more of these basic residues changed to glutamate. Surprisingly, all the resulting strains, including one in which four out of five of the basic residues were substituted to glutamate (K73R75K112R113/EEEE), had normal IFT and nearly normal length flagella. Substitution of one or two residues (K73R75/EE, R85E, and K112R113/EE) had no effect on flagellar regeneration kinetics, indicating normal tubulin incorporation into the cell's axoneme. More severe mutations (K73R75R85/EEE and K73R75K112R113/EEEE) resulted in slightly slower flagellar regeneration, suggesting a subtle reduction in tubulin incorporation. Because the effects of modifying the putative tubulin-binding residues of IFT81 were mild, we propose that tubulin binding at the IFT81/IFT74 site is mediated primarily by IFT74; alternatively, tubulin transport may be supplemented by diffusion or binding to other IFT-particle proteins.

P149**Board Number: B256****Chlamydomonas IFT43 is essential for the integrity of IFT complex A and required for flagellar assembly.**B. Zhu¹, J. Pan²;¹Tsinghua, Beijing, China, ²School of Life Sciences, Tsinghua University, Beijing, China

The assembly and maintenance of flagella and cilia depends on Intraflagellar transport (IFT). Mutations in the gene encoding IFT43, a subunit of the IFT complex A, cause Sensenbrenner syndrome in humans. In our genetic screens, we find an aflagellate insertional mutant that is disrupted in IFT43, identified through RESDA based PCR cloning strategy. Most mutant cells form clumps of 4 cells within one mother cell wall. After lysis treatment to release the cells from mother cell wall, no cells with flagella could be detected under light microscope. Transformation of the mutants with HA-tagged IFT43 rescued the mutant phenotype, confirming that IFT43 is the causal gene. Thus, IFT43 is essential for flagellar assembly. Similar to other IFT proteins, IFT43 is enriched at the basal body region and present in the flagella. YFP-tagged IFT43 exhibits intraflagellar transport and IFT43 is a part of IFT A complex as evidenced by sucrose gradient analyses and co-immunoprecipitation. IFT43 affects the stability and integrity of IFT-A but not complex B in that the amount of IFT139 in the mutants was reduced and a smaller IFT-A complex was formed in the *ift43* mutant. EM analysis showed that *ift43* mutant has residual flagella that barely protrude out of the flagellar collar. Surprisingly, no IFT particles were found to accumulate in the short flagella revealed by EM in the *ift43* mutants. The possible function of IFT43 in IFT will be discussed.

P150**Board Number: B257****Chlamydomonas MKS1 is required for fully assembly of flagella beyond the transition zone.**W. Chen¹, H. Ho², C. Tsao¹;¹Department of Biological Science and Technology, National University of Tainan, Tainan, Taiwan,²Department of Anatomy, Tzu-Chi University, Hualien, Taiwan

A *Chlamydomonas* mutant strain Lu3 was obtained by insertional mutagenesis and a visual screen for motility defects. Genotyping revealed that the insertion of an exogenous marker in the Lu3 genome causes a deletion of a 60-kb region, which contains 14 genes including flagellar inner dynein arm I1 intermediate chain *IC140* and *Chlamydomonas MKS1* ortholog. *MKS1* is a component of the transition zone complex, and the defect of human *MKS1* leads to Meckel-Gruber Syndrome. The growth of *Chlamydomonas* Lu3 strain showed no difference comparing to the *cw15* reference strain although Lu3 lost normal motility. Unlike *Chlamydomonas cep290* mutant, which lacks a transition zone protein required for integrity of the microtubule-membrane connector at the flagellar base but could still

assemble axonemes (Craigie et al. 2010), morphology of the transition zone in Lu3 cells appeared normal. Lu3 cells failed to assemble full length flagella, and the axonemal doublet microtubule terminated abruptly distal to the transition zone. These observations indicate that *Chlamydomonas MKS1* is required for the fully assembly of axonemes beyond the transition zone but is not essential for the microtubule-membrane connector.

Board Number: B258

Chlamydomonas CC2D2A localizes to the proximal flagellar transition zone and is required for normal flagellar protein content and flagellar assembly.

B. Craigie¹, J.M. Brown¹, Y. Hou¹, G.B. Witman¹;

¹Department of Cell and Developmental Biology, Univ Massachusetts Med Sch, Worcester, MA

The transition zone (TZ), the region at the base of cilia and flagella where the triplet microtubules of the basal body transition into doublets, contains a large number of highly conserved proteins whose cognate genes are often mutated in human ciliopathies. Mutations in *CC2D2A* result in severe ciliopathies characterized by pleiotropic developmental defects and neonatal lethality (Meckel syndrome), or cystic kidney disease, blindness, brain malformation, and mental deficit (Joubert syndrome). In vertebrates, *CC2D2A* has been reported to localize to the TZ and interact with other TZ proteins; however, the specific molecular function of *CC2D2A* is unknown. We are using multiple *Chlamydomonas* TZ mutants to elucidate the functional, structural, and biochemical consequences of disruption of TZ integrity, and we have isolated a mutant harboring an insertion in an exon near the middle of *Chlamydomonas CC2D2A*. The mutant cells have defects in flagellar assembly and fail to hatch out of the mother cell wall following mitosis, but cells grow flagella following digestion of the mother cell wall by autolysin treatment. In each of two rounds of backcrossing to wild-type cells, the mutation segregated 100% with the phenotype, and the phenotype was completely rescued by transformation with a genomic construct encoding HA-tagged *CC2D2A*, indicating that the phenotype results from the mutation in *CC2D2A*. *CC2D2A*-HA localizes to the TZ, slightly proximal to and partially overlapping with the TZ protein CEP290. CEP290, which is required for normal assembly of the microtubule-membrane Y connectors within the TZ, localizes normally within the TZ of the *cc2d2a* mutant; consistent with this, the Y connectors are unperturbed in the *cc2d2a* mutant. Conversely, in the absence of CEP290, *CC2D2A*-HA no longer localizes to the TZ, and instead accumulates on or near the basal bodies, indicating that CEP290 and/or the Y connectors are required to localize *CC2D2A* to the TZ. A third TZ protein, NPHP4, which is located distal to CEP290 in the TZ, is not required to localize either CEP290 or *CC2D2A* to the TZ, and is also dispensable for Y connector formation. A triple-mutant strain, harboring the *cep290*, *nphp4*, and *cc2d2a* mutations, displays slower growth kinetics, indicating that loss of all three proteins might perturb cell cycle progression. Finally, biochemical analysis of isolated *cc2d2a* mutant flagella revealed protein content abnormalities in the membrane + matrix fraction of the isolated flagella, indicating that *CC2D2A*, like CEP290 and NPHP4, is required for establishing and/or maintaining normal flagellar protein content.

P152**Board Number: B259****Architectural variation at the base of the cilia is required for cilia structure and function diversity.**S.C. Jana¹, P. Machado^{1,2}, J. Rocha¹, S. Mendonça¹, S. Werner¹, M. Bettencourt-Dias¹;¹Instituto Gulbenkian de Ciência, Oeiras, Portugal, ²EMBL, Heidelberg, Germany

Cilia are microtubule-based membrane protrusions conserved across evolution involved in cell motility, fluid flow and sensing. The diversity in functions is generally attributed to a core conserved microtubule-based structure, the axoneme, decorated by different structures, membrane and signaling systems. Here we study four classes of cilia that represent very diverse motility and sensory functions within a single organism, the fruit fly. We uncover that the base of the cilia, the basal body and transition zone, is much more diverse than previously thought, showing large variation in number, length, ultrastructure, and connection to other cellular structures. We further demonstrate that basal body diversity is imparted by differential regulation of evolutionarily conserved core components. The tissue specific regulation of core basal body and transition zone genes suggests mechanisms that generate tissue specific phenotypes in human ciliopathic syndromes.

P153**Board Number: B260****Kinesin-2 and kinesin-9 are required for ciliogenesis during rapid development.**E.J. Tomei¹, S.M. Wolniak¹;¹Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

Spermatogenesis in the semi-aquatic fern, *Marsilea vestita*, is a rapid, synchronous process that is initiated when dry microspores are placed in water. Development is post-transcriptionally driven and can be divided into two phases. The first phase consists of a series of mitotic divisions that produce 7 sterile cells and 32 spermatids. During the second phase, each spermatid differentiates into a corkscrew-shaped motile spermatozoid with ~144 cilia. Ciliogenesis occurs on basal bodies that are positioned in two rows at regular intervals along the dorsal face of a coiled microtubule ribbon. Kinesin motor proteins are known to participate in both mitosis and ciliogenesis and provide the unique opportunity to study the mechanisms that regulate both stages of development using one class of proteins. Through RNAseq, we assembled a transcriptome that shows the abundance of transcripts throughout development. Over 150 kinesin-like sequences were identified in this transcriptome that represent at least 57 unique kinesin transcripts. Based on alignments of the kinesin motor domain, members of the kinesin-2, -4/10, -5, -7, -8, -9, -13, -14, -15, -16, -18, and -19 families as well as several orphan kinesins were found. This complement of kinesins is similar to other plants that make ciliated spermatozoids, such as *P. patens*. In *M. vestita* most of the kinesin transcripts (84%) change in abundance during gametophyte development. Kinesin mRNAs that decrease in abundance (44%) encode proteins thought to be involved in mitosis, while those that increase in abundance during development (40%) have

proposed roles in ciliogenesis. Kinesin-2 and -9 are only found in ciliated organisms, and the abundance of these transcripts increases ~12-fold during later stages of spermatogenesis. This increase in transcript abundance is independent of transcription and is instead results from the unmasking and processing of stored pre-mRNAs. RNAi knockdowns show that kinesin-2 is required for the later divisions of spermatogenous cells and that both kinesin-2 and -9 are required for *de novo* basal body formation and ciliogenesis. Without kinesin-2, most spermatozooids contain two or more coiled microtubule ribbons with attached cilia and very large cell bodies. Those that emerge from the spore have cilia that are substantially longer than controls. Kinesin-9 knockdowns have basal bodies that are irregularly positioned and cilia are not localized in the anterior portion of the spermatozoid. Spermatozoid swimming behavior in kinesin-2 and -9 knockdowns is altered because of resultant defects in ciliogenesis. Kinesin-2 knockdowns can only swim or quiver in place while kinesin-9 knockdowns swim erratically compared to controls. (Supported by NSF grant MCB-0842525 to SMW).

Meckelin guides orientation of basal bodies along the striated rootlet.

J. Van Houten¹, T. Picariello¹, M. Valentine¹, A. Nabi¹, J. Yano¹;

¹Univ Vermont, Burlington, VT

Meckelin (MKS3) is a protein of the primary cilia transition zone that functions in ciliogenesis and ciliary gating. MKS3 appears to have similar functions and location in *Paramecium tetraurelia* since FLAG-MKS3 is found associated with and slightly above each basal body and RNAi for MKS3 leads to loss of cilia. However, RNAi for MKS3 also leads to the disorganization of rows of basal bodies that normally run from anterior to posterior. In the areas of misalignments, the basal bodies with their post ciliary and transverse rootlets are found rotated and out of their rows. However, the rootlets are attached to the basal bodies at the expected angles relative to each other. We propose that MKS3 guides new basal bodies as they move toward the anterior of the cell along the striated rootlet (SR) of the parent basal body. These SRs are aligned along the rows of basal bodies; new basal bodies do not yet have their own SR. The loss of MKS3 results in loss of interactions between the new basal body and the parent basal body SR. Without a guide to maintain orientation, the new basal bodies migrate out their rows and out of line and, when they form their SRs, these rootlets do not project toward the anterior as expected. To test for interactions of MKS3 with SR components, we first identified potential SR proteins, expressed them with epitope tags and determined whether they were located in the SR. Of the 24 potential SR protein genes, 13 were selected as representative of sets of paralogs for epitope tagging. Nine of them were associated with the SR, often with non-uniform distributions. Those sequences with SF assemblin domains (similar to those in the *Chlamydomonas* rootlet proteins) coded for proteins that we found in the *Paramecium* SRs; conversely those without this domain were not in the rootlets. MKS3 interacted sufficiently (directly or indirectly) with the striated rootlet proteins to pull them down with a GST-fusion of the 252 C-terminal residues of the *Paramecium* MKS3. We thank J. Beisson for the anti-SR antibody. P20 GM103449; P30 GM103498; R01 GM 59988

P155**Board Number: B262****Asymmetrically localized Fop1 stabilizes basal bodies.**B.A. Bayless¹, T. Giddings², I.M. Cheeseman³, C.G. Pearson⁴;¹Cells, Stem Cells and Development, University of Colorado- Anschutz Medical Center, Aurora, CO,²Molecular, Cellular and Developmental Biology, University of Colorado at Boulder, Boulder, CO,³Whitehead Inst Biomed Res, Cambridge, MA, ⁴Department of Cell and Developmental Biology, University of Colorado-Anschutz Medical Center, Aurora, CO

Motile cilia are necessary for directed extracellular fluid flow. Basal bodies position the cilium and anchor the mechanical forces produced by ciliary beating. The basal body is made up of a set of nine triplet microtubule blades arranged in a cylinder. These microtubules are somehow stabilized to maintain the basal body during ciliary beating. The ciliary beat pattern is asymmetric, a unidirectional power stroke is followed by a refractory stroke which occurs along the same axis. The bulk of the force that the basal body experiences from ciliary beating likely occurs along this axis. The basal body assembly factor Bld10/Cep135 is also necessary to stabilize basal bodies, in *bld10Δ* cells, triplet microtubules are unstable and their disassembly initiates at the triplet microtubules along the axis of the cilium beat stroke. Inhibiting ciliary beating rescues the basal body disassembly phenotype suggesting that Bld10 stabilizes the triplet microtubules from the forces of ciliary beating. Poc1 and Fop1 interact with Bld10, stabilize basal bodies, and localize along the entire length of the basal body. We examined the relationship between Poc1 and Fop1, and find that Poc1 is necessary for the temporal loading of Fop1 into the basal body. Interestingly, Fop1 localizes asymmetrically to the basal body at triplet microtubules that align with the axis of the ciliary beat stroke. We hypothesize that Fop1 helps to stabilize the triplet microtubules on the sides of the basal body that experience the most force from ciliary beating. Taken together, our data suggest that Bld10, Fop1 and Poc1 are stability factors for the basal body and Poc1 helps to load Fop1 asymmetrically along the triplet microtubules.

P156**Board Number: B263****SPEF1 regulates the length of central microtubules in 9+2 motile cilia.**M. Guha¹;¹Cellular Biology, The University of Georgia, Athens, GA

SPEF1 is a microtubule-binding protein with a calponin homology (CH) domain, and structural similarity to the End Binding (EB) plus end tracking proteins. SPEF1 homologs are present in most ciliated organisms. The ciliate *Tetrahymena thermophila* has two paralogs of SPEF1. Cells lacking both of these paralogs swim very slowly and have fewer but normal length cilia. Ultrastructural studies revealed a mixture of normal 9+2 and abnormal 9+1 or 9+0 axoneme cross-sections, indicating defects in the assembly of central microtubules. Longitudinal sections revealed that frequently the proximal portions of the central microtubules (near the minus ends) were truncated. Purified SPEF1 bound to microtubules

in a sedimentation assay. Phylogenetic studies revealed that SPEF1 is absent in species with cilia naturally lacking central microtubules. Taken together, these results suggest that SPEF1 regulates the length of the central microtubules; possibly by affecting the stability of their minus ends. Interestingly, a knockout strain lacking a conserved central pair protein, PF20, also has fewer cilia. Thus, in *Tetrahymena* defects in the central apparatus are associated with reduced ciliogenesis.

Board Number: B264

Cep164, but not EB1, is essential for centriolar localization of TTBK2 and its function in ciliogenesis.

T. Nagai¹, O. Toshiaki¹, S. Chiba¹, K. Mizuno¹;

¹Tohoku Univ., Sendai, Japan

Primary cilia are microtubule-based antenna-like organelles that emanates from the mother centriole-derived basal body in most quiescent mammalian cells. Primary cilia transduce chemical and mechanical signals from the extracellular milieu and play critical roles in the development and homeostasis of many tissues. Defects in formation and/or function of primary cilia are associated with many human diseases, including polycystic kidney disease, retinal degeneration and neurological defects. In ciliogenesis, a centriolar protein CP110 is removed from the distal region of the mother centriole, which allows the mother centriole to move and dock to the plasma membrane via the distal appendages of the mother centriole and to nucleate the ciliary axoneme. CP110 and its interactor Cep97 suppress ciliogenesis by blocking axonemal microtubule assembly; therefore, removal of CP110 from the mother centriole is required for initiating axoneme extension and ciliogenesis. Tau tubulin kinase-2 (TTBK2) has an essential role in initiation of ciliogenesis by promoting CP110 removal and recruitment of intraflagellar transport (IFT) protein complexes. When cells are growth-arrested by serum starvation, TTBK2 is recruited to the distal region of the mother centriole. Therefore, the centriolar localization of TTBK2 is a key step in initiation of ciliogenesis. Previous studies demonstrated that TTBK2 binds to EB1 and Cep164, both of which are essential for ciliogenesis. However, the roles of the binding of these proteins in ciliogenesis and centriolar localization of TTBK2 have remained unclear. To elucidate the mechanisms underlying centriolar localization of TTBK2, we analyzed the roles of EB1 and Cep164 in TTBK2 localization. TTBK2 bound to EB1 and Cep164 through two SxIP motifs and a proline-rich motif in the C-terminal region of TTBK2, respectively. TTBK2 mutants at SxIP motifs did not localize at the plus-ends of microtubules, but localized at the mother centriole, and they rescued the defect in ciliogenesis upon TTBK2 knockdown. These results suggest that EB1 is not essential for centriolar localization of TTBK2. In contrast, depletion of Cep164 or overexpression of Cep164-N, which can bind to TTBK2 but not localize on the centriole, suppressed centriolar localization of TTBK2. Furthermore, non-Cep164-binding mutants of TTBK2 at the proline-rich motif did not rescue the defects in ciliogenesis and CP110 removal upon TTBK2 knockdown. These results suggest that Cep164, but not EB1 is essential for centriolar localization of TTBK2 in the initiation of ciliogenesis. We also showed that TTBK2 phosphorylates Cep164 and Cep97 and inhibits the interaction between Cep164 and its binding protein Dishevelled-3.

P158**Board Number: B265****The G-domain of the Joubert syndrome protein ARL13B is required for anchoring to the axoneme and uniform distribution along the cilium.**E. Revenkova¹, G.L. Gusella², T. Tedeschi¹, C. Iomini¹;¹Department of Ophthalmology, Icahn School of Medicine at Mount Sinai, New York, NY, ²Department of Medicine, Icahn School of Medicine at Mount Sinai, New York, NY

Cilia-mediated signal transduction involves precise targeting and localization of selected molecules along the ciliary membrane, but the molecular mechanism underlying these events is unclear. ARL13B is a membrane-associated small G-protein that localizes along the cilium and functions in ciliary protein transport and signaling. In human, mutations of ARL13B cause Joubert syndrome, and in model organisms ARL13B deficiencies lead to structural defects in cilia and mislocalization of ciliary proteins.

To gain mechanistic insight into ARL13B activity and positioning along the ciliary membrane, we sought to identify interaction partners essential for its function in the cilium. Using a tandem affinity purification (TAP) approach and mass spectrometry, we found that the major proteins co-purifying with TAP-tagged ARL13B from ciliated RPE cells were alpha- and beta-tubulins. This interaction was confirmed by immunoprecipitation of both GST-tagged and endogenous ARL13B from cell extracts. Moreover, GST pull-down assay using a mixture of purified GST-ARL13B and purified tubulin demonstrated that the interaction with tubulin is direct. Mapping of the tubulin-interacting regions of ARL13B revealed that the G-domain and significantly truncated fragments of the G-domain, but not the coiled-coil region, interact with soluble tubulin.

To address the function of the G-domain within the ciliary compartment, we obtained an ARL13B mutant lacking the G-domain (ARL13B- Δ GD) but retaining the ciliary localization. In wild-type mouse embryonic fibroblasts (MEFs), wild-type ARL13B or mutant ARL13B- Δ GD, which were expressed as GFP fusions using lentiviral vectors, followed the distribution of the endogenous ARL13B along the whole cilium. In contrast to the even distribution in wild-type cells, in *Arl13b* null (*hnn*) MEFs ARL13B- Δ GD accumulated at the distal tip and dramatically diminished along the cilium. While the overexpression of ARL13B- Δ GD caused cilium elongation in wild-type cells, it failed to rescue shortened cilia in *hnn* MEFs.

To test whether ARL13B G-domain is required for anchoring ARL13B to the ciliary axoneme, we performed in vitro pull down of GST-ARL13B fragments using axonemes purified from *Chlamydomonas* flagella. The assay showed that both full-length ARL13B and the G-domain bind isolated axonemes, while the ARL13B coil-coil domain does not, indicating that ARL13B interacts with axoneme through its G-domain capable of binding to tubulin.

We conclude that the G-domain of ARL13B is not required for trafficking to the cilium but it is indispensable for proper axonemal distribution of ARL13B.

P159**Board Number: B266****Primary cilia in neural progenitors are regulated by neutral sphingomyelinase 2 and ceramide.**

Q. He¹, G. Wang¹, M.B. Dinkins¹, S. Wakada¹, S. Dasgupta¹, J. Kong¹, S.D. Spassieva², E. Bieberich¹;
¹Department of Neuroscience and Regenerative Medicine, Georgia Regents University, Augusta, GA,
²Med Univ South Carolina, Charleston, SC

We show here that human embryonic stem (ES) and induced pluripotent stem (iPS) cell - derived neuroprogenitors (NPs) develop primary cilia. Ciliogenesis depends on the sphingolipid ceramide and its interaction with atypical PKC (aPKC), both of which distribute to the primary cilium and the apicolateral cell membrane in NP rosettes. Neural differentiation of human ES cells to NPs is concurrent with a 3-fold elevation of ceramide, in particular saturated, long chain C16:0 ceramide (N-palmitoyl sphingosine) and non-saturated, very long chain C24:1 ceramide (Nnervonoyl sphingosine). Decreasing ceramide levels by inhibiting ceramide synthase or neutral sphingomyelinase 2 (nSMase2) leads to translocation of membrane-bound aPKC to the cytosol, concurrent with its activation and the phosphorylation of its substrate Aurora kinase A (AurA). Inhibition of aPKC, AurA, or a downstream target of AurA, HDAC6, restores ciliogenesis in ceramide-depleted cells. Importantly, addition of exogenous C24:1 ceramide reestablishes membrane association of aPKC, restores primary cilia, and accelerates neuronal process formation. Taken together, these results suggest that ceramide prevents activation of HDAC6 by cytosolic aPKC and AurA, which promotes acetylation of tubulin in primary cilia and potentially, neuronal processes. This is the first report on the critical role for ceramide generated by nSMase2 in stem cell ciliogenesis and differentiation. (Supported by grant NSF00028 and AHASE00089)

P160**Board Number: B267****A new step in ciliogenesis: The ANO1 Nimbus.**

C.C. Ruppensburg¹, P.G. Donlin-Asp¹, G.J. Bassell^{1,2}, C. Hartzell¹;
¹Cell Biology, Emory University School of Medicine, Atlanta, GA, ²Neurology, Emory University School of Medicine, Atlanta, GA

Many cells possess a single, non-motile, primary cilium that is thought to be a sensory transducer akin to a cellular antenna. Ciliogenesis involves migration of the basal body to the cell surface followed by outgrowth of the axoneme by intraflagellar transport. We have identified another early step in cilium development, formation of a novel structure - the *nimbus*. Prior to cilia extension, ANO1, a Ca²⁺-activated Cl⁻ channel, is organized into a torus-shaped structure along with other ciliary proteins including the small GTPases CDC42 and Arl13b, exocyst complex components, and acetylated α -tubulin and γ -tubulin. Furthermore, we have identified this region as an area of RNA localization. This structure we call the *nimbus* forms an interface between the microtubule cytoskeleton of the nascent cilium and

the surrounding cortical actin cytoskeleton. During ciliogenesis, the nimbus disassembles and ciliary components, including ANO1, move into the cilium. Our data support a model where the nimbus provides a scaffold for staging of ciliary components and cilia assembly and expands to include the potential role of RNA localization in cilium formation.

Actin and microtubule-interacting protein Girdin promotes ciliogenesis by regulating basal body positioning.

I. Nechipurenko¹, A. Olivier-Mason¹, J. Kennedy², O.E. Blacque², P. Sengupta¹;

¹Biology, Brandeis University, Waltham, MA, ²Univ Coll Dublin, Dublin, Ireland

Primary cilia are present on the surface of most cell types in metazoans and have recently emerged as key mediators of diverse signaling pathways critical for embryonic development and adult tissue homeostasis. Cilia from all studied organisms share a conserved core organization comprised of a microtubule-based axoneme surrounded by a specialized membrane. Primary cilium assembly is a multi-step process that relies on mother centriole-to-basal body (BB) maturation, BB migration and anchoring to membrane, establishment of the 'ciliary gate', and axoneme elongation from the BB via intraflagellar transport (IFT) of ciliary components. Although actin and microtubule networks are pivotal for ciliogenesis, the molecular mechanisms regulating cytoskeletal dynamics during different steps of cilia biogenesis are not well understood. We find that the actin and microtubule-interacting protein Girdin localizes to the BB in *C. elegans* sensory neurons and mammalian cells. Loss of *girdin* function in *C. elegans* results in defective sensory cilia morphology, ultrastructure, and localization of BB and transition zone proteins. Similarly, Girdin knockdown in mammalian cells leads to loss of, or shortened cilia. Analysis of cytoskeletal organization shows that both actin and microtubule networks may be disrupted in mammalian cells upon Girdin knockdown, leading to altered BB positioning and decreased IFT accumulation at the ciliary base. Mammalian Girdin is known to couple extracellular cues to actin dynamics during cell migration. Our preliminary findings suggest that it may also coordinate cytoskeletal dynamics to ensure proper BB positioning and cilia assembly. We will present our ongoing efforts to further characterize a novel role for this highly conserved protein in primary cilia biogenesis and function in *C. elegans* sensory neurons and mammalian cells.

Centrosome Assembly and Functions 1

P162

Board Number: B270

The centrosome is also an actin-organizing center, ATOC.

F. Farina¹, J. Gaillard¹, C. Guérin¹, L. Blanchoin¹, J. Sillibourne*², M. Théry²;

¹iRTSV, CEA, Grenoble, France, ²iRTSV, CEA, Paris, France

The centrosome is the main microtubule-organizing centre. It is involved in the regulation of cell polarity, cell motility and cell division. Although centrosome functions mainly depend on microtubules, the actin network has been shown to be involved in several key centrosome activities such as centrosome positioning at the cell centre, membrane docking during ciliogenesis or immune synapse formation as well as mitotic spindle assembly and positioning. However, the centrosome-actin connection has remained elusive. Actin and actin-binding proteins have been detected at the centrosome by proteomic analyses and immuno-stainings, but experimental data demonstrating the capacity of centrosome to organize actin filaments and interact with the actin network are still missing.

Here, we provide the first compelling evidence that centrosomes assemble and anchor actin filaments. Centrosomes were isolated from human T lymphocytes expressing eGFP-centrin. As expected, they induced the nucleation of microtubules in the presence of purified tubulin dimers, but they also promoted the assembly of large radial arrays of actin filaments in the presence of actin monomers. These networks appeared to stem from short filaments, stably and tightly bound to the purified centrosomes. These filaments could not be disassembled by actin depolymerizing drugs. Highly stable actin filaments were also present at the centrosome of living cells. Centrosome displayed the same capacity to promote the growth of long filaments in the presence of purified actin monomers after removal of cell membrane. The actin organizing property of centrosome in living cells was further demonstrated by time-lapse monitoring of lymphocytes, in which a cytoplasmic actin cloud permanently accompanied the moving centrosome.

These results point toward a new role for the centrosome as an actin-organizing centre. They shine some light on numerous prior observations of centrosome and actin network mutually influencing each other.

P163**Board Number: B271****Centrosomes promote efficient spindle assembly, maintain cell viability, and help orient spindles in epithelial tissue during development.**J.S. Poulton¹, J.C. Cuningham¹, M. Peifer¹;¹Department of Biology, University North Carolina, Chapel Hill, NC

Mitotic spindles are critical for accurate chromosome segregation. Centrosomes, the primary microtubule nucleating centers of animal cells, play key roles in forming and orienting mitotic spindles. However, the survival of *Drosophila* without centrosomes suggested they are dispensable in somatic cells, challenging the canonical view. We used fly wing disc epithelia as a model to resolve these conflicting hypotheses, revealing that centrosomes play vital roles in spindle assembly, function, and orientation. Many acentrosomal cells exhibit prolonged spindle assembly, chromosome mis-segregation, DNA damage, misoriented divisions, and eventual apoptosis. We found that multiple mechanisms buffer the effects of centrosome loss, including alternative microtubule nucleation pathways (Augmin and RanGTP) and the Spindle Assembly Checkpoint (SAC). Apoptosis of acentrosomal cells is mediated by JNK signaling, which also drives compensatory proliferation to maintain tissue integrity and viability. These data reveal the importance of centrosomes in fly epithelia, but also demonstrate the robust compensatory mechanisms at the cellular and organismal level. Interestingly, these mechanisms are insufficient when we disrupt the SAC in acentrosomal cells. We are currently exploring how this affects brain development, which is grossly perturbed in the absence of both centrosomes and the SAC, and may serve as a model for microcephaly.

P164**Board Number: B272****The centrosome as a phoenix organelle: burned by its own proteasome during fever and revived by its own molecular chaperone Hsp70.**S. Doxsey¹, A. Vertii²;¹Univ Massachusetts Med Sch, Worcester, MA, ²PMM, Univ Massachusetts Med Sch, Worcester, MA

The centrosome is a non-membranous organelle that performs many essential functions including microtubule nucleation/organization, ciliogenesis, cell division, membrane trafficking, and immunological synapse formation. The immune response during inflammation is often accompanied by elevated body temperature. Although the detrimental effect of heat shock on centrosome is established, the physiological relevance and mechanisms of centrosome damage remain elusive. Here we provide evidence that the febrile condition results in centrosome damage in patients' leukocytes. We find that local proteasome machinery at the centrosome is responsible for centrosome damage and functional inactivation of centrosome substructures. This heat-induced centrosome degradation pathway appears to be unique to the centrosome, as another non-membranous organelle, the midbody,

remains unchanged following heat shock. Forced targeting of the molecular chaperone, Hsp70-GFP, to the centrosome prevents centrosome inactivation, whereas centrosome-excluded Hsp70 or chaperone-inactive mutants fail to protect the centrosome. This novel mechanism of centrosome regulation during fever is an important aspect of the previously demonstrated role of centrosomes in the immune response.

Plk1 controls PCM assembly by phosphorylating SPD-2 and SPD-5 in *C. elegans*.

S.D. Ochoa¹, V. Viscardi¹, E. Zanin¹, S. Bahmanyar¹, A. Desai¹, K. Oegema¹;

¹Ludwig Institute for Cancer Research, La Jolla, CA

Centrosomes, the major microtubule organizing centers in animal cells, are composed of a centriole pair surrounded by a matrix of pericentriolar material (PCM) that nucleates and anchors microtubules. Centrioles direct assembly of the PCM, which expands during mitotic entry in a process termed centrosome maturation; the expanded PCM is subsequently disassembled during mitotic exit. The mechanisms that restrict PCM assembly around centrioles and regulate its cell cycle dynamics remain poorly understood. Here we use the *C. elegans* embryo to analyze the regulation of PCM assembly. Genome-wide screens have identified 4 *C. elegans* proteins that are required for PCM assembly. SPD-5 is a large coiled-coil protein that is thought to be the major component of the PCM matrix. PCM assembly also requires SPD-2, Aurora A, and the polo family kinase Plk1. We confirmed the essential role of Plk1 in PCM assembly by constructing *C. elegans* strains in which the only source of PLK-1 was a single copy transgene expressing either wild-type PLK-1 (PLK-1WT) or an analog-sensitive “Shokat” mutant (PLK-1AS), in which the catalytic pocket was mutated to accept bulky purine analogs and enable kinase inhibition by the cell-permeable PP1 analog 1NM-PP1. Strains also included a transgene expressing the centrosomal marker GFP:: γ -tubulin to monitor the PCM. Addition of 1NM-PP1 to permeabilized embryos during S-phase prior to nuclear envelope breakdown abolished mitotic PCM expansion in embryos carrying the plk-1AS, but not the plk-1WT, transgene. Addition of 1NM-PP1 to embryos arrested in metaphase with a proteasome inhibitor also led to rapid disassembly of the mitotic PCM in embryos carrying the plk-1AS, but not the plk-1WT, transgene, indicating that Plk1 activity is essential for both establishment and maintenance of mitotic PCM. To understand how Plk1 contributes to PCM assembly, we are analyzing the consequences of mutating all predicted Plk1 sites that are conserved among nematodes, either individually or in localized groups, in SPD-2 (7 sites) and SPD-5 (25 sites). We have already identified 2 Plk1 sites in SPD-2 and 2 sites in SPD-5 that are essential for PCM assembly, suggesting that Plk1 regulates SPD-5 polymerization by phosphorylating both SPD-2 and SPD-5.

P166**Board Number: B274****Regulated assembly of a supramolecular centrosome scaffold *in vitro*.**J. Woodruff¹, O. Wueseke¹, V. Viscardi², J. Mahamid³, K. Oegema², A. Hyman¹;¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ²Ludwig Institute for Cancer Research, La Jolla, CA, ³Max Planck Institute of Biochemistry, Martinsried, Germany

A centrosome comprises a pair of centrioles surrounded by an amorphous protein mass called the pericentriolar material (PCM). Despite its importance as major microtubule-organizing center, the mechanism of PCM assembly and its regulation are not understood. In a *C. elegans* embryo, the coiled-coil protein SPD-5 is essential for PCM assembly. We found that recombinant SPD-5 can polymerize to form micrometer-sized porous networks *in vitro*. Network assembly was accelerated by two conserved regulators that control PCM assembly *in vivo*, Polo-like kinase-1 and SPD-2/Cep192. Interestingly, only the assembled SPD-5 networks, and not unassembled SPD-5 protein, functioned as a scaffold for other PCM proteins. Our results suggest that PCM size and binding capacity emerge from the regulated formation of a porous network from one coiled-coil protein. Furthermore, these results suggest that PCM growth is autocatalytic, such that polymerized SPD-5 can recruit additional SPD-5 and its own positive regulators, leading to rapid network expansion.

P167**Board Number: B275****Plk1 binds to the two distinct phospho-motifs on a centrosomal scaffold, Cep192, to promote bipolar spindle formation.**L. Meng¹, J. Park², T. Kim², K. Lee²;¹National Institute of Health, Bethesda, MD, ²NIH/NCI, Bethesda, MD

Serving as microtubule (MT)-organizing centers, centrosomes play a key role in bipolar spindle formation during mitosis. A centrosomal scaffold protein, Cep192, is required for proper centrosome organization and bipolar spindle assembly. However, how it promotes these events remains largely unknown. A recent study with *Xenopus* extracts suggested that Plx1 interacts with the p-T46 motif of Cep192 to form a Cep192-dependent AurA-Plx1 cascade critical for the establishment of bipolar spindles. Here we demonstrated that, in cultured human cells, Cep192 recruits AurA and Plk1 in a cooperative manner and this event is important to promote the reciprocal activation of the latter two enzymes at centrosomes. Strikingly, Plk1 interacted with human Cep192 through two distinct phospho-motifs—the p-T44 motif (which is analogous to the *Xenopus* p-T46 motif) and a yet uncharacterized p-S995 motif—in a manner that requires its C-terminal noncatalytic polo-box domain (PBD). Intriguingly, the interaction of Plk1 with the p-T44 motif required the presence of AurA, whereas the interaction with the p-T995 motif occurred only in the absence of AurA, suggesting that Plk1 binds to Cep192 in two biochemically distinguishable modes. Consistent with this view, loss of either one of these interactions induced a mild defect in bipolar spindle formation and mitotic progression as a result of improper recruitment of Plk1 and γ -

tubulin to centrosomes. Under the same conditions, elimination of both interactions induced a greatly enhanced defect in these processes, suggesting that the defect associated with the loss of T44- and S995-dependent interactions is additive. Taken together, we propose that Plk1 forms two functionally non-overlapping complexes with Cep192 to promote centrosome-based bipolar spindle formation and therefore proper M-phase progression.

Measuring the in-vivo Activity of Separase at Centrosome.

F.G. Agircan¹, E. Schiebel¹;

¹ZMBH, Heidelberg, Germany

Separase is best known for its function in sister chromatid separation at the metaphase-anaphase transition. It also has a role in centriole disengagement in late mitosis/G1. To gain insight into the activity of separase at centrosomes, we developed two separase activity sensors: mCherry-Scc1^{(142-467)- Δ NLS}-eGFP-PACT and mCherry-kendrin⁽²⁰⁵⁹⁻²³⁹⁸⁾-eGFP-PACT. Both localize to the centrosomes and enabled us to monitor local separase activity at the centrosome in real time. Both centrosomal sensors were cleaved by separase before anaphase onset, earlier than the corresponding H2B-mCherry-Scc1⁽¹⁴²⁻⁴⁶⁷⁾-eGFP sensor at chromosomes. This indicates that substrate cleavage by separase is not synchronous in the cells. Depletion of the proteins astrin or Aki1, which have been described as inhibitors of centrosomal separase, did not lead to a significant activation of separase at centrosomes, emphasizing the importance of direct separase activity measurements at the centrosomes. Inhibition of polo-like kinase Plk1, on the other hand, decreased the separase activity towards the Scc1 but not the kendrin reporter. Together these findings indicate that Plk1 regulates separase activity at the level of substrate affinity at centrosomes and may explain in part the role of Plk1 in centriole disengagement.

Board Number: B277

PLK1 phosphorylation is essential for the separase-dependent cleavage of pericentrin during mitotic exit.

J. Kim¹, K. Lee¹, K. Rhee¹;

¹Biological Sciences, Seoul National University, Seoul, Korea

The centrosome duplication events are tightly linked to the cell cycle. In order to duplicate in the next cell cycle, mother and daughter centrioles should be disengaged at the end of mitosis. Therefore, centriole disengagement is considered a licensing step for centriole duplication. Separase is known to play an essential role in the centriole disengagement. We and others identified pericentrin as a substrate of separase. Here, we report the importance of PLK1 phosphorylation in the separase-dependent cleavage of pericentrin. PLK1 phosphorylates multiple sites of pericentrin during mitotic

entry. We observed that separase could not cleave the phospho-resistant mutants of pericentrin during mitotic exit. Furthermore, centriole disengagement was inhibited in the cells rescued with the phospho-resistant mutants of pericentrin. Based on these results, we propose that PLK1 phosphorylation is a prerequisite step for separase-dependent cleavage of pericentrin and eventually for centriole disengagement.

The RNA-binding Protein ATX-2 Interacts with SZY-20, and Opposes ZYG-1 to limit Centrosome Size.

M. Stubenvoll¹, J. Medley¹, M. Irwin¹, M. Song¹;

¹Biological Sciences, Oakland University, Rochester, MI

Centrosomes are critical sites for controlling microtubule dynamics, and exhibit dynamic changes in size during the cell cycle. As cells progress to mitosis, centrosomes recruit more microtubules to form bipolar spindles. The *szy-20* gene encodes a centrosome-associated RNA-binding protein that negatively regulates ZYG-1, a key centrosome duplication factor. It has been shown that *szy-20* mutants possess enlarged centrosomes, causing abnormal microtubule processes and embryonic lethality. SZY-20 contains putative RNA-binding domains; mutating these domains perturbs RNA-binding by SZY-20 in vitro and its capacity to regulate centrosome size in vivo. To further elucidate the roles of SZY-20 and RNA-binding in regulating centrosome assembly and size, we sought to identify factors associated with SZY-20. By proteomics, we identified an RNA-binding protein ATX-2 reproducibly pulled-down with SZY-20. Consistent with its physical association, depleting ATX-2 produces embryonic lethality and cell division defects seen in *szy-20(bs52)* embryos, including a failure of cytokinesis and polar body extrusion, and abnormal spindle positioning. Thus, ATX-2 is required for proper cell divisions in which *atx-2* acts synergistically with *szy-20*: Knocking down ATX-2 in *szy-20(bs52)* mutants enhanced the embryonic lethality and cell division defects. Genetic analyses indicate that not only *szy-20* but also *atx-2* negatively regulates centrosome assembly. *atx-2(RNAi)* partially restores centrosome duplication to *zyg-1(it25)* embryos. Knocking down both *szy-20* and *atx-2* almost completely restored bipolar spindle formation to *zyg-1(it25)* embryos, suggesting a positive interaction between *atx-2* and *szy-20* in regulating centrosome assembly. Intriguingly, ATX-2-depleted embryos exhibit enlarged centrosomes as shown in *szy-20(bs52)*. Embryos partially depleted of ATX-2 possess significantly increased ZYG-1 and pericentriolar materials at centrosomes. Enlarged centrosomes are more evident in a null allele *atx-2(ne4297)* embryos, suggesting an inverse correlation between the amount of ATX-2 and centrosome size. Quantitative western and immunostaining analyses show that ATX-2 is nearly absent in *szy-20(bs52)*, much similarly in *atx-2(ne4297)*, but unaffected in *zyg-1* mutants. In contrast, SZY-20 levels are unaffected in *atx-2* or *zyg-1* mutants. Thus, SZY-20 acts upstream of ATX-2 and promotes the level of ATX-2, which opposes ZYG-1 to limit centrosome size. In this study we identify ATX-2 as a negative regulator of centrosome assembly and size.

P171**Board Number: B279****Determining the function of the protein PCID2 at the centrosome.**N. Schramm¹, K. Resendes¹;¹Biology, Westminster College, New Wilmington, PA

Human PCID2 is a member of the TREX2 complex which associates with the nuclear pore basket to facilitate mRNA export. Multiple components of the TREX2 complex, including PCID2, serve additional roles in the cell other than in nuclear mRNA export. Specifically, PCID2 and centrin 2 co-localize outside of the nucleus at the centrosome. Recent characterization indicates that PCID2 is present at the centrosome during the G1/S and G2/M phases of the cell cycle. The localization of Centrin 2 at the centrosome in those phases is linked to its role as required factor for centriole duplication. While the relationship between PCID2 and centrin 2 at the centrosome during these periods is not yet fully understood, we have previously shown that siRNA knockdown of centrin 2 disrupts centrosomal localization of PCID2. In contrast, PCID2 knockdown does not affect the positioning of centrin 2. Because characterization of PCID2 in human cells thus far has been limited to its roles in nuclear mRNA and protein export investigating its significance outside of the nucleus is crucial to understanding its overall role in the cell and its functional relevance at the centrosome. We are performing both siRNA knockdown of PCID2 as well as overexpression of a GFP-PCID2 recombinant plasmid to determine the effects of altering PCID2 expression levels on the centrosome. Because the PCI domain contained within PCID2 typically serves as a structurally stabilizing scaffolding unit within large complexes, it is expected that increased or decreased levels of PCID2 will produce an observable effect on positioning and assembly of the centrosome due to abnormal protein stoichiometry. We are currently testing this prediction by assessing changes in centrosome number, position and mitotic defects such as altered spindle organization via fluorescence microscopy.

P172**Board Number: B280****The role of mouse CKAP2 phosphorylation in centrosome biogenesis.**B. Yoo¹, C. Park¹, H. Kim¹, J. Park¹, C. Bae¹;¹Sungkyunkwan Univ Sch Med, Suwon, Korea

CKAP2, cytoskeleton-associated protein, is regulated during the cell cycle, with the protein being degraded in late mitosis in an APC/C-Cdh1 dependent manner. Our previous studies have suggested that cellular function of CKAP2 pertain to regulation of the mitotic spindle dynamics and proper chromosome segregation. Here we show that the effect of phosphorylation of the mouse CKAP during cell cycle on the centrosome biogenesis. Depleting the CKAP2 in NIH 3T3 induced the centrosome amplification and fragmentations leading to abnormal chromosome segregation, which was rescued by ectopic expression of wild type CKAP2. Phosphorylation is one of the key mechanisms which regulate centrosome

biogenesis and spindle assembly. We have hypothesized that phosphorylation status of the CKAP2 may be related with centrosome biogenesis. In order to explore the function of the phosphorylated CKAP2, we introduced phospho-deficient mutation at T603 which were known to be phosphorylated in human CKAP2 by Cdk1-cyclin B1, respectively. The expression of phosphorylation deficient mutant forms of mouse CKAP2, T603A could not restore the centrosomal abnormalities of CKAP2 depleted NIH 3T3 cells. These results indicates that phosphorylation of the CKAP2 is critical for both centrosome biogenesis and bipolar spindle formation. Further studies are required to elucidate the mechanisms maintaining centrosome integrity by mitosis specific phosphorylation of the CKAP2.

WDR62 a critical target for the Aurora-A overexpression phenotype?.

A. Eskat¹, M. Hoveyda¹, M. de Medina Redondo¹, M. Gstaiger², P. Meraldi³;

¹Cell Physiology and Metabolism, University of Geneva, Genève, Switzerland, ²Institute of Molecular Systems Biology, ETH Zürich, Zurich, Switzerland, ³Cell Physiology and Metabolism, University of Geneva, Geneva, Switzerland

The Aurora-A serine/threonine kinase is frequently overexpressed in many epithelial tumors, cancers of solid organs and hematological malignancies. It has been shown that overexpression of Aurora-A is implicated in causing or maintaining the malignant phenotype and resistance to taxanes, which are effective anticancerous drugs and routinely used for the treatment of many cancers. At the physiological level Aurora-A regulates many aspects of mitosis, such as mitotic entry, bipolar formation of the mitotic spindle and centrosome regulation, including centrosome separation and centrosome maturation. However, very little is known about the molecular consequences of Aurora-A overexpression and how the overexpression is linked to tumorigenesis. In the current hypothesis Aurora-A overexpression leads to a failure in the spindle assembly checkpoint in a kinase-dependent manner, which would result in chromosome segregation errors with cytokinesis failure and chromosomally unstable tetraploid cells (Anand et al., 2003). Surprisingly, we find that Aurora-A disrupts mitotic progression in a kinase-independent way. And second, we show that exogenous Aurora-A does not impair the spindle checkpoint. It is rather that Aurora-A overexpression leads to spindle orientation defects and causes the formation of DNA bridges in anaphase. These DNA bridges are known to impair cytokinesis, which in turn could result in tetraploid cells. Searching for the causes for these mitotic defects, we set out to identify the proteins that are titrated out by Aurora-A overexpression with mass spectrometry. We found WDR62 as an interaction partner, which has been recently reported as an Aurora-A activator protein (Chen et al., 2014). Mutations in this centrosomal protein lead to microcephaly in human patients (Bilgüvar et al., 2010; Nicholas et al., 2010; Yu et al., 2010). Here, we show that the abundance of WDR62 at centrosomes is reduced in Aurora-A overexpressing cells and that depletion of WDR62 gives also rise to spindle orientation defects and DNA bridges in anaphase. Rescue experiments show that co-expression of WDR62 and Aurora-A rescues the Aurora-A overexpression phenotype (DNA bridges and spindle orientation defects). Therefore we postulate that overexpression of Aurora-A

reduces WDR62 amounts in HeLa cells, which in turn leads to cell divisions with DNA bridges that disturb cytokinesis.

Localization determinants in the Mps1 amino terminus distinguish centrosomal and kinetochore targeting.

J.R. Marquardt¹, K. Beuoy¹, H.A. Fisk¹;

¹Department of Molecular Genetics, The Ohio State University, Columbus, OH

Cells have evolved elaborate mechanisms to ensure the faithful segregation of chromosomes. The centrosome, which consists of two microtubule-based centrioles, must be precisely duplicated only once in S-phase to become the poles in a proper bipolar mitotic spindle. The spindle assembly checkpoint (SAC) serves to block the progression of mitosis until all chromosomes are properly attached to spindle microtubules from both poles. Failure to regulate either of these processes has the potential to cause aneuploidy, which is a hallmark of many cancers. The kinase Mps1 has previously been shown to regulate both the duplication of centrioles in S-phase and the SAC in mitosis. This implies that different localization prompts in Mps1 govern its localization throughout the cell cycle. Here we show that separate elements in the Mps1 N-terminus, which includes the known domains N-terminal extension (NTE), tetratricopeptide repeat (TPR), and centrosome localization domain (CLD), govern localization to either the kinetochore or the centrosome. Domains that have previously been shown to be responsible for kinetochore targeting were found to be dispensable for centrosomal localization and function. A separate motif is shown to be necessary for centrosomal targeting and the interaction with the centrosomal protein voltage dependent anion channel 3 (VDAC3), which has previously been shown to recruit Mps1 to the centrosome. Deletion of this element resulted in a version of Mps1 that maintains kinetochore localization and SAC function, while failing to elicit centriole reduplication. This data is consistent with a separation of function for the kinase based on separate elements of an N-terminal localization determinant.

P175**Board Number: B283****Differential inhibition of centrosome amplification in 2-CEES-treated Saos-2 cells by antioxidants glutathione and Trolox.**R.A. Bennett¹, E. Behrens², A. Zinn³, C. Duncheon², T.J. Lamkin⁴;¹Department of Biology, University of Southern Indiana, Evansville, IN, ²University of Southern Indiana, Evansville, IN, ³Department of Biological Science, University of Toledo, Toledo, OH, ⁴Molecular Signatures Section - Molecular Genetics, Air Force Research Laboratory, Wright-Patterson AFB, OH

Mustard gas (MG) is a chemical weapon that was first used in World War I (Duchovic and Vilensky, 2007). In recent times, its mortality and morbidity combined with its simple formulation have raised concerns over its potential use by terrorist organizations and unstable governments. MG is a powerful vesicant and alkylating agent that causes DNA monoadducts and crosslinks to form (Fidder et al, 1994). Acute exposure to MG results in painful blisters and respiratory distress, whereas chronic, low-level exposure to MG, such as that which is found in facilities that manufacture it, results in higher incidences of cancer in those exposed (Smith et al, 1995; Easton et al, 1988). Although the exact mechanism of carcinogenesis is not known, it is thought that MG induces tumor formation through its ability to induce oxidative stress and DNA damage. In addition to nucleic acids as targets of MG toxicity, several proteins have been shown to either be targets of MG-induced damage or mediate its toxicity. Among these proteins are those that have been shown to regulate centrosome biology (e.g. p53, poly(ADP-ribose) polymerase, and NFκB (Ruff and Dillman, 2010). Additionally, DNA damage and oxidative stress have been shown to induce centrosome amplification (i.e. more than 2 centrosomes per cell) as well (Dodson et al, 2004; Chae et al, 2005). Centrosomes direct the segregation of chromosomes during mitosis through the formation of the bipolar mitotic spindle. Cells with amplified centrosomes during mitosis can segregate their chromosomes unequally, resulting in chromosome instability (CIN), a common phenotype of cancer cells (Fukasawa, 2005). In our studies, we utilized the widely accepted, less-hazardous surrogate of MG called 2-chloroethyl ethylsulfide (2-CEES) to determine whether or not it could induce centrosome amplification in cells and subsequent CIN. We have previously shown that 5% and 1% of untreated Saos-2 and NIH3T3 cells, respectively, exhibit centrosome amplification, while 35% and 32% of cells, respectively, treated with 250 μM 2-CEES exhibit centrosome amplification. Cells with centrosome amplification also show an increase in CIN as measured by an increase in aneuploidy in 2-CEES-treated cells (Bennett et al, 2014). Here, we show that glutathione, a scavenger of 2-CEES molecules and reactive oxygen species (ROS), reduces the percent of cells with amplified centrosomes in 2-CEES-treated Saos-2 cells from 52% to 12.5%, while treatment with the antioxidant Trolox, an inhibitor of ROS, reduces centrosome amplification in 2-CEES-treated Saos-2 cells from 37% to 24%. These data indicate that 2-CEES can induce centrosome amplification and CIN in cells and that it may do so through both its ROS-inducing and DNA damaging capacities.

P176**Board Number: B284****Understanding how aneuploidy and multipolar mitosis are formed after chrysotile and vincristine treatments.**B.A. Cortez¹, P.R. Teixeira², S.D. Redick³, S. Doxsey⁴, G. . Machado-Santelli²;¹Depto Genetica e Biologia Evolutiva, University of São Paulo, São Paulo, Brazil, ²Department of Cell and Developmental Biology, University of Sao Paulo, Sao Paulo, Brazil, ³Univ Massachusetts Med Sch, Worcester, MA, ⁴Univ Massachusetts Med Sch, Worcester, MA

Aneuploidy is a feature of solid tumors. Aneuploid cells result from errors during mitosis, such as centrosome amplification, multipolar mitosis and cytokinesis abnormalities. The capability of aneuploidy to promote and to suppress tumorigenesis has driven efforts to characterize mitotic errors that form viable and not viable aneuploid cells. We have previously shown that chrysotile, an asbestos fiber, and vincristine, a chemotherapeutic agent, are able to induce aneuploidy and multipolar mitosis. Now we directed our focus to discover possible mechanisms involved in aneuploid cell formation after these treatments. Herein we evaluated centrosome morphology, chromosome number, location of proteins required to mitosis, and origins and fates of multipolar mitosis and multinucleated cells after chrysotile and vincristine treatment. The experiments were performed using human normal epithelial cells (RPE) and human lung cancer cells (HK2). Chrysotile fibers, in normal and cancer cells, led to mislocalization of proteins involved in intercellular bridge establishment and abscission, such as Septin 9, Anillin, Aurora B and Alix. Cytokinesis regression was observed in almost 20% of cytokinesis in the cultures after fiber treatment for 24 h, resulting in tetraploid multinucleated cells. These cells were able to enter cell cycle, giving rise to multipolar mitosis and aneuploid cells in cancer and normal lineages. Vincristine treatment led to specific and common responses in normal and cancer cells. During metaphase arrest pericentrosomal matrix was fragmented but no centriole reduplication was observed, and arrested cells could be conducted to mitotic slippage in both lineages, generating multinucleated tetraploid cells. Both cell lineages showed during recovery periods increased centriole numbers and abundant pericentriolar matrix. However, normal tetraploid cells could not progress through cell cycle and neither form multipolar mitosis, while cancer tetraploid cells showed Aurora A overexpression, centrosome abnormalities, multipolar mitosis and high levels of aneuploidy. The results showed that HK2 cancer cells could proliferate even after several mitotic errors induced by chrysotile and vincristine, while RPE normal cells could only overcome errors induced by chrysotile treatment. These observations suggest that normal cells do not display protection mechanisms against aneuploid cell formation induced by chrysotile.

Feedback and Spatial Organization of the Ran Pathway in Mitosis.

D. Oh¹, D.J. Needleman^{1,2,3};

¹Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA, ²FAS Center for Systems Biology, Harvard University, Cambridge, United States, ³School of Engineering and Applied Sciences, Harvard University, Cambridge, MA

During cell division, the GTPase Ran forms gradients around chromosomes. Current models of spindle assembly assume that the size of the spindle is determined by the length of these gradients. We used a new multipoint fluorescence fluctuation spectroscopy technique to study the Ran pathway in mitosis. We found that the distribution of components of the Ran pathway which regulate microtubule behaviors is determined by their interactions with microtubules, producing a feedback in which microtubule nucleators are localized by the microtubules whose formation they stimulate. Our results indicate that gradients in Ran act to trigger spindle assembly around chromosomes, but do not produce the length scales of spindle structure. Rather, the size of the spindle results from the feedback process itself, leading to robust spindle self-organization.

Spatio-temporal Model for Silencing of the Mitotic Spindle Assembly Checkpoint.

J. Chen¹, J. Liu²;

¹NIH, Bethesda, MD, ²National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD

The spindle assembly checkpoint arrests mitotic progression until each kinetochore secures a stable attachment to the spindle. Despite fluctuating noise, this checkpoint remains robust and remarkably sensitive to even a single unattached kinetochore among many attached kinetochores; moreover, the checkpoint is silenced only after the final kinetochore-spindle attachment. Experimental observations showed that checkpoint components stream from attached kinetochores along microtubules toward spindle poles. Here, we incorporate this streaming behavior into a theoretical model that accounts for the robustness of checkpoint silencing. Poleward streams are integrated at spindle poles, but are diverted by any unattached kinetochore; consequently, accumulation of checkpoint components at spindle poles increases markedly only when every kinetochore is properly attached. This step-change robustly triggers checkpoint silencing after, and only after, the final kinetochore-spindle attachment. Our model offers a conceptual framework that highlights the role of spatiotemporal regulation in mitotic spindle checkpoint signaling and fidelity of chromosome segregation.

P179**Board Number: B287****A new role for the endocytic pathway during spindle pole formation and mitosis.**H.A. Hehnly^{1,2}, S. Doxsey³, J. Scott⁴;¹Univ Massachusetts, Worcester, MA, ²Department of Pharmacology, University of Washington Medical School, Seattle, WA, ³PMM, Univ Massachusetts Med Sch, Worcester, MA, ⁴Department of Pharmacology, University of Washington Medical School, HHMI, Seattle, WA

Rab11-GTPase-containing endosomes were recently implicated in spindle pole assembly and function, and in spindle orientation (Hehnly and Doxsey, 2014). However, whether their role in spindle assembly is due to a direct role in their spindle maturation was not characterized. During the cell cycle, specifically at growth phase to mitotic entry, the duplicated centrosomes mature into mitotic spindle poles to ultimately set up a microtubule-based spindle to separate duplicated genetic material into a mother and daughter cell. We examined Rab11-endosome tracks towards the centrosome/spindle pole in interphase cells compared to prophase cells. Surprisingly, we found that an increased number of vesicles transported at an elevated rate to spindle poles during prophase when compared to interphase. When we took a closer look, we observed that the Rab11 effector, FIP3, and Rab11-endosomes had a burst of recruitment to a single maturing spindle pole late in G2. This spindle was then characterized to be the oldest spindle pole that contained a 2-fold increase in mother centriole localized proteins (e.g. cenexin, centriolin) compared to the other. Based on our previous observation that Rab11 is localized to the appendages of the mother centriole and the appendage proteins, cenexin and centriolin, can mediate Rab11-endosomes organization and association with the centriole, we decided to examine whether cenexin- or centriolin-depletion disrupted recruitment of endosomes during spindle maturation. Interestingly, recruitment wasn't inhibited, but the preferential recruitment to the oldest spindle pole was diminished where both spindle poles now recruit similar ratios of Rab11-endosomes. Cenexin and centriolin-depleted cells assembled γ -tubulin to the maturing spindle pole, but there was no longer an asymmetric distribution. These cells, like Rab11-depleted cells, display asymmetric spindle orientation during mitosis. One possibility is that asymmetric protein recruitment to the oldest spindle pole is required to ensure division symmetry, and under conditions of Rab11-depletion or loss of mother centriole components spindle asymmetry becomes perturbed.

P180**Board Number: B288****The Nucleoporin ALADIN is Essential for Proper Mitotic Spindle Formation.**S. Carvalhal¹, K. Koehler², A. Huebner², E.R. Griffis¹;¹Centre for Gene Regulation and Expression, University of Dundee, Dundee, Scotland, ²Department of Pediatrics, Technische Universität Dresden, Dresden, Germany

In an RNAi screen for genes essential for mitotic progression, we have identified the nucleoporin ALADIN as a factor that is essential for timely chromosome alignment and spindle morphology. When ALADIN is depleted, we see a delay in chromosome alignment, hyperstretching of paired kinetochores, and destabilized K-fibres. When we examined the molecular nature of these defects, we observed that the protein NuMA retracts from its localization on spindle poles and concentrates on spindles. Conversely, we find that after ALADIN depletion, Aurora A kinase becomes less focused at centrosomes (where the active form is reduced by 40% compared to control cells) and spreads along spindle microtubules. We find that the relocalization of NuMA seen after ALADIN depletion can be phenocopied by inhibiting Aurora A; however, the localizations of other Aurora A substrates such as Eg5 and TACC3 are not perturbed by ALADIN depletion, suggesting that the effects we see are specific to a subset of Aurora A targets. We find that ALADIN, which normally enriches near spindle poles, can be recruited to centrosomes and can bind to Aurora A after this kinase is inhibited by MLN8237. We currently favor a model in which ALADIN scavenges inactive Aurora A to promote its reactivation and maintain a high concentration of this protein near spindle poles where it can phosphorylate substrates like NuMA. Curiously, ALADIN was first identified as a gene that is mutated in patients who have triple A syndrome, which impairs lacrimal, adrenal, and neural functioning. We have investigated the localization of mutant forms of ALADIN in mitosis, and have seen that some show a gain of function localization on kinetochores, while the expression of others inhibit chromosome alignment. We are currently testing whether these mutant forms are still able to interact with Aurora A, and we are beginning to use IPS cells to explore the possibility that mitotic defects underlie some of the symptoms of triple A syndrome.

P181**Board Number: B289****RanBP1 governs spindle assembly by defining mitotic Ran-GTP production.**M. Zhang¹, A. Arnaoutov¹, M. Dasso¹;¹National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD

Proper spindle formation requires a chromatin-based gradient of the small GTPase Ran, with high RanGTP levels in the vicinity of mitotic chromosomes. This gradient is established through the activity of Ran's nucleotide exchange factor (RCC1), which concentrates on chromatin. RanBP1 is a co-activator of Ran's GTPase activating protein (RanGAP1). It has been known for nearly two decades that RanBP1 also forms a stable heterotrimeric complex with RCC1 and Ran (RRR complex), which inhibits RCC1's RanGEF activity. The function of the RRR complex has remained mysterious, however, because RanBP1 is

physically separated from RCC1 during interphase. We found that the RRR complex formed readily in M-phase *Xenopus* egg extracts (CSF-XEEs). RCC1 binding to chromatin and RRR complex assembly were mutually exclusive, so that promoting RRR complex formation through the addition of recombinant RanBP1 sequestered RCC1 away from chromatin. Consistent with earlier reports, RRR complex assembly inhibited RCC1's RanGEF activity. Together, these findings suggest that the RRR complex plays a key mitotic role in determining the partitioning of RCC1 between its active chromatin-bound and inactive soluble states, thereby setting both the location and magnitude of mitotic Ran-GTP production. Notably, RCC1's association to mitotic chromatin is dynamic, and there are particularly large changes during the metaphase-to-anaphase window. However, the timing of reported RCC1 modifications suggests that they do not cause such changes. We found that RanBP1 is phosphorylated during anaphase, and that this modification disrupts the RRR complex. Further analysis showed that RanBP1 phosphorylation drove increased RCC1 binding to chromatin in cycling XEE, and thereby indirectly enhanced anaphase Ran-GTP production. This modification may also contribute to Ran pathway function in early interphase, because elevated RCC1 on anaphase chromatin should provide high levels of Ran-GTP to facilitate nuclear re-assembly. Finally, separation of RCC1 and RanBP1 after RRR complex dissociation allows RCC1 sequestration to re-forming nuclei while excluding RanBP1 into the early interphase cytosol. In summary, we have documented a novel role of the RanBP1 protein in controlling the localization and activity of Ran's nucleotide exchange factor, RCC1. We have shown that phosphorylation of RanBP1 during anaphase drives changes in RCC1 dynamics and allows increased Ran-GTP production. These findings resolve important and long-standing questions within the Ran field regarding the function of the RanBP1/Ran/RCC1 complex and its dynamics.

The budding yeast Polo-like kinase Cdc5 is spatially regulated for timely mitotic exit and adaptation to DNA damage.

V.V. Botchkarev¹, V.V. Eapen¹, V. Rossio¹, A. Matthews¹, S. Yoshida¹, J.E. Haber¹;

¹Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

Polo-like kinases regulate many events including mitotic entry, chromosome segregation, mitotic exit, cytokinesis, and adaptation to DNA damage; however, how Polo activity is regulated remains poorly understood. The budding yeast Polo-like kinase Cdc5 is regulated spatially during the cell cycle. Cdc5 accumulates in the nucleus upon mitotic entry, consistent with the fact that many known Cdc5 substrates are nuclear. Interestingly, in anaphase, we found that Cdc5 translocates from the nucleus to the cytoplasm. We took genetic and biochemical approaches to show that this nuclear-cytoplasmic translocation of Cdc5 in anaphase is required for activation of the Mitotic Exit Network (MEN). We found that the Cdc14 phosphatase, a downstream target of MEN, is required for this nuclear export of Cdc5. This finding suggests the existence of a positive feedback loop between Cdc5 and Cdc14 to regulate timely mitotic exit. Cdc5 also accumulates in the nucleus after DNA damage checkpoint-induced G2/M

arrest. However, by restricting Cdc5 localization either to the nucleus or cytoplasm, we demonstrated the requirement of both nuclear and cytoplasmic pools of Cdc5 for adaptation to DNA damage. Collectively, our data demonstrate that spatial regulation of Cdc5 is required for timely mitotic exit and adaptation to DNA damage.

Novel mechanisms of APC regulation in mouse oocyte meiosis.

I. Nabti¹, J. Carroll²;

¹cell and developmental biology, Univ Coll-London, London, England, ²Monash Univ, Melbourne, Australia

The anaphase-promoting complex (APC) is an E3 ubiquitin ligase responsible for regulated destruction of substrates at specific stages of the cell cycle. Two APC co-activators, Cdc20 and Cdh1, mediate the timing and selectivity of substrates recognition. Cdc20 recognizes substrates containing the D-box motif only, while Cdh1-bound APC mediates the ubiquitination of proteins with either D- or KEN-box motifs. Progression throughout meiosis in oocytes utilizes the same molecular players although the start-stop nature of the female meiosis invokes additional levels of regulation. Recently, we reported that cyclin-dependent kinase 1 (Cdk1) and mitogen-activated protein kinase (MAPK) play compensatory roles in regulating the APC by suppressing its activity early in prometaphase I, thereby allowing accumulation of the APC substrates essential for meiosis I. In this study we have investigated which of the APC co-activators is responsible for this APC activity. Remarkably, we find that depletion of either Cdc20 or Cdh1 failed to prevent APC activity and that depletion of both co-activators led to increased destruction of the APC substrates. Similarly, persistent destruction of the APC substrate, securin, in Cdh1 and Cdc20-depleted prophase I-arrested oocytes points to a second cell cycle stage in which APC activity can be detected even when the known co-activators are depleted. Incomplete depletion of the co-activators seems an unlikely explanation for these findings. Western blotting reveals that the proteins are efficiently depleted in both cases and functional studies show that depletion has the predicted effects on meiotic cell cycle progression. Furthermore, the fact that co-depletion leads to an increase in APC activity, points to novel additional means of APC activation in mouse oocytes. The APC activity revealed in this study targets D-box substrates only. This observation provides further support that Cdh1 is not active, as it would also be expected to recruit KEN-box containing substrates to the APC. However, the observations are also not consistent with Cdc20-mediated APC activation given that in both prometaphase and prophase I Cdc20 depletion is without effect, Cdk1 activity is required for Cdc20 function and there is no evidence that Cdc20 can stimulate the APC during the prophase I-arrest. All these findings suggest that the instability of the D-box substrates revealed in prometaphase I and also during the prophase I-arrest might well be due to activation of the APC independently of its two major co-activators.

P184**Board Number: B292****Multiple Pathways for Spindle Assembly in Mouse Oocytes.**L. Bury¹, P.A. Coelho¹, M. Zernicka-Goetz², D. Glover¹;¹Department of Genetics, University of Cambridge, Cambridge, United Kingdom, ²Department of Physiology, Development and Neuroscience, University of Cambridge, Cambridge, United Kingdom

Mammalian oocytes are naturally acentriolar, and assemble their spindles by self-organization of cytoplasmic microtubule organizing centers (MTOCs) that congress at the center of the oocyte at the time of nuclear envelope breakdown. Although Ran-GTP contributes to the generation of sufficient microtubule density, it appears that bipolar spindles are still able to form in the absence of a stable Ran-GTP gradient, implying the existence of other factors that might support spindle assembly in the maturing oocyte. A recent study investigating acentriolar spindle formation in the early mouse embryo has discovered that centriolar proteins, namely Plk4 and Cep152, which are present despite the absence of centrosomes, are crucial for microtubule nucleation and spindle assembly. However, the mechanism of acentrosomal spindle formation in the mouse oocyte is thus far unknown. It has been hypothesized that the long duration of metaphase (6-8 hours) would allow time for multiple spindle assembly factors to form a robust microtubule network, even in the absence of a Ran-GTP gradient. On the other hand, the fact that enucleation of oocytes abrogates bipolar spindle formation, has supported the idea that indeed other nuclear factors might exist that are responsible for regulating microtubule nucleation. Consistent with studies in *Xenopus* egg extracts that point to an important role of Aurora A in chromosomal MT nucleation, we find using small molecule inhibitors that Aurora A but not Auroras B/C contribute to bipolar spindle assembly in meiosis I. Using a combination of pathway-specific inhibitors and dominant negative constructs, we find that Plk4 also contributes to this process. These two protein kinases appear to act in addition to Ran-GTP to locally stabilize microtubules surrounding chromatin, and synergism between these pathways is required to build the bipolar meiotic spindle. Interestingly, these proteins and several of their partners are concentrated in the nucleus and accumulate around chromatin at the time of the initial MT nucleation following nuclear envelope breakdown. Inhibition of any of these pathways strongly reduces the early stages of MT nucleation, but does not interfere with the actin-dependent migration of chromatin to the oocyte cortex. Eventually, cytoplasmic MTOCs nucleate small aster-like spindles and meiotic exit is able to occur.

P185**Board Number: B293****Spindle Matrix Formation is Required for Cell Cycle Progression.**J. Johansen¹, C. Yao¹, C. Wang¹, Y. Li¹, J. Girton¹, K.M. Johansen¹;¹Biochemistry, Biophysics and Molecular Biology, Iowa State University, Ames, IA

A paramount issue in mitosis is the synchronization of events required for cell cycle progression, and although many previous studies have identified critical regulatory factors that act to coordinate the

myriad activities involved in setting up a spindle and organizing chromosomes upon it, how these diffusible regulatory factors are spatially organized and confined to the spindle region in the absence of a diffusion barrier after nuclear envelope breakdown (NEB) is not well understood. However, in *Drosophila* we have identified four nuclear proteins, Skeletor, Chromator, Megator, and EAST from two different nuclear compartments that interact with each other and that redistribute during prophase to form a dynamic, gel-like spindle matrix that embeds the microtubule spindle apparatus (MBoC 23:3532, 2012). This matrix exists independently of microtubules and the NE and specific interactions between spindle matrix molecules are necessary for complex formation and cohesion. In order to address how the spindle matrix interacts with cell cycle components we have taken a live imaging approach to determine the relative timing of localization and cross-interactions of these proteins. Previously, we have shown that the spindle matrix protein Megator and its human homolog Tpr have an evolutionarily conserved function as spatial regulators of the spindle assembly checkpoint proteins Mad2 and Mps1. Here we show that a number of key cell cycle proteins such as Cyclin B, Polo, Ran, 14-3-3 and Endos also are co-localized at enriched levels within the spindle matrix during mitosis and that this localization is independent of microtubules. Furthermore, prevention of spindle matrix formation by injection of a function blocking antibody to the spindle matrix protein Chromator results in cell cycle arrest prior to NEB phenocopying the triple RNAi knockdown of Cyclins A, B, and B3 (McClelland and O'Farrell, Curr. Biol. 18:245, 2008) Interestingly, in such embryos the dynamic relocation of Polo and Cyclin B to the nuclear rim and kinetochores is abrogated and Polo is not imported into the nucleus. This is in contrast to colchicine-arrested embryos where the wild-type dynamics of these proteins are maintained. Furthermore, we show that the spindle matrix prevents Pdi-GFP-marked vesicular membranes from entering the nuclear space after NEB although they are permeable to microtubules. These studies promise to provide a mechanistic framework for understanding how cell cycle factors are physically confined and organized in the spindle region in organisms with open or semi-open mitosis, allowing for spatial and temporal integration of signaling events leading to mitotic progression and chromosome segregation.

Board Number: B294

Plk4 regulation of acentriolar MTOC architecture is essential for meiotic division of mouse oocytes.

M. Luksza¹, J. Kanaan¹, V. Marthiens², R. Basto², M. Verlhac¹;

¹CIRB, UMR-CNRS 7241/INSERM U1050, Coll De France, Paris Cedex, France, ²Institut Curie, Paris, France

Spindles of most animal cells are assembled from canonical centrosomes, build up of two centrioles and their surrounding pericentriolar material. However, most oocytes lose their centrioles during their growth in the ovary yet do assemble functional meiotic spindles able to segregate chromosomes. In fully-grown mouse oocytes, acentriolar MTOCs (aMTOCs, MicroTubule Organizing Centers) gather as large pericentriolar material foci around the nuclear envelope in prophase I of meiosis. At meiosis resumption, these foci are rapidly stretched around the nuclear envelope, fragmenting into smaller

pieces in a dynein- and MT-dependent manner (Łuksza 2013). We address here the importance of such timely reorganization of aMTOCs. We show that Plk4, a major kinase in centriole duplication, plays an essential role in aMTOCs organization. First we show that endogenous Plk4 protein is present on aMTOCs in the mouse oocyte. Second, transgenic overexpression of Plk4 specifically during oocyte growth impacts the morphology of aMTOCs. Indeed it induces their precocious fragmentation in prophase I. This in turn has major consequences; increasing their MT-nucleating capacity and promoting early meiotic spindle bipolarization as well as assembly of larger spindles. Such robust spindles contain abnormal levels of incorrect bivalent attachments, which delay SAC inactivation impeding on the transition to anaphase I. These defects are not due to increased levels of Plk4 activity during meiotic divisions, since the injection of cRNAs encoding for Plk4 into fully grown oocytes does not perturb meiosis I progression nor affects aMTOCs fragmentation. We describe here a novel function for Plk4, namely in controlling pericentriolar material organization in the absence of centriole, a function that is essential for proper progression into meiosis I of mouse oocytes. Furthermore we show here that over-fragmented aMTOCs compromise Kinetochore-MTs attachments and chromosome congression during female meiosis.

The Relationship Between Localization and Function of the Chromosomal Passenger Complex in *Drosophila melanogaster* Oocytes.

R.A. Battaglia¹, S.J. Radford¹, K.S. McKim¹;

¹Waksman Institute, Piscataway, NJ

Accurate segregation of chromosomes during meiosis is required to preserve the correct amount and distribution of genetic material in eggs and sperm. Errors in chromosome segregation are the leading cause of miscarriages and also lead to genetic diseases such as Down syndrome. In female meiosis of many animals, spindle assembly occurs without centrosomes, the microtubule organizing centers of the cell. In *Drosophila* oocytes, the chromosomal passenger complex (CPC), which consists of INCENP, Aurora B kinase, Survivin, and Borealin, is required for chromosome-based spindle formation and bi-orientation of the centromeres. In addition, the CPC promotes the localization of additional spindle assembly factors, supports spindle maintenance, and participates in kinetochore assembly. How the CPC functions in all of these processes is not known, but we hypothesize that the localization of the CPC is important. At metaphase in oocytes, the CPC localizes with central spindle microtubules in a ring around the chromosomes and may be transiently at centromeres. One possibility is that the CPC starts on centromeres and then moves onto the central spindle. Alternatively, there may be two separate populations of CPC, one that localizes to centromeres and a separate population that localizes to microtubules. By creating RNAi-resistant mutant INCENP transgenes that will manipulate the localization of the CPC, we will test whether centromere-localized and/or central spindle-localized CPC

provide the functions of the CPC in oocytes. We will force the CPC to localize to the centromeres, kinetochores, chromatin and microtubules. Conversely, we will prevent CPC localization to the centromeres and microtubules. It is possible that CPC localization to chromatin or centromeres is not required for bipolar spindle formation and that when the CPC is unable to localize to centromeres, it will have only bi-orientation defects. However, if the CPC must first localize to centromeres before it can transition to the central spindle, this mutant may fail to assemble a spindle. Observation of the effect on spindle assembly and bi-orientation by these mutants will elucidate the CPC's mechanism in meiosis.

PP1 antagonises Aurora B in *Drosophila* oocytes for chromosome structure, cohesion and kinetochore localisation.

A. Das¹, K.S. McKim²;

¹Cell and Developmental Biology, Rutgers University, Piscataway, NJ, ²Waksman Institute, Piscataway, NJ

Reversible protein phosphorylation allows cells to direct progression through cell cycle. The significance of protein kinases in cell cycle regulation and progression has been well established. In *Drosophila* female germline Aurora B kinase, a member of the chromosomal passenger complex (CPC), is required for meiotic spindle assembly and chromosome segregation. We have also seen that if an Aurora B inhibitor is added after spindle assembly is complete, the spindle completely disintegrates and kinetochore proteins fail to localise. This indicates that continual phosphorylation activity is required due to either the presence of multiple phosphatases or degradation. Hence the protein phosphatases may play equally important reciprocal roles in cell cycle regulation and the processes involved. We have looked at the role of the serine/threonine protein phosphatase 1 (PP1) in female meiotic chromosome segregation and spindle assembly. In PP1 depleted oocytes we observe a gross disorganization of spindle microtubules and the length and shape of these spindles resemble prometaphase spindles suggesting a defect in progression to metaphase. In addition the karyosome, a structure into which all the chromosomes are compacted, is broken into several pieces with a loss of sister-centromere cohesion. This is surprising since PP2A is usually required for maintaining cohesion in mitotic cells. Kinetochore proteins like Spc105R however are unaffected by loss of PP1. We have also found that some but not all of these phenotypes are due to phosphorylation by Aurora B. The karyosome defect and loss of cohesion in oocytes lacking PP1 is rescued by Aurora B inhibition. In addition the loss of kinetochore protein Spc105R at centromeres upon inhibition of Aurora B is also rescued when PP1 is absent. These results suggest that PP1 may antagonize Aurora B for maintaining cohesion, karyosome integrity and kinetochore protein localization. However, the complete loss of the meiotic spindle caused by an Aurora B inhibitor is not restored by loss of PP1. Thus, other phosphatases may negatively regulate spindle assembly and/or Aurora B-dependent phosphorylation is required to maintain constant incorporation of spindle associated proteins throughout meiosis.

P189**Board Number: B301****Three-dimensional reconstruction of female meiosis in *C. elegans*.**I. Lantzsch¹, M. Srayko², S. Prohaska³, T. Müller-Reichert¹;¹Medical Faculty "Carl Gustav Carus", TU Dresden, Dresden, Germany, ²Univ Alberta, Edmonton, AB,³Zuse Institute, Berlin, Germany

In meiosis, haploid gametes are produced from a diploid progenitor cell and this process of genome haploidization differs between oogenesis and spermatogenesis. Similar to many other species, including *Drosophila*, *Xenopus*, mice and humans, the female meiotic spindles in *C. elegans* are anastral and acentrosomal [1,2]. At early metaphase, the microtubules form an elongated bipolar spindle, which is about 10 µm in length. The metaphase spindles then shorten to roughly 3-4 µm and adopt a barrel-like shape. During late anaphase, microtubules are only observed in the interzone between the separating chromosomes/chromatids. The mechanism of this reorganization of the microtubules during the metaphase-to-anaphase transition is not understood [3]. Here, we show three-dimensional reconstructions of meiotic spindles at different stages. The 3D models were obtained by correlative light and electron tomography. Our anaphase I model shows about 4000 microtubules in between the chromosomes. Currently, we are analyzing the average length and the length distribution of microtubules to test models of chromosome segregation. In addition, we are investigating, whether microtubule assembly in this anaphase 'inside-out' spindle nucleation is taking place close to the surface of the chromosomes. Parallel to this wild-type characterization of the female meiotic spindles, we are characterizing candidate genes involved in various aspects of spindle assembly. One candidate protein for 3D reconstruction is the microtubule depolymerising kinesin-13 member, KLP-7/MCAK.

P190**Board Number: B302****Feedback control of chromosome separation by a midzone Aurora B gradient.**O. Afonso¹, I. Matos^{1,2}, A. Pereira¹, P. Aguiar^{1,3}, H. Maiato^{4,5};

¹Chromosome Instability and Dynamics Laboratory, IBMC, Porto, Portugal, ²Laboratory of Mammalian Cell Biology and Development, Howard Hughes Medical Institute, The Rockefeller University, New York, NY, ³Center for Mathematics, Universidade do Porto, Porto, Portugal, ⁴Chromosome Instability Dynamics Laboratory, Instituto de Biologia Molecular e Celular, Universidade do Porto, Porto, Portugal, ⁵Cell Division Unit, Department of Experimental Biology, Faculdade de Medicina, Universidade do Porto, Porto, Portugal

Accurate chromosome segregation during mitosis requires the physical separation of sister chromatids prior to nuclear envelope reassembly (NER). However, how these two processes are coordinated

remains unknown. Using live-cell imaging, RNAi, pharmacological inhibitions and laser microsurgery in *Drosophila* S2 cells, we identified a conserved feedback control mechanism that delays chromosome decondensation and NER in response to incomplete chromosome separation during anaphase. A midzone-associated Aurora B gradient was found to monitor chromosome position along the division axis and prevent premature chromosome decondensation by retaining Condensin I. PP1/PP2A phosphatases counteract this gradient to trigger chromosome decondensation and NER. Thus, the Aurora B gradient appears to mediate a surveillance mechanism that prevents chromosome decondensation and NER until effective separation of sister chromatids. This promotes the correction and re-integration of lagging chromosomes in the main nuclei prior to completion of NER.

Chromosome segregation during male meiosis in *C. elegans*.

G. Fabig¹, J. Bruges², C. Eckmann², T. Müller-Reichert¹;

¹Medical Faculty "Carl Gustav Carus", TU Dresden, Dresden, Germany, ²MPI-CBG, Dresden, Germany

We aim to characterize male meiosis I and II in *C. elegans*. Germ cells in the male worm mature while slowly moving from the distal to the proximal part of the gonad ^[1]. During this process undifferentiated germ cells leave the mitotic region at the distal tip of the gonad and undergo a transition to early stages of meiotic prophase I. After getting disconnected from the syncytial core (rachis), the germ cells form primary spermatocytes, while undergoing a series of cytological events during the formation of the bipolar spindles. Segregation of homologous chromosomes in meiosis I and sister chromatids in meiosis II results in four haploid spermatids from one single primary spermatocyte ^[2]. We apply both light microscopy and electron tomography to gain novel insights into the dynamics and ultrastructure of the male meiotic spindles. Using light microscopy, we image meiotic divisions within immobilized males that are fluorescently labeled with GFP::gamma-tubulin and mCherry::histone H2B. We currently determine the dynamic properties of both meiotic spindles in wild-type specimens. Furthermore, we apply laser microsurgery to manipulate the segregation of the single sex chromosome. For electron tomography, we apply high-pressure freezing followed by freeze-substitution of whole animals ^[3]. After semi-thick sectioning (300 nm serial sections) through whole worms, we aim to localize the meiotic region inside the male gonad in order to reconstruct and segment different stages of meiotic spindles in ultrastructural detail. Comparing wild-type and mutant situations ^[4, 5], our long-term goal is to integrate the data on spindle dynamics and ultrastructure to develop a mechanistic model of spindle assembly and sex chromosome segregation in *C. elegans* male meiosis.

P192**Board Number: B304****Metabolic Imaging and the Role of Cellular Energy in Cell Division.**T. Sanchez¹, D. Needleman¹;¹Harvard School of Engineering and Applied Sciences, Cambridge, MA

Metabolic defects and chromosome segregation errors co-occur in cancer, non-competent embryos resulting in failed pregnancies, and aging. It is unclear to what extent metabolic defects cause chromosome segregation errors, or chromosome segregation errors cause metabolic defects, or both are caused by other factors. To study this issue, we are investigating the relationship between mitochondrial metabolism and chromosome segregation in *C. elegans* and mouse oocytes and embryos.

We are performing quantitative metabolic imaging by measuring endogenous NADH and FAD fluorescence with fluorescence lifetime imaging microscopy (FLIM), allowing us to determine the concentrations, lifetimes, and enzyme interactions of these central metabolites. Our preliminary results show clear distinctions between metabolic states of various cell types. We are quantitatively characterizing how defined biochemical and genetic perturbations produce metabolic changes in these cells, and we will study the extent of corresponding changes in spindle morphology and dynamics, and chromosome segregation rates.

P193**Board Number: B305****Adaptability of Intracellular Structures to Variations in Cell Size.**M.C. Good¹, M.D. Vahey², D.A. Fletcher^{3,4,5}, R. Heald¹;

¹Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, ²Bioengineering, University of California, Berkeley, Berkeley, CA, ³Department of Bioengineering, University of California, Berkeley, Berkeley, CA, ⁴Biophysics Graduate Group, University of California, Berkeley, Berkeley, CA, ⁵Physical Biosciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA

Cells exist in a wide variety of shapes and sizes – from round eggs millimeters in diameter to highly elongated neurons with sub-micron extensions. Despite dramatic physical differences, growth and division of these cells is dependent on functional organelles, requiring that these intracellular structures adapt to a wide range of cell geometries. The mitotic spindle, a dynamic microtubule-based structure required for chromosome segregation, provides an important example of this flexibility. During *Xenopus* early embryo development, cell volume reduces nearly one million-fold due to division in the absence of growth, and spindle size scales with the spatial dimensions of the cell. An interesting question is how intracellular size regulation is achieved. Possible explanations include changes in cytoplasmic composition tied to a developmental program or direct coupling of spindle assembly to physical parameters such as cell volume and diameter. The difficulty of modulating cell size in embryos makes it hard to differentiate between these hypotheses, necessitating the construction of cell-like system with

controllable size. By combining droplet microfluidics and cell-free cytoplasmic extracts prepared from various stages of development, I was able to generate functional spindles and nuclei inside compartments whose diameter can be tuned from microns to millimeters, recapitulating the spindle size-scaling trend observed during *Xenopus* embryogenesis. By modulating droplet diameter and geometry, I discovered that metaphase spindle size is set by compartment volume, not shape, suggesting that limiting amounts of cytoplasmic material can restrict spindle growth. Various experimental results and a mathematical model support the hypothesis that tubulin is at least one component whose levels become limited by the cell volume decrease in early development, thereby constraining spindle length and matching it to cell size. In the future, by extending this encapsulation technology to other organelles and intracellular processes, it should be possible to uncover additional principles of size regulation and identify new pathways that respond to cell size. The significance of this research lies in the intimate connection between cell size and embryo development, and the observation that cell and organelle size are often misregulated in disease.

Role of heat shock protein 70 in the assembly of mitotic spindles.

C. Fang¹, H. Kuo¹, L. Yih¹;

¹Institute of Cellular and Organismic Biology, Academia Sinica, Taipei, Taiwan

The expression of heat shock protein 70 (HSP70) is high in many tumors. The elevated level of HSP70 negatively correlates with prognosis and efficacies of chemotherapeutics, implying a supporting role of HSP70 in tumor cell survival. Accumulated studies also demonstrated that HSP70 interacts with proteins of mitotic structures including spindle poles, microtubule motors, and kinetochores, indicating that HSP70 may involve in the regulation of assembly of mitotic structures and mitosis progression. In this study, we explored the role of HSP70 during mitosis by treating cells with a HSP70 inhibitor or transducing cells with HSP70-specific shRNA. The effects of these treatments on mitosis progression, mitotic spindle assembly, and cell viability were investigated. Our results showed that HSP70 accumulated at the spindle pole and co-localized with γ -tubulin and pericentrin during mitosis. Inhibition of HSP70 or depletion of HSP70 by shRNA transduction led to disruption of microtubule assembly, formation of abnormal mitotic spindles, and interference of mitosis progression. These results indicate that HSP70 may be required for the assembly and/or maintenance of a functional mitotic spindle.

P195**Board Number: B307****Clinically Relevant Concentrations of Taxol Cause Chromosome Missegregation Rather than Mitotic Arrest.**L.M. Zasadil¹, M. Burkard², B.A. Weaver¹;¹Cell and Regenerative Biology, Univ Wisconsin-Madison, Madison, WI, ²Department of Medicine, Univ Wisconsin-Madison, Madison, WI

Taxol, a microtubule-stabilizing drug, is commonly used to study fundamental mechanisms of mitosis. It is also used in the clinical setting as a chemotherapeutic agent to treat a variety of cancers. For the three decades that taxol has been used in humans, it has been thought to exert its antitumor effects by arresting cells in mitosis, since this is observed at concentrations typically used in cell culture. After treatment with μM or high nM concentrations of taxol, cells with an intact mitotic checkpoint arrest in mitosis, which often leads to cell death. Though not directly shown, it has been widely assumed that taxol also causes mitotic arrest in patient tumors in vivo. In a clinical study, we have measured tumor response and intratumoral drug concentration in breast tumors following taxol treatment. Our data indicate that intratumoral concentrations of taxol are lower than those traditionally attained in cell culture. Moreover, mitotic arrest is not necessary for tumor shrinkage in response to taxol therapy. However, the incidence of multipolar spindles uniformly increased in patient tumors following taxol treatment. These features are mimicked by treatment of cultured cells with clinically relevant concentrations of taxol, which vary by cell type but are in the low nM range. Unlike treatment with higher concentrations, treatment with clinically relevant doses of taxol does not cause a substantial mitotic arrest or an increase in death from interphase without passage through mitosis in the presence of the drug. Instead, cells treated with clinically relevant concentrations of taxol divide with relatively normal kinetics on multipolar spindles to form two or three daughter cells, resulting in chromosome missegregation. Timelapse imaging reveals that initially bipolar spindles evolve into multipolar spindles, which are then often partially focused before anaphase onset, to produce two-or-more-way divisions of DNA. Exposure to clinically relevant doses of taxol is sufficient to induce aneuploidy in chromosomally stable cells and causes cell death in both chromosomally stable and unstable cells. The success of taxol and its presumed mechanism of action have resulted in the development of additional drugs intended to cause mitotic arrest, including those targeting Eg5 and Plk1. These drugs have not yet shown the level of clinical success taxol has, perhaps because the antitumoral effects of taxol are due to chromosome missegregation rather than mitotic arrest. Although taxol is considered highly effective, only approximately half of all patients experience tumor shrinkage after taxol treatment. At present, there is no way to identify and selectively treat patients that will benefit from taxol therapy. These data reveal an alternate mechanism of action for taxol that may be useful in identifying mechanisms of resistance to this type of chemotherapy.

P196**Board Number: B308****An RNAi screen to identify genes required for acentrosomal spindle function in *C. elegans*.**I. Wolff¹, T.J. Mullen², C.M. Heath¹, A.C. Davis¹, M. Tran¹, S.M. Wignall¹;¹Northwestern Univ, Evanston, IL, ²Northwestern Univ, Chicago, IL

During cell division in most cell types, duplicated centrosomes nucleate microtubules and ultimately form the poles of the spindle. However, in many species, oocytes lack centrosomes and therefore spindle assembly occurs through a different mechanism. Our aim is to investigate acentrosomal spindle formation by identifying proteins that are required for proper spindle assembly and chromosome congression in *C. elegans* oocyte meiosis. We have completed a screen of 2,025 genes that were previously classified as embryonic lethal in genome-wide screens. This class includes genes known to be required for acentrosomal meiotic spindle function, such as *mei-1* and *mei-2* (regulators of microtubule stability), *aspm-1* (spindle organization) and *bub-1* (kinetochore component). We screened for defects in spindle formation and/or chromosome alignment using worms co-expressing GFP::histone and GFP::tubulin to visualize chromosomes and microtubules simultaneously. Additionally, our screening strain carried a temperature-sensitive mutation affecting the Anaphase Promoting Complex (APC) that prevents entry into anaphase I, allowing us to arrest oocytes at metaphase of meiosis I to better focus on spindle formation and chromosome alignment. Out of 2,025 genes screened, depletion of 291 led to gross defects in the worm, such as aberrant gonad morphology, sterility and defective worm growth; therefore, these could not be screened for meiotic spindle defects. Of the remaining genes, 63% were embryonic lethal under our conditions. 400 of these showed defects in spindle morphology such as monopolar spindles, multipolar spindles, disorganized spindles, as well as defects in chromosome congression. As expected, *MEI-1*, *MEI-2*, *ASPM-1* and *BUB-1* were in this class and resulted in dramatic spindle morphology defects following RNAi. In addition, a number of genes that are uncharacterized in worms were shown to cause defects in spindle morphology, some of which have putative homologs in other organisms. Initial results from our screen and preliminary characterization of our candidate genes will be reported. Future characterization of the genes identified in our screen may help us better understand the mechanisms involved in acentrosomal spindle assembly.

P197**Board Number: B309****Cenexin, a mother centriole appendage protein, is required for spindle orientation during mitosis.**H. Hung¹, H. Hehnlly^{1,2}, S. Doxsey¹;¹Univ Massachusetts Med Sch, Worcester, MA, ²Univ of Washington, Seattle, WA

Polarized epithelial cells are required for organ function, but whether this polarization is initially established during late cell cycle has not been clearly resolved. One argument for establishment during late cell cycle is that the epithelial layer can undergo constant regeneration to replace dead and/or damaged cells. During this time, it is known that appropriate orientation of the mitotic spindle relative to cell polarity cues can contribute to cell fate determination, which would thus establish tissue architecture. Another contributor to spindle orientation is the spindle pole. More specifically, one of the two spindle poles contains more mother centriole appendage proteins than the other. Based on this, we propose a model where the centrosome with elevated appendage proteins and polarity cues at the cell cortex establish spindle orientation. One cell cortex polarity complex examined, NuMA/LGN/Gai, is implicated in spindle orientation through its interaction with astral microtubules. In genetically-engineered kidney epithelial cells (MDCK) we found that cells depleted of the sub-distal appendage component, Cenexin, lead to asymmetric spindle orientation in both two- and three-dimensional (3D) cell culture systems. In contrast, depletion of the distal appendage protein, Cep164 had no effect on spindle orientation. In 3D culture, Cenexin-depleted cells induced a 2-fold increase in the number of lumina compared to control, which correlated with increased spindle misorientation. Surprisingly, an increase in cortical NuMA localization, and disorganization of a microtubule destabilizer, Kif2a, at the pole was also observed with Cenexin-depletion. Taken together we propose that Cenexin modulates spindle orientation by maintaining spindle pole localized Kif2a, which regulates microtubule organization and contributes to cortical NuMA localization.

P198**Board Number: B310****Mitotic Repertoire of Acetylated Survivin.**S.P. Wheatley¹, A.M. Ajaberi¹;¹School of Life Sciences, Univ Nottingham, Nottingham, United Kingdom

Survivin is a cancer associated protein that was originally cloned as a member of the inhibitor of apoptosis (IAP) family, and later shown to be an essential mitotic protein. The dual pro-survival functions of survivin depend on the localization of the protein within immunochemically distinct pools located in cytoplasm, mitochondria, nucleus and on the chromosomes. During mitosis, survivin operates in a complex with the chromosomal passenger proteins, aurora-B kinase, borealin and INCENP, which localises initially to the centromeres where it regulates chromosomal movements, and later to the equatorial cortex of the cell where it is required for cytokinesis. The mitotic activity of survivin is

phospho-regulated by a number of kinases including Cdk1, aurora-B and plk1. Recently, it has been shown that residue K129 in its C-terminal alpha helical coil is acetylated and that this post-translational modification affects the subcellular localisation of survivin during interphase, however, whether this acetylation event contributes to the regulation of mitosis remains unknown. In this study, we ask whether mimicking acetylation by mutating this site to an alanine alters the behaviour of during mitosis. Our data demonstrate that constitutive acetylation of this site inhibits cell proliferation and causes errors in chromosome segregation during mitosis.

Microtubule dynamics are modulated by changes in cytoplasmic volume: a possible mechanism for mitotic spindle scaling.

A. Milunovic-Jevtic¹, A. Matov¹, J.W. Hazel¹, A.C. Groen², K. Ishihara², T.J. Mitchison², J. Gatlin^{1,3};
¹Department of Molecular Biology, University of Wyoming, Laramie, WY, ²Department of Systems Biology, Harvard Medical School, Boston, MA, ³Molecular Cellular Life Sciences Program, University of Wyoming, Laramie, WY

Spindle size is determined by mechanisms intrinsic to the spindle itself, such as motor-dependent sliding and microtubule polymerization dynamics, and by extrinsic mechanisms like cell size and cortical/cytoplasmic pulling forces. The combined action of these processes ensures constancy of spindle size and shape and a high fidelity of chromosome segregation during cell division. During early development in animals, changes in cell size that accompany rapid reductive divisions result in cells with smaller and smaller spindles, likely due to a progressive reduction in the available amounts of essential spindle components. The mechanistic link between component limitation and spindle size remains poorly understood. Recent studies suggest that changes in microtubule polymerization dynamics, specifically growth rate, could account for spindle scaling during development, with spindle length exhibiting a positive correlation with microtubule growth rates. This led us to predict that microtubule growth rates might be influenced by cell size. To investigate the relationship between microtubule dynamics and cell size, we combined microfluidics and cell-free extracts to encapsulate artificial microtubule organizing centers and sperm nuclei in discrete droplets of *X.laevis* egg extract. The extract was spiked with fluorescently labeled tubulin and mCherry-EB1, a protein which associates with the growing microtubule ends forming fluorescent comets. Microtubule dynamics we characterized by EB1+TIP tracking using ClusterTrack MATLAB software package. Our measurements indicate that microtubule growth velocities correlate with extract volume. These results suggest that volume-dependent modulation of microtubule growth rates is mechanism linking limiting cytoplasmic pools with changes in spindle size.

P200**Board Number: B312****Minus-End Directed Kinesin-14 Motors Align Anti-Parallel Microtubules to Control Metaphase Spindle Length.**

A. Hepperla¹, P. Willey², C.E. Coombes¹, S. Mukherjee¹, M. Winey*³, D. Odde⁴, E. Otoole⁵, M. Gardner¹;
¹Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN, ²Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN, ³MCDB, University of Colorado-Boulder, Boulder, CO, ⁴Biomedical Engineering, University of Minnesota, Minneapolis, MN, ⁵MCB, University of Colorado-Boulder, Boulder, CO

During cell division, a microtubule-based mitotic spindle mediates the faithful segregation of duplicated chromosomes into daughter cells. Proper length control of the metaphase mitotic spindle is critical to this process, and is thought to be achieved through a mechanism in which spindle pole separation forces from plus-end directed motors are balanced by forces from minus-end directed motors that pull spindle poles together. However, in contrast to this model, metaphase mitotic spindles with inactive Kinesin-14 minus-end directed motors often have shorter spindle lengths, along with poorly aligned spindle microtubules. A mechanistic explanation for this paradox is unknown. Using computational modeling, in vitro reconstitution, live-cell fluorescence microscopy, and electron microscopy, we now find that the budding yeast Kinesin-14 molecular motor Kar3-Cik1 can efficiently align spindle microtubules along the spindle axis. This then allows plus-end directed Kinesin-5 motors to efficiently exert the outward microtubule sliding forces needed for proper spindle bipolarity.

Cytokinesis 1**P201****Board Number: B313****Investigating the role of F-BAR proteins in cytokinesis.**

M. Marino¹, Y. Geng¹, O.A. Quintero¹, E.R. Griffis²;

¹Department of Biology, University of Richmond, Richmond, VA, ²Centre for Gene Regulation and Expression, University of Dundee, Dundee, Scotland

The goal of this research project is to identify the role that F-BAR proteins play during cytokinesis in *D. melanogaster* S2 cells. It was discovered that F-BAR proteins are essential for fission yeast cell division and act cooperatively as membrane-bending proteins (Martin-Garcia et al. J. Cell Sci. 2014); and recent work has shown that a *Drosophila* F-BAR protein is also required for coupling the membrane to the contractile ring (Takeda et al. Open Biology 2013). The first component of this research project is to identify if there are other F-BAR proteins involved in cytokinesis in *Drosophila* cells, and if they behave synergistically. This will be achieved by using dsRNAs to knock down six specific F-BAR containing proteins alone and in combinations. Cells treated with dsRNAs were imaged and the images were

analyzed to determine the percentage of multinucleate cells. Preliminarily, each F-BAR knockdown induced a higher percentage of multinucleate cells than untreated control cells. However, a combinatorial knockdown of two F-BARs at once was not shown to induce a stronger multinucleate phenotype.

The second component of this research project is to discover the cellular localization of the six F-BAR domain-containing proteins. The localization of these proteins will be made possible by creating GFP tagged F-BAR constructs. These constructs can be transfected into cells for fixed and live-cell imaging. When we observed GFP-F-BAR-CG8176 and mcherry-tubulin, in S2 cells spread on ConA, we discovered that the F-BAR localized in spots on the basal cell membrane radiating from the center of the cell. GFP-F-BAR-CG33094 exhibited an identical localization.

Further dsRNA knockdown experiments are required to confirm whether certain F-BAR depletions cause cytokinetic defects. Also, the matching localization of two separate F-BAR proteins suggests a shared localization among many F-BAR domain-containing proteins in S2 Cells. Further cloning and imaging is necessary to determine the localization of F-BAR proteins during the process of cytokinesis.

Board Number: B314

Cdc14 Regulates Actin Ring Formation in Budding Yeast Via Dephosphorylation of Iqg1.

K.B. Shannon¹, D.P. Miller¹;

¹Biological Sciences, Missouri ST, Rolla, MO

In budding yeast, the IQGAP protein Iqg1 is required to recruit actin filaments to the actomyosin ring, as well as for contraction of the ring during cytokinesis. Iqg1 contains four perfect CDK consensus sites in the N-terminus, and mutation of these sites to alanine (*iqg1-4A*) leads to premature formation of the actin ring prior to anaphase onset, and prevents proper actomyosin ring contraction. Since Cdc14 dephosphorylates many CDK targets, we looked at the effects of manipulating Cdc14 levels on actomyosin ring formation. Overexpression of Cdc14 induces premature actin ring formation in nocodazole arrested cells. Using a *cdc14-1* temperature sensitive mutation to inactivate Cdc14 and overexpression of Sic1 to bypass the mitotic arrest of *cdc14-1* cells, we show that Cdc14 is required for actin ring formation. This defect can be rescued by expressing *iqg1-4A*, demonstrating that Iqg1 is the sole target of Cdc14 that regulates actin ring formation. Iqg1 is the first actomyosin ring target identified for Cdc14.

P203**Board Number: B315****Anillin proteins regulate intercellular bridge stability to maintain syncytial organization of the *C. elegans* germline.**R. Amini¹, A. St-Pierre-See², N.T. Chartier², J. Labbe³;¹Systems Biology, IRIC, Univ Montral, Montreal, QC, ²Pathology and Cell Biology, IRIC, Univ Montral, Montreal, QC, ³Institute for Research in Immunology and Cancer, Department of Pathology and Cell Biology, University of Montreal, Montreal, QC

Cells typically complete their division with cytokinesis. However, during development of certain tissues, mitotic division is followed by incomplete cytokinesis, giving rise to interconnected cells in a shared cytoplasm, or syncytium. Syncytia are a conserved feature of female and male germline of most species. Despite this, how syncytium formation is regulated remains elusive. To understand this, we studied the syncytial *C. elegans* germline wherein germ cells (GCs) remain connected via intercellular bridges. Using live-cell imaging, we found that the contractility regulators ANI-1 (Anillin), NMY-2 (myosin), UNC-59 (septin), ZEN-4 (MKLP1) and CYK-7 localize to GC intercellular bridges. ANI-2, a shorter isoform of Anillin, is enriched between the two primordial GCs from the onset of GC specification during embryogenesis and further accumulates at the intercellular bridges in the gonad. Analysis of ANI-2 localization revealed that syncytial architecture occurs progressively during larval development. Loss of ANI-2 disrupted intercellular bridge integrity and resulted in GC multinucleation, and thus severe gonad disorganization. In contrast, ANI-1 depletion partially restored syncytial organization in *ani-2* mutants, suggesting that a balance of activity between the two Anillin proteins at the intercellular bridge is required for the proper organization of the syncytial germline. We are currently investigating the mechanism by which the germline syncytium is formed to understand how controlled incomplete cytokinesis promotes formation of the syncytial *C. elegans* gonad.

P204**Board Number: B316****The role of cortical dynein during *C. elegans* female meiotic spindle rotation.**J. Flynn¹, M. Ellefson¹, K. Messina¹, P. Kuehnert¹, F. McNally¹;¹Univ California-Davis, Davis, CA

Meiosis is a specialized cell division required for sexual reproduction characterized by a single round of DNA replication followed by two rounds of chromosome segregation. The molecular machine responsible for accurately segregating chromosomes is the meiotic spindle. In female meiosis, to properly segregate chromosomes the spindle must correctly orient its pole-to-pole axis perpendicular to the cell cortex. In *C. elegans*, this perpendicular orientation is achieved through a dynein dependent process called spindle rotation. Spindle rotation has been shown to correlate with increased dynein localization on the spindle poles (Ellefson 2011, *J. Cell Biol.* 193:1229). However, in the female meiotic embryo, dynein has two distinct subcellular localizations: the spindle poles and the cell cortex. This begs

the question of whether or not cortical dynein plays a role in spindle rotation during female meiosis. To address this question, we will identify proteins required for cortical localization of dynein during meiosis then test whether these proteins are required for spindle rotation. We found that dynein recruitment to the cortex is not microtubule dependent, but is LIN-5 dependent. Other candidates that may be involved in recruiting dynein to the cortex during meiosis include proteins that are known to recruit dynein to the cortex in the *C. elegans* one cell mitotic embryo (Galpha and GPR), a protein that has been shown to recruit dynein to the cortex in an anaphase specific pathway in HeLa cells (Band4.1), and a cortical protein shown to suppress lethality induced by a conditional dynein heavy chain mutant (*efa-6*). We are currently testing whether depletion of these proteins prevents cortical dynein localization and meiotic spindle rotation.

The Chromosomal Passenger Complex (CPC) couples the actin and microtubule cytoskeletons during cytokinesis.

J.E. Landino¹, R. Ohi¹, M.E. Dumas¹;

¹Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

In animal cells, the microtubule (MT) and actin cytoskeletons are remodeled throughout cell division to facilitate chromosome segregation and cytokinesis. During anaphase, MTs organize into the spindle midzone while actin and myosin assemble into the cleavage furrow. Anaphase events – chromosome segregation, centrosome separation and cleavage furrow contraction – are closely coupled in space and time, implying that mechanisms may exist to link them. Indeed, other cellular processes that rely on both cytoskeletons, such as cell migration, use signaling-based feedback mechanisms to coordinate the activities of the actin and microtubule networks. We identified a novel pathway that stabilizes spindle midzone MTs (mMTs) at the onset of cleavage furrow ingression. Stabilization of mMTs during late anaphase depends on acto-myosin contractility, strongly suggesting that cross-talk between the actin and MT cytoskeletons occurs. We found that cells lacking CPC activity do not stabilize mMTs following cleavage furrow ingression, suggesting a novel role for the CPC in regulating MT stability during cytokinesis. The CPC is transported to mMT plus ends at the onset of anaphase by the kinesin Mklp2, and we have determined that the CPC also localizes to the cell cortex during anaphase *via* direct actin binding. Additionally, overexpression of CPC components rescues cytokinetic defects caused by Mklp2 depletion indicating there may be multiple pathways for targeting the CPC to the midzone. We propose a model in which actin binding by the CPC provides a second pathway to help recruit the complex to the cleavage furrow, and maintain its localization during anaphase and cytokinesis. We also propose that actin binding allows the CPC to mediate cross-talk between the actin and MT cytoskeletons, ultimately stabilizing mMTs following cleavage furrow ingression.

P206**Board Number: B318****Rac Antagonism of Cytokinesis in the Early Sea Urchin Embryo.**A. Ellis¹, S.P. Sepulveda¹, A. Alvarez², R. De La Rosa¹, J.H. Henson³, C.B. Shuster¹;¹Biology Department, New Mexico State University, Las Cruces, NM, ²New Mexico State University, Las Cruces, NM, ³Dickinson Coll, Carlisle, PA

z, John Henson and Charles B. Shuster Rho GTPases are critical modulators of the actin cytoskeleton, and while the role of RhoA during cytokinesis is well established, less is known about how Rac and Cdc42 contribute to cytoskeletal organization during the final stages of cell division. Neither Cdc42 nor Rac is thought to be required for cytokinesis, and several studies indicate that Rac inactivation is necessary for the completion of cytokinesis, possibly by suppressing Rac-mediated cell adhesion at the cell equator. To better understand the regulation of actin in the early embryo as well as the role of Rac during cytokinesis, we performed live cell imaging of actin dynamics during the first cell division of the sea urchin embryo. Studies to date revealed that in addition to microvilli and the contractile ring, there are other distinct populations of actin filaments that underwent dramatic changes during the first mitotic division. A thin layer of cortical actin could be detected that underwent a transient thinning upon anaphase onset, only to recover shortly before cytokinesis. Additionally, there was an explosive elaboration of cytoplasmic actin occurring just prior to the metaphase-anaphase transition, which initiated at the cell surface, and extended inward towards the cell center. Interestingly, RhoA activity was necessary for all actin structures in the egg, whereas neither Rac nor Cdc42 were required. However, expression of constitutively active Rac (Q61L) resulted in early cleavage arrest with aberrant cortical actin projections. Because there are several possible downstream pathways by which Rac may antagonize cytokinesis, well-characterized, effector-binding mutants were employed. Expression of Q61L Rac containing the PAK-binding mutation (Y40C) suppressed the aberrant cortical actin projections, but still resulted in cytokinetic failure during the first two cleavages. In contrast, expression of Q61L Rac carrying the F37A mutation, which affects Arp2/3 mediated actin polymerization, resulted in normal cleavage and actin organization. Together, these findings suggest that in non-adherent, spherical cells, Rac activity plays a direct role in antagonizing the cytokinetic apparatus, possibly through the promotion of Arp2/3-nucleated actin arrays. Current efforts are focused on verifying this notion, as well as examining whether Rac plays an active role in suppressing Rho activation during anaphase and cytokinesis.

P207**Board Number: B319****Regulation of Rho GEF Rgf3 by the arrestin Art1 in fission yeast cytokinesis.**R. Davidson¹, D. Laporte², J. Wu^{1,3};¹Department of Molecular Genetics, The Ohio State University, Columbus, OH, ²Biochemistry and Cellular Genetics, Institute of Biochemistry and Cellular Genetics, Bordeaux, France, ³Department of Molecular and Cellular Biochemistry, The Ohio State University, Columbus, OH

Rho GTPases, activated by guanine nucleotide exchange factors (GEFs), are essential regulators of polarized cell growth, cytokinesis, and many other cellular processes. However, the regulations of Rho GEFs themselves are not well understood. Rgf3 is an essential GEF for Rho1 GTPase in fission yeast cytokinesis. Here we show that Rgf3 protein levels and localization are regulated by arrestin-related protein Art1. *art1Δ* cells lyse during cell separation with a thinner and defective septum. Same as Rgf3, Art1 concentrates to the contractile ring starting at early anaphase and spreads to the septum during and after ring constriction. Moreover, Art1 localization depends on its C-terminus and Art1 is important for maintaining Rgf3 protein levels. Biochemical experiments reveal that Rgf3 C-terminus binds to Art1. Using an Rgf3 conditional mutant and with mislocalization experiments, we find that Art1 and Rgf3 are interdependent for localization to the division site. As expected, active Rho1 levels at the division site are reduced in *art1Δ* and *rgf3* mutant cells. Taken together, these data reveal a role for the arrestin-family protein Art1 in regulating the protein levels and localization of the Rho GEF Rgf3, which in turn modulates active Rho1 levels to build a division septum during cytokinesis.

P208**Board Number: B320****The putative Rho-GEF Gef3 interacts with the septin complex and regulates the GTPase Rho4 during fission yeast cytokinesis.**N. Wang¹, M. Wang¹, Y. Zhu¹, T. Grosel¹, D. Sun¹, J. Wu^{1,2};¹Department of Molecular Genetics, The Ohio State University, Columbus, OH, ²Department of Molecular and Cellular Biochemistry, The Ohio State University, Columbus, OH

Rho GTPases, activated by guanine nucleotide exchange factors (GEFs), are highly conserved molecular switches for signal transduction and regulate diverse cellular processes including cell polarization and cytokinesis. The fission yeast *Schizosaccharomyces pombe* has six Rho GTPases (Cdc42 and Rho1-Rho5) and seven Rho GEFs (Scd1, Rgf1-Rgf3, and Gef1-Gef3). The Rho GEFs for Rho2-Rho5 have not been unequivocally assigned. Gef3, the smallest Rho GEF, was barely studied. Here we show that Gef3 colocalizes with septins to a non-constricting double rings at the cell equator during division-septum formation. Gef3 physically interacts with and depends on the septin complex to localize. Purified Gef3 strongly interacts with Rho4 GTPase in vitro. Consistently, Gef3 and Rho4 are in the same genetic pathways to regulate septum formation and cell separation. Although localization of Rho4 is not affected in *gef3Δ*, the localizations of two potential Rho4 effectors, glucanases Eng1 and Agn1, are

abnormal, indicating a compromised activation of Rho4. Moreover, overexpression of active Rho4 or Eng1 rescues the cytokinesis defects of exocyst mutants and mutants containing *gef3Δ*. Together, our data suggest that the putative Rho-GEF Gef3 interacts with the septin complex and regulates GTPase Rho4 for septum formation and cell separation during cytokinesis.

Board Number: B321

The RhoGAP domain in centralspindlin directly contributes to activation of RhoGEF ECT-2 during cytokinesis.

D. Zhang¹, M. Glotzer¹;

¹Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

In animal cells, the small GTPase RhoA is essential for the contractile actomyosin network that drives cytokinetic furrowing. Counterintuitively, the evolutionarily conserved protein complex, centralspindlin, which contains a subunit, CYK-4, with a Rho family GAP domain, promotes RhoA activity. The regulatory N-termini of CYK-4 and the RhoA GEF ECT-2 directly interact. Various studies have indicated that the GAP domain is important for CYK-4 function, but the underlying mechanism remains controversial.

To determine whether the catalytic activity of CYK-4 GAP domain contributes to cytokinesis, we established single-copy transgenes in *C. elegans*, and mutated the catalytic residue R459 to specifically perturb the GAP activity of CYK-4. *cyk-4^{R459A}* mutant embryos fail to complete cytokinesis. RhoA activation involves a parallel, non-essential, nematode-specific activator of ECT-2, NOP-1. *cyk-4^{R459A};nop-1* embryos exhibit extremely weak furrow ingression. Mutations in CED-10/Rac1 do not modulate the defect in *cyk-4^{R459A};nop-1* mutant embryos, demonstrating that the defect resulting from loss of catalytic activity of the GAP domain is not due to hyperactivation of CED-10/Rac1. To investigate whether furrow ingression defects result from failure to fully activate or inactivate RhoA, we examined how the defect was modulated by depletion of the primary RhoA GAP, RGA-3/4. Remarkably, depletion of RGA-3/4 allowed cytokinetic completion in both *cyk-4^{R459A}* and *cyk-4^{R459A};nop-1* mutant embryos. Binding assays revealed that CYK-4^{R459A} binds to RhoA more strongly than CYK-4. To test whether the CYK-4^{R459A} cytokinesis defect results from sequestration of RhoA, we mutated charged surface residues in CYK-4. These variants reduce RhoA binding and cause more severe RhoA activation defects than CYK-4^{R459A}. These results suggest that CYK-4 has to bind to RhoA in order to fully activate ECT-2 and that CYK-4^{R459A}•RhoA•GTP complex does not effectively fulfill this role.

To obtain independent insight into how the CYK-4 GAP domain promotes cytokinesis, we identified mutations that suppress *cyk-4(or749)* to viability (*or749* has GAP domain mutation, causing cytokinetic failure). One isolate containing a substitution mutation in ECT-2 was proven to be causative. *ect-2(xs110)* mutant embryos exhibit hypercontractility during cytokinesis in a CYK-4-dependent manner. *ect-2(xs110)* and *cyk-4(or749)* mutually suppress. These results demonstrate that the primary defect in *cyk-4(or749)* is a failure to activate RhoA.

We show that the GAP domain of CYK-4 promotes ECT-2-dependent RhoA activation, and suggest that this activity is enhanced by RhoA binding to the GAP domain of CYK-4.

MgcRacGAP's GAP activity spatially restricts active RhoA and Rac1 during cytokinesis and maintains proper adherens junction structure in epithelial cells.

E.B. Breznau¹, A. Semack², A.L. Miller²;

¹Graduate Program in Cell and Molecular Biology, University of Michigan, Ann Arbor, MI, ²Department of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI

Cytokinesis is the last step of cell division where one cell is physically separated into two. In animal cells, localized activation of the small GTPase RhoA (RhoA-GTP) in a focused equatorial zone is essential for cytokinesis. Activation of RhoA is dependent on the guanine nucleotide exchange factor Ect2, which is spatially confined at the equatorial membrane by Centralspindlin, a complex of the kinesin MKLP1 and the GTPase activating protein (GAP) MgcRacGAP (Mgc). Both the identity of the GTPase targeted by Mgc's GAP activity and the question of whether phosphorylation of Mgc at serine 386 affects the specificity of Mgc's GAP activity are controversial. Here, using *Xenopus laevis* embryos as a model system, we examine for the first time Mgc's role in the intact vertebrate epithelium. We show that Mgc's GAP activity regulates the proper spatially restricted accumulation of both RhoA-GTP and Rac1-GTP during cytokinesis in epithelial cells. Phosphorylation at serine 386 within Mgc's GAP domain is not required for proper regulation of GAP activity toward RhoA or successful cytokinesis in the intact epithelium. However, perturbing Mgc's GAP activity leads to cytokinesis failure, abnormally increased accumulation of RhoA-GTP at the cleavage furrow, and increased local accumulation of both RhoA-GTP and Rac1-GTP at cell-cell junctions. Furthermore, Mgc regulates adherens junction but not tight junction structure, and Mgc's ability to regulate adherens junctions is dependent on its GAP activity. Cells expressing a Mgc GAP-dead mutant had defects in adherens junctions, which could be rescued by expressing dominant negative RhoA, suggesting that the defects are due to misregulated active RhoA. These results indicate that Mgc's GAP activity is necessary to down-regulate the active populations of RhoA at the division site and both RhoA and Rac1 at cell-cell junctions in epithelial cells, and failure to do so results in defects in both cytokinesis and cell-cell junctions.

P211**Board Number: B323****The GAP activity of *C. elegans* CYK-4 is required for incomplete cytokinesis in the syncytial germline but not for contractile ring constriction during embryonic cytokinesis.**K. Lee¹, R. Green¹, A. Desai¹, K. Oegema¹;¹Ludwig Institute for Cancer Research, La Jolla, CA

Contractility-based remodeling of the actomyosin cell cortex partitions nuclei into distinct cells during cytokinesis. An incomplete cytokinesis-like process also partitions nuclei into membrane-bound compartments that remain cytoplasmically connected in syncytial tissues such as the *C. elegans* germline and *Drosophila* embryo. Cortical remodeling during cytokinesis is directed by regulators concentrated on the anaphase spindle, including the Rho family GTPase-activating protein (GAP) CYK-4, a subunit of the centralspindlin complex, that also includes kinesin-6. CYK-4 is also required for nuclear partitioning in the germline and thus for organismal fertility. While the importance of CYK-4 is undisputed, the activities responsible for its specific functions are controversial. CYK-4 has two functional domains: (1) a GAP domain, predicted to target a Rho family GTPase, and (2) a C1 domain, which confers association with the plasma membrane. We have tested the importance of CYK-4 GAP activity as well as of the C1 domain in *C. elegans* by deleting or mutating each domain and analyzing embryonic cytokinesis and germline nuclear partitioning. As complete inhibition of CYK-4 prevents the generation of embryos, we engineered strains with an additional wild-type CYK-4 copy that is tagged with a degron that results in its elimination at the meiosis-to-mitosis transition to enable selective analysis of the consequences of engineered mutations on embryonic cytokinesis. All mutants in the GAP and C1 domains supported central spindle assembly. Deletions of either domain, or point mutations disrupting the C1 domain, disrupted contractile ring assembly and cytokinesis. However, mutation of GAP activity (by either a single point mutation in the catalytic residue R459A or a triple point mutation targeting the catalytic Arginine plus two other conserved residues important for GTPase binding: R459A/K495A/R499E: AAE) did not disrupt contractile ring assembly and constriction in the early embryo, although it did appear to compromise cytokinesis completion as abscission failed in ~16% of R459A and ~45% of AAE embryos. In contrast to embryonic cytokinesis, all mutants in the GAP and C1 domains, including the R459A and AAE GAP activity mutants, disrupted the incomplete cytokinesis-like process that partitions nuclei in the germline and severely reduced fertility. Thus, the GAP and C1 **domains** are essential for all CYK-4 functions, but GAP **activity** is required to promote abscission during embryonic divisions and for incomplete cytokinesis in the germline but not for contractile ring assembly and constriction.

P212**Board Number: B324****Role of GTP in Septin Assembly and Dynamics in *Ashbya gossypii*.**A. Khan¹, A. Gladfelter¹;¹Dartmouth College, West Lebanon, NH

Septins are GTP binding proteins that can come together to form rod-shaped hetero-oligomers. These rod complexes can give rise to filaments that organize into higher order structures. Septins have been shown to bind and hydrolyze GTP, however the relationship between septin assembly and GTP binding/hydrolysis is unclear. Here we use the filamentous fungus *Ashbya gossypii* to study the role of GTP in septin assembly and dynamics. In *Ashbya*, there are six mitotic septins encoded by CDC10, CDC3, CDC12, CDC11A, CDC11B and SHS1. While the position of most septins in the rod complex is fixed, Cdc11 and Shs1 can compete for the terminal position where they bind and interact with Cdc12. Using GTP binding mutants, we show that nucleotide binding can change Cdc12 binding partners in the septin rod complex, possibly by changing the oligomerization interfaces. This preference for Shs1 over Cdc11 changes the rod composition, which translates to behavioral changes of higher order structures *in vivo*.

P213**Board Number: B325****Protease-dead separase is dominant negative in the *C. elegans* embryo.**X. Bai¹, D. Mitchell¹, L. Uehlein¹, J.N. Bembenek¹;¹Univ Tennessee-Knoxville, Knoxville, TN

Separase is a protease that promotes chromosome segregation at anaphase by cleaving cohesin. Several non-proteolytic functions of separase have been identified in other organisms. We found that separase is required for vesicle exocytosis during anaphase, and hypothesize that its protease activity is required. To address this, we expressed protease-dead separase in *C. elegans* embryos. We find that expression of protease-dead separase is dominant-negative in embryos, not previously reported in other systems. The *C. elegans* embryo is an ideal system to study developmental processes in a genetically tractable system. However, a major limitation is the lack of an inducible gene expression system for the embryo. We have developed two methods that allow for the propagation of lines carrying dominant-negative transgenes and have applied them to characterize expression of protease-dead separase in embryos. Using these methods, we show that protease-dead separase causes embryo lethality, and that protease-dead separase cannot rescue separase mutants. Furthermore, expression of protease dead separase interferes with chromosome segregation and vesicle trafficking during cytokinesis. In addition, ectopic accumulation of protease dead separase is observed at several putative sites of action within the cell during anaphase, including the furrow and midbody. These data suggest that protease-dead separase interferes with endogenous separase function, possibly by binding substrates and protecting them from cleavage. Identification of relevant substrates will be an important goal to understand the mechanism of separase dependent exocytosis.

P214**Board Number: B326****Reconstituted Cytokinesis Signaling.**A.C. Groen¹, P.A. Nguyen¹, M. Loose², K. Ishihara¹, M. Wühr¹, T.J. Mitchison¹, C.M. Field¹;¹Department of Systems Biology, Harvard Medical School, Boston, MA, ²Harvard Med Sch, Boston, MA

Cell division is the process whereby one cell divides into two daughter cells and is essential for many aspects of biology, including growth, immune response, and cancer (when unregulated). Successful symmetric cell division relies on precise positioning of the cleavage furrow at the midplane. During early zygotic cell divisions, astral microtubules grow from the spindle poles out to the cortex after anaphase to anchor the spindle apparatus during chromosome segregation. We developed a novel cell-free system from frog egg extracts that reconstitutes growth and interaction of asters nucleated from artificial centrosomes. Similar to embryos, these zones recruit critical cytokinesis protein complexes, such as Kif4-PRC1, Centralspindlin, and the chromosomal passenger complex (CPC). Most importantly, we observed the recruitment of cleavage furrow markers (anillin, actin, and GTP-bound RhoA) at interaction zones assembled over supported lipid bilayers (which mimic the plasma membrane). This is the first time a spindle midzone-like structure was reconstituted that can signal to the cortex to initiate the cleavage furrow. We are currently exploring the role of microtubule dynamics on recruitment of cleavage furrow signals at the zone.

P215**Board Number: B327****Differential survivin expression at the single-cell level as revealed by flow cytometry and microscopy.**A. Miletic¹, W. Kang¹, B. Scott¹, X. Li¹, L. Ma¹, S.G. Becker-Catania¹, S. Lee¹, N. Schrantz¹, P. Just¹;¹Research and Development, eBioscience, An Affymetrix Company, San Diego, CA

Survivin (also known as Birc5) is a member of the inhibitor of apoptosis (IAP) family that also includes XIAP, c-IAP1, c-IAP2, and NAIP. Like other members of the IAP family, one major function of survivin is inhibition of caspase activation, which leads to the negative regulation of apoptosis. Nevertheless, survivin also plays a critical role in mitosis and cytokinesis, during which it is expressed only during the G2/M-phase and can be found localized to the mitotic spindle and cleavage furrow/midplate. Due to its role in cell cycle progression, survivin has been found to be highly expressed in tumors and fetal tissue, but is absent in terminally-differentiated and non-proliferating cells. Moreover, deletion of survivin in developing mouse thymocytes, as well as in mature T and B cells, demonstrated that survivin is critical for cell division in lymphoid cells but not for survival. To date, very few tools are available to detect and visualize survivin expression and localization *ex vivo*. Here, we describe a novel mouse monoclonal antibody that specifically recognizes human survivin and demonstrate its utility in flow cytometry and immunocytochemistry to examine survivin expression in actively proliferating T cells. With this antibody,

researchers will be able to gain a better understanding of the role survivin plays in the balance between cell proliferation and apoptosis during cancer and development.

Effect of pituitary tumor transforming gene (PTTG1) on the self-renewal activity of placenta-derived mesenchymal stem cells.

H. Lee¹, J. Choi¹, J. Kim², S. Lee³, G. Kim¹;

¹Dept. of Biomedical Science, CHA University, Seoul, Korea, ²Dept. of Pharmacy, CHA University, Seongnam, Korea, ³Dept. of Oral Pathology, College of Dentistry, Gangneung-Wonju National University, Gangneung, Korea

In addition to differentiation potential, self-renewal capability is an important characteristic of stem cells. The limited self-renewal activity of mesenchymal stem cells is the biggest obstacle to the application of stem cell therapy in regenerative medicine. The human TERT gene enhances the self-renewal of MSCs, but the mechanism of self-renewal and the interactions among TERT gene-related molecules remain unknown. The objectives of this study were to generate immortalized MSCs derived from mesenchymal stem cells isolated from placenta (Naïve) by human TERT gene transfection using the AMAXA gene delivery system, compare their characteristics, and investigate whether increased TERT expression affects the pituitary tumor transforming gene (PTTG1) (also known as securin), which is involved in chromosome segregation during mitosis. TERT-immortalized cells (TERT+) with prolonged life span displayed high PTTG1 expression. TERT+ cells also retained the stemness capacity and multipotency of naïve cells and displayed high PTTG1 expression. However, down-regulation of PTTG1 by treatment with siRNA induced cell senescence and decreased telomerase activity. In addition, TERT bound to PTTG1 forms complex with chaperones such as Ku70 and heat shock protein 90 (HSP 90). Taken together, placental MSCs immortalized by TERT gene transfection display differentiation potential and enhance the self-renewal of MSCs through a balanced interaction of PTTG1 and chaperones. The results suggest that the interaction between TERT and PTTG1 by association of Ku70 could be important for the enhancement of the limited self-renewal activity of MSCs as well as for understanding the regulatory mechanisms of self-renewal.

P217**Board Number: B329****Cell Cycle Dependent Transcription is Regulated by Nuclear Positioning in a Syncytium with Asynchronous Nuclear Division.**S.E. Roberts¹, A.S. Gladfelter¹;¹Biological Sciences, Dartmouth College, Hanover, NH

In multinucleate cells of the fungus *Ashbya gossypii*, nuclei divide independently despite sharing a common cytoplasm. Internuclear distance is tightly regulated, with neighboring nuclei ~5 μm apart. We demonstrated that heterogeneous localization of cyclin transcripts by their association with protein aggregates promotes asynchronous division. To determine whether variability in the production of transcripts also promotes transcript spatial heterogeneity, nuclei producing cyclin transcripts were identified using single molecule RNA FISH. Cyclin transcription correlated with the cell cycle phase of the nucleus indicating that even in a shared cytoplasm nuclei have “knowledge” of their cell cycle phase. It is possible that variable transcription of cyclins contributes to variable local cytosolic concentrations of cyclin protein. If so, the volume of cytosol between neighboring nuclei may be crucial to nuclear cycle autonomy. In fact, previous data showed when nuclei cannot control their spacing they undergo synchronous division. To further investigate the relationship between nuclear spacing and division autonomy we utilized a mutant strain lacking the dynactin complex in which large nuclear clusters form with 10-30 nuclei

P218**Board Number: B330****IRBIT is a novel regulator of Ribonucleotide reductase in high eucaryotes.**M. Dasso¹, A. Arnaoutov¹;¹National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD

Ribonucleotide reductase (RNR) is an enzyme that supplies the balanced pools of deoxynucleotide triphosphates (dNTPs) necessary for DNA replication and maintenance of genomic integrity. RNR is subject to allosteric regulatory mechanisms in all eukaryotes, as well as to control by small protein inhibitors Sml1p and Spd1p in budding and fission yeast, respectively. We have found that the metazoan protein IRBIT controls RNR activity via a novel allosteric mechanism: IRBIT forms of a complex with RNR in dATP-dependent manner, stabilizing dATP in the activity site of RNR, and thus inhibiting the enzyme. Formation of the RNR-IRBIT complex is regulated through phosphorylation of IRBIT, and ablation of IRBIT expression in HeLa cells causes imbalanced dNTP pools and altered cell cycle progression. We have begun to develop model systems for examination of IRBIT function in intact organisms, and have particularly focused on analysis of the *Drosophila melanogaster* midgut, a well-characterized system for tissue generation and homeostasis. Our preliminary findings suggest that these processes are misregulated in the absence of IRBIT.

P219**Board Number: B331****Ran GTPase activates DNA damage response and cell cycle resumption, driving the evasion of cell senescence in normal and cancer cells.**P. Cekan¹, S. Ryu^{1,2}, K. Hasegawa^{1,3}, J. Lee¹, P. Kalab¹;¹NCI/NIH, Bethesda, MD, ²Well-Aging Research Center, Samsung Advanced Institute of Technology, Osan, Korea, ³Biochemistry-Biophysics, Amherst College, Amherst, MA

Several lines of evidence indicated that the small GTPase Ran could have a role in activating cell cycle resumption in the interphase. First, Ran is required for the nuclear-cytoplasmic transport of cell cycle regulators, including nuclear export of cyclin mRNAs and nuclear import of DNA replication factors. Second, the activity of Ran-regulated nuclear transport was found to be reduced in non-dividing senescent cells. Finally, previously we showed that rapidly dividing tissue culture cells expressed increased levels of RCC1, the factor required for the formation of the GTP-loaded active form of Ran. Here we show that stable cell cycle exit in normal senescent cells led to the decline of RCC1 expression and reduced RanGTP levels. In contrast, RCC1 expression was required for cell cycle resumption in colorectal carcinoma cells recovering from DNA damage-induced senescence-like state. Remarkably, RCC1 overexpression was sufficient to override the DNA damage-induced cell cycle arrest in normal epithelial cells, leading to the rise of aneuploid proliferative cells. The effects of RCC1 on cell senescence evasion in normal and cancer cells required the role of RanGTP and Exportin 1 in nuclear export and involved the activated expression of many factors promoting DNA damage repair, DNA replication and cell cycle. These results indicate that, through its interphase nuclear functions, RanGTP promotes DNA damage repair and cell cycle initiation, biasing the cellular response to genotoxic insults towards continuous proliferation in the presence of severe genomic alterations.

P220**Board Number: B332****Elm1 regulates Hsl1/Hsl7 interaction in the morphogenesis checkpoint.**H. Kang¹;¹Pharmacology, Duke University, Durham, NC

The yeast morphogenesis checkpoint prevents nuclear division prior to bud emergence through Swe1-mediated inhibition of Cdc28. After bud formation, Swe1 is targeted for degradation via sequential phosphorylation events that require localization of the kinases Elm1 and Hsl1, as well as the Swe1-binding protein Hsl7, to septin ring at the mother-bud neck. Elm1 activates Hsl1, which recruits Hsl7 to septin ring only in budded cells. How do these proteins “know” when budding has occurred? By tethering the small Hsl7-binding domain of Hsl1 to a septin, we found that this domain is sufficient to confer Hsl7 recruitment. Although the Hsl1 fragment was present before budding, Hsl7 was only recruited after budding. The Elm1 kinase was also localized to the septins only after budding. Using a Bni4-Elm1 fusion that targets the Elm1 kinase to the septin ring prior to budding, we found that

premature Elm1 targeting led to premature Hsl7 recruitment by the Hsl1 fragment. Over expression of Elm1 leads to its early localization before budding. Similarly, early localized Elm1 can also contribute to Hsl7 recruitment by Hsl1 fragment in unbudded cells. These findings suggest that Elm1 localization is the process that coordinates with bud emergence, and that it regulates Hsl1/Hsl7 interaction to promote Hsl7 recruitment and Swe1 degradation only after budding has begun.

Board Number: B333

Yeast metabolic cycle: Entry into oxidative phase is tightly coupled to the cell cycle in diverse strains and growth conditions.

A.J. Burnett¹, N. Buchler², M. Aydin²;

¹University Program in Genetics and Genomics, Duke University, Durham, NC, ²Biology, Duke University, Durham, NC

The budding yeast *Saccharomyces cerevisiae* is capable of synchronous metabolic oscillations with a period between 45 minutes and several hours when grown in chemostat conditions. This oscillation consists of alternating periods of buildup and oxidation of the storage carbohydrates trehalose and glycogen, and changes in expression of a large fraction of the transcriptome. The cell division cycle (CDC) couples strongly to this oscillation, with a single pulse of cells entering S phase once per yeast metabolic cycle (YMC). Early work showed that in some strains DNA replication and oxidative phase never overlapped, presumably to prevent damage to DNA during replication. However, more recent work in other strains has shown that DNA replication can occur both during and outside of oxidative phase.

To better understand strain-dependent and strain-independent phenotypes, we examined YMC-CDC coupling in different laboratory strains and wild-isolates across varying chemostat conditions. We show that all strains exhibit a linear relationship between YMC and CDC period, that oxidative phase can overlap DNA replication in many strains, and that the interval between entry into oxidative phase and DNA replication is invariant for a given strain across growth conditions. These data suggest that cell cycle Start is tightly coupled to events surrounding the entry into the high-metabolic-rate oxidative phase. This excludes mechanisms and rationales for cell cycle coupling involving protection of DNA from metabolic damage, and instead suggests a role for coupling in ensuring DNA replication occurs when sufficient cellular energy is available. Moreover, when combined with recent work revealing direct metabolic effects on cyclin gene expression it suggests a positive feedback loop between carbon metabolism and cell cycle Start which synchronizes compatible cellular and metabolic events to ensure they occur together.

P222**Board Number: B334****The anaphase-promoting complex works together with the SCF complex for proteolysis of the S-phase cyclin Clb6 during the transition from G1 to S phase.**S. Wu¹, V.J. Kuan², Y. Tseng³, S.C. Schuyler², Y... Juang⁴;¹Microbiology and Immunology, Tzu-Chi University, Hualien, Taiwan, ²Biomedical Sciences, Chang Gung University, Taoyuan, Taiwan, ³Institute of Medical Sciences, Tzu-Chi University, Hualien, Taiwan,⁴Mackay Medical College, New Taipei City, Taiwan

In *Saccharomyces cerevisiae*, the S-phase cyclin Clb6 is expressed shortly at the G1/S border. It has been shown that the SCF^{Cdc4} ubiquitin ligase controls Clb6 proteolysis requiring cyclin-dependent kinases and that Clb6-3A, bearing non-phosphorylatable mutations of S6A, T39A, and S147A, is hyperstabilized but still unstable in mitosis. In this study, we found that the APC^{Cdh1} form of anaphase-promoting complex, an E3 ubiquitin ligase, was required for Clb6 proteolysis in both early and late G1. *In vitro* ubiquitination assay further confirms that Clb6 is a substrate of the APC^{Cdh1}. Clb6 has a KEN box and a destruction box in its N-terminus. Mutations in the KEN box (mkb) and/or the destruction box (mdb) could enhance Clb6 stability in G1. Clb6^{mkd} bearing mutations of mkb and mdb could make cells bypass the late G1 arrest caused by the *cdc4-1* temperature-sensitive mutation depending upon CDK phosphorylation at residues S6, T39 and S147. As compared to Clb6, overexpression of Clb6-ST, bearing mutations of S6A, T39A, S147A, mkb, and mdb, had a greater effect on promoting expression of Clb2 and S-phase entry, and caused a greater G2 delay and a greater defect in cytokinesis. Furthermore, Swe1 was required for occurrence of bud emergence when Clb6-ST was overexpressed. Overall, our observations suggest that both APC^{Cdh1}- and SCF^{Cdc4}-dependent proteolysis of Clb6 at the G1/S border is crucial for proper expression of Clb2, G1/S transition, G2/M transition, and cytokinesis.

P223**Board Number: B335****Cyclin oscillations in living cells: Endogenous reporters for a quantitative view on cyclin expression and proteolysis.**M. Lachnit¹, I. Gak¹, J. Mansfeld¹;¹Cell Cycle, Biotechnology Center, Technische Universität Dresden, Dresden, Germany

Cell cycle progression is tightly controlled by oscillations of cyclins that activate distinct cyclin-dependent kinases (Cdk) at the right time. While the protein level of the Cdk generally remains constant, the levels of cyclins are precisely controlled by 'tug of war' between cyclin expression and ubiquitin-mediated proteolysis. Decades of research have revealed the key players and pathways regulating cyclin stability. Little is known, however, about the *in vivo* dynamics of cyclin oscillations and their response to cell cycle challenges due to the lack of reporters that faithfully reflect the regulation of endogenous cyclins. Using non-transformed retinal pigment epithelial cells as a model we have here employed

homologous recombination techniques to insert the gene of the fluorescent protein mVenus site-specific and in frame into the loci of cyclins A2, B1 and D1. Notably, the fluorescent fusion proteins behave comparably to the untagged cyclin indicating that measuring mVenus fluorescence is a valid readout to visualize cyclin oscillations in living cells. To relate the fluorescence data to the exact cell cycle stage we have further tagged endogenous the proliferating cell nuclear antigen (PCNA) and histone H3.1 with mRuby and mTurquoise2, respectively. Therefore, we can automatically segment and classify single cells into the exact cell cycle stage. Furthermore, the same fluorescent tag on different cyclins allows us to precisely determine their absolute and relative expression and proteolysis kinetics by quantitative live cell microscopy. As expected and validating this approach, cyclins A2 and B1 are rapidly degraded in mitosis and accumulate in S- and G2-phase, respectively. Cyclin D1 in contrast to the prevalent view oscillates in G1-phase, strongly decreases before S-phase, and then re-accumulates in G2-phase. Allowing nuclear segmentation (histone), cell cycle stage classification (PCNA) and cyclin expression (mVenus)- all dependent on endogenously-tagged proteins - the cyclin reporters will be valuable tools to get a more quantitative view on cyclin oscillations and to assay the behaviour of single cells when the cell cycle is challenged.

Phase separated RNA-protein droplets position cyclin transcripts to organize the cytosol of multinucleate cells.

H. Zhang¹, A.A. Bridges¹, P. Occhipinti¹, A.S. Gladfelter¹;

¹Biological Sciences, Dartmouth College, Hanover, NH

Syncytial cells are found throughout the biosphere from filamentous fungi to early animal development, muscle, placenta and tumor cells. Multinucleate cells face unique organizational problems and in many cases must functionally compartmentalize their cytosol for diverse processes including nuclear division and symmetry breaking. We found that in the filamentous fungus *Ashbya*, in which nuclei cycle asynchronously despite sharing a cytosol, that cyclin transcripts are clustered and kept near nuclei by binding to the RNA-binding protein, Whi3. Whi3 has a substantial polyQ tract and this aggregation-prone region is essential for clustering transcripts and asynchronous nuclear division. We hypothesized that Whi3-cyclin complexes form functional, dynamic aggregates that phase separate from bulk cytosol, potentially to control the location of cyclin protein production. We have reconstituted the cyclin transcript-polyQ protein complex and found that at physiological concentrations Whi3 and cyclin mRNAs phase separate and form liquid droplets both in buffer and in concentrated cell extracts. Biophysical measurements of the droplet properties indicate that they are dynamic, fluid and highly dependent on having mRNA and full length Whi3 protein. Similarly, in cells the ability of Whi3 protein to bind mRNA is essential for its heterogeneous localization into dynamic puncta and tubules, as well as nuclear asynchrony. These results demonstrate a function for RNA-protein granules in regulating variable and asynchronous nuclear progression and show mRNA is a critical component for the assembly process. We

propose that phase-separated droplets may be widely employed to pattern cytosol for diverse processes beyond the regulation of mRNA turnover and are likely critical for large, syncytial cell organization.

The circadian factor Period 2 modulates p53 stability and transcriptional activity in unstressed cells.

T. Gotoh¹, M. Vila-Caballer², C.S. Santosa², J. Liu², J. Yang², C.V. Finkielstein¹;

¹Biological Sciences, Virginia Tech, Blacksburg, VA, ²Biological Sciences, Virginia Tech, Blacksburg, VA

Circadian rhythms are mechanisms that measure time on a scale of about 24 h and that adjusts our bodies to external environmental signals. Core circadian clock genes are defined as genes whose protein products are necessary components for the generation and regulation of circadian rhythms. Disruption of circadian rhythm has recently emerged as a new potential risk factor in the development of cancer, pointing to the core gene *period 2 (per2)* as a tumor suppressor. However, it remains unclear how the circadian network regulates tumor suppression, nor which, if any, of its components is either the ultimate effector that influences the fate of the cell. The relevance of hPer2 to human disease is underlined by alterations in its function that impacts numerous biochemical and physiological processes and, when absent, result in the development of various cancers. We found hPer2 binds the C-terminus half of human p53 (hp53) and forms a stable trimeric complex together with hp53's negative regulator Mdm2. We determined that hPer2 binding to hp53 prevents Mdm2 from ubiquitinating and targeting hp53 by the proteasome. Accordingly, downregulation of hPer2 expression directly impacts hp53 levels whereas its overexpression influences both hp53 protein stability and transcription. Furthermore, we spatially defined the distribution of the trimeric complex within the nucleus. Lastly, we established that hPer2 binding influences hp53-mediated gene transcription (e.g., *CDKN1a*, *SFN*, *GADD45α*) in response to DNA-damage by reconstituting the p53-mediated signaling pathway in a p53^{-/-} cellular model. Overall, our findings place hPer2 directly at the heart of the hp53-mediated response by ensuring that basal levels of hp53 are available to rapidly respond to a stress conditions.

Functions of PP1-NIPP1 in cell cycle progression.

C. Winkler¹, C. Kig¹, B. Lesage¹, M. Beullens¹, A. Van Eynde¹, M. Bollen¹;

¹Department of Cellular and Molecular Medicine, Laboratory of Biosignaling Therapeutics, Leuven, Belgium

Protein Ser/Thr phosphatase 1 (PP1) forms heterodimers with dozens of structurally unrelated polypeptides that regulate substrate selection and enzymatic activity. One of the major nuclear interactors of PP1 is NIPP1, which has a ForkHead-Associated (FHA) domain that recruits a subset of

Cdk-phosphorylated proteins for dephosphorylation by associated PP1. To delineate the role of PP1-NIPP1 in cell-cycle progression we have generated cell lines (Flp-In T-REx HeLa) that inducibly express NIPP1 variants or fusions. The expression of NIPP1 caused a block in early-mid-mitosis associated with lagging chromosomes, spindle defects and a permanently activated spindle-assembly checkpoint, often culminating in mitotic cell death. This heterogeneous phenotype was also observed after expression of a FHA-binding mutant of NIPP1 but was completely absent after expression of a PP1-binding mutant. Additional data suggested that the mitotic defects induced by the overexpression of NIPP1 stem from the competitive disruption and inhibition of PP1 holoenzymes that are essential for mitotic progression. Hence, NIPP1 expressing cell lines can be used to further delineate the mitotic functions of PP1. A completely different phenotype was observed after the expression of a PP1-NIPP1 fusion. This fusion caused replication stress, associated with the accumulation of γ H2AX foci and impaired DNA repair via homologous recombination. This effect was dependent on both a functional FHA domain and PP1 activity, and could be explained by the dephosphorylation and destabilization of two FHA ligands of NIPP1 that function in homologous recombination, namely protein kinase Melk and the tumor suppressor protein CtIP. Our data show that PP1-NIPP1 contributes to the reversal of Cdk-mediated cell-cycle progression.

The deubiquitinase USP37 promotes the efficient S-phase progression and the cellular response to replication stress.

M.K. Summers¹, A.C. Burrows¹;

¹Cancer Biology, Lerner Research Institute, Cleveland Clinic, Cleveland, OH

Ubiquitin-mediated proteolysis is a key regulatory process in cell cycle progression. Recently we identified the deubiquitinase USP37 as regulator of S-phase entry. Here we report that depletion of USP37 leads to diminished cellular proliferation and loss of viability. USP37-depleted cells exhibit altered replication kinetics and increased levels of DNA damage markers γ H2AX and 53BP1. Moreover, USP37-depleted cells display significantly increased sensitivity to replication stress. Consistent with this increased sensitivity, activation of the checkpoint kinase Chk1 is attenuated in USP37-depleted cells. We have determined that decreased stability of the replication checkpoint mediator Claspin underlie the defects in Chk1 activation. USP37 interacts with and deubiquitinates Claspin. Our data suggest a model whereby temporally regulated interplay of USP37, APC^{Cdh1}, and the replication checkpoint machinery determines the timing of replication checkpoint activity that sharpens the G1/S transition and promotes the efficient completion of replication. These data provide an improved understanding of the replication checkpoint, control of APC^{Cdh1}, and maintenance of genome stability.

P228**Board Number: B340****Survival of proliferative, radio-resistant polyploid cells in *Drosophila* requires FANCD2.**H. Bretscher¹, D. Fox¹;¹Pharmacology and Cancer Biology, Duke University School of Medicine, Durham, NC

Maintaining a stable genome prevents damaged DNA, altered cellular function, and ultimately diseases such as cancer. Genome instability can result from a wide variety of cellular stresses including DNA damage. In order to prevent propagation of genome instability, diploid mitotic cells employ a DNA damage checkpoint to ensure that they do not divide with damaged DNA. Entering mitosis with damaged DNA can result in mutations and chromosome number imbalance (aneuploidy). While the response to DNA damage is well characterized in diploid mitotic cells, it has been recently observed that passage through the endocycle, a variant cell cycle in which mitosis is truncated, can alter the response to DNA damage. As a result of this alteration, endocycling murine trophoblasts and several *Drosophila* larval tissues are highly resistant to DNA damage. Unlike diploid cells, these non-proliferative cells continue to endocycle despite high levels of DNA damage.

While, most endocycled cells are terminally differentiated and do not re-enter the mitotic cell cycle, we previously established a model to address mechanisms by which the endocycle promotes genome instability during mitosis. In the *Drosophila* rectum, we found endocycled papillar cells can re-enter mitosis as polyploid cells. We show that, like other endocycled cells, papillar cells acquire radio-resistance during the endocycle. Rather than undergoing full repair of DNA breaks, papillar cells re-enter mitosis with broken chromosomes. Despite frequent DNA breaks, lagging DNA during anaphase and organism-lethal amounts of DNA damage, papillar cells develop normally and undergo surprisingly little cell death. To survive, we find that papillar cells enlist a non-canonical DNA damage mechanism to ensure that anaphase is extended to allow for incorporation of broken DNA into daughter nuclei. This survival depends on ATM and ATR, but not chk1 and chk2 kinase activity or the transcription factor p53. In addition to ATM and ATR, we find that the DNA repair protein FANCD2 is also required for cytokinesis delay and survival of damaged polyploid papillar cells. Cells lacking FANCD2 fail to incorporate broken DNA into daughter cell nuclei prior to the onset of cytokinesis, and subsequently die by mitotic catastrophe. We speculate that the mechanism used by polyploid papillar cells to survive mitosis with high levels of DNA damage may contribute to radio-resistance in cancer cells that have undergone an endocycle.

P229**Board Number: B341****Store-operated calcium entry (SOCE) controls G1/S cell cycle transition.**Y. Chen¹, M. Shen^{1,2};¹Department of Pharmacology, National Cheng Kung University Hospital, Tainan, Taiwan, ²Department of Obstetrics and Gynecology, National Cheng Kung University Hospital, Tainan, Taiwan

Background: The well-defined store-operated Ca²⁺ entry (SOCE) pathway is a ubiquitous Ca²⁺ influx pathway activated in response to depletion of intracellular Ca²⁺ stores. The major components of SOCE are stromal-interacting molecule (STIM1, STIM2) and Orai (Orai1, Orai2, Orai3). STIM1 serves a dual role as the endoplasmic reticulum Ca²⁺ sensor, and activator of SOCE. The clinical relevance of STIM1 has been highlighted in several cancers but the molecular mechanism by which SOCE involved in G1/S transition of cell cycle progression remains unclear. However, this study explores the regulatory mechanisms by which STIM1-dependent Ca²⁺ signaling controls cell cycle progression. **Results:** Here, we showed that SOCE increased in the S phase of cell cycle in different cell lines. Ca²⁺ microdomain is necessary for G1/S transition. We discovered that SOCE activity is necessary for G1/S transition but not important for S to G2/M transition. SOCE inhibitor, SKF96365 significantly inhibited G1/S transition to a similar extent to that of components of SOCE (STIM1, STIM2, Orai1) silencing. Total internal reflection fluorescence (TIRF) microscopy of living cells indicated that the increase of STIM1 trafficking to the plasma membrane in S phase but not in G0/G1 phase, suggesting STIM1 is important for the regulation of the G1/S transition. Inhibition of SOCE induced cyclin E autophagy as well as blockage of G1/S transition induced cell apoptosis. Taken together, our results revealed that the novel role of SOCE activity in controlling cell cycle progression.

P230**Board Number: B342****DRG2 binds to Wee1 for regulating cell cycle progression during G2/M phase.**S. Jang¹, N. Park², S. Kim³, J. Park⁴, I. Han⁴;¹Biomedical Research Center, University of Ulsan, Ulsan, Korea, ²Department of Medical Science, University of Ulsan, Ulsan, Korea, ³Department of biological sciences, Univeristy of Ulsan, Ulsan, Korea, ⁴Department of Biological Sciences, University of Ulsan, Ulsan, Korea

Developmentally regulated GTP-binding protein 2 (DRG2) plays important role in cell growth. Here we explored that the linkage between DRG2 and G2/M phase checkpoint function in the cell cycle progression. We observed that HeLa cell lacking DRG2 has the slower wound-healing rate than that of control cells. Flow cytometry assay and ³H incorporation assay indicated that G2/M phase arrest leads to decreased proliferatio of this cell. Depletion of DRG2 elicited the changed expression of major cell cycle determinant factors, such as cyclin A2, B1, p21^{Waf1/Cip.1}. In addition, DRG2 interacts with Wee1 kinase, a mitotic gatekeeper. These findings elucidate a noble role for DRG2 as regulator of Wee1, and therefore serve to progress G2/M phase in cell cycle.

P231**Board Number: B343****Phosphorylation of Xenopus p31comet potentiates mitotic checkpoint exit.**M. MO¹, M. Dasso², A. Arnaoutov²;¹National Institute of Health, Bethesda, MD, ²National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD

The spindle assembly checkpoint (SAC) ensures faithful segregation of mitotic sister chromatids by monitoring interactions between kinetochores (KTs) and microtubules (MTs). Defective MT-KT interactions trigger SAC activation, causing the formation of a potent inhibitory complex, the mitotic checkpoint complex (MCC), which in turn blocks the metaphase-anaphase transition. Once all KT have formed correct MT attachments, the SAC is silenced. The MCC is then disassembled through a series of poorly understood processes, allowing anaphase to ensue. It has previously been shown that the p31comet protein helps to inactivate the MCC by binding directly to Mad2, an essential MCC component. However, p31comet's regulation and mechanism of action are unclear. Xenopus egg extracts (XEEs) are an excellent in vitro system that recapitulates many aspects of cell cycle control, including the SAC. We confirmed that Xenopus p31comet was important for SAC silencing in XEEs, and observed that it was phosphorylated during the course of mitosis. Unexpectedly, our data suggest that this modification was mediated by IKK- β (Inhibitor of nuclear factor κ -B kinase-beta), but not by a panel of other well-known mitotic kinases. Depletion or chemical inhibition of IKK- β compromised SAC silencing and delayed mitotic exit, suggesting that this modification was important for p31comet regulation. We identified p31comet phosphorylation sites, and found that a p31comet phosphomimetic mutant (p31comet-EEE) shows enhanced binding of Mad2, an event critical for MCC disruption. Moreover, p31comet-EEE exhibited increased ability to disrupt MCC in XEEs, and it accelerated mitotic exit. Notably, p31comet-EEE also disrupted the association of SAC components to KT, where MCC is formed, in a dosage dependent manner. By contrast, wild type p31comet or a phosphodeficient mutant (p31comet-AAA) had no effect on KT-associated MCC. Taken together, our data indicate that phosphorylation of p31comet by IKK- β potentiates its ability to silence the SAC and may contribute to SAC silencing at the KT.

P232**Board Number: B344****Structure of cohesin subcomplex pinpoints direct shugoshin-Wapl antagonism in centromeric cohesion.**G. Zheng¹, K. Hara^{1,2}, Q. Qu¹, H. Liu¹, Z. Ouyang¹, Z. Chen¹, D. Tomchick¹, H. Yu^{3,4};¹University of Texas Southwestern Medical Center, Dallas, TX, ²School of Pharmaceutical Sciences, University of Shizuoka, Shizuoka, Japan, ³Department of Pharmacology, University of Texas Southwestern Medical Center, Dallas, TX, ⁴Howard Hughes Medical Institute, Dallas, TX

Sister-chromatid cohesion, mediated by ring-shaped cohesin complex, is a prerequisite for proper chromosome segregation and genomic stability. Errors in chromosome segregation cause chromosome aberrations and aneuloidy, which can promote tumorigenesis.

Human cohesin complex consists of four core subunits, Smc1, Smc3, Scc1, SA1/2. The loading and release of cohesin from chromosomes are tightly regulated during the cell cycle. During S phase, cohesin core subunit Smc3 is acetylated by the acetyltransferase Escp1/2, which enables the binding of the cohesin protector Sororin to cohesin through the adaptor protein Pds5. Sororin antagonizes the cohesin inhibitor Wapl to stabilize cohesin on replicated chromatin and establishes sister chromatid cohesion. In prophase, mitotic kinases phosphorylate cohesin and Sororin, triggering Wapl-dependent cohesin removal from chromosomes. A pool of cohesin at centromeres is protected by the Sgo1-PP2A complex, which binds to cohesin, dephosphorylates Sororin, and protects cohesin from Wapl at centromeres. After all sister kinetochores attach properly to the mitotic spindle and are under tension, Separase cleaves centromeric cohesin to initiate sister chromatid separation. The separated chromatids are evenly partitioned into the two daughter cells.

We reported the crystal structure of human cohesin subcomplex SA2-Scc1. SA2 has multiple helical repeats, which form a dragon-shaped structure. Scc1 makes extensive contacts with SA2, with one hot spot being particularly critical for binding. SA2-Scc1 complex is the interaction hub for cohesin regulators. Cohesin protector Sgo1 and inhibitor Wapl compete for binding to a conserved site on SA2-Scc1. Mutations of SA2 residues at this site that disrupt Wapl binding bypass the requirement for Sgo1 in cohesion protection. Thus, in addition to recruiting PP2A to dephosphorylate cohesin and sororin, Sgo1 physically shields cohesin from cohesin inhibitor Wapl. These two mechanisms collaborate to protect centromeric cohesion to the fullest extent, which makes centromeric cohesion strong enough to resist the spindle pulling force at sister kinetochores and enables the generation of kinetochore tension necessary for spindle checkpoint inactivation and accurate chromosome segregation.

Sgo1 is also known to protect meiotic cohesin at centromeres from separase-mediated cleavage during meiosis I. In preliminary results, I have shown that SA1/2, as the interaction hub, is required for separase cleavage of Scc1 at anaphase onset. It is possible that separase is recruited by SA1/2 to cleave centromeric cohesin. Overexpression of Sgo1 reduces the separase cleavage efficiency. This indicates that Sgo1 might directly compete with separase for binding SA1/2 and shield cohesin from separase. To

test this hypothesis, cohesin cleavage by separase will be reconstituted in vitro using purified proteins. Cohesin cleavage efficiency will be compared in the presence and absence of Sgo1 peptide.

Actin-capping proteins play essential roles in spindle migration and polar body protrusion in maturing mouse oocytes.

S. Namgoong¹, Y. Jo¹, N. Kim¹;

¹Animal Science, Chungbuk National University, CheongJu, Korea

Actin polymerization is essential for various stages of mammalian oocyte maturation, including asymmetric spindle migration, cortical actin cap formation, polar body extrusion, and cytokinesis. The heterodimeric actin capping protein (CP) is an essential element of the actin cytoskeleton. It binds to the fast-growing (barbed) ends of actin filaments, thereby blocking their elongation, and plays essential roles in various actin-mediated cellular processes. However, the roles of CP in mammalian oocyte maturation are poorly understood. We investigated the roles of CP in mouse oocytes, and found that CP is essential for correct asymmetric spindle migration and polar body extrusion. Experiments in which CP was knocked down or ectopically overexpressed revealed that this protein is critical for maintenance of cytoplasmic actin mesh. Perturbations in the level of CP impaired spindle migration, cytoplasmic actin mesh and polar body extrusion during oocyte maturation. Expression of capping protein inhibitory region of CARMIL reduce polar body extrusion rate of oocyte and significantly reduce cytoplasmic actin mesh. Taken together, this study shows that CP is an essential component of the actin cytoskeleton machinery, presumably controlling cytoplasmic actin mesh during oocyte maturation.

Ptychography: Label free imaging of the cell cycle and mitosis.

R. Suman¹, T.J. Henser-Brownhill¹, K. Langley², P. O'Toole¹;

¹University of York, York, England, ²Phasefocus, Sheffield, United Kingdom

The use of fluorescent probes has become commonplace for staining fixed biological specimens; however when used in living cells they can be toxic and ultimately perturb the natural function of the cell. With this in mind, there has been an emerging need for label free microscopy. Existing techniques such as Zernike phase contrast and DIC have limitations and most importantly are not quantitative. Here we report a novel stain-free, high-contrast and quantitative method for imaging live cells using a ptychographic microscope (Phasefocus VL21). The technique reconstructs an image from overlapping diffraction patterns using a ptychographical algorithm (Maiden et al., 2010), to give high contrast, quantitative information of the sample.

We have previously demonstrated the power of ptychography to quantitatively analyse cells during mitosis (Marrison et al., 2013). Here we demonstrate further measurement of the mitotic index (MI) of A549 cells in response to the cell cycle inhibitor, Nocodazole. An advantage to this imaging approach is the ability to acquire large fields of view in which data from 500+ cells can be analysed in a manner comparable to flow cytometry. Following the 6hr treatment with 10, 25 and 50ng/ml Nocodazole, the MI value also increased to 0.05, 0.23 and 0.36 respectively when compared to the control (MI= 0.03).

Furthermore we were able to use ptychography to analyse the cell cycle yielding phase characteristics related to cell thickness, cell volume and nuclear volume. Following mitosis the volume of the daughter cell increases linearly during the cell cycle and approximately doubles immediately prior to the next mitotic event. We also propose that nuclear volume remains constant through G1, but starts to increase during S phase. There is an increasing need for quantitative label-free imaging methodologies. Here we demonstrate that ptychography generates high contrast and quantitative images that not only enable cell cycle analysis using a label free non-invasive approach, but can now be used in studies where cell volume/mass are underpinning the biological function of the cell. In conjunction with in situ fluorescence imaging, the quantitative phase information can add additional and vital information that goes beyond fluorescence imaging itself.

In summary, the work highlighted here demonstrates one potential application of label-free phenotypic analysis of cells. The method is ideally suited for primary and stem cells where labels are undesirable or not possible. Furthermore the technique could also be used in many other assay types, such as anti-cancer therapeutics, cell motility and migration, cell morphology and neurodegeneration.

Identifying candidate molecules through which γ -tubulin acts to inactivate the anaphase promoting complex/cyclosome at G1/S in *Aspergillus nidulans*.

V.K. Paolillo¹, H.D. Edgerton¹, B.R. Oakley¹;

¹Molecular Biosciences, University of Kansas, Lawrence, KS

In addition to its well-established role in nucleating microtubules at microtubule organizing centers such as the centrosome and spindle-pole body, γ -tubulin has additional, essential, microtubule-independent functions that are incompletely understood. Experiments with the cold-sensitive γ -tubulin mutant *mipAD159* in the filamentous fungus *Aspergillus nidulans* revealed that γ -tubulin has an important role in inactivating the active anaphase promoting complex/cyclosome (APC/C) bound to the activator CdhA (the *A. nidulans* Cdh1 homolog) at the G₁/S transition (Edgerton-Morgan and Oakley, 2012, *J. Cell Biol.* **198**, 785-791). As a result, cyclin B is continuously destroyed in a subset of nuclei and these nuclei do not progress through the cell cycle (Nayak et al., 2010, *J. Cell Biol.* **190**, 317-330). The goal of this project is to elucidate the mechanism by which γ -tubulin inactivates APC/C^{CdhA}. Based on our data so far, we hypothesize that γ -tubulin acts through regulators of CdhA. In many organisms, initial phosphorylation and inactivation of Cdh1 occurs via cyclin A/Cdk2, which is then thought to trigger Cdh1 ubiquitination

by the Skp1-Cullin1-F-box (SCF) complex. We have identified a putative *A. nidulans* cyclin A gene, which we designate *cycA*, and a component of the SCF complex, designated *culA*, and found both to be essential for viability. If CycA is required for inactivation of APC/C^{CdhA}, the deletion of *cycA* (*cycAΔ*) is expected to result in lethality due to a continuously active APC/C^{CdhA}. It follows that deletion of *cdhA* might reverse the lethality of the *cycAΔ* and we found that this is the case. We have examined the phenotypes of *cycAΔ* and *culAΔ* using the heterokaryon rescue technique. *cycAΔ* inhibited nuclear division as expected, but, more interestingly, caused nuclei to disappear over time (as judged by fluorescently tagged histone H1) raising the possibility that *cycAΔ* may cause apoptosis. Additionally, we have found that a subset of nuclei fail to accumulate Cdk1 in *culAΔ*, similar to a phenotype observed in *mipAD159*, suggesting that APC/C^{CdhA} is constitutively active in these nuclei. Deletion of *culA* likely prevents degradation of CdhA, resulting in nuclei that accumulate constitutively active APC/C^{CdhA} and fail to progress through the cell cycle. Taken together, our data indicate that CdhA is regulated by CycA and the SCF complex in *A. nidulans* as in higher eukaryotes. They also indicate that CycA and CulA are valid candidates for proteins through which γ -tubulin acts to control APC/C^{CdhA} activity. Supported by the Irving S. Johnson Fund of the KU endowment.

A tale of two phases: How RNA-protein interactions can spatially position transcripts involved in cell cycle control and morphogenesis.

E. Langdon¹, A.S. Gladfelter², H. Zhang²;

¹Biology, Dartmouth College, Hanover, NH, ²Biological Sciences, Dartmouth College, Hanover, NH

In the multinucleate cells of the fungus, *Ashbya gossypii*, individual nuclei within this syncytial cell must find a way to functionally compartmentalize their common cytoplasm in order to regulate nuclear division and symmetry breaking events. One way they solve this organizational problem is through the heterogeneous association of low-complexity sequence/polyQ-containing RNA-binding proteins with target RNAs. We have demonstrated that the proteins, Whi3 and Puf2, bind mRNAs to form aggregate structures that create sections of cytoplasm that are differentiated from one another. Further, we showed that assembly of these proteins with key cell cycle and cell polarity transcripts allow the cell to control the diffusivity of mRNA localization through space and time. We hypothesized that the multivalent interactions of these proteins with RNAs are sufficient to drive the assembly of phase-separated droplets that form non-membranous compartments within the cytoplasm. In support of this, cell-free reconstitution techniques along with structured illumination microscopy has revealed that these proteins form different structures whether in the presence of RNA, and that these structures can physically change over time depending on the local concentration of RNAs. Currently, we are investigating how the specificity and arrangement of the protein binding sites on the mRNAs can catalyze the coalescence of these aggregation-prone proteins through the use of cell-free assays, smRNA FISH, and single molecule pull down (SiMPull) for RNAs. Further investigation will focus on the role of

the local environment and cellular stress has on controlling assembly of these physiological RNA-protein complexes.

Board Number: B349

Cyclin mRNA regulation by dynamic Whi3 RNA-protein droplets.

T. Gerbich¹, A.S. Gladfelter¹;

¹Biological Sciences, Dartmouth College, Hanover, NH

In the multinucleate filamentous fungus *Ashbya gossypii*, many aspects of cellular growth and activity are spatially and temporally confined to local zones within a single, large cell. For example, nuclei that are only micrometers apart divide asynchronously despite being bathed in the same continuous cytosol where freely diffusing components would be predicted to be equal in all regions. This raises the problem as to how in *Ashbya* functional cytoplasmic compartments can be created that give rise to local territories with distinct activity from neighboring territories. One solution employed by the fungus is to create phase-separated droplets of protein and mRNA that are distributed non-homogeneously in the cell. Asynchronous nuclear division is dependent upon the non-uniform positioning of cyclin transcripts by Whi3, an RNA-binding protein with a low complexity sequence that allows it to undergo regulated aggregation. This work considers how Whi3 complexes are regulated by environmental conditions and how the complexes function to promote local production of the cyclin, Cln3, protein. Whi3 aggregates are known to respond to cellular stresses by changing their size and distribution in a manner specific to the environmental challenge. Single molecule FISH data will be presented to show how these changes in Whi3 aggregation correspond to changes in Cln3 transcript localization. The degree to which cyclin transcripts are protected or masked by Whi3 protein complexes so as to limit translation during different phases of the cell cycle or in response to environmental stress is also being investigated. This work uses protease digestion assays combined with single molecule FISH. These data provide insight into how multinucleate cells use functional RNA-protein aggregates to create dynamic compartments that organize the cytoplasm.

How prolonged prometaphase blocks daughter cell proliferation despite normal completion of mitosis.

Y. Uetake¹, G. Sluder¹;

¹University of Massachusetts Medical School, Worcester, MA

We previously reported that when untransformed human (RPE1) cells spend >1.5 hr in prometaphase, their daughters uniformly exhibit a p38 dependent arrest in G1 despite normal division of their mothers. Transient inhibition of p38 activity allows daughters born of prolonged prometaphase to proceed

through interphase and mitosis of normal duration, yet all granddaughters arrest in G1 - suggesting a durable change in the properties of the daughter cells that cannot be erased by progression through interphase and mitosis. What happens during prolonged prometaphase and the nature of the change in daughter cell properties were unknown. Here we find that during prometaphase the progressive loss of activity of the anti-apoptotic protein MCL1 and oxidative stress at ambient oxygen levels can act independently or in concert to diminish the proliferative capacity of the daughters. Additional observations provide functional evidence that a slow activation of the apoptotic pathway participates in the initiation of the G1 arrest of daughter cells. Since some spindle defects prolong prometaphase but eventually allow mitotic checkpoint satisfaction, this phenomenon can prevent unresolved defects in mitosis from being propagated to future cell generations.

Activation of Plk1 pool in late G2 promotes mitotic commitment.

L. Gheghiani^{1,2}, O. Gavet^{1,2};

¹ Sorbonne Universités, UPMC Paris VI, UFR927, F-75005, Paris, France, ² Gustave Roussy, UMR 8200 CNRS, PR2, Villejuif, France

Activation of the master driver CyclinB1-Cdk1 in late G2 orchestrates the cell division program. How this trigger event is timely controlled during each cell cycle is still an open question. Here, we investigated upstream regulatory mechanisms focusing on the involvement of Polo-like kinase 1 (Plk1). Its activity is limiting for mitotic commitment during unperturbed cell cycles and we determined that activation of Plk1 pool is taking place in late G2 and reproducibly precedes Cyclin-B1-Cdk1 one by a few minutes. This sudden activation relies on upstream Aurora-A kinase and appears related to CyclinA2-Cdk1&2 activity level. In fact, stimulating CyclinA2-Cdk activity from late S, by inhibiting Wee1 kinase, induced a premature activation of Plk1 preceding unscheduled entry into mitosis. We determined that Plk1 associates with Cdc25C in interphase and that its activation induces concurrent Cdc25C phosphorylation before mitotic entry. Mimicking Plk1-dependent Cdc25C phosphorylation events, we found that this regulatory mechanism is sufficient to promote mitotic entry. Altogether, our results unravel some upstream molecular steps leading to CyclinB1-Cdk1 initial activation and mitotic entry.

P240**Board Number: B352****CATS (FAM64A) ALTERED EXPRESSION REDUCES PROLIFERATION OF HEMATOPOIETIC CELLS.**I. Barbutti¹, J.M. Xavier¹, S.T. Saad¹, L.F. Archangelo^{1,2};¹Hematology and Hemotherapy Center, University of Campinas, UNICAMP, Campinas, Brazil, ²University of São Paulo (USP) at Ribeirão Preto, Ribeirão Preto, Brazil

CATS (FAM64A) is a nuclear protein expressed according to the different cell cycle phases, and its expression peaks during S and G2/M. Moreover, a function in metaphase-anaphase transition has been attributed to FAM64A. The protein can be used as a marker for proliferation since its expression positively correlates with proliferation. The precise role of CATS (FAM64A) in proliferation and cell cycle control remains to be defined. The aim of this study was to investigate the effects of CATS (FAM64A) depletion and overexpression of hematopoietic cells. Lentivirus targeting CATS (FAM64A) silencing were used to transduce the U937 cells. Depletion was confirmed at RNA (qRT-PCR) and protein (Western blotting) levels. FAM64A depleted (shFAM64A) and control cells underwent functional *in vitro* assays and cell lysates were used for Western blotting analysis. Proliferation was assessed by MTT assay and colony forming unit (CFU), grown in semi-solid media without growth factors, and cell cycle assay was performed by FACS analysis of the DNA content. Overexpression of the murine Cats (Fam64a) was achieved by retrovirus transduction of primary bone marrow cells with pMIG-Fam64a. Successfully transduced cells were sorted for GFP expression, submitted to cell cycle analysis and cultivated in semi-solid media supplemented for myeloid differentiation. GM (granulocytes and monocytes), BFU-E (erythrocytes) and GEMM (progenitors) colonies and total number of cells were counted after 8 days. Cells were replated and colonies were counted after 10 days. FAM64A depletion was about 80% in shFAM64A cells. Cell proliferation was reduced in shFAM64A cells by 20% in liquid and by 66% in semi-solid media compared to control. Accordingly, a significant reduction of 12% of shFAM64A cells in S phase of the cell cycle was observed. The CYCLIN E and B1 expression were decreased in shFAM64A, whereas CYCLIN A and D1 expression were similar to control cells. Expression of *Fam64a* in mice cells was 215-fold higher in pMIG-Fam64a than in control cells. A significant reduction of GM (by 55%) and GEMM (by 78%) pMIG-Fam64a colonies was observed when compared to control, whereas GM pMIG-Fam64a colonies were reduced by 84% after replating. Total number of pMIG-Fam64A cells was also significantly reduced by 58%. Cell cycle analysis of transduced cells showed a significant reduction of 5% of cells in the S phase of the cell cycle in pMIG-Fam64a compared to control cells. Our results demonstrate that abnormal expression of FAM64A on hematopoietic cells leads to a decrease in cell proliferation which correlates with a decrease in percentage of cells in the S phase of the cell cycle. In human cells, this decrease also correlates with reduced CYCLIN E and B1 expression.

P241**Board Number: B353****CDK1-dependent Inhibition of the E3 Ubiquitin Ligase, CRL4CDT2, Ensures Robust Transition from S Phase to Mitosis.**L.F. Rizzardi¹, D. Varma¹, K.E. Coleman¹, J.P. Matson¹, S. Oh¹, J.G. Cook¹;¹Biochemistry and Biophysics, UNC Chapel Hill, Chapel Hill, NC

Replication-coupled destruction of a cohort of cell cycle proteins ensures efficient and precise genome duplication. Three proteins destroyed during replication via the CRL4CDT2 ubiquitin E3 ligase, CDT1, p21, and SET8 (PR-SET7), are also essential or important during mitosis making their re-accumulation after S phase a critical cell cycle event. During early and mid-S phase and during DNA repair, PCNA loading onto DNA (PCNADNA) triggers the interaction between CRL4CDT2 and its substrates. We have discovered that beginning in late S phase, PCNADNA is no longer sufficient to trigger CRL4CDT2-mediated degradation. A CDK1-dependent mechanism that blocks CRL4CDT2 activity by interfering with CDT2 recruitment to chromatin actively protects CRL4CDT2 substrates. We postulate that deliberate override of replication-coupled destruction allows anticipatory accumulation in late S phase; we further show that (as for CDT1) de novo SET8 re-accumulation is important for normal mitotic progression. In this manner, CDK1-dependent CRL4CDT2 inactivation contributes to efficient transition from S phase to mitosis.

P242**Board Number: B354****Diaphanous formin is required for epigenetic inheritance of CENP-A at centromeres.**C. Liu¹, Y. Mao¹;¹Department of Pathology and Cell Biology, Columbia University College of Physicians Surgeons, New York, NY

Epigenetic landscape has to be well inherited over cellular and organismal generations, largely independent of the underlying DNA sequences. In mammals, as the fundamental unit for chromosome segregation during mitosis, centromeres are defined epigenetically by nucleosomes containing the histone H3 variant CENP-A. In order to maintain centromere identity against CENP-A dilution as DNA duplicates and cell divides, newly synthesized CENP-A proteins are deposited at preexisting centromeres specifically during early G1 of each cell cycle. However, little is known about how accurate CENP-A inheritance is achieved. Recent efforts in the field have elucidated pathways involving different licensing, loading and stabilizing factors required for CENP-A deposition and maintenance, among which a small Rho GTPase molecular switch has been proposed to stabilize newly incorporated CENP-A at the centromere. The FH2 domain of mammalian diaphanous-related formin mDia2, which is a Rho family GTPase effector, has been shown to co-complex with various nucleosome proteins including histone H3

in mammalian cell proteomics (Daou et al. MBoC, 2014). Knocking down mDia2 resulted in substantially reduced levels of centromeric CENP-A revealed by quantitative imaging and high-throughput, unbiased measurement with fixed HeLa cells. Notably, this reduction was not caused by the loss of centromeres, as total number of CENP-B foci in knockdown cells was not significantly changed. A siRNA resistant construct of WT mDia2 rescued this phenotype by restoring CENP-A levels at centromeres. High resolution ratiometric live cell imaging (developed in this study) using HeLa cells stably expressing YFP-CENP-A, documented defective CENP-A loading over the 10 hour time window after anaphase onset in cells depleted of mDia2. Meanwhile, SNAP-tag pulse chase assay revealed that mDia2 is required specifically for newly synthesized CENP-A at centromeres. Furthermore, in mDia2 depleted cells, expression of actin mutants of mDia2 didn't restore CENP-A levels at centromeres. Therefore, our findings have uncovered a novel role for diaphanous formin in regulating CENP-A deposition and thus the epigenetic inheritance of centromere identity.

Spatial regulation of mitotic timing.

B. Strauss¹, M. Zernicka-Goetz², J. . Pines³;

¹The Gurdon Institute, University of Cambridge, Cambridge, England, ²Department of Physiology, Development and Neuroscience, University of Cambridge, Cambridge, United Kingdom, ³Zoology, The Gurdon Institute, University of Cambridge, Cambridge, UK

One of the most prominent characteristics of cyclin B1 is its dynamic localisation throughout the cell cycle. We, and others, have shown that cyclin B1 shuttles between the cytoplasm and the nucleus, but its greater rate of export over import ensures that the majority of cyclin B1 is cytoplasmic throughout interphase. At mitosis, cytoplasmic cyclin B1 is rapidly imported into the nucleus concomitant with the activation of its partner kinase, Cdk1. Although we understand the mechanism by which cyclin B1 is maintained in the cytoplasm, the function of this spatial distribution is still not understood. In order to study the function of cyclin B1 localisation throughout the cell cycle we made use of a cyclin B1 knock out mouse line. We have shown earlier that cyclin B1 null embryos arrest at the four-cell stage and is therefore the only truly essential cyclin in the mouse. This system allowed us to avoid the potential pitfalls of RNAi based approaches by injecting mRNAs encoding mutant forms of cyclin B1 into a genetically null background. Moreover, the large cell size of the early mouse embryo makes this system particularly well suited to study spatial controls using a 3D imaging approach. To increase throughput (as only 25% of embryos are B1 null in each experiment) we have developed a novel imaging chip that allows high resolution imaging of large numbers of mouse embryos as well as their retrieval for genotyping at the end of the experiment. Using this experimental setup we studied the role of nuclear export with respect to cell cycle timing by injecting constitutively nuclear cyclin B1 into B1 null embryos. We found that injected nuclear cyclin B1 can drive up to three division cycles. Furthermore, maintaining cyclin B1 in the nucleus had little effect on the duration of mitosis, nor did it appear to have any measurable effect on DNA replication, because both G1 and S phase durations were the same as in

embryos injected with wild type cyclin B1. Nuclear cyclin B1 did, however, significantly accelerate entry to mitosis after the end of DNA replication, as G2 phase was 40% shorter than normal. We have further tested the functionality of membrane tethered Cyclin B1 and found that it cannot drive entry into mitosis in a null background. Thus, the ability to export cyclin B1 into the cytoplasm is important for cells to regulate the correct timing of mitosis.

Cdk4/6-dependent activation of FOXM1 controls recovery from DNA damage in G1.

I.A. Shaltiel¹, M. Aprelia², A. Llopis², E.E. Voest¹, R.H. Medema³;

¹Cell Biology, Netherlands Cancer Inst, Amsterdam, Netherlands, ²Division of Cell Biology, Netherlands Cancer Institute, Amsterdam, Netherlands, ³Division of Cell Biology, the Netherlands Cancer Institute, Amsterdam, Netherlands

Most Cyclin-dependent kinases are redundant for normal cell division. We tested whether these redundancies are maintained in the abnormal situation of cell cycle reentry after a DNA damage-induced arrest in G1. Interestingly, using non-transformed RPE and BJ-Tert cells, we find that while Cdk4 is dispensable both for S-phase entry of normally proliferating cells and for cell cycle re-entry after serum starvation, it becomes essential to drive S-phase entry after irradiation. Overexpression of Cdk6 can overcome this dependence on Cdk4, indicating that the overall level of Cdk4/6 activity becomes rate-limiting during recovery. We show that Cdk4/6 kinase activity is only required once the checkpoint has been turned off, suggesting that Cdk4/6 activity is not required for DNA repair or checkpoint silencing. Indeed, DNA repair and the elimination of Cdk inhibitor proteins p21 and p27 are unaffected after depletion of Cdk4. We find that Cdk4/6 activity is required to phosphorylate pRb after irradiation, yet inactivation of pocket proteins is insufficient to allow S-phase entry after DNA damage when Cdk4 is depleted. Instead, our data demonstrate that Cdk4 drives recovery from a G1 arrest through the activation of FOXM1.

Two sequential decisions commit human cells to start the cell cycle.

S. Cappel¹, S.L. Spencer¹, M. Chung¹, A. Jaimovich¹, T. Meyer¹;

¹Department of Chemical and Systems Biology, Stanford University, Stanford, CA

One of the most fundamental decision processes in biology is the commitment of cells to enter the cell cycle and generate two daughter cells. Cell-cycle commitment in mammalian cells is thought to be regulated by a single decision point in G1 called the Restriction Point, after which growth factors are no longer required for the cell cycle to proceed. Using live-cell microscopy of cell-cycle sensors and single-

cell analysis, we have identified the moment at which cells cross the Restriction Point and find that more than three hours pass between the Restriction Point and the actual start of DNA replication. Furthermore, we find that cell stress after the Restriction Point but before the start of DNA replication results in cell-cycle exit and a return to a pre-Restriction Point state, providing evidence for another later decision to commit to the cell cycle. We present evidence for a second bistable switch regulating S-phase entry. The trigger for this second switch is the CDK2/Cyclin E-mediated partial inactivation of APCCdh1, an E3-ligase that controls the degradation of proteins necessary for S-phase progression. We show that the switch is driven by a double negative feedback between the regulatory protein Emi1 and APCCdh1. Markedly, Emi1 functions as both an inhibitor and a substrate of the APC, which generates a bistable and irreversible switch regulating S-phase entry. Thus, cells commit to the cell cycle by making two sequential decisions. They first monitor mitogen signals to decide whether to cross the Restriction Point, and then monitor stress signals to decide whether to irreversibly inactivate APCCdh1, start DNA replication, and fully commit to the cell cycle.

hNek5 interferes negatively in mitochondrial mediated apoptosis and respiration.

T.D. Hanchuk¹, P.F. Papa¹, P.G. La Guardia², A.E. Vercesi², J. Kobarg¹;

¹NACIONAL LAB OF BIOSCIENCE, Centro Nacional de Pesquisa em Energia e Materiais, Campinas, Brazil,

²Departamento de Patologia Clínica, Unicamp, Campinas, Brazil

Beside to supplying cellular energy, mitochondrias are involved in signaling, cell death and cellular differentiation and have been implicated in several human diseases. Neks (NIMA-related kinases) represent a family of mammals protein kinases that plays essential roles in cell-cycle progression, but other functions are recently related. Nek5 is the kinase with the smallest information. To characterize Nek5 functions, the yeast two-hybrid (Y2H) screening was performed. According to GO, mitochondrial proteins were identified as hNek5 partners. The mitochondria location of hNek5 was confirmed by cell fractionation followed by western blot analysis and colocalization between hNek5 and mitochondrial proteins in U2-OS and MCF-7 by confocal microscopy. As the prey are involved on apoptosis, mitochondrial transport and respiratory chain complex assembly, the involvement of hNek5 in the mitochondria context was analyzed by MTS and annexin V-FITC assay, measurement of ROS generation and the oxygen consumption. Apoptosis assay showed protective effects of hNek5 in Hek293-T's cell death after thapsigargin treatment (2uM). Stable cells expressing hNek5 or the kinase dead (K33A) version were generated using the FLP-In T-REX mammalian expression system and shRNA lentiviral particles were used to silence hNek5. Silenced cells as well as kinase dead displayed an increase on ROS formation after 4 hours of thapsigargin (2uM) treatment, but, the potentiation effects on cells death occur only after 16 hours of thapsigargin treatment. Cells expressing hNek5, showed protective effects on cell death and ROS formation. Mitochondrial respiratory chain activity of stable and depleted hNek5 cells was determined using the Oroboros Oxygraph. Mitochondrial respiratory chain activity is impaired in the presence of hNek5. Cells silenced for hNek5 presented rampant rates of electrons transfer from

ascorbate to cytochrome c and in the complex II. The partners identified by Y2H are potential substrates for hNek5 that mediates the defects on respiratory chain. In conclusion our data suggest for the first time the hNek5 mitochondrial localization and its role on cell death and cell respiration defects.

Involvement of calreticulin in α -integrin mediated survival and chemoresistance in T-cells.

C. Liu^{1,2}, S. Yap^{1,2}, P. Leclair^{1,2}, D. He^{1,2}, C. Lim^{1,2};

¹Pediatrics, University of British Columbia, Vancouver, BC, ²Child and Family Research Institute, Vancouver, BC

Cell adhesion mediated drug resistance (CAM-DR) is a major contributor to relapse in hematological malignancies. Previously, we showed that adhesion via $\alpha 4\beta 1$ or $\alpha 5\beta 1$ integrins promotes chemoresistance in Jurkat T-leukemia cells (Mol Cell Biol 33:4334). Likewise, adhesion via other integrins including $\alpha 2\beta 1$ or $\alpha L\beta 2$ also promotes chemoresistance, pointing to a common conserved signaling mechanism. The membrane proximal KxGFFKR motif is highly conserved in the cytoplasmic domain of all α -integrins. Expression of a non-integrin chimeric receptor with only KxGFFKR as the cytosolic motif rendered cells highly chemoresistant in an adhesion-independent manner. These cells exhibit high rates of calcium influx coupled with drug efflux, as well as constitutive activation of Akt pro-survival signaling. Furthermore, we found increased interaction of KxGFFKR with the calcium-binding protein, calreticulin (CRT). Recently, high frequency somatic mutations that give rise to a variant CRT protein predicted to be enriched in the cytosol (vs the endoplasmic reticulum) was implicated in the JAK-STAT pathway controlling myelo- and lympho-proliferative disorders. As CRT-integrin association can be stimulated by cell adhesion, we propose that cytosolic CRT may act as an oncogenic protein involved in cell survival and regulation of chemoresistance.

To investigate the role of CRT in CAM-DR, we generated CRT null T-cells by CRISPR-Cas mediated gene silencing, and show that CRT is implicated in integrin activation, cell adhesion, and enhanced apoptotic resistance to cytotoxic chemotherapy. Furthermore, interferon-stimulated phosphorylation of STAT3 and STAT5 is disrupted in CRT null T-cells, suggesting CRT has a vital role in coupling cytokine-mediated stimulation of JAK-STAT signaling in lymphoblasts. Ongoing investigation will further delineate the cytosol and endoplasmic reticulum specific roles of CRT in CAM-DR by intracellular targeted CRT expression enriched in the cytosol and/or ER.

P1838**Board Number: B361****iRHOM2 regulation of ADAM17 as a key regulator of epithelial growth factor signalling.**M.A. Brooke¹, S.L. Etheridge¹, B. Fell¹, D.P. Kelsell¹;¹Blizard Institute, Barts and The London School of Medicine Dentistry, London, United Kingdom

Our group has previously linked point mutations in the proteolytically inactive rhomboid protein iRHOM2 to the dominantly-inherited disease Tylosis with oesophageal Cancer (TOC), a disorder of palmo-plantar keratoderma, oral leukokeratosis, and the only known syndrome of inherited oesophageal squamous cell carcinoma susceptibility. In keratinocyte cell lines, these iRHOM2 mutations result in dysregulation of the multi-substrate ectodomain sheddase enzyme ADAM17 (TACE), an enzyme whose maturation and activation is regulated by iRHOM2.

TOC-associated iRHOM2 mutations result in increased ADAM17 maturation and translocation to the plasma membrane of keratinocytes (in both monolayer and three-dimensional epidermal-equivalent cultures), and greatly upregulated constitutive shedding of numerous ADAM17 substrates, including the EGF-family growth factors amphiregulin, TGF α and HB-EGF. This is accompanied by a phenotype of significantly increased proliferation and migration of TOC-associated iRHOM2-mutant cells relative to controls, with both the increased levels of growth factor shedding and the pro-migratory phenotype sensitive to pharmacological ADAM17 inhibition or siRNA knockdown. Excessive EGF-family growth factor signalling was also shown to result in the upregulation of Transglutaminase 1 activity in the epidermis of TOC-affected individuals and in three-dimensional TOC keratinocyte cultures relative to controls, whilst the epidermis of TOC-affected individuals is also characterised by the expression of desmosomes lacking electron-dense midlines, suggestive of the presence of a pro-migratory, wound-healing-like state in the skin. The presence of a constitutive wound-healing-like state is also supported by the very strong constitutive upregulation of IL-6 and IL-8 expression and secretion by TOC keratinocytes, secretion which is sensitive to ADAM17 knockdown despite these cytokines not being ADAM17 substrates.

In addition to regulation of EGF-family growth factor shedding, iRHOM2 may also play a role in the transactivation of EGFR signalling in response to G-protein coupled receptor (GPCR) activation, a process dependent on ADAM17 activity. Activation of the GPCR FGFR2b on keratinocytes by the growth factor KGF leads to phosphorylation of iRHOM2 and ADAM17, suggesting that activation of iRHOM2, and the interaction between it and ADAM17 may play an important role in regulating EGFR transactivation in response to GPCR signalling.

These findings reveal the central role of iRHOM2 in growth factor regulation in the skin. This, and the association of iRHOM2 mutations with oesophageal cancer may offer new insights into mechanisms of epidermal hyperproliferation and oesophageal carcinogenesis.

P1841**Board Number: B362****Pro-apoptotic role of human YPEL5, yeast ortholog MOH1, in DNA damage-induced apoptosis in tumor cells.**J. Lee¹, D. Jun², L. Xie¹, Y. Kim¹;¹School of Life Science and Biotechnology, College of Natural Sciences, Kyungpook National University, Daegu, Korea, ²Institute of Life Science and Biotechnology, Kyungpook National University, Daegu, Korea

During comprehensive sequence analysis of human chromosome, a novel gene family consisting of five members (YPEL1 through YPEL5) showed high conservation among eukaryotes from yeast to human. To understand the functional role of YPEL5, which is distinct from the other four members, we employed the budding yeast (*Saccharomyces cerevisiae*) mutant possessing disrupted yeast ortholog MOH1 gene, and compared its physiological characteristics with those of the wild-type strain. The mutant for the MOH1 gene exhibited an enhanced resistance to UVC (254 nm) irradiation and genotoxic agents as compared with the wild-type. This phenomenon was abrogated when the disrupted MOH1 gene in the mutant was restored by transformation of the human YPEL5 gene. In tumor cells, the level of YPEL5 was up-regulated following treatment with genotoxic agents and the up-regulation of YPEL5 at the transcription level appeared to depend on the tumor suppressor p53. Whereas the overexpression of YPEL5 augmented DNA damage agent-induced caspase cascade activation, the down-regulation of YPEL5 could suppress the apoptotic events. These results demonstrate the functional conservation of YPEL5 protein between lower and higher eukaryotes, which is involved in DNA damage-induced apoptosis, and provide insights into the molecular and cellular function of the YPEL family proteins.

P1842**Board Number: B363****Mechanisms of p53-dependent Cell Fate Choice.**K.D. Sullivan¹, J.M. Espinosa¹;¹HHMI and MCDB Department, University of Colorado, Boulder, CO

The p53 tumor suppressor governs cellular stress responses ranging from cell cycle arrest to apoptosis; however, the molecular mechanisms of these cell fate decisions remain poorly understood. Attempts at small molecule activation of p53 have fallen short clinically as they result in reversible cell cycle arrest in the majority of cancer cell types. We have performed genome-wide shRNA screens with one such small molecule, Nutlin-3, to identify genes that are lethal with non-genotoxic activation of p53 and discovered that the ATM and MET kinases regulate p53-dependent cell fate choice. Genetic or pharmacological interference with ATM or MET converts the cellular response to Nutlin-3 from cell cycle arrest to apoptosis. Nutlin-3 and ATM synthetic lethality owes to functions of ATM outside the DNA damage response. We show that inhibition of ATM results in accumulation of intracellular reactive oxygen species (ROS), and that these ROS are involved in the synthetic lethality as the phenotype is abrogated by addition of the ROS scavenger N-acetyl-cysteine. Furthermore, knockdown of several p53-inducible

antioxidant genes including SESN1/2 and TP53INP1 further sensitizes cells to Nutlin-3 and ATM synthetic lethality. We demonstrate that ROS increases associated with a loss in ATM activity correlate with accumulation of mitochondria and provide evidence that this may be linked to defects in autophagy. Finally, to identify genes that are required for Nutlin-3 and ATM induced synthetic lethality; we performed a positive selection screen that identified several promising candidates of diverse biological function. Further studies are also under way to better understand the conservation of synthetic lethality across cancer types and between drugs with different mechanisms of action.

Transformation of normal cells to cancer cells that are able to form tumors and even metastasize is a multi step process where molecular changes of high complexity are acquired. By using a four-stage isogenic human cell model that mimics the route to malignancy we demonstrate how a transcriptomics approach with subsequent protein analysis can be used to define the molecular changes that accompany the mechanisms related to immortalization, transformation and invasion/metastasis separately and identify potential biomarkers for malignancy. Additionally, we are currently investigating the impacts of hypoxia by studying differential protein expression and spatial distributions of proteins under different oxygen levels. This project is performed in close collaboration with the Human Protein Atlas (HPA) project and with the use of RNA sequencing in combination with the HPA collection of antibodies covering the whole human proteome and high-resolution microscopy, protein expression can be studied on a single cell level. Our results show that about 1300 genes are differentially expressed across the cell model and that the majority of the genes are downregulated, supporting the principle of dedifferentiation en route to malignancy. [1]

1. Danielsson, F., et al., Majority of differentially expressed genes are down-regulated during malignant transformation in a four-stage model. Proceedings of the National Academy of Sciences of the United States of America, 2013. 110(17): p. 6853-8.

P1846**Board Number: B365****p21-activated kinase 4 promotes breast cancer initiation and progression.**

T. Costa¹, T. Zhuang¹, M. Zhao¹, Z. Li¹, U. Rabenhorst¹, H. Olofsson¹, P. Hernandez Varas¹, J. Lorent², S. Strömblad¹;

¹Department of Biosciences and Nutrition, Karolinska Institute, Stockholm, Sweden, ²Department of Oncology-Pathology, Karolinska Institute, Stockholm, Sweden

p21-activated kinase 4 (PAK4) is overexpressed in diverse human cancers and plays a pivotal role in several cancer-associated cellular events.

To elucidate the role of PAK4 in breast cancer initiation and progression *in vivo*, we have generated transgenic mice that overexpress PAK4 in the mammary gland (MMTV-PAK4). MMTV-PAK4 mice exhibit atypical hyperplasias that eventually progress to cancer, indicating that PAK4 overexpression in the mammary gland is sufficient *per se* to increase the spontaneous mammary carcinoma incidence.

Conversely, we have also established mice with conditional PAK4 depletion in the mammary epithelium (PAK4 floxed;MMTV-Cre). Conditional knockout of PAK4 significantly delays PyMT-driven mammary tumourigenesis. Consistently, ablation of PAK4 inhibited human breast cancer xenograft growth in mice.

Through the combination of several global approaches (including exome sequencing to identify genetic events that accompany PAK4-driven tumourigenesis and global expression profiling of cancer cells upon PAK4 inhibition) we aim to gain a comprehensive insight into how PAK4 regulates breast cancer initiation and progression.

P1848**Board Number: B366****Characterization of the SW13 adrenal adenocarcinoma cell line and induction of subtype switching by HDAC1 inhibition.**

M.R. Davis¹, J.J. Daggett¹, A.S. Pascual¹, K.E. Cooper¹, K.J. Leyva², E.E. Hull¹;

¹Biomedical Sciences, Midwestern University, Glendale, AZ, ²Microbiology Immunology, Midwestern University, Glendale, AZ

The human adrenal carcinoma SW13 cell line can switch between a subtype which expresses the tumor-suppressor gene Brahma (Brm), SW13+, and one that does not, SW13-. Unlike many tumor suppressor genes, which are often mutated, in SW13- cells loss of Brm expression occurs post-transcriptionally and can be restored via histone deacetylase (HDAC) inhibition. However, many of the previously characterized Brm inducing HDAC inhibitors are toxic, broad-spectrum inhibitors which have limited downstream use, and provide little insight into the specificity of epigenetic Brm suppression. In this work we sought to further characterize the oncogenic potential of the two SW13 subtypes, and to

investigate the potential epigenetic regulators that contribute to the subtype switching. Cell growth and colony formation assays revealed that Brm deficient SW13- cells have both a faster cell number doubling time and an increased rate of anchorage-independent growth, while SW13+ cells appear to express higher levels of MMP. Next, we screened multiple HDAC inhibitors for their ability to induce switching between the SW13 subtypes in an effort to identify the specific HDAC enzyme(s) necessary for this conversion. Immunofluorescence and gene expression analyses suggest that inhibition of HDAC1 most efficiently increases the rate of conversion between SW13- and SW13+ cells, and that it does so in a dose dependent manner. Furthermore, after conversion to SW13+ there is increased acetylation on histone H3 but not histone H4 when compared to levels in SW13-, suggesting that the role of acetylation on the H3 tail may play an essential role in the subtype switch. Pathway-specific quantitative RT-PCR profiling arrays uncovered significant differences in the expression of multiple genes involved in epigenetic chromatin remodeling as well as epigenetic chromatin modification, indicating that these two subtypes also have unique gene expression profiles that could contribute to Brm regulation and maintenance of the subtype switch. These studies provide new insight into the functional consequences of Brm loss in the SW13 cell type and reveal potential targets for the reversal of Brm epigenetic silencing.

Ewing sarcoma is an aggressive pediatric cancer of the bone and soft tissues characterized by a chromosomal translocation involving EWS and an Ets transcription factor, usually Fli-1. EWS-Fli-1 fusions comprise 85% of Ewing sarcoma cases. Ewing sarcoma cells are dependent upon EWS-Fli-1 for growth and survival, yet little is known about EWS-Fli-1's biochemical characteristics. Using a proximity-dependent biotinylation technique, BioID, we identified cation-independent mannose 6-phosphate receptor (CIMPR) as a protein located in the vicinity of EWS-Fli-1. CIMPR is a cargo transporter which facilitates the movement of lysosomal hydrolases between the trans-Golgi network and the endosome, which are then transferred to the lysosome. We verified the interaction of CIMPR with EWS-Fli-1 by co-immunoprecipitation and discovered the role of lysosomes in regulating EWS-Fli-1 stability. Inhibition of lysosome function by chloroquine stabilized EWS-Fli-1 protein levels, while inhibition of the mTORC1 pathway by torin 1, which activates the TFEB-lysosome pathway, degraded EWS-Fli-1. These results suggest that lysosomal activation may provide a therapeutic means to modulate EWS-Fli-1 levels.

P1852**Board Number: B368****Hypersensitivity to DNA double strand breaks in late G2 protects against checkpoint adaptation.**L. Krenning¹, F.M. Feringa¹, R.H. Medema¹;¹Division of Cell Biology, the Netherlands Cancer Institute, Amsterdam, Netherlands

The cellular response to DNA damage ranges from transient cell cycle arrest to the induction of apoptosis or senescence. It is generally thought that permanent cell cycle withdrawal is initiated in response to severe, irreparable DNA damage. This way cells can prevent the propagation of a damaged genome. Alternatively, some cells may enter mitosis in the presence of DNA damage, a process known as checkpoint adaptation. This is a potentially dangerous process, as the propagation of damaged DNA may compromise genome integrity. Using live-cell microscopy to study the effects of DNA damage on cell fate decisions we have identified that a fraction of cycling cells are hypersensitive to DNA double strand breaks. This fraction represents cells that are damaged just prior to mitotic entry. These cells respond to DNA damage by activating the anaphase promoting complex / cyclosome in complex with its coactivator Cdh1 (APC/CCdh1) and undergo permanent cell-cycle exit, even in response to low amounts of DSBs. During unperturbed G2 progression the APC/CCdh1 is inhibited by Early mitotic inhibitor (Emi1)-binding to Cdh1, and CDK-dependent phosphorylation of Cdh1. However, as Emi1 levels decline towards the later stages of G2, these cells become critically dependent on CDK activity for APC/CCdh1-inhibition. Indeed, inhibiting CDKs in unstressed cells is sufficient to induce APC/CCdh1-activation specifically in late G2 cells. Conversely, preventing DNA damage-induced CDK inhibition prevents APC/CCdh1 activation in late G2 cells. In addition, overexpression of Emi1 prevents the DNA damage induced activation of APC/CCdh1. We continue to show that this cell cycle exit mechanism functions to prevent late G2 cells from entering mitosis in the presence of DNA double strand breaks, and therefore acts to prevent checkpoint adaptation and guard genome stability.

P1855**Board Number: B369****The role of RhoGAPs in basal-like breast cancer.**C.D. Lawson^{1,2}, K.L. Rossman², C. Fan³, C.M. Perou³, K. Burrige¹, C.J. Der²;¹Department of Cell Biology and Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC,²Department of Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC, ³Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC

The basal-like subtype of human breast cancer accounts for a disproportionately high percentage of overall breast cancer recurrence and death, and the current therapeutic options for this cancer are ineffective. Hence, elucidating the signaling pathways that are responsible for driving the growth of basal-like tumors may identify novel targets for the development of effective therapies. Rho family small GTPases have been implicated previously in promoting tumor cell proliferation, invasion, and metastatic

growth in a variety of cancers. These proteins are activated by guanine nucleotide exchange factors (GEFs) and, in the context of cancer, overexpressed RhoGEFs can function as oncogenes which cause hyper-elevated Rho GTPase activity. In contrast, GTPase-activating proteins (GAPs), which return Rho GTPases to an inactive, GDP-bound state, have generally been presumed to act as tumor suppressors. Surprisingly, microarray analysis of the expression of Rho GTPases, GEFs, and GAPs across a panel of human breast tumors revealed that a number of RhoGAP genes were significantly upregulated in basal-like breast cancers (BLBCs). These preliminary results suggest that RhoGAPs may play an unexpected role in promoting tumor growth. The aim of our research is therefore to validate and characterize the role of two of these RhoGAPs, RacGAP1 (also known as MgcRacGAP and CYK4) and ArhGAP11A (also known as MP-GAP), in BLBC development. In human BLBC cell lines, shRNA-mediated knockdown of either of these genes resulted in a significant defect in proliferation relative to control cells, in addition to distinct morphological changes. Furthermore, knockdown of RacGAP1 caused an increase in the number of multinucleated cells, consistent with a previously-established role for this Rac-specific GAP in regulating cytokinesis. In contrast, ArhGAP11A, a relatively poorly-characterized Rho-specific GAP, caused BLBC cell lines to accumulate in the G1 phase of the cell cycle upon its knockdown, indicative of a role in regulating cell cycle progression. In summary, we have established that two RhoGAPs, RacGAP1 and ArhGAP11A, are critical to the growth of BLBC cell lines. Experiments to establish the precise mechanisms through which these GAPs elicit each phenotype are ongoing. This work was supported by the U.S. Army Medical Research and Materiel Command under Award No. W81XWH-14-1-0033.

Epigenetic silencing of MARVELD1 gene attenuates nonsense-mediated mRNA decay in lung cancer and represents a potential biomarker for detection of malignancy.

M. Shi¹;

¹School of Life Science and Technology, Harbin Institute of Technology, Harbin, China

Nonsense-mediated mRNA decay (NMD) pathway, a well-known mRNA quality control system, rapidly degrades mRNAs with harboring translation premature termination codons (PTC) in post-transcriptional process. Recent studies suggest that NMD regulation might implicate in tumorigenesis; however, the mechanism is poorly defined. Here, we found that novel nuclear factor MARVELD1 and the epigenetic modification of MARVELD1 promoter are involved in NMD regulation. We demonstrated that the expression of MARVELD1 gene is down-regulated in lung cancer, especially in small cell lung cancer. The reduced MARVELD1 level in lung cancer is due to its promoter hypermethylation. Treatment with DNA methyltransferase inhibitor can restore MARVELD1 expression. In addition, MARVELD1 physically interacts with NMD factor SMG1 and NMD target PTC-mRNA. The decreased MARVELD1 expression in lung cancer reduces NMD efficiency through diminishing the association of NMD complex component UPF1/SMG1 with PTC-mRNA. These results suggest that the epigenetic modification of MARVELD1 promoter links with the regulatory mechanism of NMD pathway in lung cancer cells.

P1858**Board Number: B371****Identifying the c-MET phosphorylation site regulated by CD82 in prostate tumor cells.**V. Janardan¹, J. Shady¹;¹Biomedical Sciences; Cell and Molecular Biology, Grand Valley State University, Allendale, MI

CD82 (KAI), a metastasis tumor suppressor protein is under-expressed in prostate as well as several other types of metastatic cancers. It inhibits cancer metastasis, but the mechanism through which regulation happens remains unclear. Various pathways are being explored in this lab, including regulation of c-MET, a growth factor receptor observed to have increased activation in tumor cells.

CD82 and c-MET do not co-localize, suggesting that CD82 indirectly downregulates c-MET. To be expressed, c-MET first needs to bind to its ligand, HGF. This growth factor encourages phosphorylation of c-MET, consequently activating it. C-Met has four tyrosine phosphorylation sites that include p-Tyr 1003, p-Tyr 1234/1235, p-Tyr 1349 and p-Tyr 1365. Knowing how each phosphorylation site of c-Met affects downstream signaling event, our lab is focused in identifying which site is regulated by CD82. Another tetraspanin CD151, which promotes tumor progression and metastasis, has been shown to associate with c-Met and the integrins, which CD82 associates with. We are currently exploring the levels and expression of CD151 and its association with c-Met in the presence and absence of CD82. This we believe will provide additional insight into how CD82 overall regulates c-Met and prevents prostate tumor metastasis.

P1859**Board Number: B372****p53 protein reduces centrosome amplification in human cells exposed to subtoxic levels of 2-chloroethyl ethylsulfide (2-CEES).**J.D. Fulkerson¹, E. Behrens², A. Zinn^{2,3}, C. Duncheon², T.J. Lamkin⁴, R.A. Bennett⁵;¹Biology, University of Southern Indiana, Evansville, IN, ²University of Southern Indiana, Evansville, IN,³Biological Sciences, University of Toledo, Toledo, OH, ⁴Molecular Signatures Section - Molecular Genetics, Air Force Research Laboratory, Wright-Patterson AFB, OH, ⁵Department of Biology, University of Southern Indiana, Evansville, IN

Mustard gas is a simple molecule that was first used as a chemical weapon in World War I. It is a powerful vesicant and alkylating agent that causes painful blisters on epithelial surfaces and increases the incidence of cancer in those exposed. The mechanism of mustard gas toxicity and tumorigenesis is not well understood but is thought to be mediated by its ability to induce oxidative stress and DNA damage. Interestingly, several proteins (including p53) that have been shown to either be targets of mustard gas or mediate mustard gas toxicity have also been shown to regulate centrosome duplication.

Centrosomes are small, non-membrane bound organelles that direct the segregation of chromosomes during mitosis through the formation of the bipolar mitotic spindle. Cells with more or less than two centrosomes during mitosis can segregate their chromosomes unequally, resulting in chromosome instability, a common phenotype of cancer cells. In our studies, we show that subtoxic levels of a mustard gas analog, 2-chloroethyl ethylsulfide (2-CEES), induces centrosome amplification and chromosome instability (CIN) in cells lacking p53. Additionally, we show that the reintroduction of p53 protein to cells exposed to subtoxic levels of 2-chloroethyl ethylsulfide (2-CEES) reduces centrosome amplification in, which may retard the mutation rate necessary for tumorigenesis. These data may support previous demonstrations of mustard gas toxicity targeting p53.

Epigenetic mechanisms can drive the development and progression of cancer. Epigenetic changes in tumor cells hold particular promise as therapeutic targets because, unlike gene mutations, they are reversible. In one well characterized epigenetic mechanism the SWI/SNF enzymes control gene expression through their ATP-dependent remodeling of chromatin structure. We found that the levels of BRG1, one of two mutually exclusive SWI/SNF ATPases, were up-regulated in human and mouse primary mammary tumors. Reduction of BRG1 expression decreased cancer cell proliferation and tumorigenesis in a panel of breast cancer cell lines *in vitro*, and in MDA-MB-231 xenografts. Depletion of BRG1 reprogrammed cancer cell metabolism, decreasing DNA, RNA and lipid synthesis. BRG1 controlled *de novo* fatty acid synthesis via transcriptional regulation of key lipogenic enzymes, including Acetyl-CoA Carboxylase, Fatty Acid Synthase, and ATP Citrate Lyase. We propose that targeting BRG1 could reverse the higher proliferation-supporting rates of *de novo* fatty acid synthesis observed in tumors even when exogenous fatty acids are abundant. In support of this idea, reduction of BRG1 sensitized breast cancer cells to chemotherapeutic drugs used clinically. Therefore, BRG1 may be a novel and promising target for the epigenetic treatment of breast cancer.

P1863**Board Number: B374****Is Hsp90 inhibitor efficacy dependent on Cullin 5 expression?.**S. Wicks¹, G. Heck¹, T. Atuobi¹, E. Ehrlich¹;¹Biological Sciences, Towson University, Baltimore, MD

Cancer is the second leading cause of death in the United States. Despite considerable progress in development of new cancer therapeutics, over half a million people are expected to die from cancer this year. Hsp90 inhibitors target Hsp90, a chaperone whose clients include oncogenes that are overexpressed in many different cancers. Inhibition of Hsp90 results in proteasomal degradation of clients and inhibition of related signaling pathways in cancer cells. Despite its promise, Hsp90 inhibitors have shown little efficacy in clinical trials. Cullin 5 (Cul5), a ubiquitin ligase involved in regulation of Hsp90 clients, has been shown to be down-regulated in breast cancer cells suggesting that variation in Cul5 gene expression may be negatively impacting Hsp90 inhibitor efficacy. We have previously reported that Cul5 is required for the geldanamycin-induced degradation of two clinically relevant Hsp90 clients, ErbB2 and Hif1a. Through analysis of gene expression data from 62 cases of breast invasive carcinoma obtained from The Cancer Genome Atlas, we observed decreased expression of Cul5 in tumor compared to normal tissue in all but 11 patients ($t = -5.6155$, $df = 61$, $p\text{-value} = 5.119e-07$). Here we demonstrate that Cul5 expression correlates with sensitivity to 17-AAG. Downregulation of Cul5 expression in AU565 cells resulted in complete resistance to 17-AAG, where as control cells exhibited almost 80% cytotoxicity. Sensitivity to 17-AAG correlated with Cul5 transcript levels in breast cancer cell lines. MCF-7 cells expressed Cul5 at levels two-fold higher than MDA-MB-468 cells and were more than three times as sensitive to killing by 17-AAG. This data suggests that variation in Cul5 expression may be responsible, in part, for the variation in sensitivity to Hsp90 inhibitors observed in the clinic. By establishing Cul5 as a critical player in the response to Hsp90 inhibitors, we can study Cul5 downregulation in cancer with the goal of increasing Hsp90 inhibitor efficacy, thereby enhancing survival and quality of life for affected individuals.

P1866**Board Number: B375****CDKN3 plays an important role in cellular transformation by Abl oncogenes.**J. Chen¹, K. Chen¹, G. Guo¹;¹Chinese Academy Scis-Inst Microbiol, Beijing, China

Previous studies have revealed that deregulation of multiple signaling pathways associated with cell survival and proliferation, including phosphoinositide-3-kinase (PI3K)/AKT, RAS, and Janus kinase (JAK)/signal transducer and activator of transcription (STAT), underlies Abl oncogene induced tumorigenesis. However, the precise mechanisms by which Bcr-Abl causes leukemogenesis are not fully clarified. CDKN3 (cyclin-dependent kinase inhibitor 3), a dual specificity protein phosphatase, dephosphorylates cyclin-dependent kinases (CDKs) and thus functions as a key negative regulator of cell

cycle progression. Deregulation or mutations of CDKN3 have been shown to play roles in various cancers. However, the function of CDKN3 in Bcr-Abl-mediated chronic myelogenous leukemia (CML) remains unknown. Here we found that CDKN3 acts as a key inhibitor in Bcr-Abl-mediated leukemogenesis. Overexpression of CDKN3 sensitized the K562 leukemic cells to imatinib-induced apoptosis and dramatically inhibited K562 xenografted tumor growth in nude mouse model. Forced expression of CDKN3 significantly reduced the efficiency of Bcr-Abl-mediated transformation of FDCP1 cells to growth factor independence. In contrast, depletion of CDKN3 expression conferred resistance to imatinib-induced apoptosis in the leukemic cells and accelerated the growth of xenograph leukemia in mice. In addition, we found that CDKN3 mutant (CDKN3-C140S) devoid of the phosphatase activity failed to affect the K562 leukemic cell survival and xenografted tumor growth, suggesting that the phosphatase of CDKN3 was required for its tumor suppressor function. Furthermore, we observed that overexpression of CDKN3 reduced the leukemic cell survival by dephosphorylating CDK2, thereby inhibiting CDK2-dependent XIAP expression. Moreover, overexpression of CDKN3 delayed G1/S transition in K562 leukemic cells. Our results highlight the importance of CDKN3 in Bcr-Abl-mediated leukemogenesis, and provide new insights into diagnostics and therapeutics of the leukemia.

Inhibitors of Skp2 E3/Cks1 ligase complex prevent degradation of p27kip1 as a novel therapeutic approach to estrogen-induced type I endometrial cancer.

S.C. Pavlides¹, B.R. Rueda², E. Rothenberg¹, S.V. Blank¹, K.R. Mittal¹, T. Cardozo¹, L.I. Gold¹;

¹New York Univ Sch Med, New York, NY, ²Vincent Center for Reproductive Biology, Harvard medical school, Boston, MA

In many human cancers, the tumor suppressor, p27kip1 (p27), a cyclin-dependent kinase inhibitor critical to cell cycle arrest, undergoes perpetual ubiquitin-mediated proteasomal degradation by the E3 ligase complex SCF-Skp2/Cks1 and/or cytoplasmic mislocalization; lack of nuclear p27 causes aberrant cell cycle progression and cytoplasmic p27 mediates cell migration/metastasis. We previously showed that estrogen (E2) induces Skp2-dependent degradation of p27 and cell proliferation in primary endometrial epithelial cells (EECs) and endometrial carcinoma (ECA) cell lines (e.g., ECC-1) suggesting a pathogenic mechanism for type I endometrial carcinoma (ECA), an estrogen (E2)-linked cancer. The current studies show that treatment of ECC-1 cells with small molecule inhibitors of Skp2/Cks1 E3 ligase activity (Skp2E3LIs) increase protein levels of p27, increase p27 half-life by 6 hours and inhibit cell proliferation (IC50 14µM) by G1 phase block and not by apoptosis. Two of five SKP2E3LIs, C2 and C20 specifically increase p27 in the nucleus by 2-fold while decreasing p27 in the cytoplasm by 33% in 18 hours in both ECC-1 cells and primary ECA cells. Similarly, by Super Resolution Microscopy, Skp2E3LIs increased nuclear p27 by 1.8-fold. In addition, C2 and C20 prevent both E2-induced proliferation and degradation of nuclear p27. Importantly, C2, C5, and N1 injected into ovariectomized, E2-primed mice increase nuclear p27 in uterine epithelial cells with a concomitant 42-62% decrease in proliferation. Taken together, these data suggest that Skp2E3LIs function in the nucleus to prevent E2-induced

degradation of p27 to regain growth control by directly blocking p27 ubiquitylation and subsequent degradation suggesting that these inhibitors have potential to prevent ECA since E2-induced hyperplasia precedes carcinoma. Skp2E3LIs enable a chemical biology approach to understanding the functional significance of the ubiquitin pathway in p27-mediated dysregulation of the cell cycle in cancer, and importantly, are the first specific proteasome inhibitors that pharmacologically target the binding interaction between the E3ligase, SCF-Skp2/Cks1 and p27 to critically stabilize nuclear p27 and prevent cell cycle progression. These targeted inhibitors represent a major therapeutic advancement over general proteasome inhibitors for cancers characterized by SCF-Skp2/Cks1-mediated destruction of p27.

Molecular and cellular mechanisms of Pin1-mediated Grb7 degradation in regulation of cancer progression.

Y. Tai¹, L. Tung¹, Y. Lin¹, T. Li², T. Shen¹;

¹Natl Taiwan Univ, Taipei, Taiwan, ²Natl Taiwan Univ Coll Med, Taipei, Taiwan

Growth factor receptor bound protein-7 (Grb7) is a multi-domain adaptor protein in cooperation with numerous tyrosine kinases to regulate various cellular signaling and functions. Indeed, co-overexpression of Grb7 with EGFR or Her2 is related to cancer progression and malignancy, therefore, Grb7 serves a prognostic marker and therapeutic target in cancers. However, it remains largely unknown the regulatory and signaling mechanisms of Grb7 in regulating these various cellular functions. Here, we observed a novel interaction between Pin1 and Grb7 by a yeast two-hybrid screening. The prolyl cis/trans isomerase Pin1 functions as a regulator to isomerize the pSer/Thr-Pro bond(s), which conferring a conformational change and leading to alterations in protein functionality, stability, and/or intracellular localization. By mutational analyses, we found that Pin1 enables directly interacting with Grb7 through the phospho-Ser194-Pro motif on Grb7 and the WW domain of Pin1. In addition, knockdown of Pin1 expression through lentiviral-mediated gene silencing could prolong Grb7 protein stability. Utilizing cycloheximide pulse-assay and quantitative RT-PCR analysis, we conclude that Pin1 could negatively regulate Grb7 protein stability at the post-translational level. In fact, we found that Pin1 could exert its isomerase activity to modulate Grb7 protein expression in an ubiquitin/proteasome-dependent proteolysis pathway. Collectively, our data suggested that the Pin1-Grb7 complex formation enables negatively regulating tumor progression and/or malignant processes due to the influence of Grb7 protein expression.

NR2F1 regulates epithelial identity and maintains quiescence of a stem cell-like subpopulation of pre-malignant mammary cells.

M.S. Sosa^{1,2}, J.A. Aguirre-Ghiso^{1,2};

¹Division of Hematology and Oncology, Mount Sinai School of Medicine, Department of Medicine, NY,

²Black Family Stem Cell Institute, Manhattan, NY

Invasive tumor cells are known to be able to complete all steps of the metastatic cascade. However, new evidence shows that pre-malignant cells (from lesions histopathologically defined as non-invasive, i.e. DCIS, ADH) can disseminate and, as disseminated tumor cells (DTCs), enter a non-proliferative state for prolonged periods. Early DTCs are proposed to contribute to metastasis, but the mechanisms that would allow cells considered sessile to complete all steps of metastasis are unknown. Here we report that the orphan nuclear receptor NR2F1 is downregulated in human pre-malignant and malignant lesions. Further, in MMTV-ErbB2+ pre-malignant mammary epithelial cells (MECs) downregulation of NR2F1 activates a motile phenotype and this is coincident with the detection of circulating tumor cells (CTCs) and DTCs in lungs and bone marrow. Knock down of basal NR2F1 levels in pre-malignant ErbB2+ MECs induced cell motility, loss of laminin-V deposition, β -catenin delocalization from the membrane and dramatic loss of E-cadherin junctions. Interestingly, TWIST, SNAIL and ROR1 mRNA levels became upregulated upon NR2F1 depletion. These results suggest that NR2F1 expression maintains epithelial identity and suppresses epithelial-mesenchymal transition (EMT), possibly by blocking WNT signaling. Knock down of NR2F1 in ErbB2+ pre-malignant MECs also enhanced mammosphere formation efficiency and this was accompanied by upregulation of the pluripotency transcription factor NANOG. These findings suggest that NR2F1 limits the spreading of ErbB2+ pre-malignant cells and it promotes a differentiated epithelial identity by promoting quiescence and limiting the activation of a stem cell-like program. Our findings provide for the first time evidence that NR2F1 functions in mammary epithelial cells as a suppressor of pluripotency and dissemination during early stages of tumor progression. We propose that therapies that might restore expression of NR2F1 might allow limiting early dissemination and the progression to metastasis of already disseminated tumor cells.

P248**Board Number: B379****Bundling of the actin cortex by Erk phosphorylated Eps8 is essential for high cortex tension and the bleb-based migration of melanoma cells.**J. Logue¹, A. Cartagena-Rivera², R. Chadwick², C. Waterman³;¹NHLBI/NIDCD, National Institutes of Health, Bethesda, MD, ²NIDCD, National Institutes of Health, Bethesda, MD, ³National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD

Melanoma is a cancer that is known for its rapid spreading and low survivability. Within the confines of tissues, a growing body of evidence suggests that cancer cells frequently use blebs to migrate.

Melanoma cells are hyper-contractile because of an activating mutation in the Erk signaling pathway (B-Raf V600E) that pre-disposes cells to blebbing. Epidermal growth factor pathway substrate 8 (Eps8) is an actin bundling and capping protein whose capping activity is inhibited by Erk phosphorylation. We hypothesized that Eps8 may act as a key effector of Erk to modulate actin cortex mechanics and thereby mediate bleb-based migration of cancer cells. We used live cell imaging of fluorescent probes and atomic force microscopy (AFM) to test this hypothesis in human melanoma A375 cells. We found that Eps8 rapidly localized to newly formed bleb membranes, co-incident with the assembly of cortical F-actin, suggesting it regulates actin in blebs. When cells were confined under agarose, they migrated rapidly in the direction of a very large bleb (50% or more of total cell area), which we call a "leader bleb," and which exhibited co-localization of Eps8 with actin along its cortex. Depletion of Eps8 by siRNA reduced leader bleb size and prohibited bleb-based migration. Re-expression of wild-type Eps8 but not a bundling-defective mutant rescued leader bleb size, indicating a critical role for actin bundling by Eps8 in bleb-based migration. Re-expression of a capping-deficient Eps8 mutant in Eps8 knockdown cells rescued leader bleb size, but re-expression of a mutant with constitutive capping activity induced by substitution of Erk phosphorylation sites (S624A/T628A) did not. This suggests that down-regulation of Eps8 capping activity by Erk is required for leader bleb formation. Total Internal Reflection Fluorescence (TIRF) microscopy showed that WT or capping defective Eps8, but not bundling defective or non-phosphorylatable Eps8 could effectively bundle the actin cortex, suggesting that the capping activity of Eps8 antagonizes its efficiency as an actin bundler. Using a Fluorescence Resonance Energy Transfer (FRET)-based biosensor of Erk activity we found that Erk activity exhibited a gradient from front-to-back in leader blebs. Atomic Force Microscopy (AFM) of blebbing cells showed that cortex tension was reduced in cells over-expressing a dominant negative bundling-defective Eps8 mutant or non-phosphorylatable Eps8, while cells over-expressing a dominant negative capping-deficient Eps8 had elevated cortex tension. Collectively, our results suggest a model in which a gradient of Erk activity in leader blebs locally regulates Eps8 to create a gradient of actin bundling and high cortex tension to drive the bleb-based migration of melanoma cells.

P249**Board Number: B380****Contact inhibition of locomotion in a fibrillar-like microenvironment during breast cancer progression.**D.F. Milano¹, S.K. Muthuswamy², A.R. Asthagiri^{1,3};¹Department of Chemical Engineering, Northeastern University, Boston, MA, ²Princess Margaret Cancer Center, University of Toronto, Toronto, ON, ³Department of Bioengineering, Northeastern University, Boston, MA

Recent work demonstrated that cancer cells invade through a 3-D microenvironment composed of fibers. Tumor-associated fibroblasts help facilitate this invasion by aligning fibers perpendicular to the tumor-stromal interface. Invasion of the tumor boundary is more efficient when metastatic cancer cells migrate along these fibers, which serve as adhesive, directional cues out of the primary tumor. Yet, much of our current understanding about how cancer cells acquire invasive capabilities is based on studies using non-fibrillar, standard 2-D environments. A hallmark of invasive cancer cells is the loss of contact inhibition of locomotion (CIL). To begin to examine the nature of CIL in confined, fibrillar-like microenvironments, we utilized surfaces with micropatterned stripes whose high aspect ratio emulates a protein fiber. Time-lapse microscopy was used to quantitatively compare homotypic interactions between non-transformed mammary epithelial cells (MCF-10A) and metastatic breast cancer cells (MDA-MB-231). Cells were confined on patterned lines with widths from 6 to 33 microns. Pairwise collisions between cells were imaged in real-time and scored as bouncing or sliding collisions using frame-by-frame image analysis. The fraction of sliding collisions was measured as a representative metric to quantify the loss of CIL and reported as a function of patterned line width. Our data reveal that MDA-MB-231 cells do overcome CIL even in confined 1D microenvironments. In fact, our results demonstrate the ability of these metastatic cells to evade CIL is significantly enhanced in more confined 1D-like microenvironments, suggesting the migratory advantage of triple negative breast cancer cells may be particularly well tuned to the spatial constraints of the local tumor microenvironment. Additionally, we examined the role of partitioning defective homolog 3 (PAR3), a known suppressor of metastasis in breast cancer and regulator of CIL *in vivo*, by itself and in combination with the proto-oncogene ErbB2, on CIL in confined microenvironments. Our analysis showed PAR3 knockdown alone had no effect on the observed frequency of sliding collisions but did decrease the duration of bouncing collisions to a level indistinguishable from MDA-MB-231 cells. Activation of ErbB2 alone in MCF-10A cells did lead to a slight increase the ability of cells to slide, however, the greatest increase in sliding ability was observed when ErbB2 was activated in PAR3 knockdown cells. The cooperative nature of ErbB2 activation and PAR3 knockdown to facilitate a more invasive phenotype agrees with previous work performed *in vivo* and validates this platform as a novel tool to quantitatively investigate CIL in a physiological *ex vivo* microenvironment.

P250**Board Number: B381****Role of aberrant vimentin expression in early and late events of human oral cancer.**M. Vaidya¹, C.C. Dmello¹, S.S. Sawant¹, H. Alam²;¹Vaidya Lab, ACTREC-TMC, Navi Mumbai, India, ²Dept. of Molecular and Cellular Oncology, The University of Texas M D Anderson Cancer Center, Houston, TX

Vimentin is an intermediate filament protein predominantly expressed in mesenchymal cells (Lazarides E, 1982). Its association has been shown with progression of many cancers including carcinomas (Satelli A, Li S, 2011). In our earlier study, we had seen the expression of vimentin in oral leukoplakia and submucous fibrosis which are known premalignant lesions for human oral cancer (SS Sawant et al, 2013). Its presence in premalignant lesions suggests the possibility of its role in early oncogenesis. Hence we overexpressed vimentin in human oral premalignant derived cell line to ask if vimentin is one of the causes or just a consequence of the process of neoplastic development. Although no difference was seen between the transformation potential of vimentin overexpressing vs vector control clones using soft agar colony forming assay, critical EMT and stemness related molecular changes were observed amongst them using reverse transcriptase PCR. Therefore further chemical carcinogenic stimuli were given using benzopyrene to both the clones till they showed an anchorage-independent state of growth in soft agar. Remarkably vimentin expressing clones showed more number of soft agar colonies as compared to vector control clones. Vimentin is well reported in late events of cancer progression but the molecular pathway underlying it is unclear hence we downregulated vimentin in oral cancer derived cell line using shRNA technology. We found increased surface levels and decreased biological turnover of $\beta 4$ integrin in absence of vimentin. It was seen that the normal function of $\beta 4$ integrin as mechanical adhesive device was enhanced while its signaling function remained unaltered upon vimentin downregulation. Another important proteins that we found altered upon vimentin knockdown, were the pair of K5/K14. Our data suggests that vimentin may regulate the pair of K5/K14 transcriptionally through delta p63 alpha to contribute in transformation potential of the cancer cell. Also similar correlations in expression levels of vimentin/beta4 and vimentin/K14 were seen in human oral tumor samples. Collectively this study provides insights into role of vimentin in the process of human oral oncogenesis.

P251**Board Number: B382****Identification of an ErbB2+ early disseminating pre-malignant cancer cell sub-population with metastatic potential.**K. Harper¹, M. Sosa¹, H. Hosseini², A. Avivar-Valderas¹, N. Chandandeep¹, R.J. Davis³, C. Klein², D. Entenberg⁴, J.S. Condeelis⁵, E. Farias¹, J.A. Recent clinical evidence suggests that cells are capable of disseminating from “pre-invasive” breast cancer lesions. It has been proposed that these early disseminating cancer cells (eDCCs) lodge into secondary sites, enter a state of dormancy, escape conventional therapy, and potentially evolve through different pathways from the primary tumor to form metastases. However, the mechanisms that endow pre-malignant cells to disseminate and their behavior in target organs remain unknown. Here we show that ErbB2+ pre-malignant cancer cells, while non-tumorigenic are highly efficient in disseminating. While a majority of these eDCCs remain dormant in target organs they are still endowed with a metastatic capacity. We identified an ErbB2^{HIGH}/p38^{LOW}/E-cadherin^{LOW} population of pre-malignant mammary epithelial cells (MECs), which undergo a Wnt-dependent EMT and disseminate. Using intravital imaging of transgenic ErbB2-T-CFP pre-malignant lesions we imaged this process at high resolution revealing that ErbB2^{HIGH}/p38^{LOW}/E-cadherin^{LOW} cells display activate cancer cell motility, invadopodia formation and intravasation capacity. This correlated with CK8/18+/HER2+ circulating cancer cells as well as eDCCs in the lung and bone marrow of mice, a process that was enhanced following 2 weeks of systemic p38 α / β inhibition. We conclude that at pre-malignant stages p38 α / β antagonizes ErbB2 signaling restricting early dissemination of cells, and that early dissemination is a source of predominantly dormant eDCC with metastasis initiating capacity that might contribute to relapse.

P252**Board Number: B383****Heterogeneity in cell-matrix adhesion as an indicator of metastatic state.**A. Fuhrmann¹, T. Tlsty², A.J. Engler¹;¹Bioengineering, University of California, San Diego, La Jolla, CA, ²University of California, San Francisco, San Francisco, CA

Cancer cells have great genetic diversity, which may be reflected in varied metastatic potential. As it has been difficult to determine a comprehensive set of genetic markers to define a metastasizing cell population, we propose a common behavior, i.e. cell-matrix adhesion, that may be differentially

regulated in metastasizing versus non-metastasizing cancer cells. To assess cell-matrix adhesion strength in a heterogeneous population of breast cancer cells, we employed a spinning disc device where cells adhering to matrix-coated substrates were exposed to radially-dependent shear. Within a cell population, cells at the center or edge experience low or high matrix detachment forces, respectively. Highly metastatic cancer cell lines, e.g. MDA-MB-231 and MDA-MB-468, exhibit the same detachment behavior as non-malignant MCF10A and non-metastatic MCF7 cells in the presence of tumor-like concentrations of magnesium and calcium, which regulate integrin activation. However at stromal concentrations of these cations, only the adhesion of metastatic cells was drastically lowered and broadly distributed, suggesting that the most metastatic cells may be more sensitive to lower cation concentrations. Average attachment strength—defined as the shear required to detach 50% of cells, i.e. τ_{50} —and restoration of attachment-homogeneity gradually increased with cation concentration with the greatest sensitivity occurring between 0.01 and 0.50 mM, which falls within the physiological range for both stroma and tumor. Moreover, focal adhesion assembly in MDA-MB-231 cells was highly dependent on cations: at stromal concentrations, cells had more labile adhesions compared to large, stable adhesions at tumor-like concentrations. These changes were absent in non-metastatic cells, indicating that variances in attachment strength and adhesion assembly in the absence of cations may be cell state dependent. Indeed after selecting for strongly attaching metastatic cells, cells maintained their strong attachment phenotype for several days, but stochastically return to heterogeneous adhesion strength over several weeks. Migration and invasion of selected MDA-MB-231 cells were markedly impeded versus their non-selected or non-metastatic counterparts, i.e. sensitivity to cation removal indicates higher invasion potential. These results suggest a potential biophysical mechanism to differentially regulate cell metastasis.

Mismatch in cell mechanical properties in co-cultures can lead to enhanced cell motility: A Brownian Dynamics Simulation.

J. Butcher¹, D. Kolbman¹, M. Das¹;

¹Physics and Astronomy, Rochester Institute of Technology, Rochester, NY

Recent experiments suggest that the mechanical stiffness of cells and their interaction with their surroundings undergo remarkable changes during tumor progression [1,2]. An intriguing experimental result in this area suggests that the mismatch in the elasticity and adhesive properties between cancer cells and non-cancerous cells in a co-culture may lead to enhanced cancer cell motility [2]. Motivated by this, we study a mathematical model of a 2D co-culture of cells with different stiffnesses and adhesivity using active Brownian Dynamics simulations. We characterize cell motility by studying particle trajectories, mean square displacements and correlation functions. We find that in a binary system of softer and stiffer particles, the softer particles are more motile, and the difference in motility between the two types of particles is enhanced with increase in difference between their stiffnesses. We also find that introducing particle-particle adhesion to the stiffer particles can further increase the motility of the

softer particles. Our study may provide insights into the interplay of mechanical and statistical mechanical properties underlying the enhanced motility of cancer cells during metastasis [2].

Joined forces of cancer cells and fibroblasts against the basement membrane.

A. Glentis¹, V. Gurchenkov¹, M. Schoumacher¹, F. Zaccarini², P. Mariani³, D. Vignjevic¹;

¹Institut Curie, Paris, France, ²AP-HP Hopitaux de Paris, Paris, France, ³Hopital Curie, Paris, France

In carcinoma in situ, the basement membrane represents a physical barrier that prevents spreading of primary tumor to adjacent tissues. It is believed that cancer cells perforate basement membranes. However, stromal cells such as carcinoma-associated fibroblasts also secrete matrix proteinases. Therefore, the question is who is invading whom – do cancer cells invade stroma or possibly stroma is invading tumor cells? Using human colon cancer cells and primary human fibroblasts isolated from tumors and adjacent normal tissues, we addressed if cancer cells and fibroblasts are invading the basement membrane simultaneously or they work together but have distinct functions. Analyzing human colon cancer samples, we observed that invasive tumors contain higher amount of fibroblasts in general and higher proportion of CAFs (α SMA+) compared to non-invasive tumors or healthy tissues. We isolated fibroblasts from fresh human colon tumors of different stages (CAFs) and from the adjacent normal tissues (NAFs). A combination of markers was used to discriminate fibroblasts from other cell types to validate the purity of isolated cells and to discriminate NAFs from CAFs. In co-culture experiments on Matrigel-coated transfilters, both NAFs and CAFs induced migration and invasion of HT29, intrinsically non-invasive colon cancer cells. On contrary, in an assay containing native, mesenteric basement membrane that separates cancer cells on one side and fibroblasts embedded in collagen I on the other, we found that only CAFs are able to stimulate invasion of cancer cells. CAFs stimulated invasion of cancer cells when physically present in the assay and, in a lesser amount, via paracrine ways. Proteomic study using SILAC, showed that CAFs secrete more proteases, extracellular matrix proteins, and proteins that modify the matrix compared to NAFs, pointing to a matrix-remodeling role in invasion. Live cell imaging showed that fibroblasts and cancer cells are communicating through the basement membrane via cellular protrusions long time before the actual translocation of cancer cells is detected. We are currently testing a role of CAF-derived molecules in basement membrane remodeling in order to dissect the interplay between cancer cells and CAFs in basement membrane invasion.

P255**Board Number: B386****Cortactin, a key regulator of tumor progression, promotes exosome secretion.**

Exosome secretion from cancer cells is thought to drive cancer aggressiveness. Presumably, exosome secretion is a regulated event; however little is known about the molecular regulators or how this is altered in cancer. In this study, we show that the tumor-overexpressed cytoskeletal protein cortactin plays an important role in controlling exosome secretion. Inhibition or overexpression of cortactin respectively inhibited or upregulated the number of exosomes secreted from cells. Proteomic analysis indicated that cortactin only affected the number of vesicles but not their cargo content. Live imaging experiments revealed that cortactin controls exosome secretion by controlling trafficking from late endosomes. These data may explain the reported association of cortactin overexpression with tumor aggressiveness and poor patient prognosis.

P256**Board Number: B387****Effect of Vitamin C on the Cytotoxicity of Vemurafenib or Doxorubicin Human Malignant Melanoma Cells.**

G. Gao¹, G. Yang¹, Y. Ma¹, I. wang¹, Y. Yang¹;
¹Emporia State University, Emporia, KS

Objective: The goal of this study is to identify the effect of vitamin C on the cytotoxicity induced by Vemurafenib or Doxorubicin in human malignant melanoma cells. **Methods:** The effect of vitamin C on the cytotoxicity induced by Vemurafenib or Doxorubicin were examined by cell viability assay, wounding healing assays, and Transwell migration assay to measure its effects on cell proliferation, migration, and invasion. The apoptotic cell percentage were determined by flow cytometry. **Results:** Vitamin C alleviated the cytotoxic effects of Doxorubicin or Vemurafenib on proliferation, migration, and invasion of human malignant melanoma cells when the concentration of vitamin C was relatively low (=5mM). Vitamin C significantly reduced the percentage of apoptotic cells induced by Doxorubin or Vemurafenib when the concentration was low (1mM). **Conclusion:** Vitamin C showed the dual roles in the cytotoxicity induced by Vemurafenib or Doxorubicin in malignant melanoma cells depending upon the concentrations. Vitamin C alleviated the cytotoxic effect of Doxorubicin or Vemurafenib on human melanoma cells when the concentration was low. However, when the concentration of vitamin C become higher, it enhanced the cytotoxic effect of Doxorubicin or Vemurafenib on malignant melanoma cells.

P257**Board Number: B388****Rosehip (*Rosa canina*) extracts prevent serum-stimulated migration of human glioblastoma cells.**F.S. Ogunsemowo¹;¹Department of Biology, North Carolina AT State University, Greensboro, NC

Glioblastoma multiforme (GBM) are the most common and most aggressive intracranial tumors. Malignant gliomas are characterized by their diffuse invasion of surrounding brain tissue. Despite modern diagnostics and treatments the median survival time is less than a year; and over the past decades no significant increase in survival of patients suffering from this disease has been achieved. Thus, alternative treatment and prevention options are necessary to combat this disease. Natural products represent a source of potential chemical molecules exhibiting anti-oncogenic properties. An example is Rosehip (*Rosa canina*); rosehips are blossoms from the wild rose and frequently used as an herbal medicine. Recently our laboratory has shown that rosehip extracts exert anticancer activities *in vitro*, by inhibiting proliferation of GBM cells. Preliminary data from our laboratory shows that rosehip extracts are able to prevent breast cancer cell migration. Therefore, we investigated the efficacy of rosehip extracts in preventing cell migration of human GBM cell lines. We hypothesize that GBM cell migration will be prevented when exposed to rosehip as a result of interference of cell signaling pathways. Wound healing assays were performed to examine the anti-migratory effects of rosehip extracts (1mg/ml) on human GBM cell lines, U-251 MG and U-87 MG. The data demonstrate that rosehip extracts facilitate inhibition of serum-stimulated cell migration more effectively than MAPK (UO126) and AKT (LY294002) inhibitors. We extended this investigation by examining whether rosehip extracts could prevent EGF-induced cell migration. Rosehip extracts did not prevent EGF-induced migration, suggesting that an alternative mechanism is promoting EGF-associated migration in these cells. These data suggest that rosehip extracts may serve as an alternative therapy for treating certain populations of malignant gliomas.

P258**Board Number: B389****Metastasis Upregulated Genes Have Distinct Function in *C. elegans* Cell Migrations.**S.A. Vetrone^{1,2}, M. Kato², P. Sternberg²;¹Biology, Whittier College, Whittier, CA, ²HHMI, Biology and Biological Engineering, California Institute of Technology, Pasadena, CA

Cell migration is vital for normal animal development but also contributes to the invasive spreading of early stage metastatic cancer. From two published databases, we compiled 107 genes unregulated in either breast cancer or melanoma metastases and investigated their requirement in two *Caenorhabditis*

elegans cell migrations: the male linker cell (LC) and hermaphrodite distal tip cells (DTC) which have similar functions as gonadal leader cells that undergo a complex migration while pulling non-motile followers. We performed an RNAi screen to identify genes implicated in normal LC and DTC migrations. Thirty-two genes from the metastasis list were required for the cell migration of which 13 genes effected the migration of both LC and DTC, 18 genes effected only LC migration, and 4 genes only DTC migration. The genes used by both cell types corresponded to genes involved in cell cycle activity, adhesion, cytoskeleton organization, protein degradation activity, spliceosome activity, ubiquitin-like modification and function, and peptidase inhibition. The genes used by only the LC corresponded to genes involved in adhesion, cytoskeletal organization, methyltransferase activity, metalloproteinase activity, and signaling. Those genes used by only DTC corresponded to genes involved in signaling, peptidase inhibition, and utrophin activity. The significant differences among the developmental cell migrations and the overlap in genes shared between the two metastases underscores the value of characterizing diverse genes and considering cell type in developing treatments.

DIBUTYLTIN-INDUCED ALTERATIONS OF INTERLEUKIN 1 beta SECRETION FROM HUMAN IMMUNE CELLS.

S. Brown¹, S. Tehrani², M. Whalen²;

¹Biological Sciences, Tennessee State University, Nashville, TN, ²Chemistry, Tennessee State University, Nashville, TN

Dibutyltin (DBT) is an organotin compound that is used as a stabilizer in polyvinyl chloride (PVC) plastics (including pipes that distribute drinking water and bottles) and as a de-worming agent in poultry. DBT is found in human blood samples, and DBT exposures alter the secretion of tumor necrosis factor alpha (TNF α) from lymphocytes. Interleukin 1 beta (IL-1 β) is a pro-inflammatory cytokine that promotes cell growth, tissue repair, and immune response regulation. Produced predominately by both monocytes and macrophages, IL-1 β appears to increase the invasiveness of certain tumors. The aim of the current study is to determine whether exposure to DBT alters the secretion of IL-1 β from increasingly reconstituted preparations of human immune cells. We examined whether exposure to DBT concentrations of 0.05 to 5 μ M after 24h, 48h, or 6 days alters IL-1 β secretion in a preparation of highly enriched human NK cells, a monocyte-depleted preparation of human peripheral blood mononuclear cells (PBMCs) (MD-PBMCs), PBMCs, granulocytes, and a preparation combining both PBMCs and granulocytes. The levels of IL-1 β were monitored using an enzyme-linked immunosorbent assay (ELISA). The results indicated that DBT alters IL-1 β secretion from all of the above cells preparations. The high concentrations of DBT (5 and 2.5 μ M) decreased the secretion of IL-1 β , while some of the lower concentrations of DBT (0.1 and 0.05 μ M) increased the secretion of IL-1 β . The concentrations and lengths of exposure to DBT that caused statistically significant increases in IL-1 β secretion from human immune cells varied from one donor to the next. Therefore, the data indicates that DBT-induced alterations of IL-1 β secretion from immune cells may potentially affect immune function and cancer

invasiveness. An additional aim is to examine the signaling pathways involved in the DBT-induced increases in IL-1 β secretion from MD-PBMCs, which are a preparation that primarily consists of T and NK lymphocytes. MD-PBMCs will be treated with inhibitors of pathways that regulate IL-1 β secretion (IL-1 β cleavage inhibitor, ERK $\frac{1}{2}$ pathway inhibitors (PD98059, U), p38 inhibitor (SB202190), and NF κ B inhibitor (BAY 11-7085)) 1h prior to adding DBT concentrations of 0.1 and 0.05 μ M for 24h.

Oncogene-expressing cells collaborate to evade microenvironmental restraint.

A.J. Hughes¹, N. Jee^{2,3}, M. Todhunter^{2,4}, Z.J. Gartner^{2,5};

¹Physiology Course at Marine Biological Laboratory, Woods Hole, MA, ²Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, ³Chemistry and Chemical Biology Graduate Program, University of California, San Francisco, San Francisco, CA, ⁴Tetrad Graduate Program, University of California, San Francisco, San Francisco, CA, ⁵Center for Systems and Synthetic Biology, University of California, San Francisco, San Francisco, CA

Healthy tissue can harbor a high frequency of “occult” cancer; in which isolated transformed cells do not progress into overt tumors. We hypothesized that multiple transformed cells can collaborate to accelerate the earliest stages of tumor progression.

To test this hypothesis, we studied the growth trajectories of small (~8 cell) 3D microtissues comprising wild-type MCF10A (WT) mammary epithelial cells intermixed with MCF10AT (Ras) cells that expressed low levels of a constitutively active H-Ras oncogene. H-Ras expression confers cells with increased rates of cell motility and proliferation. During culture in Matrigel over 7 days, we quantified the growth rates of each cell type by tracking fluorescent nuclear reporters of cell identity by confocal microscopy.

Mixed tissues containing single Ras cells showed a broad diversity of growth trajectories over 7 days of culture. Ras cells either expanded rapidly through the WT population (an “escape” trajectory), did not expand through the population (“restraint”), or reached a steady-state fraction of the cell population while also triggering rapid expansion of both the WT and Ras cell populations (“collaboration”). In contrast, cell assemblies containing two or more Ras cells were far more likely to show collaboration rather than restraint trajectories.

Our data suggests that a tipping point can exist wherein an increase in the frequency of oncogene-expressing cells amongst wild-type neighbors triggers a transition between restrained and collaborative proliferation of entire cell collectives.

P261**Board Number: B392****Mechanisms of Transendothelial Migration by Invasive Breast Carcinoma Cells from Patients.**J. Pignatelli¹, S. Goswami^{1,2}, J.G. Jones^{1,3,4}, X. Chen¹, J.S. Condeelis¹, M.H. Oktay^{1,4};¹Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ²Department of Biology, Yeshiva University, New York, NY, ³Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY, ⁴Department of Pathology, Albert Einstein College of Medicine, Bronx, NY

The majority of breast cancer related deaths are not due to the primary tumor, but rather to the spread of distant metastatic tumors. Our lab has previously described the identification of the tumor microenvironment of metastasis (TMEM) in mouse and human mammary tumors, sites where transendothelial migration (TEM) occurs and therefore intravasation. The constituent cells of TMEM are an endothelial cell, a perivascular macrophage and an invasive Mena-over expressing tumor cell in direct contact. TMEM are present in human invasive breast tumors and the density of TMEM is positively associated with the risk of developing metastases.

Using invasive ductal carcinoma cells of the breast obtained from patients by fine needle aspiration, we demonstrated that intravasation-directed transendothelial migration of these cancer cells requires macrophages and, depending on clinical subtype, involves either paracrine, or both paracrine and autocrine signaling. Compared to the total population of primary breast cancer cells assayed, cells capable of transendothelial migration expressed relatively high Mena^{INV} and low Mena^{11a} levels, independently of clinical subtype. Mena^{INV} and Mena^{11a} are functionally distinct isoforms of Mena, a key regulator of motility and invasion. Furthermore, relative Mena^{INV} expression correlated with the density of TMEM, which were previously shown to correlate with risk of metastasis in patients. Our data reveal targetable signaling events required for transendothelial migration of human breast cancer cells, and indicate that relative Mena^{INV} levels and TMEM frequency are correlated prognostic markers of metastasis and therapeutic targets for most human breast cancers.

P262**Board Number: B393****Transendothelial migration of uveal melanoma cells.**M.D. Onken¹, J. Li¹, J.A. Cooper¹;¹Department of Cell Biology and Physiology, Washington University School of Medicine, Saint Louis, MO

Uveal melanoma (UM) is cancer arising from the pigmented layers of the eye that is highly metastatic and only spreads through the bloodstream. Almost half of UM patients develop distant metastatic disease, most often in the liver, even after the tumor-bearing eye is completely removed. The key to understanding and targeting UM metastasis is in understanding how circulating tumors cells enter and

exit the bloodstream and then invade and colonize distant organs. We use primary human dermal microvascular endothelial (HDMVEC) monolayers grown on polyacrylamide soft substrates that mimic the physiological stiffness of normal tissue as a model of the blood vessel wall. To these monolayers, we add UM cells and follow their transendothelial migration. We found that UM cells transmigrate via a unique route that is distinct from the transendothelial migration common to immune cells. During this multistep process, UM cells identify HDMVEC cell-cell junctions and then intercalate between adjacent HDMVECs, taking on a flattened morphology while maintaining contacts with the adjacent endothelial cells. UM cells remain intercalated for an extended period in a state reminiscent of vasculogenic mimicry. After intercalation, UM cells extend invasive projections beneath adjacent HDMVECs, and use these to migrate beneath the monolayer. Immunofluorescence in fixed monolayers revealed cortical actin networks with strong cortactin staining within these invasive projections. We used UM cells expressing F-tractin, a fluorescent fusion protein that specifically binds filamentous actin without disrupting actin function, to image of actin dynamics in live cells. Time-lapse confocal images revealed complex actin-rich projections invading and sampling the interface between the endothelial monolayer and the substrate. Dynamic actin cytoskeleton reorganization was also apparent as cells migrated under the monolayer. We used blocking antibodies to identify cell adhesion molecules that were involved in UM transmigration. We found that blocking VCAM1 inhibited early intercalation but enhanced overall migration, suggesting VCAM1 might be necessary for initiation and maintenance of intercalation. BAP1 is the major metastasis suppressor in human UM tumors. We knocked down BAP1 in our uveal melanoma cell lines, and found that loss of BAP1 had no significant effect on initiation or intercalation of UM cells. However, overall migration was significantly enhanced by BAP1 knockdown. Our studies show that UM transendothelial migration occurs in two phases: vasculogenic intercalation that depends upon VCAM1 adhesion, and subsequent invasion under the monolayer, which is regulated by BAP1.

Dissecting the Mechanism of Tumor Cell and Macrophage Streaming Towards Blood Vessels.

E. Leung¹, P. Rougerie¹, V.P. Sharma^{1,2}, R.J. Eddy¹, J.S. Condeelis¹;

¹Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ²Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY

In vivo, breast tumor cells have been observed to migrate with macrophages on collagen fibers towards blood vessels in a process known as “streaming.” Mechanistically, the interactions of the macrophages and tumor cells have been characterized to involve an EGF and CSF-1 paracrine loop with macrophages secreting EGF and tumor cells releasing CSF-1 to attract each other. However, the signaling molecule that is responsible for the directional migration of both the tumor cells and macrophages towards the blood vessel has not been determined.

By plating MTLn3 breast tumor cells and primary bone-marrow derived macrophages (BMMs) on micro-patterned substrates that mimic the diameter and composition of the collagen fibers found in vivo, we

observed that tumor cells and macrophages align together to form “pairs.” However, the tumor cells and macrophages did not demonstrate directional or biased migration towards one direction within the assay. However, directional migration of tumor cells could be established when beads coated with either NIH3T3 fibroblasts or human umbilical vein endothelial cells (HUVEC), both known sources of HGF, were placed at one end of the micro-patterned “collagen fibers” within the assay. This directional migration was inhibited with an HGF inhibitor, suggesting that HGF is the molecule responsible for the directional migration of tumor cells towards blood vessels. This combination of cells; tumor cell, macrophage and endothelial/fibroblast, when placed on a linear substrate, reconstituted streaming in vitro with speed, directional persistence and cell migration characteristics like those observed in vivo during tumor cell streaming toward blood vessels.

A Novel Bone Bioreactor Used to Model Bone Metastasis Ex Vivo.

R.J. Romero Moreno¹, K. Jackson², T. Coughlin², T. Kriepke², L. Nystrom³, G. Niebur², L.E. Littlepage¹; ¹Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, ²Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, IN, ³Orthopaedic Surgery and Rehabilitation, Loyola University Chicago, Chicago, IL

Bone metastases are incurable. Understanding what drives cancer to metastasize to bone and identifying treatments that eliminate bone metastasis are essential to improving the survival and quality of life of cancer patients with metastasis to bone. The current methods used to study bone metastasis are restricted to in vitro tissue culture models and to in vivo animal models, both of which have several limitations. The in vitro tissue cultures lack the 3-D environment of heterogeneous cell types of the bone and marrow, and in vivo animal models often are limited by the confounding primary tumor burden. Both options generally are not applicable to rapid screening aimed at targeting bone metastases. In this interdisciplinary project, we use a novel bone bioreactor to culture mouse bone explants, study bone metastases, and develop therapies to help breast cancer patients that have developed bone metastases. The objective of this research is to develop an experimental system that preserves the 3-D environment and heterogeneous culture conditions (bone, marrow, and cancer cells) within the physiological context of an intact bone environment and apply the technology to develop faster screening techniques than the ones available in current animal models.

We will use this ex vivo bone culture bioreactor to identify the molecular factors that contribute to develop bone metastases and to aid in the screenings of new drugs aimed at targeting bone metastasis in breast cancer patients. We will validate the bioreactor as a means to understand the stages of metastatic tumor colonization, progression, and response to therapies. After validation in a murine model, our bioreactor will make it possible to study metastatic cancer progression temporally and independently from primary tumor growth. Because this system is amenable for investigating bone colonization by multiple cancer types, this study also has general application beyond breast cancer. Due

the usage of bone explants and vibrational technology that is currently available to patients, this study has high translational value.

Due the limitations of current methodologies and lack of exploration to improve them, our unique interdisciplinary perspective to attack this problem will result in high impact publications in the fields of cancer and bone behavior.

Multiclonal Seeding is a Frequent Route to Metastatic Spread.

K. Cheung¹, V. Padmanaban¹, K. Schipper¹, V. Silvestri¹, A. Ewald²;

¹Oncology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Introduction: A foundational concept in metastasis research is that primary tumors first dissociate into single cancer cells in order to seed distant sites. The requirement for a single-cell seed forms an important tenet for common molecular models of metastasis including the epithelial-mesenchymal transition. However, the experimental evidence for the single-cell seed model of metastasis remains limited. Furthermore, circulating tumor cell clusters are detectable in the bloodstream and therefore multiclonal seeding events are also possible. In this study, we experimentally isolated the relative contributions of single and multiclonal seeds and uncovered that multiclonal seeding is a frequent route to metastatic spread.

Methods: We devised a lineage tracing strategy using Rainbow transgenic mice to reveal the clonal origin of lung metastases in MMTV-PyMT mice, a commonly used mouse model of metastatic breast cancer. Primary PyMT tumor organoids that express a genetically encoded Rainbow construct were treated with Cre in order to induce random assortment of color labeling, and then injected orthotopically into the mammary fat pad of host mice. Lung metastases were then scored for the number of unique colors.

Results: If lung metastases arise exclusively from single seeds then each lung metastases should express only one color. Surprisingly, we observed frequent multicolor lung metastases (mean 32%, maximum 61%, N=998 metastases). By implanting tumor organoids labeled with distinct colors into separate flanks of host mice, we observed that these multiclonal seeding events occur predominantly in a single step rather than by serial colonization of single cells. To address why multiclonal seeding might be advantageous, we flow sorted trypsinized tumor cells, gating by size. This enabled us to obtain fractions of single cells and cell clusters of increasing size distributions. Interestingly, we observed that cell clusters had 10-fold higher colony formation and superior survival relative to isolated single cells. Work is underway to test the lung colonization potential of single cells versus cell clusters using tail-vein metastasis assays.

Conclusions: Our results challenge the requirement for single cell seeding in metastatic colonization and establish the importance of a parallel route for metastatic spread involving collective multiclonal dissemination. Furthermore, our data suggest a fundamental mechanism for cell growth and survival mediated by cell-cell contacts. We suggest that disrupting cell contacts may limit cancer cell survival and metastatic spread.

Establishing 3-dimensional Spheroids from the Nasopharyngeal Carcinoma (NPC) cell line HK1 to investigate their Growth and Invasion behavior and test their Sensitivity to Flavopiridol.

N. Mohana Kumaran¹, K. Muniandy², P. Siva Sankar¹, A. Khoo Soo Beng³, V. Balakrishnan²;

¹School of Biological Sciences, Universiti Sains Malaysia, Penang, Malaysia, ²Institute for Research in Molecular Medicine (INFORMM), Penang, Malaysia, ³Molecular Pathology Unit, Institute for Medical Research (IMR), Kuala Lumpur, Malaysia

Most anti-NPC drug activity studies have come from work performed with two-dimensional (2D) culture assays. 2D culture systems ignore the fact that NPC cells do not live in isolation but are oriented in a 3D space, establishing contact with the stroma, i.e. extracellular matrix and other cell types such as endothelial cells, fibroblasts and immune cells. Three-dimensional (3D) cultures represent a good compromise between the lack of a microenvironment encountered under 2D culture conditions and the great complexity of the *in vivo* animal models. 3D culture mirrors the tumour architecture and microenvironment more closely than 2D, recreates the oxygen/nutrient gradient with a hypoxic zone and a central necrosis and allows interaction between NPC cells and their stroma, when provided. This close resemblance to the situation encountered *in vivo* facilitates more realistic study of NPC growth, invasion and drug response. The objective of this study is to establish a 3D model from the HK1 NPC cell line to determine the growth and invasion behavior of the spheroids on the collagen matrix and to test the sensitivity of the spheroids to chemotherapeutic drugs. Approximately 5000 NPC cells were seeded onto concave agar and left to form spheroids for 72 hours. Once the spheroids have formed, they were harvested and embedded onto the collagen matrix. Spheroid growth and invasion were documented by taking phase contrast images every 24 hours using an inverted fluorescence microscope. Spheroid growth and invasion were quantified by image analysis software's. The HK1 cells formed compact spheroids within 72 hours. Our observation from the 10 days experiments revealed that spheroids gradually grew and invaded into the collagen matrix, showing that the HK1 spheroids are capable of growth and invasion. We also observed formation of holes in the spheroids, which could be explained by cell death under hypoxia. Progressing from these experiments, the HK1 spheroids were employed to perform a drug sensitivity assay using the chemotherapeutic drug, Flavopiridol. The drug had a dose-dependent inhibition of spheroid growth and invasion. Our future endeavor will be to employ the spheroids to study whether Flavopiridol will sensitize the NPC cells to small molecule inhibitors which targets the intrinsic apoptosis pathway for NPC therapy and to establish spheroids from the Epstein -

Barr virus (EBV) positive NPC cell line, C666-1 to observe if the spheroids exhibit the same growth and invasion behavior as the HK1 or whether the EBV infection dictates for any changes.

A novel 3D cell culture system using FP001 for in vitro evaluation of anticancer compounds.

T. Kanaki¹;

¹Nissan Chemical Industries, Ltd, Shiraoka, Japan

Recently, a number of approaches have been developed to generate 3-dimensional (3D) cell culture models to mimic in vivo environments for cancer studies; e.g. scaffolds, microcarriers, and spheroids. However, these approaches remain some problems such as applying them into high throughput screening (HTS) systems and improving the efficiency of anti-cancer drug discovery. In this study, we identified FP001 as the polymer materials, and developed a novel 3D cell culture medium using FP001 which has the ability to form cancer cell spheroids in normally-distributed and appropriate size. 3D cell cultures system using ultra-low attachment multi-well plates in combination with FP001 exhibited >3-fold increase in the number of A549 cells after 5-day culture as compared to that without FP001. The positive effect of FP001 was applicable to a wide variety of cancer cell lines and was clearly beneficial for HTS. As for the cell proliferation of HeLa and A549, the 3D culture system was more sensitive to AKT inhibitors and MEK inhibitors, compared with that employs 2D monolayer culture condition. Furthermore, Heparin-binding EGF-like growth factor, an EGF receptor ligand, clearly stimulated the growth of SKOV3 and A431 cells in the 3D culture system, but not in monolayer culture one. In conclusion, we established a novel method for the 3D culture of cancer cells under low attachment condition by using FP001, which was available for HTS and showed high sensitivity to molecularly-targeted drugs, EGF signal inhibitors. Our approach would facilitate the development of novel models for in vitro evaluation of anticancer compounds.

Utilizing 3-D Collagen Cultures to Represent In Vivo Cancerous Tumors and to Test Targeted Molecular Imaging Agents (TMIs).

A.M. Butera¹, H.D. Ophardt¹, I.M. Evans¹;

¹GSOLS, Rochester Institute of Technology, Rochester, NY

The goal of this research is to develop in vitro assay methods for the evaluation of targeting molecular imaging agents (TMIs) using confocal fluorescent microscopy (CFM). Culturing cells in two dimensions on a plastic surface results in artificial two-dimensional growth patterns of sheets of cells which do not provide a good model of a tumor growing in vivo. Most cells in the human body interact with a three-

dimensional environment, composed of other cells, matrices, fibrous layers, and adhesion proteins. In order to create a more accurate TMIA screening environment that closely mimics how tumor cells grow in the body, 3-D cultures were utilized. Collagen is a very widely used matrix for 3-D cultures due to its chemical and physical simplicity and thus was used for initial experiments. A549 cells were suspended in a liquid collagen matrix which was allowed to solidify on a glass bottom dish. The cells were then stained with a Targeted Molecular Imaging Agent (TMIA) Cy5.5-RGDyk conjugate and other stains such as NucBlue, MitoTracker Red, and Tubulin Tracker. Visualization of cultures was done using confocal microscopy. The cells grown in collagen culture formed spheroid-like structures which more closely resembled a tumor growing in vivo. These cultures are a better in vitro tumor model than cells growing on a 2D surface. Observation of the cells stained with the TMIA agent showed that the TMIA penetrated well into the spheroid structure and that the TMIA was taken into the cells by an endocytosis-like mechanism. The use of 3D collagen culture should allow more efficient TMIA to be identified and hopefully will lead to identification of TMIA agents that will penetrate and stain tumor tissue in the body.

Study on the mechanisms of pipoxolan inhibits the migration and invasion in CL1-5 human lung adenocarcinoma cells by reducing MMP-9 and MMP-2 expression.

Y. Chen¹;

¹pharmacy, Taichung, Taiwan

Pipoxolan has been shown to have antitumor effect. However, the effects of pipoxolan on lung cancer cell metastasis remains undecided. This study was to investigate how pipoxolan affect the lung cancer cell migration and invasion. This study investigated the antimigration and antiinvasion effects of pipoxolan on lung adenocarcinoma cancer cells (CL1-5 cells) and its underlying molecular mechanisms. The data demonstrates that pipoxolan does not effectively inhibit the viability of CL1-5 cells. Pipoxolan markedly suppress cell migration of CL1-5 cells by the assessment of wound scratch assay and transwell assays. Treatment of pipoxolan brought about inhibition of migration and invasion of CL1-5 cancer cells by transwell assay. And, these observations were associated with a reduction in the activities and levels of matrix metalloproteinase (MMP)-2 and MMP-9 in CL1-5 lung cancer cells. Lastly, pipoxolan at 5 µg/mL and 10 µg/mL inhibited phosphorylation c-Jun N-terminal kinase (p-JNK) of CL1-5 cells. Moreover, pipoxolan at 10 µg/mL inhibited phosphorylation p38 MAP Kinase (MAPK) of CL1-5 cells. In addition, our results also demonstrate that administration with JNK1/2 inhibitor (SP600125), and p38 inhibitor (SB203580) reduce MMP-2 and MMP-9 expressions in CL1-5 lung adenocarcinoma cancer cells. Based on these results, our conclusions show that treatment of CL1-5 lung cancer cells with pipoxolan down-regulates MMP-2 and MMP-9, which are the down-stream targets of JNK and p38 and play a critical role in CL1-5 cells metastasis. These results show a new therapeutic potential for pipoxolan in anti-metastatic therapy.

P270**Board Number: B405****Podoplanin-expressing CAFs Lead and Enhance the Local Invasion of Cancer Cells in Lung Adenocarcinoma.**S. Neri¹, G. Ishii¹, A. Ochiai¹;¹Pathology Division, National Cancer Center Hospital East, Kashiwa, Japan

Cancer-associated fibroblasts (CAFs) communicate with cancer cells and play important roles in cancer invasion. We previously observed that lung adenocarcinoma patients with podoplanin (PDPN)-expressing CAFs frequently exhibited the local invasion of cancer cells. In this study, we established a novel collagen invasion assay model in which cancer cells and CAFs were co-cultured; we then analyzed the mechanisms governing how cancer cell invasion was promoted by PDPN(+) CAFs. We found that PDPN(+) CAFs invaded the collagen matrix to a greater extent, with more cancer cells invading within tracks created by the CAFs, compared with control CAFs. After intravenous injection in the mouse tail vein, PDPN(+) CAFs invaded and promoted cancer cell invasion into the lung parenchyma, compared with control CAFs. Among the lung adenocarcinoma patients, we observed some cases with PDPN(+) CAFs at the invasive front of the tumor. These cases predominantly exhibited pleural invasion of cancer cells, known as pathological invasiveness. Our results indicated that PDPN(+) CAFs were tumor-promoting CAFs that lead and enhance the local invasion of cancer cells.

P271**Board Number: B406****Plant Polyphenols Reduce Migration Ability of Human Melanoma Cells.**C. Jones¹, C.A. Joseph¹, V.S. Parmar², A.L. DePass¹;¹Department of Biology, Long Island University, Brooklyn, NY, ²Department of Chemistry, University of Delhi, New Delhi, India

Melanoma is the most serious type of malignant skin cancer due to its ability to metastasize, and appears highly resistant to many forms of cancer treatments. Plant polyphenols have a number of beneficial health effects, and are well noted for their anti-cancer properties. To develop more effective treatments for melanoma, we assessed the chemotherapeutic potential of various plant polyphenol analogs on the migration ability of A375 human melanoma cells as an *in vitro* model. Treatment of A375 cells with polyphenols MLN-1249, MLN-1337, and MLN-2287 resulted in inhibition of cell migration. Employing cell viability assays, the compounds resulted in dose-dependent cytotoxicity at concentrations ranging from 0 to 100 μ M. Using cell invasion assays, we found that the polyphenols inhibited activity on cell migration at concentrations of 1 μ M over a 72 h time period. The inhibition of cell migration correlates to the expression of genes involved in the apoptosis, NF κ B, and epithelial-to-mesenchymal transition pathways. Together, these results show that the polyphenols have the ability to inhibit cell migration, a crucial step of metastasis.

P272**Board Number: B407****An Examination of Obesity-induced Epithelial to Mesenchymal Transition in Melanoma Cells.**S.S. Papas¹, E. Brandon²;¹Biology, Mississippi College, Clinton, MS, ²Biology, Mississippi College, Clinton, MS

Recent studies have shown that obesity worsens the prognosis of several cancers, including melanoma. Evidence suggests that cytokines such as leptin and resistin, promote the growth, epithelial-to-mesenchymal transition (EMT), and subsequent metastasis of melanoma tumor cells. Our research focuses on extending this understanding by discerning the connection between adipocyte's presence and tumor cell proliferation and migration. Additionally, concentrating on the mTOR signaling pathway as a means for regulation of EMT, we seek to add detail to the otherwise vague mechanisms concerning obesity-associated metastasis of solid tumor cells. To test the hypothesis that tumor cell proliferation is increased by the presence of adipocytes, we co-cultured mouse adipocytes and melanoma cells. Control and experimental melanoma cells were counted at three time points during their treatments; comparisons of the tumor cell growth at 0, 24, and 48 hours, revealed enhanced growth as a result of adipocyte presence. Melanoma cells cultured with adipocytes grew faster than the melanoma cells cultured alone. Growth rates were significantly increased in the co-cultured melanoma cells ($13,163 \pm 3.22$ vs. $10,307 \pm 1.17$ cells/mL/day, Student's T-test $p = 0.01$). Additionally, preliminary data suggests that the co-cultured melanoma cells migrate more than melanoma cells cultured alone. Cells going through EMT have increased levels of vimentin and phosphorylated mTOR. Western blots will be used to determine whether the co-cultured melanoma cells follow this pattern. Adipocytes directly promote the growth of melanoma cells and migration also appears to increase as a result of co-culturing. These results support our previous finding of increased melanoma tumor growth in obese mice. This may occur because of mTOR activation, which remains to be determined. Future experiments will examine the expression of the transcription factors SNAIL, Slug, and Twist in co-cultured melanoma cells.

P273**Board Number: B408****Stiffened extracellular matrix and paracrine signaling from stromal fibroblasts synergistically combine to result in both increased tumor cell invasiveness and a change in invasive strategy in a 3-D m.**J.S. McLane¹, L.A. Ligon¹;¹Biology, Rensselaer Polytechnic Inst, Troy, NY

Several changes have been described in the stroma surrounding a tumor, including changes in cellular composition, altered extracellular matrix (ECM) composition and organization, and increases in tissue

stiffness. Tumor cells are influenced by the composition, organization, and mechanical properties of the microenvironment, as well as by signals from stromal cells. The tumor-associated microenvironment can induce changes in tumor cells such as EMT and increased invasiveness. Here we sought to test whether the small increase in stiffness observed in the stroma surrounding a tumor is sufficient to induce tumor cell invasiveness. Further, we sought to determine if signaling from stromal fibroblasts can regulate tumor cell invasion in the stiffened matrix. In order to test the role of physiologically relevant stromal stiffness in initiating tumor invasion, we developed an in vitro model of a tumor in situ in which the stromal stiffness can be controlled independently of collagen concentration. We generated tumor spheroids with a basement membrane-like coating and then encapsulated them in a collagen-I based 3D hydrogel with or without fibroblasts in the “stroma”. We varied the stiffness of the hydrogel from that of normal breast (~200 Pa) to that of observed breast tumor adjacent stiffness (~800 Pa), a difference of less than 5-fold. Our results show a distinct change in invasive cellular behavior with increased stiffness, and a differential regulation of invasion by fibroblast signaling indicating both physical and paracrine links between the altered stroma and tumor behavior.

Mechanical Confinement Triggers Glioma Linear Migration Dependent On Formins.

P. MONZO¹, C. Guetta¹, A. Krishnasamy¹, B. Ladoux^{1,2}, M.P. Sheetz^{3,4};

¹Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ²Institut Jacques Monod, Université Paris Diderot CNRS, Paris, France, ³Mechanobiology Institute, National University of Singapore, Singapore, NY, ⁴Biological Sciences, Columbia University, New York, NY

Glioblastoma are extremely aggressive brain tumors characterized by their resistance to radio- and chemotherapy and their highly invasive properties. Glioblastoma cells have the remarkable capability to insinuate themselves throughout the brain. Since they migrate in a confined environment, we analyzed their movement on micropatterned lines coated with laminin to mimic the tracks that glioma cells follow when invading the brain. We found that they adopted an efficient linear migration mode upon confinement to lines. During this linear migration, antiparallel streams of cells were observed along the axis of the laminin tracks. Within these streams, individual cells adopted a spindle shape and used a 2 phase saltatory motion that depended on microtubules and contractile actin bundles, and involved paxillin-containing adhesions. Surprisingly, we found that this linear migration mode was dependent on formins but independent of Arp2/3. Finally, we found that in confined conditions glioma cells expressed a specific mDia2 isoform offering a promising target for cancer therapy development.

P275**Board Number: B410****Co-culture with mature adipocytes promotes morphological changes and growth of breast cancer cells.**Y. Lee¹, J. Koo¹;¹Department of Pathology, Severance Hosp, Seoul, Korea

The crosstalk between tumor cells and adjacent stroma plays a significant role in tumor growth and progression. In the breast, the main stroma cell types are fibroblasts and adipocytes. Fibroblasts are widely suggested as stimulating the invasion of breast cancer cells. Although emerging evidences suggest that adipocytes contribute to tumorigenesis in breast cancer, its mechanism remains to be elucidated. In this study, we show that mature adipocytes promote morphological changes and growth of human breast cancer cells. Co-culture of MCF-7 (luminal type) with mature adipocytes exhibited spindle-like structures without other stimuli, compared to MCF-7 cells co-cultivated with preadipocytes. Furthermore, MDA-MB-435S and MDA-MB-231 cells, well-known Triple Negative Breast Cancer (TNBC type), co-cultivated with mature adipocytes induced extensive morphologic change and incomplete EMT. However, co-culture with mature adipocytes has no effect on MDA-MB-453 (Her2 type) and MDA-MB 468 (TNBC type) cells. After co-culture of MDA-MB-231 with mature adipocytes, the cancer cell upregulated mRNA and protein expression of vimentin. Five breast cancer cell lines cultured in the presence of mature adipocytes showed an increase in cell proliferation compared to cancer cell alone culture. These data suggest that mature adipocytes can promote tumor growth and metastasis by causing incomplete EMT via phenotypic change of MCF-7, MDA-MB-435S, and MDA-MB-231 cells.

Cancer Therapy 1**P276****Board Number: B411****Identification of natural products with selective activity against triple-negative breast cancer molecular subtypes.**A.J. Robles¹, L. Du², S. Cai², J.B. King², R.H. Cichewicz², S.L. Mooberry^{1,3,4};¹Department of Pharmacology, The University of Texas Health Science Center at San Antonio, San Antonio, TX, ²Natural Products Discovery Group, Department of Chemistry and Biochemistry, University of Oklahoma, Norman, OK, ³Department of Medicine, The University of Texas Health Science Center at San Antonio, San Antonio, TX, ⁴Cancer Therapy and Research Center, The University of Texas Health Science Center at San Antonio, San Antonio, TX

Triple-negative breast cancers (TNBCs) are tumors lacking estrogen receptor/progesterone receptor expression and amplification of HER2. These tumors respond initially to cytotoxic chemotherapy but have a poor prognosis and drug resistance often develops. TNBCs are heterogeneous cancers without

clear molecular targets for the development of new therapies. Genetic subtyping of 587 TNBC patients by Lehman and Bauer (2011 *J Clin Invest*) identified 6 subtypes of TNBC with distinct genetic alterations, allowing for the first time the ability to search for targeted therapies for TNBC subtypes.

High-content screening was used to evaluate 4,336 fungal and 1,392 plant extracts for selective efficacy against 5 TNBC subtypes. We identified 11 extracts with selective cytotoxic and/or antiproliferative activity against cell lines representing the different TNBC subtypes. Bioassay-guided fractionation of a fungal extract yielded a novel compound, maximiscin, which was found to have selective cytotoxic efficacy against the MDA-MB-468 cell line of the basal-like 1 subtype. Additionally, we isolated deguelin, which had selective activity in the MDA-MB-453 cells of the luminal androgen receptor (LAR) subtype.

Cellular studies were conducted to investigate the molecular mechanisms of action of each compound and to potentially identify new pharmacological targets for TNBC. Initial studies showed that maximiscin caused an accumulation of cells in G1. Protein microarray studies gave a preliminary indication that maximiscin increased levels of phospho-p53, which was consistent with the observed G1 accumulation. Additionally, maximiscin caused a reduction of phospho-S6K and phospho-rS6 levels relative to vehicle-treated cells after 8 h of treatment, suggesting inhibition of the mTOR signaling pathway may be involved in its mechanism of action. A small decrease in cellular levels of phospho-Stat1 and phospho-Stat3 was also observed beginning 8 h after maximiscin treatment. Maximiscin induced apoptosis of MDA-MB-468 cells, but DNA double-strand breaks did not occur prior to the accumulation of cleaved PARP, suggesting that DNA damage is not the primary mechanism of action.

Based on published studies of deguelin and the knowledge that LAR TNBC cells are particularly sensitive to Hsp90 inhibition, we hypothesized that deguelin selectively inhibits growth of MDA-MB-453 cells by inhibiting Hsp90 and modulating androgen receptor (AR) function. Preliminary results suggest deguelin modulates AR levels but does not directly bind Hsp90. Studies focused on further defining the mechanisms of action of each of these compounds are ongoing. These results demonstrate that novel compounds with potential therapeutic value for the treatment of TNBC subtypes can be identified from nature.

P277**Board Number: B412****Rosehip (*Rosa canina*) extracts prevent MAPK and AKT-mediated cell proliferation and migration in African American triple negative breast cancer cells.**P. Cagle¹, T. Coburn^{2,3}, A. Shofoluwe², P.M. Martin²;¹Energy and Environmental Systems, North Carolina AT State University, Greensboro, NC, ²Department of Biology, North Carolina AT State University, Greensboro, NC, ³Energy and Environmental Systems, NC AT State University, Greensboro, NC

Triple Negative Breast Cancer (TNBC) is an aggressive form of breast cancer, characterized by its lack of the human epidermal growth factor receptor-2 (HER-2), the estrogen receptor (ER), and the progesterone receptor (PR). The high prevalence of triple negative tumors is more commonly observed in African American (AA) women. Akt and MAPK have been shown to promote cell proliferation and migration in TNBC and MAPK expression may be an underlying mechanism contributing to the generation of chemo-resistance in triple negative breast cancer. Currently, the existing targeted therapy is of minimal benefit in TNBCs. Furthermore, adverse side effects and the emergence of drug-resistant cancer cells are of great concern. Natural products have received growing interest in recent years as an alternative medicine with potential anti-oncogenic properties. Rosehip extracts have been used as dietary supplements to relieve symptoms associated with gastrointestinal disorders and arthritis, and in our laboratory it has been shown to prevent cell proliferation in glioblastomas. This study investigated the efficacy of rosehip extracts in preventing proliferation and migration of an AA triple negative breast cancer cell line (HCC1806). HCC1806 cells treated with rosehip extracts (1mg/mL -25ng/mL) demonstrated a significant decrease in cell proliferation. The observed decrease in cell proliferation was equal to or better than the decrease of cell proliferation observed when inhibitors of the MAPK (U0126, 10 μ M) or AKT (LY294002, 20 μ M) signaling pathways were utilized. Rosehip extracts also demonstrate anti-migratory potential. Additionally, pretreatment of this cell line with rosehip extracts selectively decreased AKT, MAPK, p70S6K, and S6 phosphorylation suggesting these extracts prevent AA TNBC cell proliferation and migration by blocking both the MAPK and AKT signaling mechanisms. Western blot analysis and apoptosis studies demonstrate that rosehip extracts inhibit cell proliferation without promoting apoptosis. To investigate the potential clinical application of rosehip extracts we examined whether rosehip extracts could enhance the chemotherapeutic properties of Doxorubicin (20 μ M). Rosehip extracts enhanced the anti-proliferative effect of Doxorubicin by promoting apoptosis. These data suggest that rosehip extracts are capable of decreasing cell proliferation and migration in an AA triple negative breast cancer cell line. Moreover, rosehip extracts promote apoptosis and demonstrate a synergistic inhibition of cell proliferation, when given in combination with Doxorubicin. This investigation demonstrates that rosehip extracts may serve as either an alternative or complimentary treatment to current chemotherapeutic regimens for TNBC, especially in AA women.

P278**Board Number: B413****Electrophilic Nitroalkenes Cause Degradation of NFκB RelA in Triple Negative Breast Cancer Cells.**C. Woodcock¹, S.R. Woodcock¹, N. Davidson², B.A. Freeman¹, Y. Huang²;¹Pharmacology and Chemical Biology, Univ Pittsburgh, Pittsburgh, PA, ²University of Pittsburgh Cancer Institute, Pittsburgh, PA

Triple negative breast cancer (TNBC), which lacks estrogen receptor (ER), progesterone receptor (PR) and Her2/Neu, is an aggressive and therapy-resistant metastatic cancer that accounts for up to 20% of breast cancer incidence in the US. Women with TNBC are at higher risk for early relapse within 5 years of treatment, and recurrent tumors become more aggressive and invasive. Current chemotherapy for TNBC is limited because of ill-defined targets and poor efficacy; therefore, there is an unmet need for novel therapeutic agents with improved efficacy that can also prevent disease recurrence. Electrophilic fatty acids are endogenously-generated signaling mediators that modulate cell differentiation and proliferation via post-translational modification of functionally-significant nucleophilic amino acids (Cys, His) of transcriptional regulatory proteins such as NFκB, PPAR α , and Keap1/Nrf2. Preliminary studies have revealed that an exemplary electrophilic fatty acid nitroalkene, 10-nitro-oleic acid (OA-NO₂), displays potential therapeutic value in TNBC cells, by preferentially reducing the growth and viability of two TNBC human breast ductal epithelial cell lines (MDA-MB-231, MDA-MB-468), but not normal MCF10A cells. Essential to proliferation and survival, NFκB plays an important role in TNBC development, and its signaling actions are constitutively activated in ER-negative breast cancer cell lines and primary tumors. Notably, the protein level of NFκB RelA/p65 subunit was diminished in TNBC cells upon OA-NO₂ treatment. Therefore, it is hypothesized that electrophilic fatty acids reduce TNBC cell proliferation and survival through down-regulation of NFκB expression and signaling. We have demonstrated that fatty acid nitroalkenes induce caspase-3 activation and down-regulate transcript levels of NFκB-regulated genes, cyclin D1 and the pro-survival genes, bcl-xL and survivin, in TNBC cells. Moreover, nitro-fatty acids promote p65/RelA protein polyubiquitination via nitroalkylation of p65/RelA in TNBC cells. Overall, this study will help to extend our current knowledge of diverse electrophile functions with proteins, and also serve as a prelude to the clinical study of electrophilic nitrated lipids as therapeutic agents that may display a high selectivity for killing TNBC cells/tumors.

P279**Board Number: B414****Differential Sensitivity of Breast Cancer Cell Lines to Diverse Microtubule Targeting Agents.**A.L. Risinger¹, N. Dybdal-Hargreaves¹, S.L. Mooberry^{2,3,4};¹Pharmacology, Univ Texas Hlth Sci Ctr-San Antonio, San Antonio, TX, ²Department of Pharmacology, The University of Texas Health Science Center at San Antonio, San Antonio, TX, ³Department of Medicine, The University of Texas Health Science Center at San Antonio, San Antonio, TX, ⁴Cancer Therapy and Research Center, The University of Texas Health Science Center at San Antonio, San Antonio, TX

Microtubule targeting agents (MTAs) are some of the most important drugs used in the treatment of a wide range of malignancies. New evidence suggests that the anticancer effects of these agents are not only due to antimitotic actions, but also to disruption of interphase signaling processes that require a functional microtubule network. Microtubules play fundamental roles in cellular trafficking, metabolism and cell signaling and it is not unreasonable that in the context of an oncogene driven cancer cell, disruption of microtubule-dependent processes could inhibit essential transport and signaling, ultimately leading to cytotoxicity. If this is the case, then cell lines representing different molecular phenotypes and oncogenic drivers would be expected to be differentially sensitive to diverse MTAs that have subtly different mechanisms of action. To test this, the effects of 6 MTAs, including both microtubule stabilizers and microtubule depolymerizers, were evaluated in 8 cell lines representing the major classes of breast cancer, including triple negative subtypes. An initial observation is that there was no correlation between the cell doubling rate and sensitivity for either antiproliferative or cytotoxic effects of any of the MTAs. This discounts the notion that cell lines are differentially sensitive only by virtue of their proliferation rate. Second, profound differences among the cell lines were seen. Some are intrinsically resistant to all the drugs tested, for example HCC1937 and T47D cells, while most of the other cell lines have a wide range of sensitivities to the different agents. The MDA-MB-231 cell line is sensitive to the antiproliferative effects of each of the MTAs, yet total growth inhibition was achieved with only 2 of the 6 drugs, vinorelbine and eribulin, at concentrations up to 10 μ M. Third, there was no indication of differential sensitivity across this panel to either microtubule stabilizers or destabilizers, but to individual drugs of each of these classes. For example, Hs578T cells are sensitive to eribulin, vinorelbine, paclitaxel and ixabepilone, yet resistant to docetaxel. Fourth, a variety of dose response relationships were observed, including the classic sigmoidal log dose response curves, inverted U-shaped curves, bi and triphasic curves. Together these data show that there are substantial differences among the potency and efficacy of MTAs even at the in vitro level. Our data suggest that in vitro studies can be useful to begin to understand the mechanistic differences among these agents in the context of different oncogenic signatures. These studies can assist in the elucidation of the multiple mechanisms by which disruption of microtubules can impact cell function and ultimately cell viability.

P280**Board Number: B415****Ceramide-induced secretion of exosome-associated breast cancer resistance protein and reduction of doxorubicin resistance in human breast cancer MDA-MB-231 cells.**

J. Kong¹, Q. He², G. Wang², S. Dasgupta², M.B. Dinkins², G. Zhu¹, S.D. Spassieva³, E. Bieberich²;
¹Georgia Regents University, Augusta, GA, ²Department of Neuroscience and Regenerative Medicine, Georgia Regents University, Augusta, GA, ³Med Univ South Carolina, Charleston, SC

Many breast cancer cells acquire multidrug resistance (MDR) mediated by ABC transporters such as breast cancer resistance protein (BCRP/ABCG2). Here we show that incubation of human breast cancer MDA-MB-231 cells with farnesoid X receptor antagonist guggulsterone (gug) and retinoid X receptor agonist bexarotene (bex) elevated ceramide, a sphingolipid known to induce exosome secretion. The gug+bex combination reduced cellular levels of BCRP to 20% of control cells by inducing its association and secretion with exosomes. Exogenous C6 ceramide also induced secretion of BCRP-associated exosomes, while siRNA-mediated knockdown or GW4869-mediated inhibition of neutral sphingomyelinase 2 (nSMase2), an enzyme generating ceramide, restored cellular BCRP. Immunocytochemistry showed that ceramide elevation and concurrent loss of cellular BCRP was prominent in Aldefluor-labeled breast cancer stem-like cells. These cells no longer excluded the BCRP substrate Hoechst 33342 and showed caspase activation and apoptosis induction. Consistent with reduced BCRP, ABC transporter assays showed that gug+bex increased doxorubicin retention and that the combination of gug+bex with doxorubicin enhanced cell death by more than 5-fold. Taken together, our results suggest a novel mechanism by which ceramide induces BCRP secretion and reduces MDR, which may be useful as adjuvant drug treatment for sensitizing breast cancer cells and cancer stem cells to chemotherapy. Supported by NIH and NSF.

P281**Board Number: B416****The Microtubule Stabilizer Taccalonolide AJ Inhibits EGFR Signaling and Transport in Breast Cancer Cells.**

C.C. Rohena¹, N. Dybdal-Hargreaves¹, S.L. Mooberry^{2,3,4};
¹Pharmacology, Univ Texas Hlth Sci Ctr-San Antonio, San Antonio, TX, ²Department of Pharmacology, The University of Texas Health Science Center at San Antonio, San Antonio, TX, ³Department of Medicine, The University of Texas Health Science Center at San Antonio, San Antonio, TX, ⁴Center Therapy and Research Center, The University of Texas Health Science Center at San Antonio, San Antonio, TX

Breast cancer is the second most diagnosed cancer in women, with millions of women suffering from the disease worldwide. Microtubule stabilizers are some of the most important drugs used in the

treatment of breast cancer. The taxanes, paclitaxel and docetaxel are some of the most valuable agents used in the treatment of breast cancer. However, there remains a need for new microtubule stabilizers that can overcome some of the limitations of the taxanes. The taccalonolides are a class of microtubule stabilizers isolated from plants of the genus *Tacca*. The taccalonolides bind covalently to microtubules, have the ability to overcome drug resistance due to the overexpression of PgP, and have shown excellent activity in paclitaxel resistant xenograft models. Recent evidence suggests that the ability of microtubule targeting agents (MTAs) to interrupt microtubule-dependent functions in interphase cells contributes to their anticancer actions. The specific signaling events interrupted by MTAs and mechanistic differences among MTAs are only beginning to be investigated. EGFR is overexpressed in 40% of breast cancers and in triple negative breast cancers EGFR overexpression occurs in 75% of cases. Following ligand binding, activated EGFR is internalized and transported to the endosome, events which are dependent on microtubules. The effects of taccalonolide AJ and paclitaxel on microtubule-dependent EGFR trafficking were evaluated in a panel of breast cancer cell lines, including BT549, MDA-MB-468 and T47D. Our results show that taccalonolide AJ and paclitaxel inhibit EGFR internalization causing the receptor to be retained at the cell periphery following ligand stimulation. This impaired trafficking inhibited the phosphorylation of EGFR's downstream targets, as evidenced by lower levels of ERK1/2, AKT and STAT3 phosphorylation. Surprisingly, taccalonolide AJ was much more effective at inhibiting the phosphorylation of these downstream targets. These data suggest that microtubule stabilizers can modulate EGFR pathways in distinct ways. Identification of the specific signaling pathways and downstream targets interrupted by the different MTAs might identify new rational drug combinations. This has the potential to identify patient populations that would benefit from different MTAs based on the specific signaling defects in their tumors and thus better responses. Our study evaluating differences among microtubule stabilizers begins to shed some light into the complex and subtly different mechanisms of action of these drugs.

Reishi sensitizes EGFR-overexpressing inflammatory breast cancer cells to the tyrosine kinase inhibitor erlotinib.

I.J. Suarez-Arroyo¹, G. Maldonado-Martinez¹, L.A. Cubano¹, M. Martinez-Montemayor²;

¹Univ Central Del Caribe - Sch Med, Bayamon, PR, ²Univ Central Del Caribe-Sch Med, Bayamon, PR

Inflammatory Breast Cancer (IBC) is the most aggressive, and lethal type of breast cancer. Its lethality stems from its unique ability of forming tumor spheroids, which invade the dermal lymphatics causing the inflammatory phenotype. Within these spheroids, in IBC cell lines and human tissues, the Epidermal Growth Factor Receptor (EGFR) is overexpressed and it is associated with increasing IBC tumor growth rates, invasion and metastasis. Moreover, the high incidence of resistance to EGFR Tyrosine Kinase Inhibitors (TKIs) has greatly diminished the effectiveness of this chemotherapeutic drug. Thus, we aimed to investigate Reishi's therapeutic potential in IBC, focusing on the regulation of the EGFR signaling cascade and its contribution to the IBC cellular response when treated in combination with erlotinib.

SUM-149 IBC cells were treated with various concentrations of erlotinib, Reishi, or their combination for 72h. In order to study the molecular mechanism for the improved effects of the combination treatment we successfully developed an IBC erlotinib resistant cell line, rSUM-149 cells, which were also treated with erlotinib, Reishi or their combination. Treatment effects were tested on IBC cell viability, invasion via Transwell Invasion Assays, cell migration using FluoroBlok™ Cell Culture Inserts, tumor spheroid formation via three-dimensional cell culture, and immunoblots. Statistical analyses include a One-way ANOVA with post-hoc test using the Dunnett's multiple comparisons estimator and p was set at ≤ 0.05 . Our results show that Reishi sensitizes parental and resistant SUM-149 cells to erlotinib treatment after 72h (ANOVA, $F = 104.1$; p

P283

Board Number: B418

Ganoderma lucidum decreases the phosphorylation of STAT-3 in in vitro and in vivo inflammatory breast cancer models.

Y. Loperena¹, L.A. Cubano², M. Martinez-Montemayor³;

¹Univ Central Del Caribe-Sch Med, Bayamón, PR, ²Univ Central Del Caribe - Sch Med, Bayamon, PR, ³Univ Central Del Caribe-Sch Med, Bayamon, PR

Inflammatory Breast Cancer (IBC) is an aggressive form of breast cancer (BC) with symptoms that include a diffuse redness and swelling of the breast. Unique pathological findings indicate the presence of tumor emboli invading the dermal lymphatics of the breast; a process that is partly responsible for the inflammatory phenotype. However, these tumors produce inflammatory mediators such interleukin-6 (IL-6), which may act as a growth factor to contribute to cancer progression, invasion and metastasis via the activation of the Janus Kinase-2/Signal Transducer and Activator of Transcription 3 (STAT-3) pathway. Our published data demonstrates that the medicinal mushroom, *Ganoderma lucidum* (Reishi), disintegrates tumor emboli and modulates the abundance of proteins involved in invasion cascades. In the current study, we assessed the effects of Reishi on inflammatory markers focusing on the IL-6/JAK-2/STAT-3 pathway both *in vitro* and *in vivo*. SUM-149 IBC and SUM-102 non-IBC BC cells were treated with vehicle, or Reishi at different time points to determine cancer cell viability, invasion via three-dimensional culture assays and protein abundance via immunoblots. *In vivo* studies were carried out in female severe combined immunodeficient (SCID) mice that were treated with vehicle or 7mg/kgBW, 14mg/kgBW and 28mg/kgBW of Reishi for 2wk. SCID mice were then injected with SUM-149 IBC cells in their lower right mammary fat pad and Reishi treatment was continuously administered for 12 wks. Our data from the *in vitro* study suggests that Reishi reduces cancer cell viability, and Reishi has an immunomodulatory role in SUM-149 IBC cell line, demonstrated by its ability to reduce the secretion of IL-6 and reduced phosphorylation of STAT-3 in SUM-149 cells. Cell invasion studies show that Reishi reduces invasion in IBC cells. Interestingly, Reishi reduces SUM-102 BC cell viability; however it does not affect STAT-3 signaling in the cell line. Our *in vivo* results show that Reishi does not change tumor volume, when mice were treated with any concentrations of Reishi. However, the phosphorylation of STAT-3 in tumor lysates significantly decreases in a concentration dependent manner. Future efforts are

focused on understanding the invasion effects on the SUM-102 non-IBC BC cell line, and on the implications of STAT3 inactivation in IBC. This project was sponsored by Title V PPOHA US Department of Education #P031M105050, NIH/NIMHD # 8G12 MD 007583, NIH/NIGMS #P20 GM103475, NIH/NIMHD U54 MD008149.

The Rac Inhibitor EHop-016 Reduces Mammary Tumor Growth, Metastasis, and Angiogenesis.

L. Castillo-Pichardo^{1,2}, T. Humphries-Bickley¹, C. de la Parra³, E. Hernandez³, L.A. Cubano⁴, J. Rodriguez-Orengo³, S.F. Dharmawardhane³;

¹Biochemistry, University of Puerto Rico Medical Sciences Campus, San Juan, PR, ²Pathology and Laboratory Medicine, Universidad Central del Caribe, Bayamon, PR, ³University of Puerto Rico Medical Sciences Campus, San Juan, PR, ⁴Anatomy and Cell Biology, Universidad Central del Caribe, Bayamon, PR

The Rho family GTPases Rac and Cdc42 play pivotal roles in actin cytoskeleton reorganization during migration/invasion and thus, metastasis; as well as epithelial to mesenchymal transition, transcription, cell proliferation, cell cycle progression, apoptosis, vesicle dynamics, angiogenesis, and cell adhesions. In many human cancers, Rac proteins are hyperactive due to the upregulation of their upstream effectors, guanine nucleotide exchange factors (GEFs). Therefore, we have characterized a series of small molecules designed to inhibit the interaction of Rac and Cdc42 with their GEFs. We reported the development of EHop-016, a small molecule compound, which inhibits Rac1 and Rac3 activities of metastatic cancer cells with an IC₅₀ of 1 μM, and blocks the interaction of Rac with the oncogene and Rac and Cdc42 GEF Vav. EHop-016 also inhibits the activity of Cdc42 at higher concentrations, the Rac downstream effector p21-activated kinase (PAK), lamellipodia extension, migration, and viability of metastatic breast cancer cells. In this study, we further investigated the in vitro and in vivo action of EHop-016 in metastatic cancer, and report that EHop-016 inhibits the Rac activities of breast and prostate cancer cells, and human umbilical vein endothelial cells (HUVEC). EHop-016 may inhibit metastatic cancer cell viability by downregulating Akt and Jun kinase activities and c-Myc and Cyclin D expression, as well as increasing caspase 3/7 activities. Next, we tested the efficacy of EHop-016 in a nude mouse model of experimental metastasis, where female athymic nude mice bearing mammary fat pad tumors established from GFP-MDA-MB-435 cells were treated with 0, 5, 10, 25, or 40 mg/kg body weight (BW) EHop-016. Tumor growth and metastasis were quantified using fluorescence in vivo image analysis. We found that at 25 mg/kg BW, EHop-016 significantly reduces mammary fat pad tumor growth, metastasis, and angiogenesis. As quantified by ultra high pressure liquid chromatography (UPLC)/ mass spectrometry (MS/MS), EHop-016 was detectable in the plasma of nude mice at 17-23 ng/mL levels at 12 h following intraperitoneal (i.p.) administration of 10-25 mg/kg BW EHop-016. The EHop-016 mediated inhibition of angiogenesis in vivo was confirmed by in vitro tube formation assays of HUVECs. In conclusion, EHop-016 has potential as an anticancer compound to inhibit cancer progression

via multiple Rac-directed mechanisms. Moreover, EHop-016 is a useful tool to study Rac function in human disease in vitro and in vivo.

Inhibition of thromboxane pathway, a promising new treatment against lung cancer.

G.G. Chen¹, Y. Liu¹, R. Huang¹, M. Li¹, M. Underwood¹;

¹Surgery, The Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong

The efficacy of available treatments for the majority of lung cancer is still far from satisfactory, mainly due to lack of good therapeutic targets or severe side-effects. Recently, thromboxane (TX) pathway has been demonstrated to play a role in lung cancer development. Since the TX pathway is downstream of cyclooxygenase (COX), the inhibition of relevant targets in the TX pathway can avoid affecting the entire COX system, and thus improve the specificity of the treatment and reduce side-effects. In this study, we tested the TX inhibitor, and the TX receptor (TXR) blocker in lung cancer cells to check their effects on tumor cell proliferation, growth and apoptosis. A smoking carcinogen NNK-induced mouse lung tumor model was established to determine the effect of these inhibitors on the growth of lung tumor in vivo, and to examine the possible toxic effects of these treatments on liver and renal functions. Our results showed that TX was able to function as a critical mediator for tumor-promoting effects of COX-2 in lung cancer. Both TX specific inhibitors and TXR blockers could completely block NNK-mediated cell proliferation via inducing apoptosis. TXR agonist U46619 reconstituted a near full proliferative response to NNK when TXS was inhibited, affirming the role of TXR in tumor cell proliferation and growth. However, the dual TX inhibitor BM567 which inhibits both TX and TXR did not offer better suppression, compared with single TX inhibitor or TXR blocker, suggesting that TX and TXR were likely to function in a same channel to promote the tumor growth. The lung tumor model showed that the TX inhibitor led to the significant arrest of the tumor growth. Furthermore, TX inhibitors neither affected the daily activity of mice, nor caused damages to liver and kidney. In conclusion, the inhibition of TX pathway can lead to the significant suppression of lung tumor in vitro and in vivo without producing significant side-effects.

P286**Board Number: B421****Anti-Mullerian Hormone (AMH) and its Receptor AMHRII provide a TGF- β -Associated Pro-Survival Signaling Loop in Lung Cancer.**T.N. Beck¹, E. Nicolas², Y. Zhou³, I. Serebriiskii⁴, E.A. Golemis⁴;¹Molecular and Cell Biology and Genetics, Drexel University/Fox Chase Cancer Center, Philadelphia, PA,²Genotyping and Real-Time PCR, Fox Chase Cancer Center, Philadelphia, PA, ³Epidemiology andBiostatistics, Fox Chase Cancer Center, Philadelphia, PA, ⁴Developmental Therapeutics Program, Fox Chase Cancer Center, Philadelphia, PA

Signaling changes associated with epithelial-mesenchymal transition (EMT) affect prognosis and response to survival in lung cancer. The molecular chaperone heat shock protein 90 (HSP90) supports the activity of many protein clients associated with lung cancer pathogenesis including ERBB2, MET, BRAF and TGFBR1. Because of the dependence of cancer cells on HSP90 function, HSP90 inhibitors such as ganetespib selectively kill cancer cells, and are showing promising activity in clinical trials. We used RNAi screening to identify genes influencing lung cancer cell resistance to ganetespib. Depletion of Anti-Mullerian Hormone (AMH) and its receptor, AMH receptor type II (AMHR2), strongly sensitized cells to ganetespib in three RAS-mutated and one EML4-ALK expressing lung cancer cell lines. This was surprising, as neither the expression of AMH nor its receptor has ever been reported in lung cancer. Instead, almost all studies of AMH to date have focused on its role in differentiation of gonadal tissue, where it activates a cell surface receptor upstream of the SMAD genes, which are common effectors in the lung cancer-relevant TGF- β cascade, which controls EMT. Using multiple approaches, we have experimentally confirmed the expression of AMH and surface expression of AMHR2 in lung cancer cell lines, and mining of public databanks suggests that both proteins are expressed in a subset of lung cancer samples and cell lines. Surprisingly, we observed that depletion of AMH and AMHR2 induced EMT-like features, including downregulation of cadherins and assumption of a mesenchymal morphology. Conversely, ganetespib treatment increased epithelial features. These findings suggest that resistance to HSP90 inhibition may differ from resistance to traditional chemotherapeutics. In line with this hypothesis, we found that depletion of AMH and AMHR2 did not sensitize cells to cisplatin, while depletion of E-cadherin sensitized cells to HSP90 inhibition. Mechanistically, AMH and AMHR2 depletion depressed activity of NF- κ B and AKT, both critical EMT and survival regulators. These results for the first time indicate the presence of an AMH-AMHR2-NF κ B-AKT pro-survival signaling axis of therapeutic relevance in lung cancer. Further, our results also suggest that AMH, AMHR2 and EMT-associated proteins may serve as biomarkers to predict resistance to HSP90 inhibitors, and that it may be more beneficial to prime lung tumors with HSP90 inhibitors, to induce MET and decrease survival signaling, prior to treatment with chemotherapy.

P287**Board Number: B422****Molecular mechanisms underlying lung cancer progression.**J. Hooda¹, D. Cadinu¹, M. Alam², A. Shah², T.M. Cao², R. Brekken³, L. Zhang¹;¹Molecular and Cell Biology, Univ Texas-Dallas, Richardson, TX, ²Molecular and Cell Biology, University of Texas at Dallas, Richardson, TX, ³Division of Surgical Oncology, University of Texas Southwestern Medical Center, Dallas, TX

Altered metabolism is a hallmark of the transformed state in cancer progression. Recent studies have uncovered a plethora of metabolic alterations in cancer cells. One important finding is that mitochondrial respiration is amplified in certain human cancer cells. Recently, using a matched pair of cell lines representing normal nonmalignant HBEC30KT and non-small-cell lung cancer (NSCLC) HCC4017 cells developed from the same patient, we identified metabolic changes linked with the transformation of normal to cancer cells. We found that oxygen consumption and heme synthesis were intensified significantly in lung cancer cells, compared to the normal cells. Furthermore, the levels of heme uptake proteins and oxygen-utilizing hemoproteins were dramatically increased in cancer cells and xenograft tumors. Interestingly, we found that inhibition of heme synthesis or mitochondrial function preferentially suppressed cancer cell proliferation, colony formation and cell migration. These results demonstrated that heme availability is significantly increased in cancer cells and tumors, which leads to elevated production of hemoproteins, resulting in intensified oxygen consumption and cellular energy production for fueling cancer cell progression. Further, we also found that lowering heme availability sensitized NSCLC cells to paclitaxel. We measured the oxygen consumption of 6 NSCLC cell lines in the absence of 3 key metabolites individually and found that the levels of oxygen consumption increased in all the cell lines in the absence of glucose, while it decreased in the absence of glycine or glutamine in 4 of the cell lines. Experiments are currently underway to elucidate the roles of heme in cancer cell bioenergetics and function under different metabolic conditions.

P288**Board Number: B423****Antitumor studies of Modified L- Penetratin Peptide as a molecule targeting E2F in Prostate Cancer.**T. Shaik¹, N. Bansal¹, N.J. Farley¹, J. Kerrigan², E.E. Abali³, D. Banerjee¹, J.R. Bertino¹;¹Department of Medicine and Pharmacology, Rutgers Cancer Institute of New Jersey, New Brunswick, NJ, ²Department of Cancer Pharmacology and Preclinical Therapeutics, Rutgers Cancer Institute of New Jersey, New Brunswick, NJ, ³Department of Biochemistry and Molecular Biology, Rutgers Robert Wood Johnson Medical School, Piscataway, NJ

BACKGROUND: Mutation or inactivation of the retinoblastoma protein (pRB) is frequently involved in castrate resistant prostate cancer tumorigenesis resulting in overexpression/deregulation of E2F activity. E2F1-3a overexpression induces genes involved in DNA synthesis and leads to abnormal cellular

proliferation, tumor growth and invasion. Therefore, inhibiting the overexpression of one or more activating E2Fs is a recognized target in cancer therapeutics. In our previous studies we showed that a novel penetratin coupled 7-mer peptide (PEP), bound tightly to an immobilized consensus E2F1 promoter sequence, was cytotoxic to many malignant cell lines including Burkitt lymphoma cells, pRB negative small cell lung cancer cells and DU145 prostate cancer cells. Furthermore, treatment of tumor xenografts of DU145 tumors propagated in mice with a PEGylated liposome encapsulated PEP caused tumor regression; but tumor growth resumed when the drug was stopped.

OBJECTIVE: As the PEP was unstable in serum, we examined the antitumor activity and stability of two different modified penetratin peptides – 1. D- Arg penetratin peptide (substituting L- Arginine with D- Arginine in the peptide sequence); 2. N-acetylated, C-methylated penetratin peptide (end capping the peptide).

METHODS: DU145 (prostate cancer), H196 and H82 (small cell lung cancer) cells were used. To compare the efficacy of the peptides, we tested the IC50s of peptides at different time points in various cell lines by MTS assay. Stability tests were performed by incubating the peptides in RPMI media containing 10% FBS for 24 hours and then measuring cell viability using MTS assay. Drug combination experiment results were analyzed using the combination index method developed by Chou and Talalay.

RESULTS: D- Arg penetratin peptide was more potent compared to L- Arg penetratin peptide and it was found to be more resistant to degradation by serum proteases than the L- form. The other modified form, N-acetylated, C-methylated PEP was marginally more effective than the unmodified PEP. Drug combination studies showed that D- Arg penetratin peptide in combination with docetaxel, caused additive cytotoxicity against DU 145 cells. Our findings validate D- Arg peptide, an inhibitor of E2F1, as a drug for targeted molecular therapy of prostate cancers with elevated levels of activated E2F's; and encourage future modifications of the peptide that include all D- amino acid substituted peptide.

Acknowledgments: Supported by Lung Cancer Research Foundation and H82 cells were given by Dr. Piyali Das Gupta, Marshall University, West Virginia.

Study of the Effects of Lysophosphatidic Acid on Lymphatic Metastasis of Prostate Cancer.

W. Chen¹, Y. Lin¹, K. Lin¹, C. Lin¹, P. Wu¹, H. Lee¹;

¹Life science, National Taiwan University, Taipei, Taiwan

Clinical evidences suggested that lymphangiogenesis and lymphatic metastasis are important processes during the progression of prostate cancer. Vascular endothelial growth factor (VEGF)-C was shown to be a key regulator during these processes. Our previous studies demonstrated that lysophosphatidic acid (LPA) enhances VEGF-C expression in human endothelial cells. However, the effects of LPA on VEGF-C expression in prostate cancer remain elusive. We demonstrated that LPA enhanced VEGF-C expression

in three different human prostate cancer cell lines. Moreover, the enhancement effect is mediated through activating LPA1/3, reactive oxygen species (ROS) generation, and action of lens epithelium derived growth factor (LEDGF). Furthermore, PC-3 cells were injected in nude mice followed by LPA1/3 antagonist Ki16425 treatment to evaluate the effects of chemical inhibition on LPA receptor in blocking lymphatic metastasis of prostate cancer. We monitored the endothelial and lymphatic markers expression in the xenografts by immunochemistry stainings. We demonstrated that Ki16425 treatment reduced lymphatic markers expression in tumors. These results may potentially lead to future strategies for preventing lymphatic metastasis of prostate cancer.

Systematic interrogation of druggable pathways in pancreatic adenocarcinoma.

E. Ferrer-Lorenzo¹, D.P. Nussbaum¹, P. Winter¹, K. Wood¹;

¹Pharmacology and Cancer Biology, Duke University, Durham, NC

Despite significant advances in the development of cancer treatment in the last 20 years the best available therapies have marginally improved the survival rate of treated pancreatic cancer patients (from 3% to 6% five-year survival), making it still one of the deadliest malignancies. Single standard of care cytotoxic and targeted therapies demonstrate little to no effect on patient survival. Even though we now understand some of the main mutated genetic factors present in pancreatic tumors, their role in drug response remains poorly understood. To identify drug-sensitizing genetic targets in cancer cells we have developed a high-throughput screening platform. In this methodology, pooled lentiviral libraries containing hundreds of knockout constructs specific for cancer-related genes are used to infect cancer cells. By treating the infected populations with therapeutic agents we are able to identify genetic targets that when inhibited synergize with existing drugs to cause increased cell death. We piloted this type of screening platform in HCT-116 cells, a KRAS mutant, MEK inhibitor resistant colorectal cancer cell line, using the MEK-inhibitor AZD-2644 and a pooled shRNA library. This study identified 4-7 target genes that when knocked down sensitized the previously resistant HCT-116 cells to AZD-2644. To conduct a more robust and representative sensitization screen we developed a lentiviral CRISPR-Cas9 library. By performing screens in a panel of pancreatic cancer cell lines, we have identified both cell line dependencies and sensitizers to targeted and cytotoxic chemotherapies. The findings from these screens provide potential mechanistic insights into the key survival signaling programs in pancreatic cancer as well as new therapeutic strategies.

P291**Board Number: B426****Treatment of pancreatic cancer cell lines with high-affinity galectin-3 inhibitor further confirms novel intracellular function of galectin-3 and implications in anti-cancer therapy.**J. Stegmayr^{1,2}, G. Sharma¹, M. Carlsson^{1,3}, S. Oredsson², U.J. Nilsson⁴, H. Leffler¹;¹Department of Laboratory Medicine, Lund University, Lund, Sweden, ²Department of Biology, Lund University, Lund, Sweden, ³Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark, ⁴Department of Chemistry, Lund University, Lund, Sweden

Galectin-3, a protein with the affinity for β -galactosides, has been implicated in a number of cancer-related functions. In pancreatic cancer cell lines, for example, galectin-3 knockdown results in decreased proliferation and migration, and increased gemcitabine-induced apoptosis. Surprisingly, treatment of the pancreatic cancer cell lines MIA PaCa-2 and PanC-1 with a novel high-affinity (K_d in the low nM range) galectin-3 antagonist, bis-{3,3'-deoxy-3,3'-[4-(3-fluorophenyl)-1H-1,2,3-triazol-1-yl]}-1,1'-sulfanediyl-di- β -D-galactopyranoside, had no effect on cell proliferation or gemcitabine-induced cell death. The lack of effect was not due to insufficient intracellular accessibility of the galectin-3 antagonist, because it efficiently inhibited accumulation of galectin-3 around glycy-L-phenylalanine 2-naphthylamide (GPN)-damaged lysosomes, a phenomenon known to depend on the carbohydrate-binding activity of cytosolic galectin-3. The inhibition of galectin-3 accumulation around GPN-damaged lysosomes by the antagonist was seen to be both time- and dose-dependent, as investigated by quantifying galectin-3 puncta formation using immunocytochemistry and confocal microscopy. This indirectly suggests that the proliferation promoting and apoptosis inhibiting effects of galectin-3 may not require its carbohydrate-binding activity. Additionally, treatment of both of the pancreatic cancer cell lines with GPN in combination with the galectin-3 antagonist led to an increased reduction in cell viability compared to treatment with GPN alone, suggesting a protective role of galectin-3 after lysosomal insult. Taken together these results further endorse a novel intracellular function of cytosolic galectin-3, which is to accumulate around and protect lysosomes upon damage, which in turn may render galectin-3 antagonist interesting agents in anti-cancer therapy.

P292**Board Number: B427****Pharmacological activation of myosin II to correct pancreatic cancer cell mechanics.**A. Surcel¹, Q. Zhu², E.S. Schiffhauer¹, H. West-Foyle¹, R.A. Anders², D. Robinson^{1,3};¹Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD, ³Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine, Baltimore, MD

Pancreatic ductal adenocarcinoma (PDAC) annually affects 44,000 people in the U.S. and has an abysmal five-year survival rate of around 6%, which is nearly unchanged over the past 40 years. Pharmacological strategies for treating cancer have primarily focused on inhibiting cell growth through specific genetic pathways, which typically either fail to abolish the disease or lead to compensatory regulatory changes and subsequently, to drug resistance. Importantly, alterations in mechanical properties are a common feature of cancer cells, yet targeting cell mechanics remains an under-utilized approach for drug development.

Here we develop a system for targeting cell mechanics for the discovery of novel therapeutics. We designed a live-cell, high-throughput chemical screen to identify mechanical modulators in *Dictyostelium discoideum*. We characterized 4-hydroxyacetophenone (4-HAP), which increases the cellular cortical tension by enhancing the cortical localization of the mechanoenzyme myosin II, independent of myosin heavy-chain phosphorylation regulation. To shift cell mechanics, 4-HAP requires myosin II, including its full power stroke. We further establish that changes in key cytoskeletal protein distributions correlate with the changes in the biomechanical profile of PDAC progression. In addition to actin-crosslinkers, we detect that non-muscle myosin II distributions vary across PDAC states: specifically myosin IIA increases, myosin IIB decreases, and myosin IIC increases in metastatic cells. We further demonstrate that invasive pancreatic cancer cells are more deformable than normal pancreatic ductal epithelial cells, a mechanical profile that was partially corrected with 4-HAP. Tests of 4-HAP in mouse models of metastatic pancreatic disease are underway. Overall, 4-HAP modifies non-muscle myosin II-based cell mechanics across phyla and disease states and provides proof-of-concept that cell mechanics offer a rich drug target space, allowing for possible corrective modulation of tumor cell behavior.

P293**Board Number: B428****Modulation of the Unfolded Protein Response in Multiple Myeloma.**J. Thomas¹, y. argon²;¹children's hospital of philadelphia, Philadelphia, PA, ²children's hospital of philadelphia, philadelphia, PA

Multiple Myeloma (MM) is the second most common hematological malignancy in the U.S.A. with over 20,000 new cases reported each year and a life expectancy in the range of 3-6 years. MM is

characterized by increased numbers of bone marrow plasma cells that secrete copious quantities of antibodies. The IRE1 kinase/ribonuclease arm of the unfolded protein response (UPR) is activated in MM cells and is necessary for their ability to sustain antibody production. The UPR is initially cytoprotective in that it alleviates ER stress that results from this sustained antibody production. However, IRE1 activity can be modulated to promote apoptosis through both the JNK and regulated IRE1-dependent decay of mRNAs (RIDD) pathways. The clinical proteasome inhibitor Bortezomib (Bz) is the most common drug used to treat MM. Since IRE1 activity is transient, the progression of MM that is characterized by Bz resistant clones under selection pressure may occur due to eventual attenuation of IRE1. Therefore, a single-cell assay method to detect and tract IRE1 activity in Bz resistant clones will be invaluable in understanding how to target therapy resistance. Our lab is developing a fluorescent protein reporter that will be able to identify individual MM cells and determine if a correlation exists between Bz resistance and attenuation of IRE1 activity. Our way IRE1 activity can be attenuated in Bz resistant clones is through a new modulator of IRE1 that was discovered in the Argon lab: the ER enzyme PDIA6, which binds to IRE1 and terminates its XBP1s activity. We are interested in determining if knockdown of PDIA6 in multiple myeloma will increase sensitivity to Bz due to prolonged activation of IRE1. The ability to identify Bz resistant clones, and modulate their IRE1 activity could be a novel therapeutic approach to treat MM.

Extracellular matrix mechanics causes systematic variation in cancer cell proliferation and responses to drugs against myeloid leukemias.

J. Shin^{1,2}, D.J. Mooney^{1,2};

¹School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, ²The Wyss Institute for Biologically Inspired Engineering, Boston, MA

Emerging evidence pinpoints the bone marrow (BM) milieu as a cell extrinsic contributor to the pathophysiology and chemotherapeutic resistance of cancer. Cancer progression is frequently associated with profound alterations in the BM microenvironment by collagen deposition that leads to fibrosis and changes in mechanical properties of the matrix. While the relevance of extracellular matrix mechanics in solid tumors has been investigated, its role in causing the progression and drug resistance of blood cancers or “liquid tumors” remains unclear. Myeloid leukemias consist of a number of disease subtypes defined by distinct genetic mutations and constitutive activation of signaling pathways. Some of these pathways, including Protein Kinase B (AKT), are involved in mechanotransduction, and hence may influence sensitivities of leukemia cells to matrix stiffness. The study is thus based on the hypothesis that matrix stiffness differentially regulates cell proliferation of myeloid leukemia subtypes. By culturing cells in an engineered 3D hydrogel system with tunable stiffness and independent control of ligand density, we demonstrate distinct *ex vivo* cell proliferation profiles and colony growth patterns in response to matrix mechanics for different leukemia subtypes, including human acute and chronic myeloid leukemias (AML and CML). Importantly, *ex vivo* growth of leukemia cells in this system reflects

in vivo growth observed in a xenograft human myeloid sarcoma model, which is generated by subcutaneously implanting leukemia cells encapsulated in the hydrogel with different stiffness. Varying ligand density further modulates leukemia cell proliferation. Interestingly, CML cells are resistant to an AKT inhibitor in the 3D hydrogel compared to the standard plastic culture, while AML cells are generally responsive to the treatment. Further studies reveal that CML cells in the viscous matrix are more resistant to existing drugs (e.g. Imatinib) than those in the solid matrix. Drug screening studies show that different small molecules can be classified based on pharmacodynamics and cell proliferation kinetics profiles of CML cells in different matrix mechanics. Using this approach, we have identified a subset of drugs that may be useful to inhibit CML cell proliferation regardless of matrix mechanics. The results suggest a potential approach to design a drug regimen to reduce the probability of minimal residual disease that could be present in different microenvironments, which can be tailored to individual blood cancer subtypes prior to administration.

Blockage of prion protein-HOP engagement impairs glioblastoma growth and improves overall survival.

M.H. Lopes¹, T.G. Santos², B.R. Rodrigues², V.R. Martins²;

¹Cell and Developmental Biology, University of Sao Paulo, Sao Paulo, Brazil, ²Cellular and Molecular Biology, A C Camargo Cancer Center, Sao Paulo, Brazil

Glioblastomas (GBMs) are resistant to current therapy protocols and identification of molecules that target these tumors is crucial. Interaction of secreted heat-shock protein 70 (Hsp70)–Hsp90-organizing protein (HOP) with cellular prion protein (PrPC) triggers a large number of trophic effects in the nervous system. We found that both PrPC and HOP are highly expressed in human GBM samples relative to non-tumoral tissue or astrocytoma grades I–III. High levels of PrPC and HOP were associated with greater GBM proliferation and lower patient survival. HOP–PrPC binding increased GBM proliferation *in vitro* via phosphatidylinositol 3-kinase and extracellular-signal-regulated kinase pathways, and a HOP peptide mimicking the PrPC binding site (HOP230–245) abrogates this effect. PrPC knockdown impaired tumor growth and increased survival of mice with tumors. In mice, intratumor delivery of HOP230–245 peptide impaired proliferation and promoted apoptosis of GBM cells. In addition, treatment with HOP230–245 peptide inhibited tumor growth, maintained cognitive performance and improved survival. Thus, together, the present results indicate that interfering with PrPC–HOP engagement is a promising approach for GBM therapy.

P296**Board Number: B431****Effect of MiR-26a on Human Malignant Melanoma Cells.**G. Yang¹, G. Gao¹, J. Jiang¹, Y. Yang¹;¹Emporia State University, Emporia, KS

Objective: The goal of this study is to examine the effect of Let-7a on the proliferation and invasiveness of human malignant melanoma cells and identify the gene(s) that Let-7a targets to affect the growth and metastasis of melanoma cells. **Methods:** The effect of Let-7a on proliferation, migration and invasion was measured by cell viability assay and Wounding healing assays, and Transwell migration assay, respectively. The expressions of MITF, and MAP4K3 genes at protein level were measured by Western blot. Cell cycle progression was determined by flow cytometer. **Results:** Let-7a displayed a significant ($p < 0.05$) inhibitory effect on the proliferation, migration and invasion on SKMEL-28 and WM1552C human melanoma cell lines. In addition, Let-7a induced cell cycle arrest at G1 phase. MITF gene was down-regulated by Let-7a in melanoma cells. **Conclusion:** Let-7a inhibited the growth, migration and invasion, also induced cell cycle arrest at G1 phase in human malignant melanoma cells. The expression of MITF was suppressed by Let-7a in SKMEL-28 and WM1552C melanoma cell lines. Taken together, these data suggests Let-7a act as tumor suppressors in melanoma cells and have the potential to function as a novel therapeutic small molecule against human malignant melanoma.

P297**Board Number: B432****P53 interactome and β -tubulin isotypes as biomarkers for head and neck squamous cell carcinoma.**S. Lobert¹, M.E. Graichen¹, R.D. Hamilton¹, K.T. Pitman², M.R. Garrett¹, C. Hicks¹, T. Koganti¹;¹Univ Mississippi Med Ctr, Jackson, MS, ²Banner MD Anderson Cancer Center, Gilbert, AZ

In 2014, more than 40,000 people in the United States will be diagnosed with head and neck squamous cell cancer (HNSCC) and nearly 8,400 people will die of the disease (www.cancer.org/acs/groups). A reduction in the activity of the tumor suppressor p53 in large numbers of patients with HNSCC is associated with HPV infection and HPV infection is often linked to better patient outcomes; however, little is known regarding molecular targets that might lead to better therapies and improved outcomes for these patients. The incorporation of taxanes into the standard cisplatin/5-fluouracil initial chemotherapy for HNSCC has been associated with improved response rate and survival. Taxanes target the beta-subunit of the tubulin heterodimers, the major protein in microtubules, and halt cell division at G2/M phase. Both laboratory and clinical research suggest a link between beta-tubulin expression and cancer patient survival, indicating that patterns of expression for beta-tubulin isotypes along with activity of tumor suppressors such as p53 or micro-RNAs could be useful prognostic biomarkers and could suggest therapeutic targets. In this study we used quantitative real time PCR and microarray analysis to compare HNSCC samples and associated normal tissues from 33 patients. We measured

mRNA for six beta-tubulin isotypes: classes I, IIA, IIB, III, IVB and V, using quantitative real time PCR and in addition, used microarray analysis to explore the expression of > 30,000 genes. We found reduced activity of the p53 interactome is associated with progressive disease at two years and elevated beta-tubulin class III was linked to a trend for disease-free survival over the same time period.

Characterization of particle-endothelium interaction using particles functionalized with dual antibodies in a complex synthetic microvascular network.

Y. Tang^{1,2}, G. Lamberti³, M.F. Kiani⁴, B. Wang^{1,2};

¹Temple University, Philadelphia, PA, ²Biomedical Engineering, Widener University, Chester, PA,

³Department of Mechanical Engineering, Temple University, Philadelphia, PA, ⁴College of Engineering, Temple University, Philadelphia, PA

The interaction between leukocytes and receptors on the endothelium play a key role in the early response to tissue injury. Research has shown that drug carrier particle rolling velocity increases dramatically with the increase of carrier size which affects their final attachment efficiency. The objective of this study is to characterize the rolling and adhesion profile of different size functionalized particles in a synthetic microvascular network (SMN).

Functionalized particles were prepared by coating their surfaces with different ratios of antibodies against adhesion molecules ICAM-1 and E-selectin. Our modified Geographic Information System (GIS) approach was used to digitize the microvascular networks and generate the SMN on PDMS. The rolling velocity and adhesion profile of functionalized 2 & 10 μm particles was quantified in the SMN pre-coated with TNF- α activated human umbilical vein endothelial cells under shear conditions from 0 – 280 sec^{-1} .

Single antibody coated 10 μm particles roll at a higher speed than its 2 μm counterparts. Particle adhesion increased significantly with decreasing shear in SMNs. Increasing particle size from 2 μm to 10 μm did not change its binding efficiency significantly in SMNs, which is different from what have been reported in the traditional parallel plate flow channel.

Particles functionalized with both a rolling molecule and an adhesion particle can more realistically mimic the leukocyte-endothelium interaction in a SMN. These findings have important implications for better understanding the mechanisms behind inflammatory pathologies and for optimizing the design of carriers for targeted drug delivery.

P299**Board Number: B434****The Effect of Androgen on Cell Proliferation in Prostate Cancer In Vitro Models.**S. Turner¹, D. Lamb²;¹Department of Biology, Prairie View AM University, Prairie View, TX, ²Departments of Urology and Molecular Cellular Biology. , Baylor College of Medicine, Houston, TX

Prostate Cancer (PCa) is the second most common cancer amongst older men, and one of six men is diagnosed with PCa in their lifetime. Of note, one in 30 men diagnosed with PCa will succumb to their disease. African-American males and men over the age of 50 are at an increased risk. PCa has a multifactorial etiology. Typically, PCa is a slow growing cancer; most men will never know they have the disease. During the early stages of PCa, men experience few to no symptoms. Currently, 85 percent of American men are diagnosed with PCa in its early stages, which are treatable, allowing these men to carry out a moderately normal life. Unlike other cancers, victims of PCa will die due unrelated causes. The growth of PCa is androgen responsive. The effect of androgens, such as testosterone (T) and dihydrotestosterone (DHT) is mediated through its interactions with the androgen receptor (AR), which plays crucial roles in cell proliferation and differentiation,(processes important for prostate development and PCa, respectively). AR activity is associated with disease progression and therefore, the men with advanced disease are treated with androgen ablation therapy. For this study, human PCa cell lines, LNCaP cells and PC3, which lack androgen receptors, were used. LNCaP are androgen responsive while PC3 are androgen insensitive. R1881 is a synthetic androgen used to study the effects of androgen action. Studies in LNCaP cells show a bimodal effect of androgens on cell proliferation. Low concentrations (<10nM R1881) drive proliferation and high concentrations (>10nM) inhibit proliferation. The purpose of this project was to examine the effect of several concentrations of R1881 on cell proliferation in LNCaP and PC3 cells using several cell quantification techniques. These included counting using the vi-cell, a trypan blue cell analyzer, a Hemocytometer, and a WST (tetrazolium salt viability) assay to determine cell proliferation for a range of days. It was hypothesized that the growth of LNCaP cells at higher concentrations of R1881 would be inhibited; however PC3 cells would not be inhibited. Using the aforementioned techniques, it was found that more than 10nM of R1881 inhibits cell proliferation in LNCaP cells, and less than 10nM of R1881 stimulated cellular proliferation in these cells, indicating these are sensitive to androgens. Furthermore, no effects were seen on PC3 cellular proliferation with lower concentrations of R1881. In conclusion, androgens working through the androgen receptor exhibit a dosage sensitive action on LNCaP growth *in vitro*.

P300**Board Number: B435****A Cure for Prostate Cancer is Possible.**A.A. Sinha¹;¹Univ. of Minnesota , V A Med Ctr Genetics, Cell Biology , Minneapolis, MN

Androgen ablation/deprivation by castration, chemical castration by diethylstilbestrol (DES), or by a variety of FDA-approved drugs has provided palliative treatment for prostate cancer (PCa). Our objective was to find the reasons for the treatment failures. To do this we studied untreated and DES treated biopsies for localization of androgen (AR) and estrogen (ER) receptors using antibodies and immunogold techniques. We examined biopsies of eight DES treated (ranging from 37 days to 18 years) and 18 untreated PCa patients with Gleason histological score 7 and higher grade tumors. Epon-embedded thick sections prepared with a Reichert-Jung microtome were stained with methylene blue. We used two types of androgen receptor antibodies (AR, N-20, Santa Cruz Biotechnol., CA, and anti-AR-V-7 (Precision antibody, A& G Pharmaceutical, Inc. Columbia, MD) and estrogen receptors (ERbeta, H-150, Santa Cruz). Receptors were localized using immunogold techniques and protein A conjugated to 15nm gold particles enhanced with silver. Androgen and estrogen receptors were localized in acini and invasive cells of untreated and DES treated sections. At the electron microscopic level, estrogen receptors localized on the nuclear membranes and the adjacent heterochromatin, but not in nucleoli. Analysis of data indicated that androgen ablation was incomplete since androgen receptors were present in both treated and untreated samples. This led to review of the steroid biosynthetic pathway. This pathway utilizes one or more specific enzymes to catalyze, for example, cholesterol into pregnenolone followed by enzymes that leads to production of progesterone then to testosterone and finally to estrogen. Androgen ablation, undoubtedly, decreases the supply of testosterone in prostate, but it does not inhibit the production of the enzymes in the steroid pathway. Enzymes involved in catalyzing progesterone to testosterone ought to be inhibited for androgen ablation. Since progesterone, testosterone and estrogen and their receptors are found in malignant prostate, inhibitions of enzymes are essential for suppressing production and supply of gonadal steroid hormones to cancer cells. Presence of estrogen receptors in untreated and DES treated PCa indicates that androgen ablation was bypassed in the prostate. Our study indicates that in addition to androgen ablation, we must also inhibit enzymes that catalyze progesterone for the production of testosterone. In conclusion, we suggest that inhibition of enzymes catalyzing cholesterol to pregnenolone have the potential of not only significantly improving treatment of PCa, but also of breast cancer and other hormone-dependent cancers.

The author is grateful to the Research Service of the Minneapolis Veterans Affairs Medical Center for providing laboratory and research facilities. Since the funding expired, this work was completed by the volunteered effort of AAS. There is no conflict of interest in publication of this abstract. We give special thanks to Mr. Francis E. Pomroy, Jr. who is expert in immunogold localization and electron microscopy autoradiography.

P301**Board Number: B436****CuS + Graphene Oxide + Folate nanocompound = X factor in Photothermal Therapy.**D.M. Peterson¹, D. Gilbert², S. Henderson-Jones³, A. Novelo², K. Manns², L.E. Carson⁴, A. Oki⁵, E.C. Regisford²;¹Biology, Prairie View AM University, Prairie View, TX, ²Department of Biology, Prairie View AM University, Prairie View, TX, ³Prairie View AM University, Prairie View, TX, ⁴Cooperative Agricultural Research Center, Prairie View AM University, Prairie View, TX, ⁵Chemistry Department, Prairie View AM University, Praire View, TX

Photothermal Therapy (PTT) is a novel approach at cellular irradiation. PTT manipulates electromagnetic radiation of select particles at an excitable wavelength. Inferred, radiofrequency, microwaves, and ultrasonic wavelengths have all been used to elicit excitation. Excitation, due to photons transfer of electromagnetic energy to selected particles, leads to release of heat energy via vibration. Heat builds up in the cell causing cell membrane lysis leading to cellular death. Copper sulfide (CuS) a black colloid, is used as irradiant. To transport CuS into the cell, Graphene Oxide a single layer form of graphite, is used as its vehicle. In order to deliver CuS + Graphene Oxide to a targeted cancer cell, a known cancer biomarker must be identified. Many cancer cell lines increase up-regulation of the folic acid receptors, these receptors bind to Folate as its ligand. Thus, this study takes advantage of folate's ability to act as ligand to bind the CuS + Graphene Oxide to cell surface and induce its cellular uptake via endocytosis. Once the compound is inside the cell, a practitioner may irradiate the targeted area with an external light source. This targeted approach will only kill cells that have up-taken the CuS + Graphene Oxide+ Folate compound. Finding the optimal concentration of the nanoparticle compounds is paramount. SKOV-3, Hela, A549, and hFOB-1 cell lines were used. Cells were treated with [50ng/ml], [100ng/ml], [200 ng/ml], [400 ng/ml], and [800 ng/ml] concentrations of CuS, Folate, Graphene oxide, Graphene oxide + Folate, CuS + Folate, and Graphene oxide + Folate + CuS, and an untreated control group. An assay , specifically, 3-(4,5-dimethylthiazolyl-2)-2, 5 diphenyltetrazolium bromide (MTT) assay was then used to measure cell viability and proliferation.

P302**Board Number: B437****Dihydrocucurbitacin B potently induces apoptosis in acute leukemic cell lines of B, T and promyelocytic origin.**M. Martlock¹, T. Laakko Train¹;¹Department of Biology, Elon University, Elon, NC

Leukemia is responsible for 25% of cancer diagnoses in patients under age 20. While major advances have been made in treatments, effectiveness varies depending on the type of leukemia and there is still

significant mortality. Cucurbitacins are a group of compounds derived from plants that have been shown to have anti-inflammatory and anti-tumor effects. The cucurbitacin dihydrocucurbitacin B (DHB) is a compound found in *Cayaponia tayuya*, a Brazilian tree thought to have anti-inflammatory properties. Previous work from our lab has shown that treatment of leukemic cells with DHB or *tayuya* extract causes an increase in apoptosis in an acute T-cell leukemia cell line (Jurkat). To determine whether DHB had similar effects on other types of leukemic cells, additional cell lines were investigated. Cells were cultured with or without DHB at concentrations ranging from 0.25-25 μM from six to 24 hours. Apoptosis was detected by Annexin V and propidium iodide (PI) staining of cells followed by flow cytometric analysis. Significant increases in Annexin V+/PI- (early and late apoptotic) cells were observed within hours of exposure to the lowest (0.25 μM) concentration tested. After 24 hours with 2.5 μM DHB, the mean percent of apoptotic cells significantly increased from 13.2% in controls to 44.6% (a 3.4-fold increase) in treated samples. To determine if this response was similar in different types of leukemic cells, the RAJI cell line (Burkitt B-cell lymphoma) and HL-60 cell line (an acute promyelocytic leukemia) were cultured with varying concentrations of DHB. Results similar to those observed in Jurkat cells were observed with RAJI cells; after 24 hours without or with 2.5 μM DHB, the average percent apoptosis increased nearly 3-fold from 11.5% in controls to 31.2%, respectively. Interestingly, the promyelocytic line, HL-60, showed a more dramatic increase in apoptosis under the same conditions. The average percent apoptosis increased nearly 20-fold, from 4.5% in controls to 89.0% in treated samples. This data indicates that DHB potently induces apoptosis in a variety of different leukemic cell types and cells of myeloid lineage had a much greater response than those of lymphoid origin. Future studies will investigate how primary immune cells respond to DHB and explore potential mechanisms for induction of apoptosis.

POTENTIAL THERAPEUTIC STRATEGY FOR NON-MUSCLE INVASIVE BLADDER CANCER (NMIBC) TREATMENT: EFFECTS OF DOXORUBICIN AND CISPLATIN LOADED IN REDUCED GRAPHENE OXIDE ON THE PI3K AND PTEN REGULATION.

R. VILLELA¹, P.V. Garcia¹, M.A. Aguiar e Silva¹, N. Duran², H.J. Ceragioli³, W.J. Fávaro¹;

¹Structural and Functional Biology, University of Campinas (UNICAMP), Campinas, Brazil, ²Institute of Chemistry, University of Campinas (UNICAMP), Campinas, Brazil, ³FEEC, University of Campinas (UNICAMP), Campinas, Brazil

Background: Bladder cancer is the most common malignancy of the urinary tract. The recommended first-line treatment for non-muscle invasive bladder cancer (NMIBC), following transurethral resection, is an induction course plus maintenance with intravesical *Bacillus Calmette-Guerin* (BCG). However, BCG immunotherapy causes undesirable effects, which contributes to treatment interruption besides increasing cancer index recurrence after treatment. In this context, graphene oxide (GO) and/or reduced graphene oxide (rGO) has attracted increasing interest in the field of biological detection, drug delivery,

and cancer therapies. Thus, the aims of this study were to characterize and to compare the antitumor effects of Doxorubicin (DOX) and Cisplatin (CIS) functionalized in rGO on NMIBC. **Methods:** The protocol to induce NMIBC was the following: twenty-five female Fischer 344 rats received 1.5 mg/kg dose of N-methyl-N-nitrosourea (MNU) intravesically (I.V.) and the 5 Control animals (Group 1) had received physiological saline. After MNU treatment, the Cancer group (Group 2) received the same treatment as Group 1; The Cancer+rGO group (Group 3) received 2.0 mg/mL dose of reduced graphene oxide; The Cancer+rGO+CIS group (Group 4) received 1.5 mg/kg dose of cisplatin; The Cancer+rGO+DOXO group (Group 5) received 3.0 mg/mL dose of doxorubicin; The Cancer+rGO+CIS+DOXO group (Group 6) received the same treatment as Groups 3, 4 and 5; all treatments I.V. for 6 weeks. After 16 weeks, all bladders were collected for histopathological and immunohistochemical analysis. **Results:** The results demonstrated that 100% of animals from Group 2 showed carcinoma with invasion of the lamina propria (pT1). Similarly, the Groups 3 and 4 showed high-grade papillary carcinoma (pTa), carcinoma *in situ* (pTis) and pT1 in 60%, 20% and 20% of animals, respectively. The Group 5 showed pTis, pTa and low-grade intraurothelial neoplasia in 60%, 20% and 20% of animals, respectively. There was a better histological recovery in the Group 6, which showed 40% of flat hyperplasia, 40% of low-grade intraurothelial neoplasia and 20% of pTis. Intensified PI3K (Phosphatidylinositol-4,5-bisphosphate 3-kinase) immunoreactivities was observed in the Groups 2, 3, 4 and 5 when compared to Group 6. In contrast, the Groups 2, 3, 4 and 5 showed weak PTEN (Phosphatase and tensin homolog) immunoreactivities in relation to Groups 1 and 6. **Conclusions:** The tumor regression grades were correlated with increased PTEN and decreased PI3K reactivities in the Cancer+rGO+CIS+DOXO group. Taking together, the data suggest the great potential of reduced graphene oxide as carrier system of doxorubicin and cisplatin, and as nanoformulation for NMIBC.

EVALUATION OF NEW HDACs INHIBITORS OVER TUMORAL AND NORMAL CELL LINES.

E.M. Jiménez¹, C.T. Muñoz², T.M. Percino²;

¹ESM-CINVESTAV, Instituto Politécnico Nacional, México, D.F., Mexico, ²Instituto Politécnico Nacional, México, D.F., Mexico

HDAC inhibitors (HDACi) have been prove over diverse antitumoral effects such as cell growth inhibition, differentiation induction and apoptosis triggers¹. In this work we prove the antitumoral action of new HDACi previously synthetized with HDAC inhibition activity reported², over three tumoral cell lines: MCF-7, HepG2 and HeLa, as well as, two normal cells that normally present damage in the chemotherapy process like endothelial cells and kidney cells. HDACs are considered as one promising target in the development of new antitumoral agents, due to their actions on apoptosis, cell proliferation, metastasis and cell growth inhibition. Different HDACi have been reported as antitumoral compounds, between them there are the isoindoline analogues^{3y4}. In 2014 this group reported a series of insoindolines-2-sustituted as new HDACi, these compounds show a good HDAC inhibitory activity,

that is why in this work there was evaluated their antitumoral capacity over different tumoral cell lines from mammary cancer, hepatocarcinome and cervical uterin cancer. Due the importance of the adverse reactions in patients treated with several antitumoral agents, we considered of relevance to prove this new agents over possible toxic effects on turn over cells like endothelial, and cells usually very exposed to chemical agents due to elimination process as kidney cells. Our findings showed that all isoindolines evaluated produced growth inhibition of tumoral cells, specially compounds 1b, 1f and 2d. Whereas isoindolines 1a, 2a, 2b and 2c showed minor cytotoxicity on endothelial cells and kidney cells. By microscopy we observed the effects that denote a possible apoptotic pathway in tumoral cells. Therefore isoindolines-2-substituted can be used as possible antitumoral agents with low cytotoxicity in normal cells in the treatment of mammary cancer, hepatocarcinome and cervic uterine cancer.

Using confocal laser scanning microscopy to monitor targeted delivery of chemotherapeutic agents.

L.L. Stojanovic¹, S. Pokropinski¹, B.M. Hoffman², E.R. Trivedi², T. Hai¹, J.P. DiOrio¹;

¹Baxter Healthcare Corporation, Round Lake, IL, ²Northwestern University, Evanston, IL

OBJECTIVE: The objective of this study is to use confocal laser scanning microscopy (CLSM) to monitor drug uptake and movement within MDA-MB-231 breast cancer cells.

BACKGROUND: A favorable property of chemotherapeutic agents is the preferential delivery of cancer drug to the tumor tissue, lessening damage to healthy surrounding tissue. An experimental drug conjugate was used for this study and consisted of two components. Component A (A) acts as a delivery vector for cancer therapeutics, binding to LDL and entering the cell via the LDL-receptor pathway. Once the drug conjugate is in the cell, it moves into the lysosomes where the low pH environment cleaves off

drug component B (B). Drug component B is the cancer therapeutic doxorubicin that travels to the nucleus where it intercalates into the DNA to prevent transcription and eventually leads to cell death.

METHODS: Human breast cancer cell line, MDA-MB-231 cells were maintained in DMEM/1% Penicillin-Streptomycin/10% Fetal Bovine Serum. The cells were plated in poly-l-lysine coated Mattek dishes and incubated overnight. The drug was added to the cells followed by overnight incubation. After rinsing the cells, wheat germ agglutinin (WGA)-Alexa Fluor 488 was added, followed by fixing and cover slipping using Prolong® Gold containing DAPI. Samples were imaged on a Nikon A1Rsi CLSM at 405nm (DAPI, blue), 488nm (WGA, green), 561nm (B, orange) and 638nm (A, red). Each channel was acquired separately to avoid emission cross over between channels.

To demonstrate the movement of the drug to the lysosomes, the cells were incubated with the drug as above, stained with LysoTracker® and imaged live. In addition, cells were blocked with LDL/heparin and imaged live to prevent the uptake of the drug into the cells. In each case, negative controls were imaged in parallel.

RESULTS: Confocal laser scanning microscopy was utilized to: 1) image the drug incorporation into MDA-MB-231 breast cancer cells, 2) demonstrate the localization of the drug in the lysosomes and 3) show that the conjugate uptake is LDL-mediated.

CONCLUSION: We used confocal microscopy to demonstrate the uptake of the drug into the cell, movement to the lysosome, followed by the nucleus. We also verified the mechanism by blocking the uptake of the drug.

The effects of vanadyl sulphate on rat glioma cells ultrastructure.

H.M. Kutlu¹, D. Vejselova¹;

¹Biology, Anadolu Univ, Eskisehir, Turkey

Vanadium compounds were stated to have different effects on the cells as to be genotoxic, lipid peroxidative, erythrocyte hemolytic and effective in inhibition of neoplastic progression. One of the most popular vanadium salts is vanadyl sulphate that is investigated in different types of cells, also in vivo. In this study vanadyl sulphate was used with an aim to detect the effects of a vanadium compound on the rat glioma cells (C6) ultrastructure. The effects of vanadyl sulphate on glioma cell ultrastructure were investigated using a transmission electron microscopic assay. For this manner, C6 cells treated with IC50 concentration (100 µM) of vanadyl sulphate for 24 hours were fixed in glutaraldehyde (2,5% in 0,1 M phosphate buffer) at pH 7.4 and embedded in agar. Embedded samples were left in phosphate buffer at +4 °C, overnight and post fixed in osmium tetroxide. Post-fixed cells were dehydrated in graded ethanol: 70, 90, 96 and 100% than embedded in EPON 812 epoxy and left 48 hours in oven for polymerization. The samples sectioned on ultramicrotome (Leica, UC6) were stained in uranyl acetate and lead citrate than photographed on transmission electron microscope (FEI, Tecnai BioTWIN). In our

results it has been showed major changes on C6 cells ultrastructure indicating apoptosis caused by vanadyl sulphate as membrane blebbings, nuclear fragmentation, horseshoe nucleus and shrinkage on cells. From our findings it can be concluded that vanadyl sulphate possess anticarcinogenic effects on C6 cells showing its effects with clear apoptotic sparks and may be successful agent in drug desingning for cancer treatment but further investigations are required.

Glioblastoma (GB) is the most frequent and most malignant human brain tumor. Prognosis for patients with GB remains dismal, as median survival after diagnosis varies from six months to one year. This is due to the inability of current treatment strategies to address the highly invasive nature of this disease. Thus, new therapeutic strategies are required. Doxazosin, a quinazoline compound, is a selective α 1-adrenoceptor antagonist used for treatment of high blood pressure and benign prostate tumor. In addition, it has also been demonstrated that doxazosin affects prostate cancer cells survival. In this context, the aim of this study was to evaluate the effect of doxazosin on C6 rat glioma cells. C6 cells were cultured with DMEM and treated with doxazosin at different concentrations. Cellular density and viability were determined by Suforhodamine B (SRB) and MTT assays, respectively. Cell death was analyzed by Propidium Iodide (PI) and Annexin V/PI staining. Cell cycle profiles were determined by flow cytometry (FACS Calibur, BD Bioscience). Cytotoxicity assays were performed in non-tumor cells, organotypic hippocampal culture slices and primary astrocyte cultures. Data are expressed as means \pm SD. All results are representative of at least 4 independent experiments. Differences between mean values were considered significant when $p < 0.05$. Doxazosin decreased cell density and induced cell death at concentrations that did not show toxic effect on non-tumor cells. Doxazosin also blocked cell cycle progression at the G1 phase at 150 μ M and 180 μ M, thus inhibiting cell proliferation. This study shows that doxazosin has antitumoral effects on C6 rat glioma cells at concentrations that are not toxic to non-tumor cells. This points to a promising perspective of further research on the effect of doxazosin for development of novel drugs for treatment of brain tumors.

P308**Board Number: B443****Discovery of a novel human pancreatic tumor stem cell targeting agent, CEP1430, through three-dimensional (3D) stem cell culture assay.**J.M. Harris¹, C.R. Sharma^{1,2}, M.R. Sharma¹, M.B. Navel¹, N. Amezcua¹, R.R. Rodriguez¹, S. Satish¹, J.R. Martinez¹, J. Jani¹, J.P. Sharma¹;¹Stem Cell Biology, Celprogen Inc, Torrance, CA, ²Celprogen Inc., Torrance, CA

Three-dimensional (3D) in vitro culture of cancer stem cells has long been advocated as a better model of the malignant phenotype that is most (more?) closely related to tumorigenicity in vivo. Moreover, new drug development requires simple in vitro models that resemble the in vivo situation to select most promising compound(s) utilizing minimal number of experimental animals.. Chemotherapy or concomitant chemoradiotherapy are frequently used in clinic to improve overall survival and organ preservation of cancer patients. Despite limited initial benefits, this approach encounters significant morbidity and mortality. Therefore reliable chemosensitivity assays are needed to accurately predict and guide clinicians to select the right individual treatment options for optimum benefit to cancer patients. . The purpose of this study is to examine and evaluate optimum drug candidates in vitro using primary patient tumor cells and cancer stem cells derived from tumors. . The primary pancreatic tumor samples obtained after surgery or biopsy, were placed immediately in Celprogen Tumor Transportation Media and shipped at 4-8 OC for processing. Tissues were washed with 1X PBS solution and aseptically cut into 0.5 mm sections and cultured in 6-well tissue culture plates with an insert pre-coated with ECM. All cancer cell types remain viable and maintain their native architecture for at least 14 days and incorporated DNA measured by adding EdU(5-ethynyl-2'-deoxyuridine) to the culture. In vitro efficacy of various therapeutic agents targeting major signaling pathways (wnt,Notch,PI3K,MAPK,STAT) and standard chemotherapeutic agents were tested using DNA uptake and TUNNEL assays to determine growth inhibition index. All test agents were also tested utilizing the patient's Pancreatic Cancer Stem Cell Cultures established with Celprogen's Media and ECM. Expression of PDX-1, SHH, CD24, CD44, CD133, EpCAM, CBX7, OCT4, SNAIL, SLUG, TWIST, Ki-67, E-cadherin, β -catenin and vimentin were quantified by qPCR or immunocytochemistry. Among the 1000 compounds screen tested, Gemcitabine, Taxol, Fluorouracil, Leucovorin, Irinotecan, and Oxaliptin were not effective against Pancreatic Cancer Stem cell (CSC) but were effective on tumor cells (differentiated CSCs). Our six lead small molecules [CEP1430,1431,1432,1433,1435&1436] were effective against Pancreatic CSC targeting selected pathways. CEP1430 shows promise as a better therapeutic agent against Pancreatic CSC and when tested in SCID mice model with once daily administration for 30 days without any adverse effects. CEP1430 reduced the tumor volume in the treated group by 80-90 %, when compared with the control group.

Profile of matrix metallo-proteinases (MMP) and chemokine receptors in prostate cancer stem cells.

S. Rentala¹;

¹GITAM University, Department of Biotechnology (GIT), Visakhapatnam, India

Background – Recently, we identified CD133+MDR1+Oct4+ prostate cancer stem cells (PCSCs) in human prostate cancer tissues. The matrix metallo-proteinase (MMP) profile and the expression of chemokine receptors of such progenitors is currently unknown and may affect their in vivo metastasis. In this study, we determined the matrix metallo-proteinase profile and the expression of chemokine receptors of prostate cancer progenitors. Methods and Results — PCSCs were isolated from prostate cancer tissue subjects and expression of matrix metallo-proteinase profile and the expression of chemokine receptors were determined. PCSCs had high expression of MMP-2, and MMP-9, moderate expression of MMP-7 and MMP11. Out of CXC chemokines receptors, CXCR4 is highly expressed and out of CC chemokines, CCR1, CCR2, CCR3 and CCR5 are highly expressed and other C chemokines and CX3C chemokines are minimally expressed. Moreover, PCSCs showed increased levels of SDF1 α and its binding to CXCR4 receptor. Conclusion — This data for the first time show a broad spectrum of matrix metallo-proteinase profile and the expression of chemokine receptors in prostate cancer progenitors and suggest the potential importance of matrix metallo-proteinase and chemokine receptors in mediating PCSCs mediated metastasis.

Tetraspanin CD82 regulates acute myelogenous leukemia cell homing and β -catenin signaling through the stabilization and clustering of membrane-bound proteins.

K.D. Marjon¹, C.M. Termini¹, K.L. Karlen¹, C.E. Soria¹, K.E. Sanders¹, C.A. Saito-Reis¹, J.M. Gillette¹;

¹Department of Pathology, University of New Mexico Health Sciences Center, Albuquerque, NM

Patients with aggressive leukemia such as acute myelogenous leukemia (AML) often present with bone marrow failure because this form of leukemia homes and engrafts to the bone marrow, outcompeting normal hematopoiesis. In this aggressive form of AML, the surface expression of the membrane-bound tetraspanin, CD82, is often dysregulated. To understand how CD82 regulates the cellular behavior of AML, we used an AML cell line, KG1a, and stably generated CD82 knocked down (CD82KD) and overexpressing (CD82OE) cells. Interestingly when these cells were used for homing assays in NOD scid gamma mice, we found that CD82KD cells home to the bone marrow significantly less than control cells.

In parallel to these findings, primary AML patient samples with higher CD82 surface expression home significantly better to the bone marrow than patient samples with lower surface expression of CD82. We next wanted to assess the surface expression of adhesion molecules that play a role in homing to the bone marrow such as integrins, cadherins and selectins. We found that N-cadherin surface expression was significantly decreased on the CD82KD cells compared to control and CD82OE cells. Consistent with this finding, we observed a significant decrease in the binding of CD82KD cells to plate-bound N-cadherin when compared to CD82OE and control cells. We also observed that CD82 is immunoprecipitated with N-cadherin, signifying an interaction on the cell membrane and a point of potential cellular regulation. Next, we identified that β -catenin and down stream signaling were significantly dysregulated between all cells lines. We found that CD82KD cells have a marked increase in nuclear LEF1, a down stream target of active β -catenin signaling, where as the CD82OE cells had a significant decrease in LEF1 nuclear localization. Since clustering of N-cadherin can regulate β -catenin signaling, we wanted to determine if there was a CD82-mediated organizational difference of N-cadherin on the cell membrane. Using superresolution imaging, we found that N-cadherin and CD82 molecular clustering is significantly different between all cell lines. Additionally the glycosylation of CD82 has been implicated as a regulator of protein-protein interactions. We determined that cells overexpressing an unglycosylated form of CD82, home significantly better to the bone marrow than control cells and have a marked increase in both N-cadherin molecular density and CD82 cluster diameter. Together these data provide significant insight and the potential mechanism for how CD82 molecular organization dictates cellular behavior. Furthermore, these data highlight that while protein expression is important, cellular function is largely controlled by protein organization on the cell membrane.

BLOCKADE OF ADENOSINE SIGNALING REVERSES CHEMORESISTANCE AND GROWTH OF GLIOBLASTOMA.

C.A. Quezada¹, W.X. Garrido¹, A. Torres¹, Y. Vargas¹, D. Uribe¹, R.E. San Martín¹;

¹Instituto de Bioquímica y Microbiología, Universidad Austral de Chile, Valdivia, Chile

Background. Glioblastoma multiforme (GBM) is the primary cause of death among brain cancer. Despite all efforts to improve the treatment currently, there is no cure for recurrence, mainly due to the phenomenon of multiple drug resistance (MDR) through MRP1/MRP3 transporters, which makes ineffective conventional chemotherapy. It has been attributed to the subpopulation Glioblastoma Stem-like Cells (GSCs) to be responsible of recurrence. Also, GSCs exhibit an extreme chemoresistance. Due to the fact that the nucleoside adenosine has recently been linked to the regulation of MRP transporters activity, our aim was to evaluate the blockade of both adenosine signaling or production on MDR in GSCs and experimental glioblastoma. **Methods.** Glioblastoma Stem-like Cells were derived from U87 glioblastoma cell line. The contents of Mrp1, Mrp3, adenosine receptors and 5'-ectonucleotidase were measured by western blots, flow cytometry and immunofluorescence. MRP1/MRP3 activity was

estimated measuring the extrusion of the fluorescent substrate CFDA from cells. Adenosine levels were quantified in Tyrode's buffer and 2-chloroacetaldehyde derivatives were quantified by HPLC. Cell viability was assayed by the MTT reduction method and flow cytometry. Apoptosis was assayed by flow cytometry. Cells were treated with the inhibitor of 5'-ectonucleotidase AOPCP, selective antagonists for adenosine receptors (DPCPX (30 nM), ZM241385 (10 nM), MRS1754 (50 nM), MRS1220 (10 μ M)) and the antitumoral drug vincristine (100nM). The effects on tumor growth were also evaluated in vivo. Results. GSCs were refractory to antitumoral drug vincristine. The antagonist of adenosine A3 receptor (MRS1220) and CD73 inhibitor (AOPCP) in combination with vincristine were the only treatments that showed a decrease in cell viability in vitro. Moreover, MRS1220-vincristine increased notably the percentage of apoptosis. In both adherents and GSCs, MRS1220 and AOPCP decreased the expression and activity of MRP1/MRP3. In vivo tests showed that co-therapy using MRS1220 decreases the tumor size by ~90% following administration for 9 days. In addition, this treatment caused a decreased expression of proliferation markers and MRP1/MRP3. Conclusions. Based on these findings we propose the use of adenosine A3 antagonists or 5'-ectonucleotidase inhibitors as coadjuvants for pro-apoptotic and chemosensitizing effects in GBM treatment. The Effects of VEGFA in CD34+ cells.

B. Palodetto¹, F.A. Corrocher¹, F.M. Roversi¹, M.O. Baratti¹, P. de Melo Campos², A.S. Duarte¹, S.T. Saad³;
¹Hematology and Hemotherapy Center, University of Campinas-Unicamp, Campinas/SP, Brazil,
²Hematology and Hemotherapy Center, University of Campinas (UNICAMP), Campinas, Brazil,
³Hematology and Hemotherapy Center, University of Campinas, UNICAMP, Campinas, Brazil

Angiogenesis plays a key role in growth and metastasis of solid tumors and recently has been reported in hematologic diseases. The angiogenic "switch" is mediated by several pro and anti-angiogenic factors and the most common is VEGFA. The VEGFA gene encodes the vascular endothelial growth factor which is a pro-angiogenic cytokine that can stimulate endothelial cells to proliferate, migrate and increases membrane permeability to plasma proteins. Several studies had described an increase of VEGFA expression in patients with acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS) and this increase correlates to worse prognosis. Previous studies from our group found overexpression of VEGFA in CD34⁺ cells from patients with low-risk MDS in microarray assays. To validate these results, we selected 21 samples of CD34⁺ cells from bone marrow of 12 MDS patients (WHO classification: Low Risk: RARS= 03, RCMD= 03; and High Risk: RAEB I = 01, RAEB II= 05), 04 secondary AML patients, 05 *de novo* AML patients and 04 health donors. After analysis by Real-Time PCR, using HPRT as normalizer, we found a higher expression of VEGFA in low-risk MDS patients compared to control group and decrease of VEGFA expression during disease progression. We also found a statistically significant difference between the VEGFA expression in low-risk and *de novo* AML patients (2.95 [0.57-7.69], P=0.01Mann-Whitney test). To a better knowledge of VEGFA effects we isolated CD34⁺ cells from 03 umbilical cord blood and cultured then on DMEM medium (Dulbecco's Modified Eagle's Medium) supplemented with

20% fetal bovine serum, 50 µg/mL Stem Cell Factor, 30 µg/mL Interleukin 3 and VEGFA recombinant protein at concentrations of 25ng/mL, 50ng/mL or 100ng/mL for 96 hours. We performed apoptosis, cell cycle, cell proliferation and colony-forming assays and compared the results with CD34⁺ control cells (without VEGFA treatment). We identified a significant increase in cell proliferation ($118.2 \pm 2.7\%$ vs $100 \pm 0.5\%$, $P=0.02$ Paired t-test) and colony formation (111.9 ± 3.4 vs $88.88 \pm 5.1\%$, $P=0.01$ Paired t-test) in CD34⁺ cells treated with VEGFA 100 ng/mL compared to control cells. We found no statistical difference in apoptosis and cell cycle of CD34⁺ cells after VEGFA treatment. These results suggest that overexpression of VEGFA in CD34⁺ cells may confer advantage to the MDS stem cells of the patients, contributing to pathogenesis.

Expression patterns of F-Actin and Nanog, an embryonic stem cell marker, in monolayer and spheroid culture of human liver carcinoma cell line.

R.G. Aktas¹, O.E. Tok²;

¹Cancer and Stem Cell Research Center, Maltepe University, Istanbul, Turkey, ²Histology and Embryology Department, Bezm-i Alem University, Istanbul, Turkey

Recent studies report that cancer stem cells are responsible for tumor relapse, metastasis, and chemoresistance. Nanog, a cell-fate regulatory molecule known to be important for embryonic stem cell self-renewal, also plays a novel role in tumor development. Expression of Nanog in tumor tissue is correlated with the stage of disease and prognosis. It has also been suggested that heterogeneity in liver cancer is a result of the hierarchical organization of cancer stem cells. Actin is considered as another protein, which regulates stem cell fate decisions in tumour.

It was aimed to (i) examine expression patterns of F-actin and nanog in monolayer and spheroid culture of human liver hepatocellular carcinoma cell line (HepG2 cells), (ii) evaluate if the maintenance of 3D structure in culture effects presence and location of actin and nanog in cells and (iii) observe the changes at the level of these two proteins during different cultivation period.

HepG2 cells were seeded on coverslips. They were grown in Minimum Essential Medium (ATCC) which contain 10% fetal serum bovine. Cells, which were 60%, 80%, 100% confluent were fixed with acetone. After fixation, they were first labeled with fluorescent phallotoxins (Invitrogen). Same cells were also labeled with nanog(D73G4, Cell Signaling) as primary antibody and then anti-rabbit Dylight-550(Abcam). LSM700(Carl Zeiss) and Eclipse90i(Nikon) were used for examination of the expression of F-actin and nanog.

The results suggest that the actin cytoskeleton in monolayer cells show stress fiber formation while spheroids have cortical actin organization. When confluency increase, more peripherally located actin filaments become visible. The density of actin labeled regions per cell does not differ significantly while

the cultivation period increases. Labeling pattern and density are not correlated with the size of spheroids.

Cytoplasmic and nuclear staining for nanog is evident for some cells in different days during cultivation. The number of the cells labeled with nanog increases as the confluency increases. Some spheroids do not contain nanog-labeled cells while centrally located labeled cells are clear in the others. Staining pattern in monolayer cells and spheroids remain the same.

A number of studies have shown that tension forces and cell shape can determine cell fate in a variety of cell types. Actin distribution pattern in liver cancer cells might also be the part of this process. More studies are needed to clarify how stage and prognosis of the disease change according to the presence and different subcellular localization of nanog in cancer cells.

Vascular niche specific bidirectional PDGF signaling mediated via glioma stem cell-endothelial cross-talk regulates tumor progression in glioblastoma.

A. Sharma¹, A. Shiras¹;

¹Lab3, National Centre for Cell Science, Pune, India

Glioblastoma (GBM) is a Grade IV glioma often displaying a highly vascular phenotype with extensive angiogenesis occurring due to a steadily proliferating endothelial cell (EC) population via paracrine interactions with glioma cells. Although, antiangiogenic therapies are emerging as front line treatment modality in glioblastoma, dearth of appropriate in vitro models to study glioma cell- endothelial cell interactions are essentially hindered due to lack of targetable novel signaling pathways. Human glioma stem cells (hGSC), surrounded by EC niche in tumor microenvironment, are known for tumor growth, therapeutic resistance, and recurrence. However, study of hGSC-EC physical interactions in cell culture system remains obscure till date due to unique growth conditions for each cell type. We have isolated multiple tumor matched hGSCs and ECs from primary human GBM tissues and developed novel 2D, 3D in vitro co culture systems to study role of tumor microenvironment and niche in glioma pathogenesis. Our in vivo studies demonstrate that mutual interactions of GSC-EC occur via niche specific PDGF signaling which promotes proliferation, migration of ECs thereby accelerating GBM angiogenesis. We using a 3D co-culture model of individually labeled GSCs and ECs show that GSCs extensively migrate on EC conduits while simultaneously promoting their proliferation. Next, we show that under radiation conditions hGSC migration is supported by endothelial cells and this could potentially be responsible for hGSCs escape from primary tumor during radiotherapy. Taken together, we show here that PDGF axis acts as a double edge sword for GBM which regulates angiogenesis and GSC migratory phenotype. Thus, targeting niche PDGF signaling cannot only curb GSC regulated angiogenesis, but also prevent EC assisted GSC migration. Additionally, we propose that our novel GSC-EC co-culture model has immense potential for in-depth studies to understand GSC-EC interactions and will provide an excellent platform to develop new therapeutics by identification of crucial niche pathways.

P315**Board Number: B450****Investigating the Role of Cancer Stem Cells in HeLa Cell Cultures.**D. Zhao¹, N.L. Marianelli²;¹Lycoming College, Williamsport, PA, ²Biology, Lycoming College, Williamsport, PA

The goal of our research is to study the role of cancer stem cells in the proliferation of HeLa cancer cells. Ultimately, we would like to develop a method for targeting cancer stem cells with chemotherapy as opposed to current methods which focus on only the cancer cells themselves, in hopes that without the presence of stem cells the cancer cells will undergo apoptosis. We stain for stem cell markers to confirm the presence of stem cells in the HeLa cell culture. We then remove these stem cells from the culture and conduct further research on their proliferation. We use fluorochoime-labeled antibodies and a fluorescent microscope to study the isolated stem cells. These stem cells undergo further experimentation, including Western Blotting, RT-PCR, and genome sequencing to determine levels of specific proteins and molecules within them. By this way we identify some molecules that can be targeted for treatment during chemotherapy.

P316**Board Number: B451****Characteristics of cancer stem cells in rhabdomyosarcoma.**D. Zhao¹, A.K. Follweiler²;¹Lycoming College, Williamsport, PA, ²Biology, Lycoming College, Williamsport, PA

Researchers have found that cancer cells are not all the same. Within a malignant tumor, there are a variety of types of cells. Cancer stem cells (CSCs) are cancer cells that have the ability to reproduce themselves and give rise to all cell types found in the tumors. Cancer stem cells (CSCs) have been identified in a number of tumors; however the CSCs of rhabdomyosarcoma (RMS) have not been identified. The goal of this study was to identify Stem Cells in RMS by side population analysis and characterize the population using the functional approach. We found that a particular population can be enriched from eRMS. This could a potential drug target for rhabdomyosarcoma (RMS).

P317**Board Number: B452****Identification of differentially expressed microRNAs defining heterogeneity of cancer cells by microarray chip analysis.**Y. Kim¹, M. Kim¹, N. Kim¹;¹Seoul National University, Seoul, Korea

Introduction/Objectives: Intratumoral heterogeneity is a histological hallmark in all tumor types and major barrier against effective cancer therapy. Especially, human malignant mesothelioma that is mainly associated with asbestos exposure is known to be extremely heterogeneous with regards to morphology as well as molecular phenotypes, resulting in poor response to conventional cancer therapy. This study was performed to investigate the global microRNA expression profile of distinct subpopulations of MS1 cell line, a human malignant mesothelioma cell line. **Materials and Methods:** The MS1 cells were cultured in RPMI1640 media with supplements and subjected to the side population (SP) assay composed of Hoechst 33342 dye staining and subsequent flow cytometry. Total RNAs were isolated from the sorted subpopulation cells, SP and non-SP fractions, followed by labeling and hybridization of miRNAs Affymetrix GeneChip miRNA Arrays for 16 hours at 48 °C and 60 rpm. After hybridization, the chips were stained and washed in a Genechip Fluidics Station 450 and scanned by using a Genechip Array scanner 3000 7G. After data extract and normalization, the analysis of differentially expressed microRNAs was performed. **Results:** A total of 294 miRNAs including 158 up-regulated and 136 down-regulated were identified based on the criteria of 1.5 fold difference and a p-value < 0.05, and a total of 16,983 target genes were identified. In ontology analysis, transcription regulator activity and positive regulation of gene expression were the most significantly enriched GO terms in biological process and molecular function categories, respectively.

Conclusion: The microarray for microRNA expression analysis revealed differentially regulated microRNAs between SP and NSP fractions.

Impact statement: This study will provide valuable information for the understanding of regulatory function of microRNAs in the generation and maintenance of more aggressive cancer cell subpopulations.

Mitotic inhibition of the DNA double-strand break response preserves genomic integrity.

A. Orthwein¹, A. Fradet-Turcotte¹, S. Noordermeer¹, M. Canny¹, C. Brun¹, J. Strecker¹, C. Escibano-Diaz¹, D. Durocher¹;

¹Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, ON

Exogenous and endogenous DNA-damaging agents continuously threaten genome integrity and can cause cytotoxic DNA double-strand breaks (DSBs). Interphase cells have evolved dynamic and sensitive mechanisms to detect, signal, and repair DNA DSBs. A central component of this response is mediated through ubiquitin (Ub) signaling controlled by the E3 ubiquitin ligases RNF8/RNF168. RNF8/RNF168 ubiquitylate chromatin and promotes the recruitment of 53BP1 to DSBs, an important factor in classical non-homologous end-joining (C-NHEJ). In stark contrast, mitotic cells inactivate the Ub-dependent signaling and repair of DNA DSBs, a phenomenon first observed 60 years ago, but the significance of this inhibition remains elusive.

We investigated how mitosis blocks the DNA DSB response and determined the consequences of its reactivation. We identified a phosphorylation site in RNF8 downstream of its forkhead-associated (FHA) domain, which prevents the RNF8-MDC1 interaction and the initiation of the ubiquitylation of chromatin. Mutation of this site to alanine restores RNF8 recruitment to DSBs in mitosis, but fails to mobilize 53BP1 as monitored by immunofluorescence, suggesting the presence of a second inhibitory mechanism. We previously characterized an Ub-dependent recruitment (UDR) motif in 53BP1 that recognizes RNF168-dependent H2A Ub mark on nucleosomes. Interestingly, we observed that mitotic 53BP1 UDR motif is phosphorylated at two sites, which abrogates binding to ubiquitylated nucleosomes. Mutation of these two sites to alanine restores 53BP1 capacity to read ubiquitylated H2A and allows its recruitment to DSBs. Reactivation of RNF8 and 53BP1 in mitosis restores DNA repair, but is paradoxically deleterious. Indeed, restoration of the DNA DSB response in mitosis leads to Aurora B kinase-dependent sister chromatid fusions that produce dicentric chromosomes and the formation of micronuclei, a hallmark of aneuploidy.

Our findings reveal the complexity and the importance of regulating the DNA DSB response in mitosis. Through multiple phosphorylation events, mitotic cells block the Ub-dependent DNA DSB response, thus minimizing the risk of mitotic sister chromatid fusions.

P319**Board Number: B455****The Role of Centromere Defects in Cancer Formation and Progression.**T. Beh^{1,2}, B. Kim^{1,2}, P. Kalitsis^{1,2};¹Murdoch Children's Research Institute, Royal Children's Hospital, Parkville, Australia, ²Department of Paediatrics, The University of Melbourne, Parkville, Australia

The centromere is a unique region on each chromosome that functions as the site of kinetochore assembly and sister chromatid cohesion during mitosis and meiosis. Hence, the centromere plays a crucial role in genome inheritance, ensuring proper segregation of sister chromatids into each daughter cell. Despite its importance, the centromere has been relatively under investigated partly due to its reputation as part of the genomic 'junk DNA' post Human Genome Project. Its tract of highly repetitive sequences which spans several megabases also poses technical challenges for sequence assembly. Thus, to date, the centromeric sequence remains unresolved and its functional studies at the molecular level are inadequate. To contribute to the area of centromere research, my project aims to study centromere-related abnormalities using the NCI-60 panel comprising of 60 human cancer cell lines to characterize the spectrum of centromeric defects including occurrences of dicentric and neocentric chromosomes using the combination of fluorescent in situ hybridization (FISH) and immunocytochemistry. T-47D, a breast cancer cell line, was found to have high percentage of metaphase spreads with a neocentric chromosome which was identified via Multiplex-FISH to be a chromosome derived largely from Chromosome 3 with a small fragment of Chromosome 5. Chromatin immunoprecipitation (ChIP) using antibody against CENP-A followed by NextGen Sequencing revealed that the approximately 100kb neocentromere region was formed at the position 164,575,000 – 164,675,000bp adjacent to the SI (sucrase-isomaltase (alpha-glucosidase)) gene in the 3q26.1 band of Chromosome 3. This marks the first neocentromere reported in a human cancer cell line.

P320**Board Number: B456****Anti-SON protein "TSA-omics" Reveals a Gradient in Gene Density and Elevated Gene Expression as a Function of Proximity to Nuclear Speckles.**Y. Chen¹, Y. Zhang², J. Ma², A.S. Belmont¹;¹Department of Cell and Developmental Biology, University of Illinois at Urbana-Champaign, Urbana, IL,²Department of Bioengineering, University of Illinois at Urbana-Champaign, Urbana, IL

Here we report development of a new genomic mapping method that measures genome proximity to nuclear speckles. Unexpectedly, this method also revealed Mbp-scale looping between the nuclear periphery and nuclear speckles from a single genomic plot. Genome-wide computational analysis demonstrates that a gradient in nuclear speckle proximity is mirrored by a gradient in both gene density and the distribution of highly expressed genes, with genomic regions closest to nuclear speckles showing peaks in gene density and the highest enrichment of highly expressed genes.

Our approach uses Tyramide Signal Amplification (TSA) immunostaining to create a gradient of biotin labeling from the target throughout the nucleus. Importantly, labeling can be directly visualized by immunofluorescence microscopy prior to DNA isolation and genomic analysis. Using nuclear speckle marker protein SON as the labeling target, we mapped the whole genome position relative to nuclear speckles in human erythroleukemia K562 cells, revealing distinct genome domains: speckle-proximal, speckle-distal, and connecting transition zones. Speckle-proximal domains correlate with gene-rich chromosome “R” bands, consistent with earlier cytological observations. Speckle-distal domains, appearing as valleys in the genomic proximity plot, correlate strongly with Lamina-Associated Domains (LADs). Transition zones extending over several Mbp frequently appear as linear ramps in the proximity plot, connecting valleys with peaks of speckle association. 3D immuno-FISH confirms that speckle-proximal domains associate at high frequency with nuclear speckles, while speckle-distal domains locate away from speckles, frequently near the nuclear periphery. FISH visualization of a 5Mbp transition zone revealed a linear signal typically stretching between the nuclear periphery and an interiorly located nuclear speckle, suggesting the capability of revealing Mbp-scale looping of interphase chromosomes between the nuclear periphery and nuclear speckles directly from the TSA genomic plot. Besides a gradient in gene density and highly expressed genes relative to nuclear speckle proximity, computational analysis also revealed a striking correlation of the density of specific histone modifications and chromatin-related marks with distance to nuclear speckles.

We anticipate this simple proximity-mapping method will provide a valuable tool to measure the spatial proximity of the genome to a variety of nuclear compartments. Simultaneous mapping of genome proximity to different nuclear compartments may allow deconvolution of 3D nuclear organization. The simplicity of this mapping approach makes it ideal for investigating the dynamics of nuclear organization and its correlation with changes in gene expression.

Lambda exonuclease, the cornerstone of nascent strand sequencing to map replication origins genome-wide, digests GC-rich DNA inefficiently and stalls at G quadruplex structures.

M.S. Foulk^{*1}, J.M. Urban^{*2}, C. Casella³, S.A. Gerbi²;

¹Department of Biology, Mercyhurst University, Erie, PA, ²BioMed Division, Brown University, Providence, RI, ³Institute for Molecular Medicine, University of Southern Denmark, Odense, Denmark

*These authors are equal contributors.

What defines metazoan origins of DNA replication remains poorly understood and suffers from a small sample size of well-characterized origins. Nascent strand sequencing (NS-seq) to discover origins genome-wide has the potential to vastly expand the set of known metazoan origins and thus identify features for their specification. Previous studies on individual origins concluded that origins are AT-rich. However, recent NS-seq results suggested that origins in multicellular eukaryotes are GC-rich and

correlated with G quadruplex (G4) structures. Therefore, G4s could be the long sought after feature that specifies metazoan origins. However, these conclusions rely upon the purity of the nascent strand DNA preparations in NS-seq that were enriched by Lambda exonuclease (Lexo), a 5' to 3' directed exonuclease that digests parental DNA while leaving nascent strands intact due to the presence of RNA primers at their 5' ends. Moreover, Bubble-Trap sequencing, an origin mapping technique that does not use Lexo, did not support the notion that G4s were a defining feature of metazoan origins. Thus, there is a need to understand the biases incurred by Lexo and whether Lexo enriches G4s independent of nascent strands.

We took biochemical and genomics approaches to determine if Lexo digests all parental DNA sequences equally. We report that Lexo does not efficiently digest G4 structures in a plasmid. Moreover, Lexo digestion of non-replicating genomic DNA (LexoG0) enriches GC-rich DNA and G4 structures genome-wide. We used LexoG0 data as a control to computationally eliminate potential false positives from NS-seq data and validated this approach at the rDNA locus. Whereas controlling with total genomic DNA results in enriching the entire rDNA locus, controlling with LexoG0 enriches only the known origins. When this LexoG0 control is applied genome-wide, NS-seq peaks are no longer GC-rich. In addition, only 6.8% of all G4s in the genome overlap with the corrected NS-seq peaks, suggesting that G4s are not a general determinant for origin specification. However, about a third of the NS-seq corrected peaks overlapped with G4s. In further analysis, we observed a periodic spacing of G4 motifs and nucleosomes around the peak summits suggesting that G4s may help to position nucleosomes. This may create a nucleosome-free region where the pre-replication complex can form at this subset of origins. Finally, we demonstrate that use of Na⁺ instead of K⁺ in the Lexo digestion buffer improves the ability of Lexo to digest G4s. Based on our computational and biochemical results, we propose ways to increase both the sensitivity and specificity of NS-seq for genome-wide identification of replication origins.

Functional role of chromosome refolding during mating type switching in yeast.

B. Avsaroglu¹, K. Li¹, G. Bronk¹, J.E. Haber², J. Kondev¹;

¹Department of Physics, Brandeis University, Waltham, MA, ²Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

Haploid yeast, *Saccharomyces cerevisiae*, cells can switch their mating type by replacing one *MAT* allele with the DNA sequence of the opposite mating type, copied from a distant locus. Mating type switching in yeast is a highly choreographed repair event in which a DNA double strand break (DSB) created at the *MAT* locus is repaired by homologous recombination using one of the two silent donors, *HML* α or *HMR* α , located near the two ends on the same chromosome. *MAT* α cells recombine with *HML* 90% of the time, and this preference to use *HML* is dependent on a nearby cis-acting locus, the recombination enhancer (RE). The RE sequence physically interacts with the *MAT* locus after a DSB, thereby increasing the frequency of collisions between *HML* and *MAT*.

To observe the kinetics of switching and changes in chromosome conformation, we imaged two-color fluorescent reporters inserted near *MAT* and *HML*, and measured the three-dimensional distances between the two loci in live cells or in fixed cells that were collected at different time points before and after a DSB is induced. In addition we measured the percent usage of *HML* during *MAT* switching.

We have compared these experimental observations to a polymer model of yeast chromosome III to compute the distribution of distances between *MAT* and *HML* loci before and after the break. We find that the polymer model predictions are in quantitative agreement with the experimental distances before and after the break, thus establishing a biophysical basis of this gene conversion event. Moreover our calculations show that by refolding chromosome III after a DSB, via tethering RE at *MAT*, polymer entropy drives donor preference in yeast mating type switching.

The organization and architecture of *Bacillus subtilis* chromosome revealed by super-resolution microscopy and HiC.

A. Le Gall¹, M. Marbouty², D. Cattoni¹, A. Cournac², S. Koh³, H. Murray³, J. Mozziconacci⁴, R. Koszul², M. Nollmann¹;

¹Centre de Biochimie Structurale, Montpellier, France, ²Institut Pasteur, Paris, France, ³Newcastle University, Newcastle, UK, ⁴Université Pierre et Marie Curie, Paris, France

In eukaryotes and bacteria, chromosome organization and segregation needs to be carefully orchestrated to ensure faithful transmission of genetic material during cell division. The molecular mechanisms responsible for bacterial chromosome organization and segregation remain elusive, possibly because these processes are highly influenced by the action of many DNA metabolic processes overlapping in time and space (e.g. replication, transcription, or repair). Here, we investigate the higher-order organization of DNA in *B. subtilis* by using a combination of chromosome-capture technologies and super-resolution microscopies. First, we found that specific barriers act to separate the chromosome into specific higher-order domains at different length-scales. Notably, higher-order domains are visible in single cells and their number increases with cell cycle progression. The number of domains and their genetic and cellular localization are found to depend on transcriptional activity. Secondly, our data reveal that replication severely affects the three-dimensional organization of the chromosome and highlight two molecular factors involved in this replication-induced re-organization. Finally, we determined the ultra-structural organization and dynamical behaviour of replication domains and their role in chromosome organization and segregation

P324**Board Number: B460****Labeling chromosomes in live cells: a CRISPR picture.**H. Ma¹, A. Nissen², P. ReyesGutierrez¹, S. Wolfe¹, S. Zhang², T. Pederson¹;¹Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, ²Department of Electrical Engineering and Computer Science, University of Central Florida, Orlando, FL

Understanding the locations and dynamics of interphase chromosomes is a major goal in the field of nuclear organization and function. Fluorescence in situ hybridization (FISH) has been a major tool, manifest in its most all-encompassing form as Spectral Karyotyping (SKY), also known as. As important as these fixed cell methods are for a static picture, there is a parallel need to determine the locations and dynamics of interphase chromosomes in live cells, as has been done recently with TALEs. Here we report a multicolor CRISPR-based method for labeling individual chromosomes in human cells. It is based on computational mining of the human genome for chromosome-specific tandemly repetitive sequences combined with extensively optimized small guide RNAs for three different Cas9 orthologs. Using this method we have labeled the complete human karyotype. In confirmation of FISH results, we found in these live cell studies that the gene-rich chromosome 19 occupies a central position whereas the gene-poor chromosome 18 is located at the nuclear periphery. In addition, we found that chromosome 17 and the five acrocentric chromosomes (13, 14, 15, 21, 22) had central locations whereas chromosomes 3 and 7 tended to be located at or close to the nuclear periphery. We also examined the localization of the five Nucleolus Organizer Region-bearing acrocentric chromosomes in relation to nucleoli in diploid human RPE cells and observed that one copy of each chromosome was located close to a nucleolus, while the other was not. Finally, our method also labeled the heterochromatin at the pericentromeric region of 9q12. Most recently, we have developed dual-color versions of this method and are also applying it to study translocations in human tumor cells.

P325**Board Number: B461****Association of chromatin with the nuclear envelope supports stable nuclear mechanics.**S.M. Schreiner¹, P. Koo², Y. Zhao³, S. Mochrie³, M.C. King¹;¹Department of Cell Biology, Yale University, New Haven, CT, ²Physics, Yale University, New Haven, CT, ³Applied Physics, Yale University, New Haven, CT

Cells must constantly withstand mechanical stresses derived from both extracellular and intracellular forces. These forces can be transmitted to the cell's nucleus through connections with the cytoskeleton, raising the possibility that defects in nuclear mechanics can impact the cell's ability to withstand mechanical stress. The nuclear lamina, in particular lamin A, is often considered to be the primary mechanical defense of the mammalian nucleus. However, lamins are part of an integrated network of

proteins, lipids, and chromatin, all of which contribute to the ensemble mechanical properties of the nucleus. Yeast, which lack a nuclear lamina, provide a model system in which to study the lamin-independent contributions of chromatin and proteins residing in the nuclear membrane to nuclear mechanics. Here, we have combined a quantitative imaging platform capable of measuring 3D nuclear contours in live cells with an *in vitro* optical tweezers assay to probe the mechanical properties of *S. pombe* nuclei. In live cells, we find that association of chromatin with the inner nuclear membrane (INM) through integral membrane proteins is required for a normal mechanical response to microtubule (MT) forces. Increasing loss of integral INM proteins results in highly deformable nuclei that are subject to catastrophic failures in nuclear envelope integrity, specifically in response to exogenous forces from MTs. Loss of integral INM proteins that associate with the centromeres results in the most highly deformed nuclei *in vivo*. This observation supports a model in which the association of heterochromatin with the nuclear envelope adjacent to the spindle pole body, the yeast centrosome equivalent, helps buffer MT-driven forces. Further, our findings suggest that organisms without a nuclear lamina and with similar heterochromatin-centrosome interfaces have adopted a chromosome organization that contributes to the mechanical stability of nuclei. Using optical tweezers, we find that nuclei lacking integral INM proteins are less stiff than wild type nuclei, particularly when force is applied at rates that recapitulate the kinetics of MT dynamics *in vivo*. Wild type mitotic nuclei, in which chromatin is globally released from the INM, are extremely soft, raising the possibility that a transition in nuclear mechanics may support segregation of daughter nuclei during a period when forces are instead balanced between spindle poles. Together our data support a model in which the physical association of chromatin with the INM provides the stiffness necessary to buffer cytoskeletal forces in interphase while the deformability of mitotic nuclei supports nuclear division.

Nuclear organization has been implicated in regulation of gene activity. Recently, large developmentally regulated regions of the genome that dynamically associate with the nuclear lamina, the so called Lamina Associated Domains (LADs), have been identified. Intriguingly the dynamic re-organization of these regions has been implicated in cell-type specific gene regulation. We and others have identified developmentally regulated genes that reside in these dynamically associating regions, which we call variable LAD (vLADs). However, little is known about the mechanisms underlying LAD organization, establishment and scaffolding to the nuclear lamina. In order to identify DNA sequences able to

establish a *de novo* LAD, we utilized our tagged chromosomal insertion site system (TCIS). Using TCIS we identified small sequences from borders of fibroblast specific vLADs that are sufficient to target these ectopic sites to the nuclear periphery. These relocating sequences are enriched in motifs for Ying-Yang1 (YY1), BTB/POZ domain transcription factors (i.e. Zbtb7b) and CTCF. Knockdown of these proteins or lamin A/C, but not lamin A, led to a loss of lamina association. In addition, targeted recruitment of YY1 proteins facilitated ectopic LAD formation dependent on histone H3 lysine 27 trimethylation (H3K27me3) and histone H3 lysine di- and tri-methylation (H3K9me2/3). Additionally, we show that endogenous loci are dependent upon lamin A/C, YY1, H3K27me3 and H3K9me2/3 for maintenance of lamina proximal positioning. Taken together, these results reveal a mechanism for LAD recruitment implicating the involvement of tissue specific factors and epigenetic modifications.

Repo-Man is a repressive chromatin modulator in the interphase nuclei.

I. Castro¹, J. Budzak¹, M.L. Di Giacinto¹, H. Foster¹, A. Reynolds², K.S. Ullman³, P. Vagnarelli¹;
¹Life sciences, Brunel University, Uxbridge, England, ²ETC, Brunel University, Uxbridge, England,
³Oncological Sciences, University of Utah, Salt Lake City, UT

Upon mitotic exit, the establishment of the nuclear lamina on the newly formed G1 nucleus coupled to a controlled program of chromosome de-condensation ensures the organisation of chromatin inside the nucleus. The transition from mitosis to interphase requires the removal of mitotic histone modifications; Repo-Man/PP1 is one of the phosphatases involved in this process and specifically removes phospho-residues on the H3 tail (T3, S10, and S28). In the G1 nuclei, Repo-Man is nuclear with enrichment at the nuclear periphery. The nuclear periphery is associated with transcription repression due to the absence of transcription machinery (e.g. RNAPII) and accumulation of repressive chromatin modifiers and histone marks. Here we show that Repo-Man is important for chromatin organisation through association with components of the Nuclear Pore Complex (NPC) and formation of a repressive heterochromatic environment. Repo-Man is tethered to the nuclear periphery via the nucleoporin Nup153 that we had previously identified in a proteomic screen for Repo-Man interactors. Repo-Man establishes interactions with chromatin at the nuclear periphery possibly via its Histone binding domain, as its depletion causes the re-localisation of the peripheral bound Chr13q towards the nuclear interior. Finally, targeting of Repo-Man to a specific locus is sufficient to generate local enrichment of repressive marks of transcription, such as H3K27me3 and HP1. And, consistent with this, depletion of Repo-Man compromises the distribution of HP1 foci. These data suggest that Repo-Man is involved in shaping chromatin organisation and forming nuclear architecture upon mitotic exit.

P328**Board Number: B464****Principles of Self-Organizing Genome Architecture During Human Muscle Cell Differentiation.**D. Neems¹, S.T. Kosak¹, A. Garza-Gongora¹;¹Department of Cell and Molecular Biology, Northwestern University, Feinberg School of Medicine, Chicago, IL

The organization of the human genome within the nucleus is non-random; however, the guiding principles of this behavior are not fully understood. Our work suggests that the three-dimensional configuration of the genome is related to a linear distribution of co-regulated genes. Using myogenesis as a model system, we seek to uncover how these linear gene clusters may give rise to lineage specific nuclear topologies. Myogenesis represents an ideal system for studying this phenomenon, as it is easily amenable to modeling and the formation of syncytia provides unique experimental opportunities, such as studying the effects of the cell cycle. Using whole genome expression analysis during the process of myogenesis, we have identified human chromosome 1 (HSA1) to be a 'hotspot' for linear clusters of differentially regulated muscle-specific genes. We have found both long linear stretches of contiguous co-regulated genes and a significant number of topologically associated domains (TADs) enriched for myogenic genes. Importantly, we find that myogenin, a master regulator of muscle development, is within a TAD enriched for other myogenic genes. This TAD undergoes a significant change in nuclear organization upon differentiation, whereas other highly expressed genes found within HSA1 but outside enriched TADs do not. The myogenin-containing TAD's pattern of organization results in repositioning away from the nuclear periphery in conjunction with a reduction in inter-allelic distance. To determine if this developmental reorganization is specific, we simultaneously examined the myogenin-containing TAD and those upstream and downstream, creating three unique signals over a 1 Mbp region. The myogenin TAD showed a more dramatic phenotype than either neighboring region, confirming that activity was derived from that domain. Furthermore, the single cell nature of our study allowed us to confirm a high propensity for myogenin allele polarization with regards to inter-HSA1 distance. The observed reduced inter-allelic distance may serve a function in stabilizing the expression from each allele by bringing them into the same sub-nuclear microenvironment. This conclusion is supported by RNA-FISH experiments that show a positive correlation between intensity differences and microns between RNA-FISH signals in myotubes with two unique signals. Finally, taking advantage of naturally occurring cell fusion in myogenesis, we are also able to determine the cell cycle dependency of the various phenomenon observed during syncytial formation. We propose that the linear gene distribution, specifically the co-linearity of developmentally regulated genes, underlie observed changes in three-dimensional positioning and may indicate epigenetic regulation through genome organization.

P329**Board Number: B465****Analysis of foci created by the telomere binding protein POT-1 in *C. elegans*.**F. Peng¹, L. Shtessel², S. Ahmed^{2,3}, P.S. Maddox³;¹Curriculum in Genetics and Molecular Biology, University of North Carolina, Chapel Hill, NC,²Department of Genetics, University of North Carolina, Chapel Hill, NC, ³Department of Biology, University of North Carolina, Chapel Hill, NC

Telomeres are tracts of tandem DNA repeats that protect the ends of linear chromosomes from replicative erosion and from being identified and repaired as double-strand breaks. Shelterin is a complex of proteins found to directly associate with telomeres and functions to distinguish telomeres from double-strand breaks. The shelterin component POT1 binds to single stranded telomeric DNA, which is present at the chromosome terminus and also likely at the displacement loop (T-loop) created by strand invasion of the 3' overhang into the telomeric duplex. POT1 homologues have recently been identified and characterised in *C. elegans*. A transgene expressing *pot-1::mCherry* reveals strong punctate foci within the germline corresponding to discrete telomeric termini. Here, we examine the dynamics of POT-1 foci in the germline and during early development within living embryos using time-lapse imaging. Using various end-to-end chromosomal fusions, we interrogate the behaviour of POT-1 in the context of fused chromosomal ends harbouring telomeric repeats of varying lengths and show that creation of POT-1 foci does not require a chromosome terminus. We also analyse POT-1::mCherry foci in genetic backgrounds where telomerase activity is abolished, leading to shortened telomeres, and in mutants causing telomere elongation, as occurs with mutant *pot-1*. Our results suggest that POT-1 creates large, discrete structures within the nucleus that, perhaps surprisingly, are independent of both telomere length and of chromosome termini. We are testing the hypothesis that dynamics of POT-1 foci during development could be relevant to telomere biology.

P330**Board Number: B466****Annotation of genes located on the highly heterochromatic F element in *Drosophila biarmipes*.**A.R. Kneubehl¹, L.E. Guerriero¹, R.E. Boody¹, J.L. Sanford¹;¹Biological and Allied Health Sciences, Ohio Northern University, Ada, OH

The Muller F element, chromosome four in *Drosophila*, is commonly referred to as the dot chromosome and is unique among *Drosophila* autosomes in that it is highly heterochromatic and contains a high density of repetitive sequence. Furthermore, comparative genomic analyses of the F element shows that it contains a similar proportion of active genes as compared to euchromatic control regions. The Genomics Education Partnership (GEP) of Washington University, St. Louis strives to elucidate the evolutionary and gene regulatory mechanics behind this unique gene expression. Undergraduate researchers from colleges and universities across the nation perform sequence improvement and

manually annotate genes of recently sequenced *Drosophila* species. The present study focuses on annotation of contigs 3, 22, 37, 42, and 43 of the *Drosophila biarmipes* assembly, using standard annotation protocols. Briefly, NCBI BLAST was utilized for sequence alignment of contigs with the *Drosophila melanogaster* reference sequence and the UCSC Genome Browser was used to create gene models of all gene isoforms located on the investigated contigs. Results indicated that contig 3 of the *D. biarmipes* assembly contains the Mes2 gene, while contig 22 contains the CG6914 and CG14459 genes, and contig 37 contains the Oct-TyrR and CG7139 genes. Annotation of contig 42 and 43 revealed the presence of the bent gene on both contigs. Contig 42 contains the entirety of the bent gene; whereas, contig 43 contains half of the bent gene and all exons of the MED26 gene. The final gene models constructed from the annotation of these genes include: start and stop coordinates, exon coordinates for all the gene isoforms and verification of canonical splice donor and splice acceptor sites. Finally, dot plot analysis revealed sequence conservation between the *D. biarmipes* genes and their *D. melanogaster* orthologue. Future work will focus on annotating the transcription start sites for these genes, as well motif hunting to discover conserved sequence motifs that may be involved in regulating the expression of these F element genes. Overall, analyses of the gene structure of F element genes across multiple *Drosophila* species, including genes annotated in this study, will help to elucidate the cellular mechanisms responsible for gene expression within highly heterochromatic regions.

Basal activity of a PARP1-NuA4 complex varies dramatically between breast cancer cell lines.

K. Krukenberg¹, J.A. Steen², T.J. Mitchison¹;

¹Department of Systems Biology, Harvard Medical School, Boston, MA, ²The F.M. Kirby Neurobiology Center, Boston Children's Hospital, Boston, MA

Poly(ADP-ribose) (PAR) is an important but poorly understood post-translational modification involved in multiple biological processes including transcription, DNA damage repair and other stress responses. Control of protein PARylation is a balance between the activity of multiple poly(ADP-ribose) polymerases (PARPs) that catalyze the serial addition of ADP-ribose onto acceptor proteins to form linear and branched chains, and a PAR glycohydrolase (PARG) removing this modification from the protein surface. Despite their importance, fundamental questions about the regulation and cellular functions of PARPs remain unanswered. We are addressing these questions through an improved quantitative assay measuring PARP activity in cell lysates and through biochemical and proteomics methods determining PARP interaction partners. Much of the work done on PARPs has focused on their role in DNA damage. To gain insight into other potentially critical roles, we took an unbiased approach and analyzed cell lines grown under normal conditions in the absence of DNA damage. We found that basal PARP1 activity varies across breast cancer cell lines. The increase in basal activity appears to be independent of DNA damage, the most characterized PARP1 activation mechanism. The observed increase in PARP1 activity in some cell lines is due to a small fraction of activated PARP1. The activated

PARP1 is in complex with the chromatin remodeling complex NuA4, and the activity of PARP1 is dependent upon subunits of NuA4. Our findings demonstrate that PARP1 exists in multiple distinct activation states both within cells and between cell types, and we identified a new interaction/activation partner for PARP1. Overall, these studies expand our basic biochemical understanding of PARP1 and our understanding of its role in aspects of cell physiology outside of the DNA damage response.

Glucose causes neurodegeneration in induced orexin neurons.

K. Hayakawa¹, K. Shiota¹;

¹Dep. of Anim. Res. Sci., The University of Tokyo, Tokyo, Japan

Degeneration of orexin-producing neurons causes diseases related to sleep, metabolism, and motivation, and it is considered to be caused by physiological changes such as aging or the onset of diabetes. Analyses on orexin neurons are difficult since orexin neurons exist only thousands of cells in hypothalamus. We previously reported that mouse embryonic stem cells could be induced to differentiate into orexin neurons by treating them with N-acetyl-D-mannosamine (ManNAc). This induction is achieved by the repression of O-GlcNAc transferase (Ogt) and the histone de-acetylase Sirt1 on the *Hcr* gene locus coding for prepro-orexin. Therefore, this culture system can be utilized to explore the factors and mechanisms of neurodegeneration in orexin neurons. Here, we aimed to generate orexin neurons from human induced pluripotent stem cells (hiPSCs) and to find the cause of neurodegeneration. Twenty days after the neural induction, we detected *HCRT* gene expression in the cells cultured in a medium supplemented with ManNAc. The hiPSCs-derived *HCRT*-expressing cells behaved similar to the *in vivo* cells, because orexin peptides were released to the medium owing to the treatment with ghrelin, which was in contrast to the result obtained following treatment with leptin, Npy, and glucose. In these induced orexin neurons, the *HCRT* gene showed higher acetylation on H3/H4. Concomitantly, histone acetyltransferase, p300, CBP, and MEGA5 (also called O-GlcNAcase) were colocalized at the *HCRT* gene locus in the orexin neurons. Considering the fact that treatment with OGT and SIRT1 inhibitors could increase the induction efficiency of orexin neurons from hiPSCs to approximately five-fold, the suppression of these proteins was a critical epigenetic event in orexin neurogenesis, common to humans and mice alike. To study the mechanism of loss of orexin neurons, we evaluated orexin expression in long-term culture. When orexin neurons derived from hiPSCs were cultured for over 20 days, we observed a dramatic reduction in the *HCRT* expression. Generally, in the culture medium for neural cells, glucose is present at high concentrations as compared to its concentration *in vivo*. Accordingly the *in vivo*, glucose concentration was reduced to 5 mM during long-term culture, and the results indicated that the *HCRT* expression was maintained in associated with H3/H4 hyper-acetylation and hypo-O-GlcNAcylation on the *HCRT* locus. In summary, functional orexin neurons were successfully induced from hiPSCs after increasing histone acetylation and suppression of O-GlcNAcylation and using this culture system, we revealed that glucose was involved in the degeneration of orexin neurons.

P333**Board Number: B469****Linker histone variant H1T targets rDNA repeats.**R. Tani¹, K. Hayakawa¹, S. . Tanaka¹, K. Shiota¹;¹Dep. of Anim. Res. Sci., The University of Tokyo, Tokyo, Japan

Linker histone H1 is composed of a short N-terminal domain, a central globular domain, and a long C-terminal domain (CTD). Germinal-cell-specific variants exhibit low homology with the somatic variants, particularly in the CTD. Based on the studies of somatic H1 variants, H1 is thought to condense the chromatin structures, leading to a repression of gene expression. However, our recent study revealed that H1foo, a germinal-cell-specific variant, decondensed the chromatin structures in specific regions. H1T is also a germinal-cell-specific variant and is expressed from the primary spermatocyte stage to the early spermatid stage during spermatogenesis. We hypothesized that germinal-cell-specific H1 variants possessed different functions from those of the somatic variants and had unique targeting loci. In this study, we found that the expression of H1T was detectable in tumor cell lines such as AGS and MDA-MB-231, although the expression levels were much lower than those found in the testis. Additionally, H1T was also expressed in multipotent stem cells such as mouse embryonic stem cells (mESCs), and even in myoblast cells and gastric cells. Fluorescence immunostaining revealed that H1T and the somatic H1 variants were localized in the nuclei. Interestingly, H1T was accumulated in the nucleoli regardless of cell type, whereas H1C, a somatic variant, was accumulated only in some of the cell lines.

To clarify the function of H1T, we identified H1T target loci in AGS, MDA-MB-231, and mESCs using ChIP-seq analyses. H1T, unlike the somatic H1 variants, was found to be enriched particularly in the clusters of repeated rRNA genes (rDNA repeats) in all the analyzed cells. The distribution of H1T in the rDNA region was validated through ChIP-QPCR and was compared with the H1C distribution to obtain details of their respective distribution patterns in the rDNA. H1T was enriched mostly around the transcription start sites of the pre-rRNA. To reveal the function of H1T to rDNA repeats, knockdown and overexpression experiments revealed that H1T functioned as a repressor of rDNA transcription.

These data, together with our previous report about H1foo, support the hypothesis that germinal-cell-specific H1 variants have specific biological functions. In conclusion, H1T uniquely targets rDNA repeats to repress transcription.

P334**Board Number: B470****A new paternal effect lethal is required to prime paternal chromatin for embryonic mitosis in *Drosophila*.**M.T. Levine¹, H.M. van der Wende¹, H.S. Malik²;¹Fred Hutchinson Cancer Research Center, Seattle, WA, ²HHMI and Fred Hutchinson Cancer Research Center, Seattle, WA

Eukaryotic DNA is packaged into distinct chromatin compartments that support essential, highly conserved functions. Many chromatin proteins, however, are unconserved. To gain insight into this paradox, we have characterized the ancient Heterochromatin Protein 1E (HP1E) gene in *Drosophila*, which is essential for male fertility in *D. melanogaster* but recurrently lost over evolutionary time. We report here that HP1E is a new paternal effect lethal (PEL). HP1E-depleted fathers make motile sperm that deposit paternal DNA into the egg, but these embryos arrest after only a few rounds of mitotic division. During the 1st zygotic mitosis, we observe an anaphase bridge comprised of paternal chromatin. We could rescue mitotic cycling by crossing these PEL fathers to sesame- mutant mothers, whose embryos bypass paternal DNA and instead undergo maternal haploid mitosis. This mitotic rescue implicates the paternal chromatin as the primary source of the PEL-induced embryonic arrest. Consistent with this inference, HP1E localizes to wildtype post-meiotic spermatid nuclei and persists through sperm development but disappears at sperm maturation. Our data suggest that HP1E must act pre-fertilization—during spermiogenesis—to prime the paternal genome for embryonic chromosome segregation post-fertilization. HP1E's essential function in embryonic mitosis in *D. melanogaster* makes its repeated pseudogenization in other species puzzling. In the obscura group of *Drosophila*, however, HP1E loss coincides precisely with a major karyotype rearrangement involving the highly heterochromatic X- and Y- chromosomes, including the birth of a neo-Y. This phylogenetic correlation raised the possibility of a synthetic interaction between HP1E and the sex chromosomes. To test this prediction in *D. melanogaster*, we conducted chromosome-specific, fluorescent in situ hybridization on PEL embryos fathered by HP1E-depleted males. We discovered significant enrichment only of the paternal X- and Y- chromosomes in the telophase bridges of female and male embryos, respectively. The autosomes, in contrast, segregated faithfully. The sex chromosomes harbor the longest tracts of heterochromatin across the *D. melanogaster* karyotype. We propose that HP1E depletion in the male germline results in incomplete heterochromatic DNA replication prior to the first embryonic mitosis. Under this model, a shift in the euchromatin-heterochromatin boundaries upon sex chromosome rearrangement in the obscura group released functional constraint on a once-essential HP1 gene.

P335**Board Number: B471****Effective and novel nuclear RIP protocols to study interactions between proteins and non-coding RNAs.**M.H. Hsu¹, K. Saito¹, J. Rosenfeld¹;¹Cell Biology, EMD Millipore, Temecula, CA

Chromatin is typically thought of as a complex of DNA, histones, and non-histone proteins. The RNA component of chromatin was considered to be mRNAs or traditional snRNAs that would transiently associate with chromatin during transcription. However, mounting evidence suggests that various classes of non-coding RNAs are associated with chromatin and serve regulatory functions possibly through sequence-specific hybridization and/or through structural and spatial mechanisms. Approaches that allow one to identify and characterize interactions between RNA molecules (both coding and non-coding), proteins and DNA are needed to better characterize these regulatory mechanisms.

One approach used to detect and identify non-coding RNA molecules bound to regulatory complexes is RNA-binding protein immunoprecipitation (RIP). This method allows the immunoprecipitation of protein:RNA complexes. However it is not specifically designed for the study of chromatin associated RNAs. To enable the use of RIP to study RNAs associated with chromatin, we have developed optimized methods to isolate and detect protein-associated long non-coding RNAs (lncRNAs) in chromatin. This approach is designed to allow the discovery and analysis of non-coding RNA regulatory functions. We have developed protocols for using either cross-linked or non-cross linked (native) starting materials thus allowing different types of interactions to be detected (e.g. direct vs. indirect). Our protocols show improved signal-to-noise ratios, work with varied amounts of starting materials and enable downstream analysis by either qRT-PCR or Next-Generation Sequencing. Here we present results showing the interaction of various long non-coding RNA molecules with protein complexes.

P336**Board Number: B472****Role for centromeric epigenetic regulation post terminal, non-proliferative, differentiation.**L.I. Smith¹, P.S. Maddox²;¹Genetics and Molecular Biology, University of North Carolina, Chapel Hill, NC, ²Department of Biology, University of North Carolina, Chapel Hill, NC

Centromeres are large genomic loci that act as the scaffolding point for kinetochore assembly and are necessary for microtubule based chromosome segregation during cell division. CENP-A is a histone H3 variant that serves as the epigenetic mark of centromeres and is critical for maintaining genomic stability. Although the role of centromeres in cell division is relatively well studied, very little has been done to explore the role of centromeres once a cell has terminally differentiated. We reasoned that

such a large genomic body might have a non-proliferative role in cell homeostasis. To determine if centromeres are required in terminally differentiated cells, we disrupted centromeres in adult *C. elegans* which consist of ~1,000 terminally differentiated, non-proliferative, cells and only a few stem cells (located in the germline and not required for viability). We used RNAi based protein depletion to knock down KNL-2, the most upstream regulator of CENP-A maintenance in chromosomes. In early *C. elegans* embryos, loss of KNL-2 function leads to failure of CENP-A to localize to centromeric regions. We hypothesized that KNL-2 depletion in adult animals would lead to loss of centromeric identity and reveal any hidden role for centromeres in non-proliferative cells. Adult wild type worms depleted of KNL-2 were found to have significantly shortened lifespans, indicating a possible dependency for centromeric integrity post-differentiation. We repeated the experiment in adult worms that completely lacked a germline (stem cells or somatic tissue), and found an even more significant reduction in lifespan in these worms. The CENP-A protein itself is quite long lived as revealed in pulse chase experiments in human tissue culture cells. We found that RNAi depletion of CENP-A itself did not affect lifespan in a manner significantly different from depleting a mitosis specific kinetochore protein (HIM-10) in wild type worms, likely due to the long-lived nature of CENP-A protein. However, depletion of CENP-A did significantly decrease lifespan in the longer lived gonadless worms, likely due to the increased lifespan allowing the long lived CENP-A embedded in chromatin to eventually be depleted. Our data suggest that centromere maintenance by KNL-2, is important for maintaining a healthy organism, although we can not rule out a non-centromere role for KNL-2 in post-mitotic cells. Importantly, the shortening of lifespan observed is independent of any abnormal stem cell divisions. In sum, this analysis supports the idea that the structural integrity of centromeres does have an important role post differentiation and cannot simply be discarded as a structural remnant of cell division.

A Role for Nuclear Actin in Regulating HDAC 1 and 2 Activity.

L. Serebryanny¹, C. Cruz¹, T. Hanigan², P.A. Petukhov², P. de Lanerolle¹;

¹Physiology and Biophysics, University of Illinois at Chicago, Chicago, IL, ²Medicinal Chemistry and Pharmacognosy, University of Illinois at Chicago, Chicago, IL

Class I histone deacetylases (HDACs) are known to remove acetyl groups from histone tails. This liberates positive charges on the histone tail and allows for tighter winding of DNA, preventing transcription factor interaction and gene activation. Although the functions of HDAC proteins are becoming apparent both biochemically and clinically, how this class of proteins is regulated remains poorly understood. Pulldown screens have identified a novel interaction between nuclear actin and HDAC1 and HDAC 2. Nuclear actin has been previously shown to interact with a growing host of nuclear proteins including chromatin remodeling complexes, transcription factors, and RNA polymerases. We find the interaction between Class I HDACs and nuclear actin is activity dependent as treatment with an HDAC inhibitor, Trichostatin A, decreases their association. ChIP assays on activated and Trichostatin A treated cells show an inverse correlation between HDAC and nuclear actin binding of DNA. Furthermore,

we find that increasing the concentration of actin in HeLa nuclear extracts is able to suppress overall HDAC function as measured by substrate deacetylation. Together our data identify a novel mechanism by which nuclear actin is able to bind the active HDAC 1 and 2 complexes and inhibit deacetylase activities.

Non-random arrangement of chromosomes 1, 29 and X in bovine spermatozoa.

O.S. Mudrak^{1,2}, I.B. Nazarov¹, V.O. Chagin¹, L.V. Solovjeva¹, A.V. Konovalenko³, A.O. Zalensky²;

¹Institute of Cytology, Russian Academy of Sciences, Saint-Petersburg, Russia, ²The Jones Institute for Reproductive Medicine, Eastern Virginia Medical School, Norfolk, VA, ³Public Healthcare Institution "Bureau of Forensic Medical Examination", Saint-Petersburg, Russia

Comprehensive studies of chromatin organization in human spermatozoa have demonstrated that, similarly to somatic cells, chromosomes of male gametes are organized in distinctive territories that are non-randomly located in the nucleus (Zalensky et al., 1993, 1995; Zalenskaya, Zalensky 2004, 2007; Mudrak et al., 2005; Manvelyan et al., 2008; Mudrak et al., 2012).

Apparently, these features have been preserved throughout the evolution of mammals as evidenced from studies of chromosome localization in spermatozoa of monotremes and marsupials (Greaves et al., 2001; Greaves et al., 2003), rats (Meyer-Ficca et al., 1998), and pigs (Foster et al., 2005).

The arrangement of chromosomes in the sperm nucleus may have a functional significance by influencing the sequence of post-fertilization events.

The chromosome arrangement in spermatozoa of livestock species was studied only in pigs (Foster et al., 2005). Studies of bovine male gametes were limited to identification of sex chromosomes for the selection of X and Y spermatozoa (Sharpe, Evans, 2009).

Here, using fluorescence in situ hybridization (FISH) with whole chromosome painting probes and a recently developed statistical approach (Mudrak et al., 2012), we investigate intranuclear locations of chromosomes 1 (CHR 1) and 29 (CHR 29), the largest and the smallest autosomes within the bovine karyotype, and chromosome X (CHR X) in mature spermatozoa of *Bos taurus* (domestic bulls).

We show that all these chromosomes demonstrate the preferred lateral and longitudinal intranuclear distributions in the elongated sperm nuclei. CHR1 and CHR 29 tend to be located at the opposite ends of the sperm nuclei in the longitudinal direction: CHR 1 is preferentially found in the acrosomal part, and CHR 29 in the basal part of the nucleus. Laterally, CHR 29 is located towards the nuclear periphery as compared with the more internal position of CHR 1. CHR X is located in the medial third of the nucleus, shifted towards the apical third (on the border between the apical and medial thirds) longitudinally, and is located in the center of the nucleus laterally.

We demonstrate that the patterns of intranuclear location of chromosomes in bovine spermatozoa are non-random and specific for individual chromosomes, suggesting the existence of chromatin positioning factors. Studies of the chromatin remodeling events at early stages of embryogenesis will be essential

for understanding the functional aspects of non-random genome architecture in spermatozoa.

Chromosome end protection and telomere length maintenance *cdc13-1* strains.

W. Azaizeh¹, J. Lorquet¹, K. Edwards¹, C.J. Hengartner¹, L.R. Vega¹;

¹Department of Biology, Barry University, Miami Shores, FL

Telomeres, the physical ends of eukaryotic chromosomes, function to protect DNA ends from degradation and from end to end fusion. Telomeres consist of stretches of repeated C/G-rich DNA ending with 3' single stranded G-rich overhangs. Telomere maintenance and function are facilitated by the enzyme telomerase and by many accessory proteins. Cdc13p is an essential, G-strand binding protein that functions in telomere protection and in telomerase recruitment. *cdc13-1* is a temperature sensitive allele of *CDC13*, that is defective for telomere end protection and at elevated temperatures, *cdc13-1* strains exhibit extensive C-strand strand specific degradation and show a G2/M cell cycle arrest. However, at permissive temperatures for growth, telomere length and end protection are similar to wild-type. Ku is a non-essential heterodimer composed of Ku70p and Ku80p. Ku plays multiple roles in DNA metabolism including: non-homologous end joining, recombination, telomerase recruitment and telomere end protection. The capping function of γ KU is necessary in G1. *cdc13-1*, *yku* Δ double mutants strains exhibit enhanced temperature sensitivity and impaired growth. This study examines the effect of a panel of mutations in γ KU80 on *cdc13-1* strains. Cells were monitored for growth at permissive and semi-permissive temperatures and telomere length were assayed by Southern blot. We also examined genetic interactions between *cdc13-1* and *yku80* mutant alleles and Pif1p, a helicase that inhibits telomerase activity. Our results suggest that Pif1p activity helps to promote normal telomeres length at permissive temperatures in *cdc13-1* strains, perhaps by removing telomerase that is telomere associated via an interaction with γ KU.

Construction of Human Artificial Chromosomes in a non-transformed cell line.

O. Molina¹, P. Shah¹, N. Kouprina², V. Larionov², W.C. Earnshaw¹;

¹Wellcome Trust Centre for Cell Biology, The University of Edinburgh, Edinburgh, United Kingdom,

²National Cancer Institute, National Institutes of Health, Bethesda, MD

Human Artificial Chromosomes (HACs) are extrachromosomal elements that contain a functional centromere and behave as normal chromosomes. HACs have been used to study the epigenetic regulation of centromeres and they have also been proposed as an alternative gene-delivery system

since they have a number of advantages over the current viral-based methods. However, a significant limitation of this technology is that only the human HT1080 cell line is routinely competent for de novo HAC formation. HT1080 is a transformed cell line that shows chromosome instability (CIN). The aim of this project was to construct a new HAC in a non-transformed cell line (non-CIN) in order to obtain a better tool for future chromosome biology studies. We generated a synthetic alphoid-DNA array based on the type-I satellite DNA from chromosome 21 by RCA-TAR cloning (21alphoidtetO array). This synthetic array contains tetracycline operators in every second monomer replacing the 17-bp CENP-B-box sequence. The 21alphoidtetO array was transfected into the non-transformed cell line RPE1-hTERT (46, XX; der(X)) transiently overexpressing either Mis18 α , HJURP or CENP-28 (factors involved in CENP-A recruitment) as tetR-fusion proteins. RPE1-hTERT cells overexpressing tetR-EYFP protein were used as a control. Transfectants were selected with geneticin for the vector containing the 21alphoidtetO array for approximately 21 days. Individual clones were further expanded for 7 days in the presence of geneticin. Metaphase-chromosome spreads were prepared for Fluorescence in situ Hybridization (FISH) using a DNA probe for alpha-satellite21 labelled with Spectrum Green (Abbott Molecular, Inc). A minimum of 50 metaphases were analysed in order to assess the frequency of HAC formation in each condition. Importantly, our experiments detected HAC formation in the RPE1-hTERT cells that were transfected with the 21alphoidtetO array while also transiently overexpressing Mis18 α , HJURP or CENP-28 tetR-fusion proteins. The frequency of HAC-containing metaphases in these clones was different when Mis18 α , HJURP and CENP-28 tetR-fusion proteins were overexpressed (6.55%, 4.1% and 2%, respectively). As expected, no HAC-containing metaphases were observed when the 21alphoidtetO array was transfected in cells transiently overexpressing the tetR protein as a control. Our results suggest that Mis18 α may license the chromatin for de novo kinetochore formation more efficiently than HJURP or CENP-28. Furthermore, these data showed the possibility of constructing HACs in cell lines other than HT1080. Therefore, this approach represents an important advance in HAC technology both for future chromosome biology studies and for their potential use as gene-delivery vectors.

Nuclear Lamina and Laminopathies

Abnormal processing of prelamin A in progeria affects nuclear movement and cell migration.

W. Chang¹, Y. Wang^{1,2}, H.J. Worman^{1,2}, G.G. Gundersen¹;

¹Department of Pathology and Cell Biology, Columbia University, New York, NY, ²Department of Medicine, Columbia University, New York, NY

Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic disease characterized by appearance of aging phenotypes in childhood. HGPS is caused by mutations in the LMNA gene that generate a truncated prelamin A (progerin) that cannot be processed and remains farnesylated. Lamin A anchors LINC complex nesprin and SUN proteins and we found by fluorescence recovery after photobleaching

that progerin expression reduced the mobility of nesprin-1, nesprin-2, and SUN2, but not that of nesprin-3, nesprin-4 or SUN1. Actin-dependent nuclear movement in NIH3T3 fibroblasts polarizing for migration requires the formation of nesprin-2G and SUN2 transmembrane actin-associated nuclear (TAN) lines that are anchored by lamin A (Luxton et al., Science, 2010; Folker et al, PNAS, 2011). We found that nuclear movement was inhibited in both fibroblasts from patients with HGPS and NIH3T3 fibroblasts expressing progerin. Importantly, both the mobility and nuclear movement defects were rescued by treating cells with farnesyltransferase inhibitors (FTI-276 and FTI-277) and cells expressing a CAAX mutant progerin that could not be farnesylated, exhibited normal nuclear movement. Two factors contributed to defective nuclear movement in progerin-expressing cells. First, TAN lines, which normally are fixed in place on the nucleus, moved over the nuclear surface, indicating a failure to anchor TAN lines. Unlike wild type lamin A, GFP-progerin accumulated in the TAN lines and moved with them, probably due to the association of progerin with the membrane rather than the lamina. Second, the velocity of rearward actin cable movement was dramatically reduced from 0.28 $\mu\text{m}/\text{min}$ in controls to 0.08 $\mu\text{m}/\text{min}$ in progerin-expressing cells. ZMPSTE24 is the metallopeptidase that specifically cleaves prelamin A. Mutations in ZMPSTE24 lead to an inability to process prelamin A and cause progeria and restrictive dermopathy. We found that nuclear movement was also impaired in embryonic fibroblasts from Zmpste24-null mice and this defect was rescued by FTI-277 treatment. Zmpste24-null cells showed defects in cell spreading and failed to polarize and initiate cell migration. We conclude that both the abnormal processing of prelamin A and accumulation of progerin result in defective nuclear movement and cell migration in fibroblasts and suggest that these defects may contribute to the early aging symptoms of HGPS.

LINC COMPLEXES AND THE B-TYPE LAMINS IN MAMMALIAN CONE PHOTORECEPTOR DIFFERENTIATION AND HOMEOSTASIS.

D.S. Razafsky¹, Y. Xue¹, C. Ward¹, S. Young², L. Fong³, V. Kefalov¹, D.M. Hodzic¹;

¹Ophthalmology and Visual Sciences, Washington University School of Medicine, Saint Louis, MO,

²University of California Los Angeles, Los Angeles, CA, ³University California-Los Angeles, Los Angeles, CA

Linkers of the Nucleoskeleton to the Cytoskeleton (LINC complexes) are macromolecular assemblies that span the whole nuclear envelope to physically connect chromatin and nuclear lamina to cytoskeletal components of the cytoplasm. We previously showed that LINC complexes are essential for the apical localization of cone photoreceptors nuclei. Here, using an improved transgenic mouse model, we show that cone nuclei mislocalization on the basal side of the outer nuclear layer affects cone pedicle morphology, synaptic transmission to secondary neurons as well as chromophore recycling to photosensitive cone outer segments. By contrast, the development and intrinsic phototransduction capabilities of the inner/outer segment interface remained unaffected. Because B-type lamins, which are major components of the nuclear lamina, directly interact with LINC complexes, we also examined their role in cone photoreceptor nuclei positioning. In one-month old retinas, the positioning of cone

nuclei was not affected upon genetic inactivation of LMNB1 and LMNB2 at postnatal day 6. As it turned out, our experiments directly demonstrated that lamin B1 and lamin B2 are very long-lived proteins whose clearance takes about 5 months. Despite the widely accepted assumption that B-type lamins are essential for cell viability, the morphology, function and viability of 9-month-old cone photoreceptors devoid of B-type lamins were unaffected. However, their nuclei were scattered on the apical side of the outer nuclear layer, a phenotype that was accompanied by the mislocalization of Sun1, an essential component of LINC complexes, from the nuclear envelope of cone nuclei.

Initial characterization of DdMan1, the first LEM protein identified in *Dictyostelium discoideum*.

X. Ren¹, Y. Wang¹, D.A. Larochelle¹;

¹Department of Biology, Clark University, Worcester, MA

Man1 is an integral protein of the inner nuclear membrane. It belongs to the LEM (Lap2, emerin, Man1) domain protein family based on a ~40 amino acids long LEM-domain motif at the amino-terminal region (Nicole Wagner, 2007, *Int Rev Cytol.*). We have identified a Man1 homologue protein in the eukaryotic organism *Dictyostelium discoideum*. Like higher eukaryotic LEM2 and MAN1, DdMan1 contains a N-terminal LEM motif, two predicted transmembrane segments and a C-terminal MAN1-Src1p C-terminal (MSC) domain (Feng Lin, 2005, *Hum Mol Genet*). Detergent extraction experiments suggest DdMan1 is an integral nuclear membrane protein. Similar to previously identified *Dictyostelium* nuclear envelope protein DdSun1 and the *Dictyostelium* lamin DdNE81, DdMan1 also localizes to the nuclear envelope throughout the whole cell cycle (Irene Schulz, 2009, *EJCB*; Anne Krüger, 2011, *MbOC*) (like yeasts and others lower eukaryotes, *Dictyostelium discoideum* undergoes a closed mitosis in which the nuclear envelope remains intact throughout the cell cycle). Surprisingly, fluorescence microscopy shows that DdMan1 only partially co-localizes with DdNE81, indicating the possible existence of micro-domains in the *Dictyostelium* nuclear envelope. When the first 646 amino acids, containing the LEM domain and the first transmembrane domain, of DdMan1 is overexpressed, several phenotypes were observed. 1) The nuclear envelope forms protrusions that extend into the cytosol. Fluorescence recovery after photobleaching (FRAP) experiments indicate that these are stable structures. 2) The nuclear envelope becomes grossly distorted in comparison to its normally oval or round appearance. 3) Cytoplasmic bridges that stain positive for both alpha-tubulin and DdMan1 appeared between adjacent cells. Taken together, the nuclear envelope phenotype indicates an important role of DdMan1 in nuclear envelope structure and organization.

P344**Board Number: B481****How forces generated in the cytoplasm are dissipated across the nucleoskeleton to move nuclei.**C.R. Bone¹, E.C. Tapley¹, P. Kuehnert¹, M. Gorjanacz^{2,3}, D.A. Starr¹;¹MCB, University of California Davis, Davis, CA, ²European Molecular Biology Laboratory (EMBL), Heidelberg, Germany, ³Therapeutic Research Group Oncology, Bayer HealthCare Pharmaceuticals, Berlin, Germany

Nuclear migration is a critical aspect of many developmental and cellular processes including fertilization, cell polarization, and differentiation. Disruption of proteins at the nuclear membrane responsible for nuclear migration leads to a class of diseases known as laminopathies, which includes Hutchinson-Gilford Progeria Syndrome and Emery-Dreifuss Muscular Dystrophy. For nuclear migration to occur, a bridge termed the LINC complex (for linker of the nucleoskeleton and the cytoskeleton), forms across the nuclear envelope. In *C. elegans*, the nuclear envelope bridge that functions in nuclear migration is made up of the KASH protein, UNC-83, which is recruited to the outer nuclear membrane by the SUN protein, UNC-84, in the inner nuclear membrane. This complex is thought to transduce forces generated by microtubule motors in the cytoplasm, across the nuclear envelope, and to the nucleoskeleton where the force is dissipated throughout the nucleus. We show that *C. elegans* lamin, LMN-1, is required for nuclear migration and interacts with the amino terminus of the SUN protein, UNC-84. This interaction is weakened by the UNC-84(P91S) mutation previously found to partially disrupt nuclear migration. Live imaging of nuclear migration in UNC-84(P91S) animals shows many nuclei migrate normally. However, other nuclei fail to initiate migration, while a third class of nuclei initiate migration before subsequently failing prior to completion. Our data also suggest a role for the NET5/Samp1/Ima1 homolog during nuclear migration in *C. elegans*. Interestingly, unlike in mammalian cells, *C. elegans* SAMP-1 does not require lamin for nuclear envelope localization. Additionally, RNAi experiments demonstrated SAMP-1 plays roles in organizing the mitotic spindle in the early embryo. Our working model is that the N-terminus of UNC-84 directly binds lamin to allow the transfer of force from the LINC complex to the nucleoskeleton where it is dissipated by a complex of proteins. Other inner nuclear membrane proteins, including SAMP-1, also function in these processes.

P345**Board Number: B482****The generation of topological order in the nuclear lamina - The four lamin systems.**K. Maass¹, T. Kolb², H. Herrmann¹;¹German Cancer Res Ctr, Heidelberg, Germany, ²University Erlangen-Nuernberg, Erlangen, Germany

Nuclear intermediate filament proteins (lamins) organize the interface between the nuclear envelope and chromatin. The importance of this structural network, the lamina, for cellular physiology becomes obvious by the reported 825 sequence variants in lamin genes linked to 41 associated diseases (www.interfil.org). In man, lamin B1 and lamin B2, are constitutively found within the nuclear lamina, whereas lamin A and its smaller splice form lamin C are differentially expressed during embryonic development. A-type lamins are in addition found in the nucleoplasm in the form of small soluble complexes. Notably, lamin A and lamin C do completely segregate, both in the soluble and the lamina-bound form despite the fact that their amino acid sequence is identical within the coiled coil domain that is mediating dimerization (1). In addition, we can show that lamin B1 and lamin B2 are kept segregated in cells. Hence the question arises how this order is established and maintained through the expansion of the nucleus during interphase and what the functional consequences of the coexistence of the four lamin systems are. We have studied the composition of the nuclear lamina by ectopic expression of fluorescently tagged A-type lamins in various stably transfected cell lines. We performed an integrated approach using fluorescence microscopy, differential cell extraction with the subsequent GFP-specific “pull-down” and separation of individual cell fractions by sucrose gradient centrifugation followed by Western blotting. We find that the GFP-lamin A chimeras distribute to different cell fractions than the endogenous A-type lamins. In contrast to endogenous lamin A, the majority of GFP-lamin A was extracted with buffers of both low and high detergent concentrations. Furthermore, when the GFP-lamin A chimera was precipitated with “GFP-binder” only minor amounts of the endogenous lamin A and lamin C were co-isolated indicating that they did not associate in the cell with one another, in particular did not form coiled coils. A separation by sucrose gradient centrifugation revealed that the complexes formed by GFP-lamin A differed in size from those recovered with the endogenous lamin A complexes. From this results we can conclude, that the nucleus provides a complex set of molecular mechanisms that mediates the functional organization of the four major lamin polypeptides as distinct structural entities in human cells.

(1) Kolb T, Maaß K et al. (2011) Lamin A and lamin C form homodimers and coexist in higher complex forms both in the nucleoplasmic fraction and in the lamina of cultured human cells. *Nucleus* 2, 425-433.

P346**Board Number: B483****Structural Analysis of the Nuclear Lamina by Nanoscale Resolution Microscopy.**T. Shimi¹, Y.G. Turgay², M. Kittisopikul³, A.E. Goldman¹, S.A. Adam¹, Y. Guo⁴, K. Jaqaman³, Y. Zheng^{4,5}, O. Medalia², R.D. Goldman¹;¹Department of Cell and Molecular Biology, Northwestern University, Feinberg School of Medicine, Chicago, IL, ²Department of Biochemistry, University of Zürich, Zurich, Switzerland, ³Department of Biophysics, University of Texas Southwestern Medical Center, Dallas, TX, ⁴Department of Embryology, Carnegie Institution for Science, Baltimore, MD, ⁵Department of Biology, Johns Hopkins University, Baltimore, MD

In mammalian cells, nuclear lamins are the major components of the nuclear lamina which underlies the nuclear envelope (NE). They are subdivided into the A-type lamins (LA and LC) and the B-type lamins (LB1 and LB2). However, the structural organization of each of these lamin isoforms within the lamina remains unclear. The elucidation of the 3D structural organization of each type of lamin is essential for understanding their structure and functional interactions with peripheral heterochromatic regions of interphase chromosomes. In order to study this, 3D Structured Illumination Microscopy (3D-SIM) combined with computational image analysis was performed on WI-38 human diploid fibroblasts and mouse embryonic fibroblasts (MEFs). Interestingly, LA, LB1, LB2 and LC form separate fibrillar structures which appear to overlap at their ends to form complex meshworks. Using LB1 null (*Imnb1*^{-/-}) MEFs, we also show that the lamina meshwork formed by LA/C and LB2 fibrils becomes abnormally enlarged compared to WT MEFs. The enlarged complexes of these fibrils align with peripheral elements of heterochromatin as determined by staining with anti-H3K27me3. These results suggest that LB1 regulates both the normal structure of the lamina and the normal structural links to peripheral heterochromatin. To go one step further in determining nanoscale structures of the lamina, we have used vimentin null MEFs (*Vim*^{-/-} MEFs), the nucleus of which lies in close proximity to the plasma membrane due to the loss of the juxtannuclear intermediate filament cage. This allows us to perform Stochastic optical reconstruction microscopy (STORM) with total internal reflection fluorescence microscopy (TIRF) to achieve even higher resolution images of the lamina in situ. These nuclei can also be imaged in situ by advanced cryo-electron tomography which reveals that the major filamentous structures in the lamina are not 10nm in diameter but rather are about 5 nm in diameter. We propose that these lamin nanofilaments probably associate laterally to form the lamin fibers resolved by 3D-SIM and STORM. These results are being confirmed by the observation that lamin null MEFs in which vimentin expression is silenced and *Vim*^{-/-} MEFs stably overexpressing lamins exhibit significant changes in number of lamin nanofilaments. Our results demonstrate that the lamin fibers assemble into a complex hierarchical network which changes its structure and function regionally within the nuclear lamina. This work is supported by National Institutes of Health grants (GM106023) and (CA03176).

P347**Board Number: B484****The Role of A Type Lamins in Genome Organization.**X. Wong¹, J.C. Harr¹, K.L. Reddy²;¹Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD, ²Biological Chemistry and Center for Epigenetics, Johns Hopkins University School of Medicine, Baltimore, MD

A type lamins, in particular lamins A and C, are spliceoforms of the LMNA gene. For the majority of the coding sequence, Lamin A and C are identical and as such, these two spliceoforms have been considered similar and mostly studied together. We have designed tools to specifically study the roles of these two spliceoforms independently and have uncovered differential roles of lamin A and C, at least in genome organization. We suggest that understanding the specific roles these two spliceoforms play in establishing proper genome organization will provide insights to organizational changes that occur during development and diseases such as Hutchinson-Gilford Progeria Syndrome. Additionally, we propose that other cellular functions might also be carried out differently by these two spliceoforms. As such, understanding the specific roles lamins A and C play in establishing proper cellular functions will potentially provide insights for treating the myriad of diseases of the nuclear envelope or the Laminopathies.

P348**Board Number: B485****Identifying a novel role for nuclear lamins in controlling nuclear shape changes in response to feeding.**E.M. Zeituni¹, X. Zheng¹, B. Caldwell¹, Y. Zheng^{1,2}, S.A. Farber^{1,2};¹Department of Embryology, Carnegie Institution for Science, Baltimore, MD, ²Department of Biology, Johns Hopkins University, Baltimore, MD

The nuclear lamina is a complex structure whose composition and interactions appear to dynamically change through development and across tissues. Due to its complexity and variability, fundamentally understanding the biology of the nuclear lamina in vivo remains largely out of reach. Using zebrafish larvae, we are able to observe remarkable morphological changes in intestinal epithelial cell nuclei during feeding. These enterocytes respond rapidly and robustly to the presence of nutrients, especially lipids. Morphological responses include increases in size, expansion of endoplasmic reticulum, fusion of mitochondria, lysosomal reconstruction, and the formation of lipid droplets. Interestingly, we observed a novel phenomenon: the rapid and reversible blebbing of the nuclear periphery upon feeding. This dramatic structural change of the nucleus is coupled with robust and widespread transcriptional changes. Since the nuclear lamina helps regulate both the shape of the nucleus and the transcription of genes, we examined the role of nuclear lamins in these physiologically responding enterocytes. Using zebrafish that express a human mutant allele of lamin A, called progerin, we studied the impact of a disrupted nuclear lamina on the morphology and transcriptional responses of enterocytes. Based on our

findings we have constructed a model where the nuclear lamina plays a novel role in cellular responses to nutrients.

Board Number: B486

Defective nuclear movement in lamin A deficient cells is rescued by reducing activity of Erk1/2 and Rho signaling.

S. Antoku¹, C.A. Ostlund², E.S. Folker³, H.J. Worman^{1,4}, G.G. Gundersen¹;

¹Department of Pathology and Cell Biology, Columbia University, New York, NY, ²Columbia University, New York, NY, ³Biology, Boston College, Chestnut Hill, MA, ⁴Department of Medicine, Columbia University, New York, NY

In NIH3T3 fibroblasts, the serum factor lysophosphatidic acid (LPA) stimulates actin retrograde flow to power the rearward movement of the nucleus to polarize cells for migration. Retrogradely moving actin cables are attached to the nucleus through LINC complexes of nesprin-2G and SUN2 that are thought to be anchored by lamin A (Luxton, G. et al., *Science*, 2010; Folker E., et al., *PNAS*, 2011). Expression of variants of lamin A that cause muscle dystrophies disrupts nuclear movement in fibroblasts and also causes upregulated Erk 1/2 activity (Muchir, A., et al., *JCI*, 2007). As reducing Erk 1/2 activity with MEK 1/2 inhibitors ameliorates dystrophic symptoms in a mouse model (Muchir, A. et al., *HMG*, 2009), we tested the relationship between Erk 1/2 activity and nuclear movement in NIH3T3 fibroblasts. Treatment of lamin A knockdown fibroblasts or fibroblasts expressing the lamin A disease variant, lamin A H222P, with MEK1/2 inhibitors (AZD 6244 and PD98059) rescued the defect in nuclear movement. Consistent with these results, hyperactivation of Erk 1/2 activity in NIH3T3 fibroblasts by expressing a constitutively active MEK1 S218/222D inhibited nuclear movement. The rescued nuclear movement by MEK 1/2 inhibitors in lamin A deficient fibroblasts had characteristics, including actin-dependence, similar to wild type cells. LPA also stimulates Erk1/2 activity with peak activation occurring by 5 min. Treatment of wild type fibroblasts with AZD6244 to block this Erk1/2 activation revealed that nuclear movement was initiated and completed earlier without affecting the rate of actin retrograde flow. Erk 1/2 activates Rho through GEF1-H1 (Fujushiro, S., et al., *BBRC*, 2008), so we tested whether Erk1/2 may mediate its effects on nuclear movement through Rho. Mild inhibition of Rho by C3 toxin rescued the nuclear movement defect in lamin A knockdown fibroblasts, whereas hyperactivation of Rho by CN03 toxin inhibited nuclear movement in wild-type fibroblasts. Furthermore, mild inhibition of Rho kinase by Y27632 also rescued the nuclear movement defect. Our results reveal that Erk1/2 and Rho are negative regulators of nuclear movement and suggest that lamin A may contribute to nuclear movement by maintaining Erk1/2 and Rho at low levels permissible for nuclear movement.

P350**Board Number: B487****Lamins and emerin determine mobility of SUN proteins at the nuclear envelope.**P. Isermann¹, B. Nguyen², J. Lammerding³;¹Weill Institute, Cornell University, Ithaca, NY, ²Cornell University, Ithaca, NY, ³Department of Biomedical Engineering, Cornell University, Ithaca, NY

Mutations in the nuclear envelope proteins lamin A/C, emerin, nesprin, and Sun1/2 can cause muscular dystrophy and dilated cardiomyopathy, but the molecular disease mechanism remains incompletely understood. SUN proteins at the inner nuclear membrane and nesprins at the outer nuclear membrane form the linker of the nucleoskeleton and cytoskeleton (LINC) complex, which is essential for nuclear positioning and other cell functions. Since LINC complex proteins directly interact with lamins and nesprins, mutations in any of these proteins may disrupt nucleo-cytoskeletal coupling and contribute to the disease mechanism.

To test the hypothesis that mutations or loss of lamins A/C or emerin can impair anchoring of the LINC complex at the nuclear envelope, we used fluorescence recovery after photobleaching (FRAP) of fluorescently tagged Sun1, Sun2, and Samp1 to investigate their mobility. In case of Sun1 and -2, we used full-length constructs as well as truncated versions lacking the nesprin-binding site to prevent confounding effects from interactions with the cytoskeleton via nesprin. Experiments were carried out in mouse embryonic fibroblasts lacking specific lamin isoforms, the lamin A processing enzyme Zmpste24, and in cells expressing specific emerin mutants.

Cells lacking both lamins A and C had higher mobility of Sun1 and -2 compared to wild-type controls. Cells expressing lamin A but lacking lamin C had normal mobility of Sun1, but not Sun2, whereas mobility of both Sun1 and -2 was increased in cells expressing only lamin C and no lamin A. In emerin- and lamin B1-deficient cells, Sun1 mobility was comparable to wild-type cells, but Sun2 was more mobile, similar to the results in lamin A/C-deficient cells. Expression of emerin mutants that cause impaired interaction of emerin with actin did not affect Sun2 mobility. The mobility of Samp1, which is a recently discovered binding partner of Sun2 and emerin, was increased in lamin A/C-, lamin B1-, and emerin-deficient cells. Interestingly, lamin B2 deficiency increased the mobility for Sun1/2 but not Samp1. In contrast, the emerin mutations resulted in higher mobility of Samp1, suggesting that the interaction of emerin with Samp1 may be mediated by actin. Deletion of Zmpste24, resulting in permanently farnesylated lamin A, reduced the mobility of Sun1.

Our results suggest that Sun1 and Sun2 interact with distinct nuclear lamina proteins, indicating different functions of lamin proteins. Sun1 mobility was primarily determined by interaction with lamin A, whereas Sun2 mobility was affected by any deletion of a component of the lamina, but was independent of lamin A farnesylation. Mutations in lamins and emerin may affect LINC complex function by altering SUN protein mobility.

P351**Board Number: B488****Regulation of the transcriptional coactivator MKL1 by the nuclear lamina.**M. Sledd¹, C. May¹, T. Carroll²;¹Cell Biology, Yale University, New Haven, CT, ²Dept. of Cell Biology, Yale University, New Haven, CT

The physical characteristics of animal cells, including shape and motile properties, are largely determined by the actin cytoskeleton. Diverse chemical or mechanical stimuli activate Rho-family GTPases which allow cells to rapidly alter their physical characteristics in response to changes in their microenvironment by promoting actin filament assembly. The transcriptional coactivator Megakaryoblastic Leukemia 1 (MKL1) senses monomeric actin (G-actin) levels. MKL1 is localized to the cytoplasm when bound to G-actin but translocates to the nucleus in response to actin polymerization. Once in the nucleus, MKL1 binds to Serum Response Factor (SRF) and activates target gene expression. Thus, MKL1 converts a rapid change in actin assembly into a lasting pattern of gene expression. Recently, components of the nuclear lamina, including Lamin A/C and Emerin, were shown to facilitate MKL1 localization (Ho et al, 2013). We have found that Man1, an inner nuclear membrane protein, also regulates MKL1. Man1 did not affect MKL1 nuclear translocation, however, transcription of MKL1-SRF target genes decreased with Man1 depletion. These results suggest that Emerin facilitates MKL1 nuclear localization whereas Man1 independently promotes MKL1 activity in the nucleus. We are examining the specific mechanisms by which these proteins affect MKL1 localization and activity.

Ho, C. Y. Jaalouk, D. E., Vartiainen, M. K. & Lammerding, J. Lamin A/C and emerin regulate MKL1-SRF activity by modulating actin dynamics. *Nature* 497, 507-511 (2013).

P352**Board Number: B489****Regulation of Lamin A assembly and abundance by SRF/Mkl1.**T. Carroll¹, K. Thakar¹;¹Dept. of Cell Biology, Yale University, New Haven, CT

The nuclear lamina is a dense protein meshwork that lines the nucleoplasmic face of the nuclear envelope in metazoan cells. Composed of a polymeric network of intermediate filament-like proteins called lamins, the nuclear lamina directly interacts with the genome and regulates virtually all aspects of DNA metabolism. The mechanical properties of the cellular microenvironment regulate the abundance and assembly state of Lamin A, which in turn, influences cell identity and function. The mechanosensitive signaling pathways that control Lamin A abundance and assembly state, however, have not been fully delineated. Here, we show that activation of the mechanosensitive Serum Response Factor (SRF)/Megakaryoblastic Leukemia 1 (Mkl1) transcription factor/coactivator complex leads to an increase in the abundance and decrease in the solubility of Lamin A. SRF/Mkl1 controls the expression of

genes that promote actin stress fiber assembly and cell contractility. Interestingly, Lamin A was recently shown to be required for SRF/Mkl1-dependent gene expression. We hypothesize that the requirement for Lamin A in the regulation of Mkl1/SRF activity reflects a cellular mechanism to protect genome integrity; stress fiber assembly is expected to increase the magnitude of an actin-dependent force that is applied directly to the nucleus, which would be particularly harmful in cells with defects in nuclear lamina structure. To test this hypothesis, we have developed stable cell-lines that express a constitutively active Mkl1 transgene, which should bypass the requirement for Lamin A in the activation of the SRF/Mkl1 complex. We are currently exploring the consequences for genome integrity of activating SRF/Mkl1 in the absence of a fully functional nuclear lamina.

Board Number: B490

As the beating heart stiffens in development, so does the nuclear lamina.

S. Cho^{1,2}, S. Majkut^{1,2}, J. Irianto², M. Tewari², D.E. Discher^{1,2};

¹Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA, ²Molecular and Cell Biophysics Lab, University of Pennsylvania, Philadelphia, PA

The heart is the first organ to develop in vertebrate embryos and is a mechanically stressed pump that is susceptible to defects in structural proteins of the extracellular matrix, cytoskeleton, and even the nucleus. We first show that the nucleus beats in the intact embryonic heart and that nuclear beating in vitro is regulated by matrix stiffness. However, it has been unclear when the nuclear structure protein Lamin-A turns on, which seems important because *Lmna* knockout mice are known to exhibit 'developmental defects of the heart' and die shortly after birth. We show that nuclear lamins parallel the development of mechanical stiffness and stress in normal embryos. While early embryos are well-known to be uniformly soft, our measurements using a chick embryo model show that the heart begins to stiffen almost immediately following initial differentiation, with tissue stiffness E of 1-2 kPa at embryonic day 4 (E4) increasing significantly by E6. This is accompanied by an increase in Lamin-A levels and comparatively constant Lamin-B expression with Lamin-A:B stoichiometry already known to function as a mechanosensor in adult tissue [Swift *Science* 2013]. Proteomic analyses of lamin perturbations at different stages of development likewise reveal nuclear lamins as potential embryonic stress sensors that mechanically link to cytoskeleton and the matrix, potentially feeding back to cytoskeletal maturation and differentiation.

P354**Board Number: B491****Microtubules contribute to the abnormal nuclear morphology in Hutchinson Gilford Progeria Syndrome.**Z. Tariq¹, H. Zhang¹, W. Losert², K. Cao¹;¹Dept of Cell Biology and Molecular Genetics, University of Maryland, College Park, MD, ²Dept of Physics, University of Maryland, College Park, MD

HGPS Syndrome is a genetic disorder characterized by rapid, premature aging and has been an area of interest due to its potential as a model system for normal aging. One of the hallmarks of HGPS is an abnormal nuclear shape which appears to hold clinical significance in itself, especially since a similar phenotype arises in cancer. Previous studies of this abnormality in HGPS have pointed to the accumulation of a mutant protein, progerin, as the major culprit. However, the potential interplay between the nucleus and the cytoskeleton has not been fully explored. Here we perturbed the microtubule network in both HGPS and control fibroblast cells through either microtubule drug treatments (nocodazole and taxol) or through an siRNA treatment against SUN1, an adaptor protein connecting the microtubule network and nuclear scaffolding. The nuclei of these cells then underwent two types of imaging: fluorescent microscopy and live cell spinning disc confocal microscopy. The resulting movies/images were then analyzed by an in-house MATLAB program, thereby allowing for a sensitive quantification of the nucleus. Surprisingly, we find that the microtubule network plays a positive role in normal cells and a negative role in HGPS cells in regulating nuclear shape.

Nucleocytoplasmic Transport 1**P355****Board Number: B492****The integrity of a transcriptional pulse from identical gene alleles is governed by regulated amounts of nuclear signaling factors.**A. Kalo¹, I. Kanter¹, A. Sharga¹, H. Tzemach¹, R. Singer², T. Lionnet³, Y. Shav-Tal¹;¹Faculty of Life Sciences, Bar-Ilan University, Ramat Gan, Israel, ²Albert Einstein College of Medicine, Bronx, NY, ³Janelia Farm, Ashburn, VA

Imaging of transcription in living cells using fluorescence microscopy has become an important approach for understanding nuclear gene expression dynamics. Functional interactions that combine signaling pathways and transcription factors are a mechanism used by cells to govern gene-specific responses to various stimuli. However, it is unknown if identical alleles in the nucleus respond similarly or differently to such signaling pathways, and whether the transcriptional pulse is coordinated between the alleles. Such questions can be approached using live-cell systems in which transcription from single alleles can be followed and quantified in real-time and at high resolution. The transcriptional response of the β -

actin gene to extra-cellular stimuli is a paradigm system for transcription factor complex nuclear assembly and regulation. Serum induction leads to a precisely timed pulse of β -actin transcription occurring within minutes of serum addition. We examined how the serum-induction signaling pathway governs the efficacy of the induced transcriptional pulse from several endogenous alleles of β -actin, using the MS2-tagging method for following mRNA transcription in single living cells. Our study focused on the nuclear serum response factor (SRF), the MAL transcription factor that translocates to the nucleus upon serum addition, and the actin protein. For instance, we found that lowering SRF levels led to loss of the transcriptional pulse, including a disordered response time, and reduction of activation coordination between the alleles. In contrast, reducing actin protein levels revealed a positive feedback response from the cytoplasm to the nucleus, resulting in stronger allele activation, a prolonged transcriptional response, and increased coordination between the alleles. This study reveals additional important aspects of nuclear dynamics, namely the very rapid time-frames of signal propagation from the cell membrane to the nucleus and RNA Pol II assembly on the promoter, RNA Pol II elongation rates, and nucleo-cytoplasmic transport kinetics of the mRNA wave generated by the pulse. This study on single alleles in living cells demonstrates that transcriptional pulse fidelity requires regulated amounts of nuclear signaling proteins, and that perturbations in factor levels in the nucleus eliminate the sharp pulse, resulting in either toning down or exaggeration of the transcriptional response.

Eukaryotic translation elongation factor 1 alpha 1 is Involved in the Nucleocytoplasmic Transport of Proteins Carrying an Expanded Polyalanine Tract.

L. Li¹, K. Ng², H. Chan²;

¹ Central South University, State Key Lab of Medical Genetics, Changsha, China, ²The Chinese University of Hong Kong, Hong Kong, Hong Kong

Polyalanine (poly-Ala) diseases are caused by expansion of translated GCX triplet nucleotide sequences encoding for poly-Ala tract in disease proteins. To date, nine human disorders are found to associate with poly-Ala tract expansion, including synpolydactyly type II, cleidocranial dysplasia, holoprosencephaly type 5, hand-foot-genital syndrome, blepharophimosis epicanthus inversus syndrome, mental retardation with growth hormone deficiency, Partington syndrome, congenital central hypoventilation syndrome and oculopharyngeal muscular dystrophy. Of note, eight out of nine poly-Ala disease genes encode transcription factors with important roles during development and differentiation. Previous studies demonstrate that wildtype unexpanded poly-Ala proteins localize to the cell nucleus while their respective expanded poly-Ala disease proteins primarily localize to the cytoplasm. The mislocalization of expanded polyA disease proteins causes cellular transcriptional dysregulation, which subsequently leads to cell dysfunction. Our laboratory found that expanded poly-Ala domain possesses nuclear export signal (NES) activity. By means of glutathione-S-transferase (GST) pull-down assay followed by mass spectrometry, we identified the eukaryotic translation elongation

factor 1 alpha 1 (eEF1A1) as an interacting protein of expanded poly-Ala-containing protein. Knockdown of *eEF1A1* expression suppressed expanded poly-Ala protein nuclear export. In addition, knockdown of *eEF1A1* restored the cellular function of poly-Ala-containing protein. Elucidating the mechanism behind expanded poly-Ala protein nuclear export will provide further insights into the pathogenesis of poly-Ala diseases.

Signals and blockers for karyopherin-mediated nuclear transport.

Y. Chook¹, M. Soniat¹, T. Yoshizawa¹, Q. Sun¹, H. Fung¹, T. Cagatay¹;

¹Pharmacology, University of Texas Southwestern Medical Center, Dallas, TX

Each of the ~20 different Karyopherin- β proteins (Kaps; Importins and Exportins) that mediate the majority of nuclear-cytoplasmic protein transport, recognizes distinct nuclear localization or export signals (NLSs or NESs) in their cargos. The classical-NLS, the PY-NLS, the lysine-rich K-V/I-x-K-x1,2-K/H/R NLS and the RS-domain NLS are recognized by the Imp α -Imp β heterodimer, Kap β 2 (or Trn-1), Kap121 (and its human homolog Imp-5) and TrnSR (or TNPO3), respectively. For nuclear export, only the classical NES recognized by CRM1 (or Xpo1) is currently known. NLSs and NESs for many Importins and Exportins remain uncharacterized. Core histones were previously shown to be imported by several Importins, with Importin-4 as the primary importer, but it was unclear if different Importins recognize different NLSs or a single common NLS within the histone tails. Analysis of core histones showed different distribution of binding energies within their N-terminal tails with different Importins. Two Kap pathways have recently been shown to be important for human diseases: nuclear import of RNA binding protein FUS by Kap β 2, and nuclear export by CRM1. The PY-NLS of FUS is heavily mutated, causing Kap β 2-mediated nuclear import defects in familial amyotrophic lateral sclerosis (ALS) patients. We had previously explained how the PY-NLS of FUS interacts with Kap β 2 and now expands knowledge of interactions to full length FUS and its other ligands. Finally, many tumor suppressor/growth regulatory proteins, which act in the nucleus to prevent genesis of neoplastic clones, are cargos of the Exportin CRM1. Activated oncogenic signaling pathways can alter these proteins causing inappropriate access to CRM1, mislocalization to the cytoplasm and loss of tumor suppressor activities. Small molecule CRM1 inhibitor KPT-330/Selinexor (currently in Phase 1 and 2 clinical trials for various cancers) retains dysregulated tumor suppressor proteins in the nucleus, reinitiating their antitumor, growth suppressive and pro-apoptotic activities and causes apoptosis of cancer cells while sparing normal cells. Tolerance of KPT drugs is greatly improved over the older lactone polyketide CRM1 inhibitor Leptomycin B (LMB), underscoring the importance of understanding differences in their mechanisms of action. We have shown that mechanisms of action for KPTs versus LMB are different despite both drugs binding covalently to the same CRM1 site.

P358**Board Number: B495****Recognition of the PY-Less PY-NLS by Kap β 2.**M. Soniat¹;¹Pharmacology, University of Texas Southwestern Medical Center, Dallas, TX

Import-Karyopherins or Importins bind nuclear localization signals (NLSs) to mediate the transport of proteins into the cell nucleus. Karyopherin β 2 (Kap β 2), also known as Transportin-1, is an Importin that imports various RNA binding proteins into the nucleus. Kap β 2 recognizes a targeting signal named the PY-NLS that lies within its cargos, to target them through the nuclear pore complex. PY-NLSs can be described by a set of rules, which include 1) structural disorder, 2) overall positive charge, and 3) weakly conserved sequence motifs composed of a loose N-terminal hydrophobic or basic motif and a C-terminal RX₂₋₅PY motif. Several Kap β 2 cargos such as core histones H3 and H4 do not seem to contain any recognizable PY-NLSs, and their interactions with the Importin have not been characterized. Previous biochemical studies suggest that the N-terminal tails of H3 and H4 might bind Kap β 2 in a site distinct from the PY-NLS binding site. We are using structural and biochemical analysis of Kap β 2 bound to histone tails to better understand interactions with these atypical Kap β 2 cargos. We show that the histone tails bind with high affinities to the PY-NLS binding site of Kap β 2. Our results reveal a new class of PY-NLS variants that do not contain the P-Y or homologous P- ϕ (where ϕ is a hydrophobic amino acid) motif.

P359**Board Number: B500****Exploring the Complete Spectrum of CRM1 Cargoes.**K. Kirli¹, S. Karaca², H. Urlaub², D. Görlich¹;¹Cellular Logistics, Max Planck Institute for Biophysical Chemistry, Göttingen, Germany, ²Bioanalytical Mass Spectrometry, Max Planck Institute for Biophysical Chemistry, Göttingen, Germany

CRM1 is an essential, highly conserved RanGTPase-driven exportin. It mediates biosynthetic nuclear export, counteracts leakage of cytoplasmic proteins into the nucleus, and mediates many instances of regulated nuclear export. CRM1 recognizes its cargoes through nuclear export signals (NESs), which are 10-15 residues long and contain 4-5 hydrophobic residues (Φ residues) that dock into complementary binding pockets of the exportin. So far, more than 250 CRM1 cargoes have been identified from various species; however, this probably represents just a small fraction of the actual cargo pool. To explore the complete spectrum of CRM1 dependent cargoes, we developed an optimized CRM1 affinity chromatography method. Indeed this strategy revealed hundreds of new CRM1 cargo candidates each from *S. cerevisiae*, *Xenopus laevis* and human cells. These candidates might be the direct CRM1 binders or the associated partners of CRM1 cargoes. Analysis of primary protein structure, in principle, could reveal direct CRM1 cargoes by identifying a functional NES. However, it is still a major challenge to

predict NESs with high sensitivity and accuracy. We now present a new bioinformatics NES prediction method that is based on (i) the recent crystal structures of different NES peptides in complex with CRM1. (ii) It considers new experimental data correlating systematic mutations in NES sequences with export activity and CRM1-binding strength, which suggest that a greater variety of residues are allowed at Φ positions and that the inter Φ spacers impose more constraints than previously thought. (iii) It also considers that functional NESs must be solvent exposed; it thus includes a filtering of initial hits with domain and disorder prediction tools. We validated this prediction tool with already known NESs as controls and also verified cargoes with so far unidentified NESs. With that, we were able to predict NESs of human eIF2 β and *S. pombe* Rna1p, and these predictions perfectly matched subsequent experimental validations.

Nuclear size control depends on spatial information within the cell in *Xenopus laevis* egg extracts.

Y. Hara¹, C.A. Merten¹;

¹EMBL, Heidelberg, Germany

Nuclear size changes dynamically during development and has long been observed to correlate with cell size. However, the underlying molecular mechanisms controlling nuclear scaling have remained largely unknown. Here, we combine an *in vitro* cell-free system of *Xenopus laevis* egg extract with microfluidic devices to systematically analyze the effect of spatial constraints. The speed of nuclear expansion depended on the available space surrounding the nucleus up to a threshold volume in the nanoliter range, herein referred to as the nuclear domain. Under spatial constraints smaller than the size of nuclear domain, the accumulation of membranes around the nucleus was limiting nuclear expansion. Detailed biochemical studies revealed that mechanisms sensing the space are not mainly regulated by simple diffusion of nuclear components, but rather by microtubules accumulating membranes via the motor protein dynein. This mechanism helps understanding how spatial information surrounding the nucleus, like positioning of the nucleus inside the cell, can control the nuclear expansion *in vivo*.

P361**Board Number: B502****Nuclear Import Competence during Differentiation of Multinucleated Skeletal Muscle Cells.**A.A. Cutler¹, J.B. Jackson², G.K. Pavlath³;¹BCDB, Emory University, Atlanta, GA, ²Surgery, Boston University, Boston, MA, ³Pharmacology, Emory University, Atlanta, GA

Skeletal muscle is critical for survival and quality of life. Proper gene expression is essential for myogenesis and maintenance of skeletal muscle. During myogenesis, myoblasts differentiate into myocytes, which fuse to form mature myotubes containing thousands of nuclei. Proteins that regulate gene expression are synthesized in the cytoplasm and cross the nuclear pore to access their targets in the nucleus. To cross the nuclear pore, large proteins must be bound to a nuclear transport receptor, which recognizes a nuclear localization signal (NLS) within the cargo protein. While the mechanism of protein import is well characterized, how nuclear import is regulated in differentiation as muscle cells transition from being mononucleated to multinucleated and how alterations in nuclear import impact gene expression remain unknown. We examined nuclear import in cultured primary murine myotubes using an in vitro nuclear import assay and found that a subset of nuclei were incompetent to import a protein reporter containing the most common NLS, the classical NLS (cNLS). When cNLS import-competence was investigated across myogenesis, we found that, while almost all myoblast nuclei are cNLS import-competent, as myoblasts differentiate into myocytes, only a low percentage of myonuclei are cNLS import-competent. However, as myocytes develop into mature myotubes, cNLS import is restored. Pursuing the mechanism for these differences in import competence we found an overall increase in nuclear glycosylation during myogenesis and variation in the abundance and glycosylation of several nuclear pore proteins. These results suggest that modification of the nuclear pore could be a mechanism for selectively modulating nuclear import in differentiation.

P362**Board Number: B503****Active nuclear transport is disrupted before nuclear envelope breakdown during chemotherapy induced apoptosis in HeLa cells by 5-fluorouracil but not camptothecin and its derivatives.**R. Anderson¹, C. Campbell¹, S. Broskin¹, B. Colosimo¹, K. Resendes¹;¹Biology, Westminster College, New Wilmington, PA

Chemotherapeutic agents are used to activate apoptosis to eliminate cancer cells. The stepwise mechanism they activate involves caspase-regulated breakdown of the nuclear envelope to initiate DNA fragmentation. However, there is conflicting evidence on whether nuclear transport is specifically disrupted before the destruction of the nucleus. In this study, we explored the effects of four

chemotherapeutic drugs, 5-fluorouracil (5-FU), camptothecin, and its derivatives topotecan and irinotecan, on nuclear transport during apoptosis in HeLa cells. These drugs were selected because they activate different mechanisms of apoptosis (5-FU is extrinsic and the others intrinsic) and because 5-FU is often used in combination with the camptothecin derivatives during chemotherapy. The membrane impermeable DNA dye, propidium iodide (PI), was used to determine the timing of apoptotic nuclear envelope breakdown (NEB), which was confirmed by immunofluorescence of nuclear pore proteins. Based on the PI assays functioning nuclear transport was monitored prior to NEB via immunofluorescence of Ran, the major directional regulator of nuclear protein transport, which is normally at high concentrations in the nucleus. We found that 5-FU disrupted nuclear transport before NEB, whereas camptothecin and its derivatives only displayed cytoplasmic mislocalization of the Ran concurrent with NEB. This variation in the targeted disruption of nuclear transport between 5-FU and the camptothecin drugs may stem from a variation in intrinsic versus extrinsic apoptosis. Interestingly, combination of 5-FU with camptothecin did not induce an early disruption of nuclear transport whereas 5-FU with topotecan did in fact disrupt Ran localization before NEB. Future directions will include analysis of the 5-FU and irinotecan combination and investigations into the mechanism behind the variation between targeted disruption of nuclear transport versus maintaining transport until NEB, including profiling the activation of caspases in each scenario. Overall, our results suggest that active nuclear transport may be required in certain mechanisms of apoptosis whereas its disruption may be needed in others. Because regulation of nuclear transport is altered in many cancer types this intriguing new variation in the mechanism of apoptosis could possibly be exploited when determining chemotherapeutic agents in relation to the status of nuclear transport in cancer cells.

Super-resolution microscopy study of the pre-ribosomal subunit nuclear export mechanism.

J. Kelich¹, A. Goryaynov¹, W. Yang¹;

¹Biology, Temple University, Philadelphia, PA

The existence of the nuclear envelope (NE) in eukaryotic cells provides a barrier separating nascent pre-ribosomal subunits assembled in the nucleus from matured subunits functioning to translate proteins in cytoplasm. Nuclear pore complexes (NPCs) act as the sole gatekeeper for large and small pre-ribosomal subunits (pre-60s and pre-40s) exiting the nucleus. Hindered by the diffraction limit and insufficient temporal resolution of conventional light microscopy, the precise transport mechanism including the transport kinetics and the spatial transport routes for both large and small pre-ribosomal subunits through NPCs remains largely unknown. Here we combined an innovative super-resolution single-molecule microscopic approach, termed as single-point edge-excitation sub-diffraction (SPEED) microscopy, with Förster resonance energy transfer (FRET) to obtain real-time single-molecule trajectories as well as the three-dimensional transport pathways for both pre-60s and pre-40s in live HeLa cells. Our results reveal that both pre-ribosomal subunits conduct a fast-slow-fast diffusion pattern

through the three sub-regions of the NPC (nuclear side, central channel, and cytoplasmic side) during their export time of ~14 ms for pre-60S and ~8 ms for pre-40S. Remarkably, approximately two thirds of all NPC-interacting pre-60s and pre-40s subunits successfully exit the nucleus and enter the cytoplasm resulting in much higher transport efficiencies than protein cargos and mRNAs.

Oxidative Stress Disrupts the Ran System Through Reversible Modification of Cysteine Residues in RCC1.

M. Chatterjee^{1,2}, B.M. Paschal^{1,3};

¹Center for Cell Signaling, Univ of Virginia, Charlottesville, VA, ²Cell and Developmental Biology, Univ of Virginia, Charlottesville, VA, ³Biochemistry and Molecular Genetics, Univ of Virginia, Charlottesville, VA

The small GTPase Ran acts as a key regulator of nucleocytoplasmic transport within the nucleus by promoting import complex disassembly and export complex assembly. Both reactions result in nuclear export of Ran, which is re-imported into the nucleus via a dedicated receptor NTF2. Ran, therefore, undergoes rapid and continuous shuttling between the nucleus and cytoplasm. Ran displays a steady state distribution that is ~3-fold higher in the nucleus, which we refer to as the Ran protein gradient. Here, we describe biochemical approaches used to uncover a mechanism for how oxidative stress disrupts the Ran gradient. Treating cells with the thiol oxidant diamide results in disruption of the Ran protein gradient (p

Intranuclear trafficking and export of single ribosomal subunits in mammalian cells.

L. Büttner¹, J.P. Siebrasse¹, C. Montellese², U. Kutay², U. Kubitscheck¹;

¹Institute for Physical and Theoretical Chemistry, Rheinische Friedrich-Wilhelms-University, Bonn, Germany, ²Institute of Biochemistry, ETH Zürich, Zürich, Switzerland

In eukaryotes, the assembly of ribosomes requires more than 200 RNA and protein cofactors. The exact role of many of these factors is not fully understood. Also, the dynamics of the ribosomal subunit synthesis and their complex intracellular processing, e.g. the intranuclear transport and export process of single subunits is largely unknown. The major difficulty to study these questions is the visualization of ribosomal subunits without interfering with their native behavior. Recently, we established a protein-based mRNA-labeling approach using an endogenous mRNA binding protein in the salivary gland cells of *Chironomus tentans* [1]. Now, we used a similar approach to fluorescently label ribosomal subunits in mammalian cells. Here we use Dim2/Pno1, a protein known to bind cotranscriptionally to the pre-40S-rRNA and to remain bound to it during maturation and export [2]. We created stable cell lines

expressing either Dim2-eGFP or -Snap fusion proteins under control of a tetracycline-repressor. For labeling the nuclear envelope we microinjected fluorescent NTF2, a transport factor being enriched at nuclear pores. Very sparse fluorescence labelling of the Snap-Tag was performed using nanomolar concentrations of SiR-Snap [3], what allowed extended intracellular visualization and tracking of single Dim2 and Dim2-labelled ribosomal subunits. The trajectories of single native ribosomal subunits could conveniently be followed using fast and sensitive fluorescence microscopy with HILO illumination. Since Dim2 accompanies the rRNA from the transcription site to the cytoplasm the route of transport, including the NPC passage, could directly be monitored in living cells with high space and time resolution. We found that the particles remained bound in the nucleolus for extended time periods before they diffused rapidly through the nucleoplasm and were exported across the nuclear envelope. Binding durations, diffusion constants and translocation times could quantitatively be determined.

Disordered Proteins Break the Size-Exclusion Rule of Nucleocytoplasmic Transport.

S.J. Schnell¹;

¹Biology, Temple University, Philadelphia, PA

Many intrinsically disordered proteins (IDPs) carry out important biologic functions in the nucleus; the selective mechanism of nucleocytoplasmic transport for IDPs is critical but not well understood. In this study we employed single-point edge excitation sub-diffraction microscopy to determine the transport kinetics and three-dimensional spatial transport routes for multiple natively unfolded endogenous proteins through the nuclear pore complex (NPC). Strikingly, the size criterion working for the nucleocytoplasmic transport of folded protein is not followed by IDPs; instead, the ratios between charged and hydrophobic amino acids in IDPs are the key criterion in the selectivity of NPC for IDPs.

P367**Board Number: B508****Molecular Determinants for mRNA remodeling at the Nuclear Pore Complex.**R.L. Adams¹, S.R. Wente¹;¹Vanderbilt University Medical Center, Nashville, TN

Eukaryotic mRNA is exported from the nucleus as a ribonucleoprotein particle (mRNP) coated with associated RNA binding proteins. Some of these factors assemble co-transcriptionally and dictate mRNA localization, function, and stability after export. Others are required specifically for export through nuclear pore complexes (NPCs) and are removed during mRNP remodeling by the action of the DEAD-box ATPase Dbp5 and its activating cofactor Gle1. The mechanism for remodeling specificity, by which certain RNA binding proteins in the mRNP are targeted for remodeling, has not been fully defined. In *S. cerevisiae*, the conserved NPC components Nup159 (human NUP214) and Nup42 (hCG1) are asymmetrically localized to the cytoplasmic face and both contain a phenylalanine-glycine (FG) repeat domain that binds mRNP transport receptors. In addition, Nup159 has a separate domain for Dbp5 docking, and Nup42 interacts with Gle1. We speculated that the Nup42 and Nup159 FG domains function to position the mRNPs for the terminal mRNP remodeling steps carried out by Dbp5. Indeed, deletion (Δ) of both the Nup42 and Nup159 FG domains resulted in a cold-sensitive poly(A)+ mRNA export defect. Furthermore, the *nup42 Δ FG nup159 Δ FG* mutant had synthetic lethal genetic interactions with *dbp5* and *gle1* mutants and a reduced capacity for mRNP remodeling during export. To further analyze the FG domain roles, we replaced the Nup159 or Nup42 FG domains with those from other Nups. These FG “swap” constructs differentially rescued the synthetic lethal *rat8-2 (dbp5) nup42 Δ FG nup159 Δ FG* triple mutant. Thus, only certain FG domains are functional at the NPC cytoplasmic face, providing key evidence that FG character and context play a direct role in FG domain function and mRNA export. Strikingly, fusing the Nup42 FG domain to the carboxy-terminus of Gle1 bypassed the need for the endogenous Nup42 FG domain, highlighting the importance of proximal positioning for these factors. We conclude that the Nup42 and Nup159 FG domains target specific proteins in the mRNP for remodeling by Dbp5 at the NPC. Our ongoing studies are further examining the molecular determinants for directional mRNA export through the NPC with an aim to determine the sequence of interactions between Nup159, Nup42, Gle1, Dbp5, and the mRNP.

P368**Board Number: B509****Roles of nuclear filamentous-actin in transcriptional regulation.**S. Yamazaki¹, K. Yamamoto¹, K. Sakata-Sogawa^{2,3}, M. Tokunaga^{2,3}, M. Harata¹;¹Graduate School of Agricultural Science, Tohoku University, Sendai, Miyagi, Japan, ²Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology, Yokohama, Kanagawa, Japan, ³Center for Integrative Medical Sciences, RIKEN, Yokohama, Kanagawa, Japan

In the cytoplasm, actin function is an integral component of the cytoskeleton, which plays crucial roles in a variety of cell functions. It has been revealed that actin exists also in the nucleus. However, the function and properties of nuclear actin remain elusive. Recently, we showed that actin tagged with EYFP fused with a nuclear localization signal (EYFP-NLS-actin) formed visible filamentous (F)-actin bundles in a small portion of cells, indicating the potential of actin to form filamentous architecture in the nucleus [1]. Moreover, we found that nuclear F-actin enhances general transcription. To obtain more detail about individual genes affected by nuclear actin, we applied microarray analysis using EYFP-NLS-actin expressing HeLa cells and showed that nuclear F-actin induces the expression of transcription factor genes including *OCT4* [2]. Together with a previous observation that nuclear F-actin activated *Oct4* in *Xenopus* oocytes [3], this observation suggests that this activation process is conserved in vertebrates and among cell types. To pursue mechanisms of transcription activation by nuclear F-actin, we analyzed the relationship between nuclear actin and β -catenin, which is the central transcription factor in the Wnt signaling pathway and has a role in *OCT4* transcription. Interestingly, nuclear accumulation of β -catenin was observed in HeLa cells expressing EYFP-NLS-actin, suggesting a role for nuclear F-actin in tethering β -catenin near chromatin. A luciferase reporter assay showed that the accumulation of F-actin in the nucleus enhances Wnt/ β -catenin signaling activity. These observations imply important roles of nuclear F-actin in transcriptional regulation.

P369**Board Number: B510****Nucleocytoplasmic relocation of actin in cell differentiation.**K. Yamamoto¹, S. Yamazaki¹, K. Sakata-Sogawa^{2,3}, M. Tokunaga^{2,3}, M. Harata¹;¹Graduate School of Agricultural Science, Tohoku University, Sendai, Miyagi, Japan, ²Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology, Yokohama, Kanagawa, Japan, ³Center for Integrative Medical Sciences, RIKEN, Yokohama, Kanagawa, Japan

Actin is involved in the regulation of multiple cytoplasmic functions, including cell motility, division and morphological changes. In addition, recent studies revealed that actin plays roles in epigenetic regulation. The nuclear function of actin is partly achieved by the inclusion of G-actin into chromatin remodeling complexes together with actin-related proteins (Arps). In addition, it is hypothesized that the formation of nuclear filamentous-actin (F-actin) affects functional nuclear organization. To analyze the involvement of nuclear actin in cell differentiation, we have investigated the human keratinocyte HaCaT cell line. Cell differentiation of HaCaT cells is induced with Ca^{2+} , and the progression of cell differentiation was observed by monitoring the expression level of Keratin10. When EYFP-actin or Lifeact, a probe which specifically binds to F-actin, was transfected into HaCaT cells, a transient increase of nuclear actin was observed according to the progression of cell differentiation. To induce an artificial decrease in nuclear actin, we applied Jasplakinolide, an inducer of actin polymerization. Jasplakinolide treatment reduces the G-actin pool in the cytoplasm through F-actin formation, and as a result, import of G-actin into the nucleus is reduced. The Jasplakinolide treatment repressed the differentiation of HaCaT cells, supporting the idea that accumulation of nuclear actin is required for cell differentiation. We hypothesized that one potential role for nuclear actin is in tethering β -catenin, a molecule central to Wnt signaling near chromatin via F-actin. Microscope observations showed that nuclear β -catenin is increased in HaCaT cells expressing EYFP-actin tagged with a nuclear localization signal and that nuclear F-actin is co-localized with β -catenin. These results imply that nuclear actin is involved in cell differentiation, at least, partly through affecting Wnt/ β -catenin signaling.

Altered Clathrin Dependent and Independent Endocytosis in Lysosomal Storage Disease Cells and Therapeutic Rescue by Storage Attenuation.

J. Rappaport¹, S. Muro^{1,2}, C. Garnacho³;

¹Fischell Department of Bioengineering, University of Maryland, College Park, MD, ²Institute for Bioscience and Biotechnology Research, University of Maryland, College Park, MD, ³Department of Histology and Cytology, University of Seville School of Medicine, Seville, Spain

Endocytosis and endo-lysosomal trafficking of extracellular materials and plasmalemma components regulate a plethora of biological functions. Yet, whether disease disrupts these processes remains largely unexplored. An example is that of lysosomal storage diseases (LSDs), a group of 50 genetic conditions where lysosomal enzyme deficiency causes accumulation of undegraded substances, with potential to affect endocytosis. Using fluorescence microscopy, we examined fluid-phase and ligand endocytosis via clathrin, caveolae, and macropinocytic pathways. We compared wild-type fibroblasts to those of patients with type A Niemann-Pick (NPD), type C Niemann-Pick (NPC), Gaucher, and Fabry diseases, characterized by different protein deficiencies and accumulated substrates. First, using NPD we observed altered distribution of clathrin heavy-chain and caveolin-1 toward the perinuclear region (clathrin: 85% vs. 36% in wild-type, caveolin-1: 88% vs. 28% in wild-type), and poor co-localization of these markers with transferrin (17% vs. 63% co-localization in wild-type; 1 hr) and cholera toxin B (CTB; 8% vs. 76% co-localization in wild-type). Uptake of both ligands was significantly reduced: 76% and 71% reduction in transferrin- and CTB-positive endosomes, and 20% and 35% reduced uptake rate. Bulk pinocytosis, visualized using Texas Red dextran, was decreased by 40%, and the use of single or combination pharmacological inhibitors confirmed a decreased fluid-phase uptake via both clathrin and caveolar pathways. EGF-induced macropinocytosis was also affected (67% of wild-type). Imipramine induction of lysosomal storage in wild-type fibroblasts altered endocytosis similarly to genetic NPD, and pharmacological removal of storage in NPD cells restored uptake. This suggests that lysosomal storage causes reduced endocytosis. Indeed, examination of fibroblasts from other LSDs (NPC, Gaucher, and Fabry diseases) confirmed reduced uptake via clathrin dependent (77%, 88%, and 76% reduction) and independent (68%, 43%, and 51% reduction) pathways. As a result, endocytosis of a recombinant lysosomal enzyme (NPD acid sphingomyelinase) aimed at replacement therapy, which relies on the clathrin-dependent mannose-6-phosphate receptor, was 10-fold lower as compared to enzyme delivery via drug carriers targeted to ICAM-1, known to bypass classical endocytic routes. The uptake of free enzyme vs. carrier-coupled enzyme correlated well with the reduction of lysosomal storage (3.3- vs. 1.4-fold of wild-type), and the carriers led to recovery of endocytic function (71% recovery of clathrin-mediated uptake and 150% of caveolae-mediated uptake). Endocytic behavior can differ dramatically in healthy vs. pathological conditions and this knowledge can guide the design of therapeutic interventions.

P371**Board Number: B513****Characterizing Novel Sla1-Associated Mechanisms in Clathrin Mediated Endocytosis.**T.O. Tolsma¹, S.M. Di Pietro¹;¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Clathrin mediated endocytosis is an essential cellular process used by all eukaryotes. Its many roles include the uptake of extracellular nutrients, manipulation of plasma membrane composition, and regulation of signal transduction pathways. With such a high degree of necessity, it is understandable why various disorders have been linked to the mutation of proteins involved in clathrin mediated endocytosis, including hypercholesterolemia and Alzheimer's. The process begins with the initial recruitment of specialized adaptors and early endocytic proteins to the plasma membrane. Here they aggregate through the binding of membrane proteins, receptors, and/or lipids, to establish the site of endocytosis. Clathrin, the defining component of the process, is incapable of binding membrane receptors or lipids, and requires adaptor proteins for its sequential recruitment. Next, the plasma membrane will invaginate, and a clathrin lattice will form around the lipid surface until scission occurs, and a protein coated vesicle is released into the cytoplasm. While the basic process of clathrin mediated endocytosis has been well documented, little is known about the regulatory mechanisms that control clathrin recruitment and coat formation at the plasma membrane. Since clathrin not only acts as a scaffold for the recruitment and function of various endocytic proteins, but is also believed to be an important contributor of vesicle formation and structure, identifying mechanisms that contribute to its recruitment is necessary in generating a proper understanding of clathrin mediated endocytosis.

Previously, our lab established Sla1 as the first clathrin adaptor to contain a sterile alpha motif, or SAM domain, with a role in endocytosis. Oligomerization of Sla1 through its SAM domain resembles other SAM domain proteins, but the ability to regulate its own clathrin binding was a novel function of Sla1. Our current work demonstrates a role for Sla1 in clathrin recruitment and/or coat formation. This is based on fluorescent confocal microscopy imaging of Sla1-GFP and the RFP tagged clathrin heavy chain subunit, as well as immunoblotting for clathrin in membrane and cytosol fractions of cells with mutation to the clathrin binding domain of Sla1. Furthermore, imaging of Sla1-GFP with various RFP tagged endocytic protein markers indicated a role for Sla1-Clathrin binding in normal protein dynamics, and progression of late stage mechanisms in endocytosis. In these experiments the levels of RFP tagged proteins at endocytic sites was also significantly higher, possibly indicating a compensatory mechanism resulting from defective Sla1-Clathrin binding. The goal of this project is to further our understanding of the functional role Sla1-Clathrin binding plays in endocytosis.

P372**Board Number: B514****The role of ligand size and receptor engagement density on ceramide-dependent, clathrin- and caveolae-independent endocytosis via the CAM-mediated pathway.**D. Serrano¹, E. Paul², S. Muro^{2,3};¹Biological Sciences Graduate Program, University of Maryland, College Park, MD, ²Fischell Department of Bioengineering, University of Maryland, College Park, MD, ³Institute for Bioscience and Biotechnology Research, University of Maryland, College Park, MD

Eukaryotic cells display endocytic pathways associated with uptake of multivalent ligands that can vary in size and density of receptor engagement, relevant to both their biology and translational applications. Yet, the role of these parameters in endocytosis remains relatively unexplored. We have previously described the clathrin- and caveolae-independent cell adhesion molecule (CAM)-mediated pathway, through which cells internalize natural (pathogens) and artificial (drug carriers) particle-ligands 0.1-10 μm in diameter, allowing for the systematic study of these parameters. This pathway is induced by multivalent binding to intercellular adhesion molecule 1 (ICAM-1), which recruits Na⁺/H⁺ exchanger 1 (NHE1) and acid sphingomyelinase (ASM) to binding sites. Concerted NHE1/ASM activity renders ceramide production, responsible for the size flexibility of CAM-mediated endocytosis. Here, we examined this pathway as a model to explore the role of ligand size and receptor engagement density in endocytosis. We used polystyrene particles 0.2, 1, or 4.5 μm in diameter coated with varying densities of anti-ICAM to determine binding, uptake, and ceramide enrichment using endothelial cells and fluorescence microscopy. The larger the particle, the lower the number of particles bound per cell ($\approx 100, 25, 15$; 30 min). Yet, with time (24 h), total binding reached the same total cell-surface area occupancy ($\approx 400 \mu\text{m}^2$), coinciding with saturation of available ICAM-1 molecules. Initially, particles of 0.2 and 1 μm exhibited more efficient uptake than 4.5 μm particles (70% vs. 30% uptake; 30 min), but a similar total uptake was found at saturation (90%; 24 h). Micron-sized particles elicited higher ceramide enrichment than nanometer-sized counterparts (5- vs. 2-fold over background levels). Since larger particles internalized more slowly, this suggests that larger particles require higher ceramide production for uptake. Linear regression showed that ceramide generation correlated well with density of ICAM-1 engagement of these particles. Hence, receptor signaling rendering ceramide enrichment depends on the density of receptor engagement of each individual particle, regardless of the total number of particles bound per cell. Indeed, particles with the same size but different anti-ICAM densities showed that higher ICAM-1 engagement density, accompanied with higher ceramide enrichment, elicited more efficient uptake. Overall, this work suggests that ceramide enrichment, which can be modulated by changing receptor engagement density, affects endocytosis in a size-dependent manner. This information will be valuable in the design of particles for intracellular drug delivery and may also help elucidate the ceramide-dependent endocytic mechanisms of natural p

P373**Board Number: B515****Constitutive Endocytosis and Endocytic Recycling of the Sodium-dependent Vitamin C transporter 2 (SVCT2) are regulated by ascorbic acid in a Clathrin and Rab11-dependent manner.**A.D. Covarrubias-Pinto¹, E. Papic², P. Burgos³, M.A. Castro²;¹I. Bioquímica, Universidad Austral De Chile, Valdivia, Chile, ²Universidad Austral De Chile, Valdivia, Chile,³Department of Fisiology, Universidad Austral De Chile, Valdivia, Chile

Ascorbic acid is an essential antioxidant molecule in the physiology of the brain and other organs. It is transported into the brain and neurons via the Sodium-dependent Vitamin C Transporter-2 (SVCT2). During synaptic activity ascorbic acid is released from glial reservoirs to extracellular space. Results from our laboratory have demonstrated that SVCT2 is continuously cycling to and from plasma membrane. An increase in extracellular ascorbic acid is able to induce an increase in SVCT2 localization at the plasma membrane. However the endocytic recycling mechanisms that regulate the surface expression of SVCT2 are still unknown. Methods and Results: Using HEK293T cells expressing endogenous SVCT2 we evaluated SVCT2 trafficking in presence of ascorbic acid. Immunofluorescence analyses and biotinylation assays showed an increase in surface levels of SVCT2 in cells exposed to extracellular ascorbic acid. No changes in total protein levels were observed. Inhibition of Clathrin-mediated endocytosis by K⁺ depletion showed an increase of SVCT2 levels at the cell surface. The expression of SVCT2 at the plasma membrane was increased in cells overexpressing a dominant negative Dynamin II (K44A). Dynamin is involved in Clathrin-dependent and independent endocytosis. Therefore, we evaluated surface expression of SVCT2 using Clathrin endocytosis inhibitors (cells overexpressing AP180 or dominant negative mutants of Eps15) which resulted in increased levels of SVCT2 at the plasma membrane. Finally, dominant negative versions of Rab5 or Rab11 abolished the ascorbic acid-induced increase of SVCT2 at the cell surface. Discussion: Our results revealed that the ascorbic acid-induced increase in plasma membrane SVCT2 is regulated by Clathrin and Rab11 dependent mechanisms. Epsin is an evolutionarily conserved endocytic clathrin adaptor, which is encoded by three different genes (*EPN1*, *EPN2* and *EPN3*) in mammals. Both housekeeping roles in clathrin-mediated endocytosis and a specific role in the clathrin-dependent internalization of ubiquitinated cargos have been attributed to epsin. However, its most critical function(s) in metazoan cells remain(s) elusive. To elucidate such function(s), we generated embryonic fibroblasts from conditional epsin triple knock out (TKO) mice. These cells displayed a dramatic increase in cell size and in the number and/or size of nuclei, demonstrating a role of epsin in cell division, as previously reported for other endocytic factors including clathrin. Additionally, a global defect in clathrin-mediated endocytosis with the accumulation of shallow and U-shaped pits was observed in TKO cells, supporting a role of epsin in clathrin coat invagination. These changes correlated with the accumulation of actin foci at the cell surface, typically in close proximity of arrested coated pits. A similar actin defect was previously observed in Hip1R knockdown cells. Accordingly, we found that Hip1R, a factor known to directly link the clathrin coat to actin, was no longer recruited to endocytic clathrin coated pits both in intact cells and in a cell free system. We also found that the ENTH domain of epsin binds Hip1R, while its unfolded "tail" binds actin directly. These findings, which point to a role of epsin in providing a link between endocytic clathrin coats and actin leading to deep invagination, reconcile observations on epsin function previously made in yeast and dictyostelium, with the function of epsin in metazoan cells. Finally, we report here a low affinity interaction, but potentiated by the presence of PI(4,5)P₂, between the SNARE motif of synaptobrevin2/VAMP2 and the ENTH domain of epsin. Such interaction, which is conserved from yeast to mammals, may help couple clathrin coat nucleation to incorporation of a SNARE in the nascent bud. Collectively, our results demonstrate a housekeeping role of epsin in clathrin-mediated endocytosis, in addition to cargo specific functions as suggested by previous studies. A key function of this protein is to help generate the force that leads to the invagination of clathrin coated pits as a premise to their fission.

P375**Board Number: B517****Investigating new protein components of the endocytic machinery in *Saccharomyces cerevisiae*.**K. Farrell¹, S.M. Di Pietro¹;¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Clathrin-mediated endocytosis is an important process which allows cells to control membrane lipid and protein content, signaling processes, and uptake of nutrients among other functions. The around 60 known proteins that compose the endocytic machinery in *Saccharomyces cerevisiae*, or budding yeast, have been identified and investigated by taking advantage of the ease of genetic manipulations and two-color fluorescent microscopy in this model organism. Clathrin-mediated endocytosis is highly conserved between yeast and mammals in terms of both protein content and precise timing of protein arrival. First in the endocytic process, there is an immobile phase in which clathrin and other coat components concentrate at endocytic sites. Second, another wave of proteins, such as adaptor protein Sla1, assembles about 20 seconds before actin polymerization. Third, a fast mobile stage of endocytosis occurs coinciding with actin polymerization and culminates with vesicle scission. Fourth, most coat proteins disassemble from the internalized vesicle. Despite the knowledge of so many endocytic proteins, gaps still remain in the complete understanding of the endocytic process. We attempt to fill some of these gaps with a screen of the yeast GFP library for novel endocytic-related proteins. The screen was performed with still and time lapse images using confocal microscopy. We identified proteins colocalizing with RFP-tagged Sla1, an adaptor protein present at all sites of clathrin-mediated endocytosis. Use of the GFP library will reveal proteins that have not previously been identified in knockout screenings due to viability issues or do not show an endocytic defect due to redundancy of protein function. Our screen revealed eight potential novel endocytic proteins that are currently uncharacterized. Ubx3, an unstudied protein, was selected first for further investigation based on high degree of colocalization with Sla1. Ubx3 contains a UBX domain that is structurally similar to ubiquitin, which plays multiple roles in the endocytic process. Ubx3 shows fluorescent patch dynamics similar to an endocytic coat protein. Ubx3 binds clathrin and is dependent on clathrin for patch lifetime. A knockout strain of Ubx3 displays a small but significant reduction in bulk endocytosis by Lucifer Yellow and Mup1 assays. The Ubx3 knockout also shows a significant increase in lifetime of early endocytic protein Ede1, possibly accounting for the defect in internalization. Thus, we have identified a novel component of endocytic machinery by screening the yeast GFP library.

P376**Board Number: B518****The α -arrestin ARRDC3 regulates ALIX-mediated GPCR lysosomal sorting.**M. Does¹, H. Lin¹, H. Buck¹, F. Mendez¹, J. Trejo¹;¹Pharmacology, University of California, San Diego, La Jolla, CA

G protein-coupled receptors (GPCRs) represent the largest family of transmembrane signaling receptors expressed in mammals, and lysosomal degradation of GPCRs serves to attenuate receptor signaling and desensitize cells to persistent activation. GPCR lysosomal sorting defects cause aberrant cellular responses that contribute to many diseases, including chronic inflammation and cancer metastasis. Given the diversity of GPCRs, multiple pathways exist to sort different receptors into lysosomal compartments. We have discovered a subset of GPCRs that are targeted to lysosomes by an intracellular loop 2 localized YPX_nL (where X is any amino acid) motif that are bound by the ESCRT adaptor protein ALIX. This class of GPCRs includes the purinergic receptor P2Y₁ and protease-activated receptor-1 (PAR1), the GPCR for thrombin. To investigate how ALIX-mediated GPCR lysosomal sorting is regulated, we assayed ALIX-interacting proteins for their role in YPX_nL GPCR degradation. Here, we demonstrate that the human alpha-arrestin ARRDC3 regulates ALIX-mediated lysosomal sorting of PAR1 by modulating ALIX endosomal sorting activity. ARRDC3 interacts with PAR1 and colocalizes with both PAR1 and ALIX at endosomes. ARRDC3 is required for PAR1 degradation, but not for the degradation of ubiquitinated signaling receptors. Depletion of ARRDC3 inhibits ALIX interaction with PAR1 and CHMP4, a subunit of ESCRT-III, which facilitates cargo sorting into late endosomes/lysosomes. ARRDC3 is also required for ALIX ubiquitination, a possible mechanism for regulating ALIX function at late endosomes. ARRDC3 interacts with multiple members of the Nedd4 E3 ubiquitin ligase family and may serve as an adaptor for ALIX ubiquitination. An siRNA screen of all nine human Nedd4 ligases revealed a specific function for WWP2 in the degradation of PAR1. This study reveals a novel role for alpha-arrestins and the E3 ligase WWP2 in the endosomal trafficking of non-ubiquitinated GPCRs through the regulation of the adaptor protein ALIX during lysosomal sorting.

P377**Board Number: B519****Analysis of the endocytic recycling compartment with super-resolution microscopy.**S. Xie¹, N. . Naslavsky¹, S. Caplan¹;¹Univ Nebraska Med Ctr, Omaha, NE

Endocytic recycling and endocytosis are coordinated to regulate the equilibrium of protein and lipids on the plasma membrane. Recycling occurs either directly (fast recycling), or via an organelle known as the endocytic recycling compartment (ERC). The composition of the ERC is poorly understood and is typically described as a series of tubular-vesicular membrane-bound organelles localized to the peri-nuclear region of the cell. Prominent ERC proteins include the small GTPases Rab11 and Rab8, Molecule

Interacting with Cas1-Like protein 1 (MICAL-L1), motor proteins such as Myosin Vb and KIF13a, and other regulators of recycling endosomes such as the C-terminal Eps 15 Homology Domain (EHD) proteins. Our understanding of endocytic recycling is influenced significantly by studies on transferrin, a protein internalized through clathrin-dependent endocytosis. After internalization, transferrin is sorted to Rab11-enriched recycling endosomes at the ERC and recycled to the plasma membrane in a Myosin Vb-dependent manner. However, the sorting and recycling of clathrin-independent cargos such as Major Histocompatibility Complex Class I (MHC I) and the glycosylphosphatidylinositol-anchored protein, CD59 remains ill-defined. We show that transferrin highly colocalizes with over-expressed Myosin Vb tail in the peri-nuclear area and its recycling is delayed. Using Structured Illumination Microscopy (SIM), we discovered that MHC I, CD59 and CD98 are unaffected by the overexpression of GFP-Myosin Vb tail. Moreover, although transferrin and CD59 appear to be sorted to the same peri-nuclear region, SIM analysis shows that they reside on distinct vesicles within the ERC, in close proximity with one another. Further studies on the molecular architecture and sorting of recycling endosomes will be performed with SIM- and Photoactivated Localization Microscopy (PALM)-based analysis of the key players of the recycling system. These include Rab11, MICAL-L1, EHD1, Myosin Vb and KIF13a. These data, combined with the kinetic analysis of the recycling of different cargos, will provide an in-depth understanding of the ERC, and novel insight into ERC biogenesis and function.

Macropinocytosis as a model for tracking clathrin-independent cargo sorting in space and time.

C.D. Williamson¹, J.G. Donaldson¹;

¹Cell Biology and Physiology Center, NHLBI/NIH, Bethesda, MD

After internalization by clathrin-independent endocytosis (CIE), incoming endosomes fuse to form a sorting endosome where cargo proteins are sorted for targeting to lysosomes for degradation or for recycling back to the PM. Our lab has identified CIE cargo proteins (CD44, CD98, and CD147) that contain cytosolic acidic motifs, allowing them to interact with the Hook1 adaptor protein and be rapidly recycled back to the plasma membrane via recycling tubules. Other CIE cargo proteins such as MHC Class I (MHCI) and the GPI-anchored protein CD59 remain within the sorting endosome as it matures and can then be directed into MVBs and late endosomes for degradation, or delivered back to the plasma membrane via the juxtannuclear endocytic recycling compartment. In HeLa cells, sorting of these two types of cargo proteins can be detected by colocalization of the proteins with EEA1, the kinetics of protein entry into recycling tubules, or the reappearance of endocytosed proteins back at the plasma membrane. The differential sorting of CD44, CD98 and CD147 allows these proteins to recycle to the PM directly and avoid degradation in lysosomes, making them long-lived proteins. In order to visualize cargo sorting in real-time we turned to a stimulated form of CIE, macropinocytosis, which enables cargo sorting to be captured on individual macropinosomes as they mature. The HT1080 fibrosarcoma cell line exhibits constitutive macropinocytosis due to expression of an activated form of N-Ras. We found that CD98 and

CD59 enter cells on actin and PI(3,4,5)P₃ coated macropinosomes newly formed in the lamellar region of HT1080s. After formation, these macropinosomes are pushed up against an actin barrier at the base of the lamella. Loss of actin from both the macropinosome and the base of the lamella is observed, followed by a deformation of the macropinosome as it squeezes through the barrier. Subsequent acquisition of Rab5 on the macropinosome is quickly followed by fusion with other macropinosomes and transient association of the Rab5 adaptor protein APPL1. This allows the sorting of CD98 into puncta and small tubules that emanate from the macropinosome, leaving CD59 behind. Thus, discrete cargo sorting events can be visualized by live cell microscopy in HT1080 cells, and are often captured on Rab5-positive endosomes containing either APPL1 or Hook1 proteins. This HT1080 model system compliments our current understanding of CIE protein sorting in HeLa cells, and uniquely augments our ability to visualize and investigate the mechanisms involved in endosomal cargo sorting.

Membrane raft association is a determinant of plasma membrane localization.

B. Diaz-Rohrer¹, K. Levental¹, I. Levental^{1,2};

¹Integrative Biology and Pharmacology, The University of Texas Health Science Center at Houston, Houston, TX, ²Cancer Prevention and Research Institute of Texas, Austin, TX

The organization of metazoan membranes into functional domains is a key feature of their physiology. The lipid raft hypothesis proposes lateral domains driven by preferential interactions between sterols, sphingolipids, and specific proteins as a central mechanism for the regulation of membrane structure and function; however, experimental limitations in defining raft composition and properties have prevented unequivocal demonstration of their function. In this study we establish a functional relationship between raft association and subcellular protein sorting. To quantify raft association in intact plasma membranes without detergent perturbation, we isolated Giant Plasma Membrane Vesicles (GPMVs) from cultured mast cells. These GPMVs separate into coexisting raft and non-raft phases, as defined by physical properties and lipid/protein compositions. This system provides an ideal model to microscopically analyze the structural determinants and functional consequences of protein association with membrane domains. By systematic mutation of the transmembrane and juxtamembrane domains of an integral single pass plasma membrane protein, linker for activation of T-cells (LAT), we generated a panel of variants possessing a range of raft affinities. These mutations revealed palmitoylation, transmembrane domain length, and transmembrane sequence to be critical and independent determinants of membrane raft association. Having identified the structural features determining raft association, we used our panel of mutants to establish a quantitative, functional relationship between raft association and subcellular protein sorting. We observed that plasma membrane (PM) localization was strictly dependent on raft partitioning across the entire panel of unrelated mutants, suggesting that raft association is necessary and sufficient for PM sorting of LAT. The specific defect in PM sorting was a failure to recycle non-raft variants from early endosomes, with abrogation of raft partitioning leading to mistargeting to late endosomes/lysosomes and subsequent degradation. Finally, we confirmed that

these observations are not specific to LAT, but are general to at least the three other unrelated single-pass transmembrane proteins. These findings identify structural determinants of raft association and validate lipid-driven domain formation as a mechanism for protein sorting in the endosomal system.

The role of the ubiquitin E2 conjugating enzyme UbcH5c on trafficking of the G protein-coupled receptor CXCR4.

J. Holleman¹, A. Marchese¹;

¹Pharmacology, Loyola University Chicago, Maywood, IL

G protein coupled receptors (GPCRs) belong to a superfamily of signaling receptors that mediate the cellular responses of most hormones and neurotransmitters. Dysregulated GPCR signaling is associated with several pathologies and GPCRs are often targeted clinically to treat a variety of diseases. The molecular mechanisms regulating GPCR signaling are complex and occur at multiple steps of the signal transduction cascade. In particular, direct modification of GPCRs by post-translational modifications such as phosphorylation and ubiquitination help to ensure that signaling is of the appropriate magnitude and duration. One function of these modifications is to promote receptor endocytosis and lysosomal targeting leading to GPCR degradation and long-term attenuation of signaling. For example, agonist-dependent ubiquitination of the chemokine receptor CXCR4, a prototypical GPCR, leads to its lysosomal sorting and degradation. However, the mechanisms regulating CXCR4 lysosomal sorting remain poorly understood. CXCR4 is targeted to lysosomes via the endosomal sorting complex required for transport (ESCRT) pathway. We have recently shown that ubiquitination of ESCRTs is important in regulating CXCR4 lysosomal degradation. In particular, the ubiquitination status of ESCRT-0 subunits HRS and STAM1 is regulated by two E3 ubiquitin ligases: atrophin-1 interacting protein 4 (AIP4) and deltex-3L (DTX3L). DTX3L interacts with AIP4 *in vitro* and inhibits the auto-ligase activity of AIP4. Our data suggest that ubiquitination of ESCRT-0 inhibits its sorting activity, which regulates the amount of CXCR4 targeted for lysosomal degradation. However, the precise interplay by which AIP4 and DTX3L operate to regulate ubiquitination of ESCRT-0 remains poorly understood. To explore this further, here we focused on the ubiquitin E2 conjugating enzymes that operate with DTX3L and AIP4 in cellular ubiquitination assays. AIP4 has been shown to operate with E2 enzymes UbcH5c and UbcH7, while DTX3L appears to selectively function with UbcH5c in ubiquitination reactions. Using several biochemical and immunochemical techniques including fixed cell confocal immunofluorescence microscopy coupled with *in vitro* ubiquitination assays, we sought to determine the role of the E2 enzymes in CXCR4 trafficking. We show that depletion of UbcH5c by siRNA in HeLa cells, but not its closely related isoforms UbcH5a or UbcH5b, attenuates agonist promoted degradation of CXCR4. UbcH5c depletion prevents CXCR4 trafficking from early endosomes to lysosomes, thereby, preventing CXCR4 from being degraded in the lysosome. In addition, endogenous UbcH5c colocalizes with DTX3L on the surface of early endosomes. Based on these data we hypothesize that UbcH5c operates with AIP4 and DTX3L to regulate the extent

of CXCR4 sorting into the degradative pathway. Thus, we have defined a novel role for UbcH5c in GPCR endosomal sorting.

Cortical microtubule capture machinery contributes to the yeast clathrin-independent endocytic pathway.

D.C. Prosser¹, B. Wendland¹;

¹Department of Biology, Johns Hopkins University, Baltimore, MD

Although most cell types use both clathrin-mediated (CME) and clathrin-independent (CIE) endocytic pathways, yeast have been thought to rely solely upon CME for internalization of plasma membrane cargo. We recently uncovered a second endocytic pathway in yeast that acts independently of clathrin and CME machinery, and instead relies on the small GTPase Rho1 and its effector, the formin Bni1. To date, all proteins with an identified role in the CIE pathway do not localize to the cortical actin patches that are known sites of CME, suggesting that CME and CIE occur at distinct sites. However, the mechanism by which CIE occurs in yeast is currently unclear. Here, we show that Bni1 and Spa2, a polarisome protein involved in CIE, form dynamic, short-lived patches at the cell cortex that are distinct from CME machinery proteins such as the early-coat factor Ede1 and the actin module component Abp1. Notably, several proteins implicated in CIE, including Bni1 and the polarity protein Bud6, are also linked to cortical capture of cytoplasmic microtubules. Depolymerization of microtubules with nocodazole and deletion of additional proteins involved in cortical microtubule capture inhibited the CIE pathway. Furthermore, mutation of the type V myosin Myo2, which directs vesicle, organelle and microtubule transport along actin cables, also reduced the efficiency of cargo internalization via the CIE pathway. Taken together, these data indicate that CME and CIE are spatially and mechanistically distinct, and suggest an unexpected role for the microtubule cytoskeleton in the yeast CIE pathway.

How the plasma membrane is bent to accommodate clathrin-independent endocytosis is poorly understood. Recent studies suggest the exogenous clathrin independent cargo molecules Shiga and cholera toxin induce the negative membrane curvature required for endocytic uptake by binding and cross-linking multiple copies of their glycosphingolipid receptors on the plasma membrane. But it remains unclear if toxin-induced sphingolipid crosslinking provides sufficient mechanical force for deforming the plasma membrane, or if host cell factors also contribute to this process. To test this, we imaged the uptake of cholera toxin B-subunit into surface-attached tubular invaginations in live cells. We found that a cholera toxin mutant that binds to only one glycosphingolipid receptor accumulates in tubules, and that toxin binding is entirely dispensable for membrane tubulations to form. Unexpectedly, the driving force for tubule extension was found to be supplied by the combination of microtubules, dynein, and dynactin, thus defining a novel mechanism for generation of membrane curvature during endocytic uptake at the plasma membrane.

5-HT6 receptor is negatively regulated by sorting nexin 14.

C. Ha¹;

¹Research Division, Korea Brain Research Institute, Daegu, Korea

The 5-HT6 receptor (5-HT6R) plays roles in cognition, anxiety, and learning and memory disorders, yet new details concerning its regulation remain poorly understood. In this study, we found that 5-HT6R directly interacts with SNX14 and this interaction dramatically increases internalization and degradation of 5-HT6R. Knockdown of endogenous SNX14 has the opposite effect. SNX14 is highly expressed in the brain and contains a putative regulator of G-protein signaling (RGS) domain. Although its RGS domain is found to be non-functional as a GTPase activator for Gas, we found that it specifically binds and sequesters Gas, thus inhibiting downstream cAMP production. We further found that PKA mediated phosphorylation of SNX14 inhibited its binding to Gas and diverted SNX14 from Gas binding to 5-HT6R binding, thus facilitating the endocytic degradation of the receptor. Thus, our results suggest that SNX14 is a dual endogenous negative regulator in 5-HT6R-mediated signaling pathway, modulating both signaling and trafficking of 5-HT6R.

Board Number: B526

COPI sorts ubiquitinated membrane proteins at early endosome.

P. Xu¹, T.R. Graham¹;

¹Department of Biological Sciences, Vanderbilt University, Nashville, TN

Coat proteins facilitate vesicle-mediated protein transport by selectively concentrating macromolecules into specialized membrane patches and then deforming these patches into small coated vesicles. In

budding yeast, the SNARE protein Snc1 recycles from early endosomes (EE) back to the trans-Golgi network (TGN) in a pathway that requires an ATP-powered phospholipid flippase (Drs2) and an F-box protein (Rcy1), but no clearly defined vesicle coat. Rcy1 has been implicated in ubiquitination of Snc1 (Ub-Snc1) to form a sorting signal for retrieval. To test if Snc1 uses an ubiquitin sorting signal, we fused the catalytic domain of a deubiquitinating peptidase (DUb) onto GFP-Snc1. EE to TGN transport of GFP-Snc1 was disrupted by DUb fusion to GFP-Snc1 while fusion with a catalytic inactive Dub had no effect. The sorting nexin 4 (Snx4) complex could potentially serve as a coat in this EE to TGN route; however, our results imply that Snx4 acts at a later endosome in a parallel pathway for recycling Snc1 and acts to prevent Ub-Snc1 entry into the multivesicular body pathway. COPI mutants perturb Snc1 EE to TGN transport although it is not known if COPI acts directly at the EE or if this is a secondary effect of the early secretory pathway defects. To test if COPI directly binds ubiquitinated cargo, we fused DUb and catalytic inactive DUb onto Sec27 (beta prime-COP) and Cop1 (alpha-COP). Sec27-DUb disrupted GFP-Snc1 trafficking while Sec27 fused with catalytic inactive DUb was without effect. Both Cop1-DUb and Cop1 fused with catalytic inactive DUb caused a partial GFP-Snc1 trafficking defect suggesting a nonspecific influence on alpha-COP function. Sec27-DUb does not appear to perturb COPI function in Golgi to ER transport. Structural alignment of the beta-propeller domain of Sec27 with Doa1 suggests an ubiquitin binding motif is present in this cargo-binding domain of Sec27. These results suggest that beta-COP directly selects ubiquitinated membrane protein at the EE for retrograde transport to the TGN.

Apical-basal polarity reversal in epithelial cells by PtdIns (3, 4, 5) P3-containing gene delivery vectors: enhanced entry of polyplexes into epithelial cells.

C. Wang¹, E. de Jong¹, D. Hoekstra¹, I.S. Zuhorn¹;

¹Cell biology, University medical center groningen, Groninngen, Netherlands

Polarized epithelial cells have a plasma membrane which is separated by tight junctions into two domains, apical and basolateral, with distinct protein and lipid compositions. The polarized architecture of epithelium provides a barrier to the invasion of exogenous pathogens *in vivo*. Likewise, epithelium represents a barrier to therapeutic drug and gene vectors. For efficient drug and gene delivery it is a challenge to efficiently deliver the therapeutic to epithelial barriers without damaging the integrity of the epithelial monolayer.

Apical addition of exogenous phosphatidylinositol 3,4,5-trisphosphate (PtdIns(3,4,5)P₃; PIP₃), which normally localizes exclusively basolaterally, can locally transform the apical membrane into basolateral, as exemplified by the recruitment of basolateral receptors.

Here, we investigate if apical-basal polarity reversal enhances the uptake of gene vectors at the apical membrane of kidney epithelial cells.

Polyethylenimine (PEI) was used to complex PIP3 and/or DNA (coding for GFP), forming PEI/DNA/PIP3 terplexes and PEI/DNA complexes. Fluorescently labeled terplexes and complexes were added to polarized kidney epithelial cells, and binding/uptake of the gene vectors was measured using fluorescence microscopy/FACS analysis. At t=1hr, PEI/DNA/PIP₃ terplexes colocalize with the PIP3 sensor GFP-PH-Akt, transiently expressed in MDCK cells. In addition, basolateral receptors (β -integrin, syndecan-1, and transferrin receptor) are found to colocalize with terplexes at the apical membrane. At t=72 hrs, the cellular uptake of PEI/DNA/PIP3 is two-fold higher than that of PEI/DNA, although GFP expression is lower (0.80 \pm 0.29% for PEI/DNA/PIP₃; 2.58 \pm 2.11% for PEI/DNA). This can be explained by the entrapment of terplexes within cellular organelles (endosomes, lysosomes, mitochondria), which was visualized by immunostaining for the different intracellular organelles, and by transmission electron microscopic (TEM) observation. By the aid of photosensitizer TPPS_{2a} terplexes are released from endo/lysosomes as shown by the high nuclear accumulation of fluorescently labeled oligonucleotides in 77.5 \pm 4.7% of the cells. DNA was also seen to dissociate from endo/lysosomes upon TPPS_{2a} treatment, although this did not result in improved GFP expression.

We conclude that the apical addition of PIP3-containing gene vectors to polarized epithelial cells can recruit basolateral receptors to the apical surface, improving the uptake of the vectors by the cells. Successful release of genetic cargo from endosomal compartments can be induced by subsequent treatment with a photosensitizer. PEI/DNA/PIP₃ terplexes could be a promising delivery vector to epithelial barriers *in vivo*.

A New Mode of Ligand-Dependent Notch Signaling.

N.W. Pierce¹, M.V. Nachury²;

¹Stanford Univ Sch Med, Stanford, CA, ²Dept. of Molecular and Cellular Physiology, Stanford University School of Medicine, Stanford, CA

How binding of DSL receptor ligands to Notch leads to activation by proteases remains a matter of intense investigation. Current models must grapple with a cornucopia of experimental observations. First, Notch exists on the cell surface as a stable heterodimer because of the S1 cleavage. Second, Notch's LNR repeats must be destabilized to allow proteases access to the activating S2 cleavage site. Third, upon S3 cleavage, Notch's intracellular domain (NICD) gains access to the nucleus. Fourth, endocytosis of ligand in the ligand cell is indispensable for proper Notch function. Lastly, preferential transfer of Notch's extracellular domain (NECD) into the ligand cell (trans-endocytosis) correlates with induction of Notch signaling in the Notch cell. The 'pulling model' combines these observations into a sequence of events; endocytosis of the DSL receptor creates a force that either removes the NECD or deforms the LNR region enough to allow protease cleavage. To study this process in more detail, we designed a suite of new cell culture based assays that allow quantitative localization studies of the extra and intra cellular domain of Notch1 during interaction with its ligand Dll1. We provide direct evidence that the entire Notch1 receptor is trans-endocytosed into the Dll1 cell, where the separation of the

NECD and NICD occurs in novel endosomal structures. Further, we show that the remaining NICD is trafficked back to the Notch cell, in a process similar to exosome secretion, where subsequent proteolytic processing occurs. Lastly, we show that this activated Notch is able to transfer to a third 'recipient' cell. We believe that this new mode of Notch signaling provides deep insights into the mechanism of Notch signaling and offers a basis for studying Notch signaling in pattern formation beyond just two cells.

Roles of Cerebral Cavernous Malformation 3 (CCM3) and Germinal Center Kinase III (GCKIII) in recycling endocytosis during tracheal tubulogenesis in *Drosophila*.

Y. Song¹, A. Ghabrial¹;

¹Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA

Tubes of differing cellular architecture connect into networks. In the *Drosophila* tracheal system, two tube types connect within single cells (terminal cells); however, the genes that mediate this interconnection are unknown. We characterize two genes that are essential for this process: *lotus*, required for maintaining a connection between the tubes, and *wheezy*, required to prevent local tube dilation. We find that *lotus* encodes N-ethylmaleimide sensitive factor 2 (NSF2), whereas *wheezy* encodes Germinal center kinase III (GCKIII). GCKIIIs are effectors of Cerebral cavernous malformation 3 (CCM3), a protein mutated in vascular disease. Depletion of *Ccm3* by RNA interference phenocopies *wheezy*; thus, CCM3 and GCKIII, which prevent capillary dilation in humans, prevent tube dilation in *Drosophila* trachea. Ectopic junctional and apical proteins are present in *wheezy* terminal cells, and we show that tube dilation is suppressed by reduction of NSF2, of the apical determinant *Crumbs*, or of septate junction protein *Varicose*. More interestingly, we find that Rab11 accumulates in dilation area in *wheezy* terminal cell mutant and expression of Rab11 dominant negative form can highly suppress *wheezy* dilation phenotype, which suggests a role of GckIII in regulating recycling endocytosis to prevent tube dilations.

Characterization of the mammalian Mon2/Ysl2.

L. Lu¹;

¹School of Biological Sciences, Nanyang Technological University, Singapore, Singapore

Mon2/Ysl2, which shares significant homology with Sec7 family Arf guanine nucleotide exchange factors, is poorly characterized in mammalian cells. Mon2 has been proposed as a guanine nucleotide exchange factor for a member of Arf family small GTPases—Arl1. Here, we present the first in depth characterization of mammalian Mon2. We found that Mon2 localized to trans-Golgi network which was

dependent on both its N and C termini. The depletion of Mon2 did not affect the Golgi localized or cellular active form of Arl1. Furthermore, our in vitro assay demonstrated that recombinant Mon2 did not promote guanine nucleotide exchange of Arl1. Therefore, our results suggest that Mon2 could be neither necessary nor sufficient for the guanine nucleotide exchange of Arl1. We demonstrated that Mon2 was involved in endosome-to-Golgi trafficking as its depletion accelerated the delivery of furin and CI-M6PR to Golgi after endocytosis.

Superresolution imaging of endocytosis in yeast.

M. Mund¹, A. Picco¹, M. Kaksonen¹, J. Ries¹;

¹European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

Clathrin-mediated endocytosis is a highly intricate cellular process, which in yeast involves the ordered recruitment and disassembly of around 60 proteins. Diffraction-limited live-cell microscopy has led to tremendous insight into composition and dynamics of the endocytic machinery. Electron microscopy on the other hand offers nanometer resolution, but lacks molecular specificity. Thus, the structural organization of most endocytic proteins in situ is largely unknown.

We employ localization microscopy (PALM/STORM) to study endocytic structures in *Saccharomyces cerevisiae*. This method is ideal to study static structures, which is why cells are typically fixed during sample preparation, leading to the loss of temporal resolution. This is mirrored in considerable heterogeneity among the imaged endocytic sites, which complicates their interpretation. By blocking actin polymerization using latrunculin A, we arrest the endocytic sites in comparable states, allowing us to validate previously observed structures. Our current efforts focus on the coat and actin assembly preceding scission. Here, we were able to reveal subdiffraction features of the endocytic coat protein Sla1, which is involved in the regulation of actin polymerization. We show that Sla1 assembles in a ring shape independent of membrane curvature. We also visualized Abp1, which binds throughout polymerized actin at endocytic sites. By imaging a high number of endocytic sites, we attempt to describe the dynamic organization of the endocytic actin structures. Extending the approach by automated dual-color imaging, we are pursuing to obtain a comprehensive structural picture of the endocytic machinery in yeast.

Lysosomal adaptor proteins in health and disease.

D.G. McEwan¹, I. Dikic¹;

¹Goethe University Medical School, IBCII, Frankfurt Am Main, Germany

Lysosomes are ubiquitous membrane-bound intracellular organelles with an acidic interior, central for the degradation and recycling of macromolecules delivered by endocytosis, phagocytosis, and autophagy. The lysosome, alongside the proteasome, acts as a major degradative route for the cell. In particular, it is especially adapted for the removal of large structures that the proteasome cannot process. In particular, toxic protein aggregates, damaged organelles, such as ROS-producing mitochondria, intracellular pathogens and membranes as well as acting as a source of recycled nutrients such as amino acids and lipids. It is therefore no surprise that the lysosome and lysosomal pathways contribute, both positively and negatively, to the progression of multiple diseases including cancer. We are interested in disrupting lysosome function in cancer, with emphasis on protein complexes that maintain lysosome integrity and function. We have recently identified a PLEKHM1 as a scaffold protein that couples Rab7-HOPS complex with biogenesis of lysosome and regulation of contact points with other membrane including autophagosomes. Through the interaction with Rab7-HOPS, PLEKHM1 coordinates autophagosome maturation and is also a target for the intracellular Gram-negative bacteria Salmonella. We will present data on how this complex is coordinated and how Salmonella manipulate the Lysosomal compartment through PLEKHM1-Rab7-HOPS complex. We present new data on how these processes are regulated through post-translational modifications giving us new insights into how these adaptor complexes are regulated.

Depletion of Beclin-1 increases the delivery of cathepsin D and EGF receptor to lysosomes.

A. Gonzalez¹, V. Cornejo², C. Hetz², G. Mardones¹, P. Burgos¹;

¹Department of Fisiology, Universidad Austral De Chile, Valdivia, Chile, ²Biomedical Neuroscience Institute, Faculty of Medicine, University of Chile, Santiago, Chile

Introduction: Beclin-1 is an ubiquitous protein that has a central role in autophagy. Biochemically, Beclin-1 interacts with either Vps34/PtdIns3KC3 or UVRAG forming two stable complexes referred as Beclin-1 Complex 1 and 2, respectively. These two complexes regulate the formation of PI3P a crucial phospholipid in autophagosome formation. Recent observations indicate that Beclin-1 could also play autophagy-independent roles, such as in endocytosis and protein sorting, however to date it is unclear

the contribution of Beclin-1 in these processes. The aim of this study was to investigate the role of Beclin-1 in the delivery of cargoes to lysosomes. **Material and Methods:** To generate a stable cell line depleted in Beclin-1, H4 neuroglioma cells were infected with lentiviral particles encoding a specific shRNA to Beclin-1. These cells were used to analyze the maturation of cathepsin-D, a lysosomal aspartic protease, and the degradation of the epidermal growth factor receptor (EGFR), in response to its ligand. **Results:** We observed that depletion of Beclin-1 caused a significant increase in the levels of mature cathepsin-D, and in the rate of ligand-induced EGFR degradation. Consistent with this phenotype, we observed that depletion of Beclin-1 causes a significant increase in various adaptor proteins involved in the delivery of cargoes to lysosomes. Importantly, western blot analysis revealed that Beclin-1 depletion causes a significant decrease in UVRAG protein levels, indicating a destabilization of the Beclin-1 Complex-2. **Discussion:** Our results suggest a non-autophagic role for Beclin-1, probably connected to Beclin-1 Complex-2 that seems to operate as a negative regulator in the delivery of cargoes to lysosomes. Supported by FONDECYT 1130929, Beca CONICYT 21110746 and DID-UACH.

Hepatitis B virus secretion is regulated through the activation of endocytic and autophagic compartments via Rab7 stimulation.

J. Inoue¹, E.W. Krueger¹, J. Chen¹, H. Cao¹, M.A. McNiven¹;

¹Mayo Clinic, Rochester, MN

The cellular mechanisms by which hepatitis B virus (HBV) is assembled and exported are largely undefined. Recently, it has been suggested that these steps require the multivesicular body (MVB) and the autophagic machinery. However, the mechanisms by which HBV might regulate these compartments are unclear. In this study we have found that by activating Rab7, HBV alters its own secretion by inducing dramatic changes in the morphology of MVB and autophagic compartments. These changes are characterized by the formation of numerous tubules that are dependent upon the increase in Rab7 activity observed in the HBV-expressing HepG2.2.15 cells compared to HepG2 cells. Interestingly, a transfection-based expression of the five individual viral proteins indicated that the precore protein, which is a precursor of HBeAg, was largely responsible for the increased Rab7 activity. Finally, siRNA-mediated depletion of Rab7 significantly increased the secretion of virions, suggesting that reduced delivery of the virus to the lysosome facilitates viral secretion. These novel findings provide evidence indicating that HBV can regulate its own secretion through an activation of the endo-lysosomal and autophagic pathways via Rab7 activation.

P393**Board Number: B535****The vacuole/lysosome is required for cell-cycle progression.**Y. Jin¹, L.S. Weisman¹;¹Life Sciences Institute, University of Michigan, Ann Arbor, MI

During the cell-cycle, cytoplasmic organelles are distributed to the new daughter cells. For example, in *S. cerevisiae*, there is active organelle transport from the mother to the daughter cell. In yeast, the vacuole/lysosome, which is inherited, has critical functions including maintaining hydrostatic pressure/pH, as well as recycling, storage and degradation of macromolecules. The daughter cell inherits the vacuole *via* the myosin V motor, Myo2, and the vacuole-specific adaptors, Vac17 and Vac8.

When vacuole inheritance is defective, the bud generates a new vacuole that is independent of the mother vacuole. Moreover, after cytokinesis, the new cell does not form a bud until its vacuole reaches a specific size. These results suggest that the vacuole is essential for cell viability. If true, then cells defective in both vacuole inheritance and in the *de novo* synthesis of a new vacuole, would not be viable. Indeed, *pep12 vac17* and *vps45 vac17* double mutants exhibit synthetic growth defects. That the Pep12, t-SNARE and Vps45, Sec1/Munc18-like molecule are necessary for transport to the pre-vacuolar compartment, suggests that when a mature vacuole is not inherited, Pep12/Vps45 are required for maturation of endosomes to a fully functional vacuole. Furthermore, these double mutants show a G1 cell-cycle arrest, indicating that the vacuole is required for cell-cycle progression. A clue to why the vacuole is required was revealed by the finding that the *tor1 vac17* double mutant shows synthetic growth defects. The Tor1 protein kinase is a member of the TORC1 complex, which signals from the vacuole. In further studies we found that when a vacuole is not inherited, the newly synthesized vacuole cannot recruit the major TORC1 target, Sch9. It is tempting to speculate that the newly synthesized vacuoles lack additional properties essential for normal vacuole function. Taken together, these results suggest that a functional vacuole is required for cell-cycle progression in part through the TORC1 pathway.

P394**Board Number: B536****STX13 controls the melanosome biogenesis through its regulated endosomal fusion events.**R.A. Jani¹, L. Purushothaman¹, E. Sviderskaya², D. Bennett², G. Raposo³, S. Gangi Setty¹;¹Indian Institute of Science, Bangalore, India, ²Biomedical Sciences Research Centre, St. George's, University of London, London, UK, ³Centre de Recherche, Institut Curie, Paris, France

Melanosome biogenesis is a highly regulated organelle maturation process wherein an immature compartment acquires its cargo proteins through the endocytic trafficking pathways and finally matures into a functional organelle. These processes were shown to be dependent on several protein complexes

like AP-1, AP-3, BLOC-1,2,3 (Biogenesis of Lysosome-related Organelles Complex) and in addition to KIF13A motor protein and RAB32/38 GTPases. However the cargo delivery to any membrane requires the interplay between Rabs, tethering factors and SNAREs. Mutations in these proteins result into defective melanosome maturation leading to Hermansky-Pudlak syndrome (HPS), characterized by hypopigmentation, pulmonary fibrosis, bleeding disorders and other phenotypes.

Endosomal SNARE, STX13 was known to interact with BLOC-1, however the functional role of this interaction in pigment formation is unknown. Previous studies have shown that in AP-3-deficient melanocytes this SNARE mislocalizes to melanosomes, suggesting a role for AP-3 in recycling the STX13 from melanosomes. Bioinformatic analysis of the N-terminal region of STX13 revealed two canonical motifs, ³YGP⁶L resembling the classical tyrosine-based motif (YXX ϕ) and KETNE⁸⁰L⁸¹L resembling a dileucine motif [DE]XXXL[LI] recognized by several adaptor proteins. Mutagenesis analysis of these motif had no effect on the steady state distribution of STX13 indicating that STX13 uses non-canonical residues for its sorting or recycling. Further deletion of the N-terminal region (1-129 aa) redistributes the STX13 to melanosomes. In addition we found that STX13 mediated cargo delivery to the melanosomes is affected in the VAMP7 knockdown cells. The knockdown of either VAMP7 or STX13 affect the cargo trafficking and SNARE localization to the melanosomes, Taken together our findings reveal the importance of SNARE dynamics in melanosome biogenesis.

Melanoregulin may influence melanosome distribution through its effects on the organization of lipids in the melanosome membrane.

X. Wu¹, J.A. Hammer²;

¹NIH/NHLBI, Bethesda, MD, ²LCB, NIH/NHLBI, Bethesda, MD

In mammals, pigments are made by melanocytes within a specialized organelle, the melanosome. Mature, pigment-laden melanosomes are then transferred to keratinocytes to drive the visible pigmentation of the animal's hair and skin. The dilute suppressor (*dsu*) locus is an extragenic suppressor of the pigmentation defect exhibited by mice lacking myosin Va (i.e. dilute mice). We recently showed that (i) melanoregulin, the product of the *dsu* locus, functions as a negative regulator of a shedding mechanism that drives the intercellular transfer of melanosomes from the melanocyte to the keratinocyte (Wu et al, PNAS, 2012), and (ii) that melanoregulin is stably anchored in the melanosome membrane through palmitoylation (Wu et al BBRC, 2012). An alternate model for melanoregulin function posits that the protein serves as the receptor on the melanosome membrane for dynein by recruiting the Rab7 effector RILP, which in turn recruits the dynein/dynactin complex (Ohbayashi et al, JCS, 2012). Consistently, over expression of melanoregulin drives melanosomes towards the MTOC. While we also find that over expression of melanoregulin drives melanosomes (and lysosomes in generic cells) towards the MTOC, we think this is a nonphysiological phenomenon due to an effect that excess melanoregulin may have on the organization of lipids in the melanosome membrane by virtue of melanoregulin's multiple attached lipids (myristate and up to six palmitates). Moreover, we find that

the ability of melanoregulin to promote the minus end directed movement of melanosomes/lysosomes requires Rab7 as well as RILP. Finally, while artificial anchoring of RILP in the mitochondrial outer membrane drives the organelle to the MTOC, artificial anchoring of melanoregulin does not. We conclude that melanoregulin does not serve in place of Rab7 as the anchor for the RILP/dynein/dynactin complex on the surface of melanosomes. Ongoing studies are addressing how melanoregulin's attached lipids, when present in excess, influence the kinetics of the melanosome's microtubule minus end-directed transport.

SNARE protein requirements for lytic granule exocytosis in immune cells.

W.A. Spessott¹, M. McCormick¹, M.L. Sanmillan¹, C.G. Giraudo²;

¹Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia - University of Pennsylvania, Philadelphia, PA, ²The Children's Hospital of Philadelphia - University of Pennsylvania, Philadelphia, PA

Cytotoxic T Lymphocytes (CTLs) and Natural Killer (NK) cells selectively kill virally infected or cancer cells by releasing the lytic granule content at the contact area with target cells called immunological synapse (IS). SNARE proteins are required for multiple membrane trafficking steps to mediate the maturation and final exocytosis of "fully-armed" lytic granules at the IS. Deregulation of SNARE-mediated fusion events, such as in Familial Hemophagocytic Lymphohistiocytosis-4 and -5, in which Syntaxin-11 and Munc18-2 are mutated, respectively; severely impair lytic granule release and cytotoxicity of CTL and NK-cells. Syntaxin-11 and Munc18-2 have also been shown to be essential for platelet granule secretion and other important physiological processes. However the underlying molecular mechanisms by which Syntaxin-11 and Munc18-2 control membrane trafficking and lytic granule exocytosis are still elusive. We have identified that endogenous SNAP23 and Vamp8 physically interact with Syntaxin-11 in primary CTLs. Biochemical experiments showed that these interacting proteins can form stable SNARE complexes and confirmed the specificity of these interactions. Stimulated Emission Depletion (STED) Superresolution microscopy studies positioned these SNARE proteins at the central stage to control granule exocytosis. Two pools of Syntaxin-11 were identified in CTLs, one localized to a vesicular compartment, and one localized at the plasma membrane. Suggesting that Syntaxin-11 is involved in an active recycling through the endosomal compartment. In contrast, Vamp8 was mapped to internal vesicles partially colocalizing with lytic granule markers such as Perforin and Granzyme. Cell-cell fusion experiments revealed that flipped-Stx11/SNAP23 t-SNARE complex specifically promoted membrane fusion with flipped-Vamp8 but not with flipped-Vamp3, 4 or 7. These results support the conclusion that the identified Stx11/SNAP23/Vamp8 SNARE complex can act as fusogenic SNARE complex and may play a crucial role during CTL-mediated cytotoxicity and FHL pathophysiology.

P397**Board Number: B539****A massive ectopic accumulation of lysosomes in axons that surround amyloid plaques is a defining feature of Alzheimer's disease.**S. Gowrishankar¹, P. Yuan², Y. Wu^{1,3,4}, S. Paradise¹, J. Grutzendler², P. De Camilli⁵, S.M. Ferguson¹;¹Department of Cell Biology, Yale University, New Haven, CT, ²Department of Neurology, Yale University, New Haven, CT, ³department of cell biology, 1Howard Hughes Medical Institute, New Haven, CT, ⁴CNNR program, Yale University, New Haven, CT, ⁵Department of Cell Biology, Howard Hughes Medical Institute, Program in Cellular Neuroscience, Neurodegeneration and Repair, Yale University School of Medicine, New Haven, CT

A key feature of Alzheimer's disease (AD) brain pathology is the presence of amyloid plaques. These are extracellular aggregates of the amyloid β peptide surrounded by swollen neuronal processes (dystrophic neurites). To address the molecular mechanisms underlying this aspect of Alzheimer's disease pathology, we pursued an extensive characterization of the amyloid plaques and their effects on surrounding brain tissue. We observed that axons passing in close proximity to extracellular amyloid deposits are filled by focal accumulations of lysosomes (as indicated by the presence of multiple peripheral, transmembrane and luminal proteins that molecularly define this organelle). Prominent among these lysosomal components is progranulin, a protein of the lysosomal lumen that is linked to neurodegenerative disease. The massive abundance of lysosomes in dystrophic axons adjacent to extracellular amyloid deposits stands in striking contrast to the predominant localization of lysosomes to the perikarya and dendrites of normal neurons. Thus, both the accumulation of lysosomes around A β deposits, as well as the abundance of lysosomes in axons represent a major, defining feature, of the neuropathology that accompanies amyloid plaque formation. The close relationship between amyloid plaques and axonal lysosome accumulation was observed from the earliest detectable stages of development of these deposits and precedes the recruitment of microglia to plaques. β -secretase (an essential enzyme in the production of A β) also colocalized with the lysosomal marker LAMP1 in axonal swellings, raising the possibility of a feed-back loop between extracellular A β deposits, axonal lysosomal traffic and the local production of A β . Further elucidation of the contributions of abnormal dynamics of lysosomes in Alzheimer's disease may yield important insights that point to new therapeutic targets for the disease.

P398**Board Number: B540****Identification of a Mutation in a Novel Gene Causing a Chédiak-Higashi Syndrome-Like Phenotype.**

J.C. Roney¹, M. Gunay-Aygun¹, D. Gul², T. Vilboux¹, D.M. Maynard¹, C. Toro¹, W.J. Intron¹, J.C. Mullikin^{3,4}, M. Huizing¹, W.A. Gahl¹, A.R. Cullinane¹;

¹Medical Genetics Branch, NHGRI, NIH, Bethesda, MD, ²Department of Medical Genetics, Gulhane Military Medical Academy, Ankara, Turkey, ³Comparative Genomics Analysis Unit, Cancer Genetics and Comparative Genomics Branch, NHGRI, NIH, Bethesda, MD, ⁴NIH Intramural Sequencing Center, NHGRI, NIH, Rockville, MD

Chédiak-Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by partial albinism, recurrent infections, a mild bleeding tendency, and later onset neurological involvement including learning difficulties, cerebellar dysfunction, polyneuropathies, and L-DOPA responsive Parkinsonism. CHS was diagnosed based on identification of enlarged granules on peripheral blood smear and enlarged lysosomes and lysosome-related organelles in many cell types. Previously, CHS was known to be caused only by mutations in the lysosomal trafficking regulator gene (*LYST*), which encodes a cytosolic protein proposed to function in the regulation of lysosomal size and trafficking. Some patients with CHS do not have mutations in *LYST*, suggesting that mutations in other genes could also result in a similar disorder. Here we describe a set of twins of consanguineous background who presented with hepatosplenomegaly and were diagnosed with CHS based on typical inclusions in peripheral leukocytes and in precursor cells in the bone marrow. Their subsequent clinical course was dominated by severe global developmental delay and refractory epilepsy; at age 6 years they were non-verbal and unable to sit unsupported. Cellular analysis showed enlarged lysosomes that clustered in the perinuclear regions of both patients' fibroblasts. Whole exome sequencing of one of these patients revealed no mutations in *LYST*, but identified a homozygous 1bp deletion in *WDR91*, representing a novel gene causing a CHS-like phenotype. The same mutation was identified in an affected sibling by Sanger sequencing, and segregated with disease status within the family. *WDR91* encodes WD40 Repeat 91 protein that contains several WD40 domains similar to *LYST*. These domains fold into a beta-propeller structure known to form a platform that mediates protein-protein interactions. Consistent with the severity of the mutation, *WDR91* protein expression is completely absent in the two affected individuals and likely accounts for their CHS-like phenotype. Identification of other CHS patients with *WDR91* mutations will help us understand if *WDR91*-related CHS causes the severe neurological phenotype observed in these siblings.

P399**Board Number: B541****SPPL3 cleaves CLN5 to produce a mature soluble lysosomal protein.**E. Sauvageau¹, F. Jules², D. Scott³, K. Dumaresq-Doiron³, S. Lefrançois²;¹Nephrology, Hopital Maisonneuve-Rosemont, Montreal, QC, ²Hopital Maisonneuve-Rosemont, Montreal, QC, ³Universite de Montreal, Montreal, QC

Neuronal ceroid lipofuscinoses (NLCs) are a group of recessive disorders of childhood that lead to vision loss, dementia, ataxia and premature death. 14 different genes have been linked to NCLs (CLN1-CLN14), but the functions of the proteins encoded by the majority of these genes have not been fully elucidated. Mutations in the CLN5 gene are responsible for the Finnish variant late-infantile form of NCL (Finnish vLINCL). Functionally, CLN5 is implicated in the recruitment of the retromer complex to endosomes, which is required to sort the lysosomal sorting receptors from the endosomes to the trans-Golgi network. CLN5 is translated as a 407 amino acid type II transmembrane domain containing protein that is heavily glycosylated and subsequently cleaved into a mature soluble protein. The importance of CLN5 processing on its functions and the mechanisms that cleave CLN5 into a mature soluble protein are currently unknown. We sought to identify the enzyme(s) responsible for CLN5 cleavage by testing the effect of various protease inhibitors on CLN5 processing. We found that only (Z-LL)2-ketone prevented the cleavage of CLN5 from the pro form to the mature form as the other inhibitors had no effect. (Z-LL)2-ketone inhibits the SPP family of intramembrane proteases that are known to cleave a variety of type II transmembrane proteins. To determine which member(s) of the SPP family is responsible for CLN5 processing, we overexpressed WT or catalytically dead mutants of the SPP family (SPP, SPPL2A, SPPL2B and SPPL3) and looked at their consequences on CLN5 cleavage. We found that only the catalytically dead SPPL3 was able to block CLN5 conversion from the pro to the mature form. To confirm these results, we individually knocked down the expression of each SPPs and looked at the effect on CLN5 processing. Again, only shRNA targeting SPPL3 were able to prevent the cleavage of CLN5 from the pro to the mature form. We also found that the N-terminal fragment resulting from CLN5 processing is subsequently cleaved by another member of the SPP family and degraded by the proteasome. In order to identify the cleavage site, we overexpressed CLN5-HA in HEK 293 cells, purified CLN5 using an anti-HA antibody and sent the purified protein for mass spectrometry analysis. Two potential cleavage sites were identified but so far mutations around these cleavage sites have not block CLN5 processing. Herein, we show that SPPL3, a member of the SPP intramembrane protease family, cleaves CLN5 into a mature soluble protein and a N-terminal fragment, which is subsequently cleaved by SPPs. This work further characterizes the biology of CLN5 in the hopes of identifying a therapeutic strategy.

P400**Board Number: B542****Functional characterization of Atg20 and Atg24 domains in autophagy regulation.**Y. CHEN¹, L. YU¹, W. HUANG¹;¹DEPARTMENT OF LIFE SCIENCE, NATIONAL TAIWAN UNIVERSITY, TAIPEI, Taiwan

Autophagy is a stress response mechanism that delivers cytosolic materials to the vacuole/lysosome for degradation and recycling. Because autophagy is highly activated by nutrient-starvation stresses, it had been considered simply as a non-specific catabolic pathway for a long time. Recent studies, however, have uncovered intimate relationships between selective autophagy activities and human diseases, such as pathogen infections and tissue-degenerative diseases. Based on results of animal model studies, autophagy is also proposed as a mechanism to prevent aging by eliminating dysfunctional mitochondria. All these newly reported autophagy functions rely on efficient signaling mechanisms to recognize and segregate specific cargoes for degradation, which makes the selective autophagy regulatory machinery a potential target for therapeutic manipulations. Working on a suitable model system should accelerate our studies on the molecular mechanisms of selective autophagic cargo-induced signaling processes. Several selective autophagic cargoes have been uncovered in the budding yeast *Saccharomyces cerevisiae*. Among them, the precursors of aminopeptidase I enzyme (prApe1) are delivered directly from cytosol to the vacuole through the actions of autophagy proteins under nutrient-rich growth condition. This makes prApe1 the only model for the study of the induction signaling of selective autophagy pathways in nutrient-rich environment. Because the other types of selective autophagy pathways are stimulated by nutrient-starvation conditions, which also induce non-selective autophagy activities, this makes the attribution of observed molecular events for selective or non-selective autophagy regulation difficult. We report our results on characterizing the functional domains of two BAR-domain proteins, Atg20 and Atg24, in prApe1-stimulated selective autophagy regulation.

P401**Board Number: B543****Elevated levels of FTD risk factor TMEM106B alter lysosomal/autophagosomal pathways.**J.I. Busch¹, T.L. Unger¹, R.T. Skrinak¹, N. Jain¹, W. Mayes¹, A.S. Chen-Plotkin¹;¹Neurology, University of Pennsylvania, Philadelphia, PA

Frontotemporal lobar degeneration with TDP-43 inclusions (FTLD-TDP) is an important cause of dementia in individuals under 65 years old. Common variants in the Transmembrane Protein 106B gene, or *TMEM106B*, were discovered by genome-wide association to confer genetic risk for FTLD-TDP ($p=1 \times 10^{-11}$, OR=1.6). Evidence suggests that *TMEM106B* risk variants increase one's probability for developing FTLD-TDP by increasing *TMEM106B* expression. Prior to its association with FTLD-TDP, *TMEM106B* was largely uncharacterized. *TMEM106B* has subsequently been demonstrated to be widely

expressed in the brain, with a perikaryal distribution in neurons. Moreover, TMEM106B is a Type II transmembrane protein with steady-state localization to lysosomes.

To better understand TMEM106B's role in FTLT-DTP pathophysiology, we investigated the effects of increased TMEM106B expression in multiple cell types, including primary neurons. Increased TMEM106B expression resulted in a striking cellular phenotype - extremely enlarged organelles (>3 μ m) that were positive for the lysosomal marker LAMP1. Ultrastructural analysis suggested that these organelles were late autophagic vacuoles (amphisomes/autolysosomes). Accompanying these morphological changes were alterations in autophagy and lysosomal pathways. Specifically, increasing TMEM106B expression resulted in a significant increase in the number of autophagosomes and autolysosomes. This was accompanied by the loss of highly acidified organelles, a decrease in the total number of LAMP1+ organelles, and impaired lysosomal degradation. Taken together, these results suggest loss of a functional lysosomal pool.

The cell biological effects of increased TMEM106B expression were dependent on lysosomal targeting of TMEM106B, since a point mutation in a lysosomal sorting motif abrogated these effects. These effects were also dependent on the presence of C9orf72 protein, since C9orf72 knockdown rescued these effects as well. Of note, hexanucleotide repeat expansions in *C9orf72* are the most common Mendelian cause of both FTLT-DTP and ALS. In addition, we have previously shown that *TMEM106B* acts as a genetic modifier affecting age at death in *C9orf72* expansion-associated FTLT-DTP. **Our results thus suggest that TMEM106B exerts its effects on disease risk through alteration of lysosomal and autophagy pathways. In addition, TMEM106B and C9orf72 may interact in the pathophysiology of FTLT-DTP.**

Subcellular targeting of natural and engineered anti-autophagy RavZ proteins.

V. Shteyn¹, F. Huang², G. Sirinakis¹, E.S. Allgeyer², J. Bewersdorf², T.J. Melia¹;

¹Department of Cell Biology, Yale University, New Haven, CT, ²Department of Cell Biology, Yale University School of Medicine, New Haven, CT

Autophagy involves the capture and delivery of cytosolic cargo to the lysosome for degradation, and is a key mediator of the cellular host response. Pathogens in turn, have developed mechanisms to evade the cellular host response, and we have recently described the Legionella effector RavZ as a potent inhibitor of autophagy. Upon infection, RavZ is secreted into the cytoplasm where it cleaves the lipidated LC3 protein but not the soluble form. Consistent with this biochemical function, here we show that RavZ cleaves LC3 upon starvation in HeLa and the mouse RAW 264.7 macrophage cell line. To investigate the cellular consequence of local LC3-PE depletion, we designed membrane-tethered RavZ constructs, potentially limiting RavZ activity to selective sites within the cell. First, we fuse RavZ to the endoplasmic reticulum (ER)-binding domain of cytochrome b5 (cb5(ER)). RavZ-ER co-localizes with the ER marker PDI. RavZ-ER cells show drastically reduced number of LC3 puncta, and reduced LC3-II

formation, consistent with starvation-dependent autophagosome formation occurring in close proximity to ER membranes. Next, we have generated tools for targeting RavZ to mitochondria using the mitochondrial form of cb5. I will present data exploring the effects of these two membrane-limited constructs on starvation-induced autophagy and on the more peripheral process of LC3-associated phagocytosis (LAP). We also previously showed that the catalytically-inactive point mutant of RavZ, RavZ(C258A), co-localizes with LC3 puncta. Anchored RavZ(C258A) may therefore recruit LC3 to target membranes, and I aim to apply FPALM microscopy to study the distribution of LC3 over large cargo such as mitochondria, ER and in cells undergoing LAP. Preliminary experiments on starved cells show LC3-decorated cup- and sphere-shaped structures less than 300nm in diameter. In summary, I have generated unique tools that allow us to independently manipulate autophagy subtypes. Using these tools, we are able to investigate how RavZ targets membranes, and its role in LC3-associated phagocytosis. Our preliminary studies using FPALM furthermore pave the way for understanding the organization of LC3 and upstream factors at the autophagic membrane.

Atg4 mediated release of LC3-PE is acutely sensitive to the composition and organization of the surrounding membrane.

K. Kauffman¹, B. Mugo¹, S. Nag¹, T. Agbi¹, T.J. Melia²;

¹Yale University, New Haven, CT, ²Department of Cell Biology, Yale University, New Haven, CT

Autophagy is a bulk degradation process in which material to be degraded is encapsulated in a double-membraned organelle called the autophagosome and delivered to the lysosome. The growth and maturation of the autophagosome depends upon the transient attachment of LC3 family proteins to the phospholipid headgroups of the growing autophagosome. Soon after translation, proform LC3 is cleaved by the protease Atg4 to reveal a glycine residue that is conjugated to the lipid phosphatidylethanolamine (PE) in a ubiquitin-like process. Atg4 also functions later in autophagy, cleaving LC3 back off of the lipid headgroups to allow the autophagosome to fuse with the lysosome. Each Atg4-dependent cleavage is essential; if lipidation is prevented the autophagosome does not fully mature and close, while if LC3 is never released from the autophagosome membrane, the autophagosome is unable to fuse with the lysosome to complete autophagy. Therefore, the lifetime of lipid conjugated LC3 must be regulated, but how these lipidation and delipidation rates are controlled is unknown. Here we apply in vitro reductionist methods to determine the intrinsic activities of Atg4 against soluble precursor and mature lipidated forms of LC3. We show that Atg4-mediated release of lipidated LC3 is an order of magnitude slower than processing of soluble precursor LC3. The differences in processing kinetics do not derive from differences in recognizing the protein-lipid adduct per se, but instead is due to the anchoring of the substrate LC3-PE in a bilayer membrane; simply solubilizing the membrane with detergent allows LC3-PE to be processed as quickly as fully proteinaceous soluble LC3. Further, the release of LC3-PE is sensitive to changes in membrane composition, suggesting that the lifetime of lipidated LC3 may be controlled by local alterations in membrane structure. The recognition

of soluble and lipidated substrates differs among Atg4 homologs; Atg4A is much more efficient at delipidation than Atg4B. As Atg4A is only able to process the GABARAP subfamily of LC3 proteins, the available pool of GABARAP lipidated protein may also be under distinct temporal controls from the pool of LC3 lipidated protein. Collectively, our results suggest that Atg4 is naturally tuned to work slowly on early autophagosome intermediate membranes allowing LC3-PE (or GABARAP-PE) to accumulate to high levels during autophagosome growth.

Endosomal pH in c-Met Trafficking.

S. Fan¹, Y. Numata¹, M. Numata¹;

¹Biochemistry Molecular Biology, the University of British Columbia, Vancouver, BC

Up-regulation of the receptor tyrosine kinases (RTKs) signalling cascades constitutes the basis of tumorigenesis. Signal termination that normally occurs through endosomal pH dependent ligand-receptor dissociation and receptor degradation is disrupted in various cancers. Therefore, persistent receptor-mediated signal occurs through increased recycling and elevated surface expression of these receptors. In this study, we show that neuron-enriched Na⁺/H⁺ exchanger NHE5 plays an important role in trafficking of c-Met RTK in C6 glioma cells. NHE5 is predominantly expressed in recycling endosomes of C6 cells and localizes partially to transferrin(Tfn) and Rab11 positive endosomes. By fluorescence ratiometric analysis, we show that NHE5-depletion with short-hairpin RNA significantly increases pH of Tfn positive recycling endosomes, suggesting a prominent role of NHE5 in endosomes acidification. Using biochemical approach, we show that cell surface abundance of hepatocyte growth factor (HGF) receptor c-Met is reduced by 80% in NHE5-deficient cells as a result of impaired recycling circuitry. Consequently, reduced expression of c-Met by NHE5 knockdown (KD) causes severe migratory defect and loss of cell polarity. We further demonstrate that disrupted phenotypes in NHE5 KD cells are restored by NHE5 complementation. Stable expression of shRNA-resistant human NHE5 into NHE5 KD cells acidifies endosomal pH, increases surface c-Met abundance and Rac-1 activity, and enhances cell migration. In summary, we showed that acidification of recycling endosomes by NHE5 promotes recycling of c-Met, which contributes to persistent downstream signalling cascade and enhancement of cell motility. Our study highlights critical role of endosomes pH in regulating receptor-mediated signalling through vesicular trafficking.

P405**Board Number: B547****Pathophysiology of Morbus Niemann-Pick Type C1: Membrane lipid abnormalities in cultured fibroblasts and lymphoblasts.**S. Rizk¹, K. Maalouf¹, M.H. Hodroj¹, A. Das², H.Y. Naim³;¹Lebanese American Univ, Beirut, Lebanon, ²Department of Pediatrics, Hannover Medical School, Hannover, Germany, ³Department of Physiological Chemistry, University of Veterinary Medicine Hannover, Hannover, Germany

Morbus Niemann–Pick type C1 (NPC1) is a rare, life-threatening, autosomal-recessive, neurovisceral lysosomal storage disease (LSD). It is characterized by a cellular cholesterol trafficking defect which leads to the entrapment of cholesterol and glycosphingolipids inside lysosomes. The pathophysiology of clinical symptoms in NPC1 patients is not clear. As cholesterol is a pivotal membrane component the function of biological membranes may be disturbed, specifically in the ordered structure of a particular type of membranes, detergent-resistant membranes (DRMs) and /or lipid rafts, which are enriched in glycosphingolipids and cholesterol. In cultured skin fibroblasts and lymphoblasts harboring NPC1 mutations and cells from healthy individuals (WT cells), lipid rafts were analyzed by isolating TritonX-100 DRMs and separating them on a sucrose density gradient. The distribution of the lipid rafts-associated protein flotillin2 was shown to be altered in both cell lines relative to WT cells. In contrast, the distribution of RhoA, a protein that is not associated with lipid rafts, did not change between NPC1 B-lymphocytes and fibroblasts relative to WT cells. Protein array studies were done on both NPC1 B-lymphocytes and fibroblasts in comparison with normal WT cells. In both cell lines cytochrome C as well as the heat shock proteins, HSP60 and HSP70, appeared to be less expressed in NPC1 compared to WT cells. Together, these results provide a promising basis for understanding the pathophysiology in NPC1 and propose potential biomarkers.

P406**Board Number: B548****GALECTIN-8 IS SECRETED IN APICAL EXOSOMES FROM MDCK CELLS.**C. Oyanadel¹, M. Lopez-Verrilli¹, A. Soza¹, A. Gonzalez¹;¹Inmunología Clínica y Reumatología. Fac. de Medicina. Centro de Envejecimiento y Regeneración, Fac. Ciencias Biológicas, P. Universidad Católica de Chile, Santiago, Chile

Galectin-8 belongs to a family of carbohydrate-binding proteins secreted by a nonconventional route and implicated in a variety of cellular processes, including adhesion, migration and apoptosis. Galectins are involved in apical secretion from polarized epithelial cells. Cancerous cells derived from epithelial cells have altered expression of Gal-8. Here, we generated MDCK cells permanently transfected to express Gal-8 and studied its secretion mechanism. Gal-8 was captured and precipitated with lactose-Agarose beads from the media in both steady state and pulse-chase experiments. Exosomes were isolated by successive ultracentrifugation from conditioned media of MDCK cells grown on tissue culture

dishes and Transwell filters. After 30 min of pulse labeling we found newly synthesized Gal-8 only in the apical medium. The exosome fraction characterized by the presence of CD63, Hsp70, Hsp90 and flotillin markers contained Gal-8. We detected Gal-8 resistant to trypsin digestion indicating its presence inside the exosomes. However, we detected a proportion of Gal-8 in the surface of exosomes by competition with 50 mM lactose and by immunoelectron microscopy. SDS-PAGE silver stained pattern showed differences in apical and basolateral exosomes. In addition, apoptosis induction of activated T cells used as a described test showed evidence that apically secreted exosomes containing Gal-8 are biologically active. The selective PIKfyve inhibitor described to induce accumulation of late endosomal compartments, presumably multivesicular bodies, decreased the secretion of Gal-8. All these results indicate that MDCK cells secrete apical exosomes containing Gal-8 originated at late endosomal compartments (Financial support from: FONDECY# 1141127 and CONICYT grant PFB12/2007).

Phagosome formation in Choanoflagellates (*Salpingoeca rosetta*).

N. L'Etoile¹, E.J. Adjei-Danquah¹, C. King-Smith¹;

¹Department of Biology, Saint Joseph's University, Philadelphia, PA

The link between unicellular life and multicellular animals has extensive implications in molecular and cellular biology. The emerging field of evolutionary cellular biology sheds light on this link by examining the physiological and anatomical similarities between the unicellular protists, choanoflagellates, and choanocytes, cells found in sponges in the phylum Porifera. The physical similarities between these cells are striking, but in addition, these cells are astonishingly similar in their function when choanoflagellates are in their colony form. Both choanocytes and choanoflagellates use a flagellum to create a water current that facilitates phagocytosis of prey. In colonies, the flagellum of each choanoflagellate radiates outward from the circle formed by the cells, creating a current similar to that made by the choanocytes of a sponge. We are interested in comparing phagocytic vacuole formation in single cell and colony forms. We suspect that phagosome formation in colonies will be more rapid and efficient than in single celled choanoflagellates. Single cells and colonies of *Salpingoeca rosetta* were incubated with BioParticles, which are heat killed, fluorescently labeled *Staphylococcus aureus*, and phagosome formation was quantified as phagosomes per cell in single cells and phagosomes per colony in colonies. Preliminary results showed that colonies formed 1.1 ± 0.15 phagosomes/cell (mean \pm SEM; N=23 colonies), compared to 0.51 ± 0.16 phagosomes/cell in single cells (N=37). The average number of cells per colony was 6.17 ± 0.40 (N=23). These results suggest that choanoflagellate colonies are more efficient at forming phagosomes than single cells.

P408**Board Number: B550****Induced pluripotent stem cell model of mucopolysaccharidosis type II.**R. Dobrovolny¹, J. Rybova¹, H. Poupetova¹, L. Kuchar¹, B. Asfaw¹, J. Ledvinová¹;¹Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague, Prague, Czech Republic

Mucopolysaccharidosis type II (MPSII, hunter syndrome) belongs to a family of inborn lysosomal storage disorders. The defect is caused by X-linked (IDS, Xq28) deficient activity of lysosomal iduronate-2-sulfatase (I2S) leading to an accumulation of undegraded glycosaminoglycans (GAG) in tissues throughout the body. The clinical symptoms appear in early childhood typically as ear and respiratory tracts infections, abdominal hernias and later progressively develops in severity to facial dysmorphies (a prominent forehead, a nose with a flattened bridge, and an enlarged tongue), organ involvement (enlarged liver, cardiomyopathy, airways thickening, joint stiffness) and mental and behavioral decline. The life expectancy of classical male patients is 10-20 years. The main accumulated GAGs are dermatan sulfate and heparin sulfate. The presence of these GAG in urine, deficient I2S activity in leukocytes, clinical features and finally demonstration of pathological mutation in IDS gene are the basis of the diagnosis. Enzyme replacement therapy (ERT) with idursulfase (Elaprase®), a recombinant form of human iduronate 2-sulfatase, has recently been approved in the United States and the European Union. However, only attenuated, non-neurological, form of the disease is considered for ERT as the enzyme does not cross the blood brain barrier. Mouse model of MPSII, replicating human pathology, was found useful for development of ERT and pathogenesis studies on organism level. However, it has been repeatedly shown that mouse models often reflect human disorders incompletely. Use of human tissue cultures can help to overcome some drawbacks of mouse material; however it is usually limited only to accessible cell types such as skin fibroblast. Here we report generation of induced pluripotent stem cell lines from MPSII patients. These cell lines were generated by non-integrating Sendai virus protocol (CytoTune®, LifeTechnologies). The cells expressed pluripotency markers and can be differentiated to all three germ layer. The accumulation of specific GAG was tested by immunocytofluorescence and electrophoresis. The established cellular model can be used to further study the pathobiochemistry of MPSII and novel therapeutic approaches for the disease.

P409**Board Number: B551****Fabry cardiomyocytes generated from induced pluripotent stem cells as a human model for morphology and pathobiochemistry studies.**J. Rybová, R. Dobrovolný¹, B. Asfaw¹, J. Sládková², M. Hyliš³, J. Ledvinová¹;¹Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague, Prague, Czech Republic, ²Department of Pediatrics and Adolescent Medicine, First Faculty of Medicine, Charles University in Prague, Prague, Czech Republic, ³Laboratory of Electron Microscopy, Faculty of Science, First Faculty of Medicine, Charles University in Prague, Prague, Czech Republic

Lysosomal storage disorders is a group of more than 60 genetic disease caused by functional defects in lysosomal enzymatic or non-enzymatic proteins. Fabry disease, an example of one enzymopathie, is caused by deficiency of lysosomal alpha-galactosidase A (EC 3.2.1.22). This defect leads to progressive accumulation of glycosphingolipids with terminal alpha-galactosyl moiety, dominantly globotriaosylceramide (Gb3Cer) and smaller amounts of galabiosylceramide (Ga2Cer) and blood group B antigens in lysosomes of most non-neuronal tissues (mainly heart, kidney and liver) and body fluids [Elleder in Fabry disease, Springer 2010]. Induced pluripotent stem (iPS) cells are generated from somatic cells by their reprogramming with four transcription factors Oct3/4, Sox2, c-Myc and Klf4 [Takahashi et al, 2006]. These cells provide an excellent opportunity to produce disease-relevant cell types for pathophysiology studies and development of new therapeutic approaches. We prepared transgene-free human iPS cells from urine cells isolated from Fabry patients by transduction with Sendai virus expressing reprogramming factors. Derived iPS cell lines were positive for pluripotent markers (Lin-28, Oct3/4 etc.) and alkaline phosphatase activity. Fabry disease phenotype was confirmed by determining deficient alpha-galactosidase activity. Cardiomyocytes (CM) are one of the major cell types affected in Fabry disease and therefore we decided to differentiate generated iPS cells into cardiac cells. We performed differentiation based on the work of Lian et al [Lian et al, 2012]. Generated Fabry-CM and control-CM were positive for cardiac markers (Troponin I, Nkx2.5). The efficiency of differentiation, tested by flow cytometry, was significantly smaller for Fabry-CM compared to control probably due to Fabry phenotype. Ultrastructure analysis of Fabry-CM revealed abnormally sized and shaped mitochondria, almost regularly associated with aberrant and sparse cristae, dilated endoplasmatic reticulum and membranous cytoplasmic body structures in comparison with controls. We suggest that observed damages of intracellular architectures of Fabry-CM are tightly associated with their functional pathology followed by clinical phenotype of the heart of Fabry patients, predisposed to storage. Other studies are needed to elucidate the cascade of molecular events connected with etiopathogenesis FD. Recently, it was described effective clearance of Gb3Cer by the recombinant enzyme in Fabry disease iPS cell [Iltier et al, 2014]. Trafficking of supplied enzyme within the compartments highly loaded with storage compounds will be the subject of our further studies.

P410**Board Number: B552****Mitotic Membrane Remodelling by the ESCRT machinery.**Y. Olmos^{1,2}, L. Hodgson³, J. Mantell³, P. Verkade³, J. Carlton²;¹Cancer Studies, King's College London, London, United States, ²Cancer Studies, King's College London, London, England, ³Univ Bristol-Sch Biochem, Bristol, England

The Endosomal Sorting Complex Required for Transport (ESCRT) Machinery regulates diverse membrane remodelling events that allow completion of cytokinesis, intraluminal vesicle biogenesis at the multi vesicular body and the release of enveloped retroviruses such as HIV-1. We employ here high resolution light and correlative electron microscopy to examine the localisation of ESCRT-III components through different phases of mitosis. We discover a new localisation and function for ESCRT-III in mitotic membrane remodelling during telophase and explore this function using collective 3D electron tomography.

P411**Board Number: B553****Activator of G-protein Signaling 3 (AGS3)-induced lysosomal biogenesis mediates resistance against (antibiotic-resistant) intracellular pathogens.**A. Vural¹, S. Al-Khodor², G.Y. Cheung³, C.S. Shi¹, L. Srinivasan⁴, V. Briken⁵, M. Otto³, I.D. Fraser², J.H. Kehrl¹;¹Laboratory of Immunoregulation, National Institutes of Allergy and Infectious Diseases, BETHESDA, MD,²Laboratory of Systems Biology, National Institute of Allergy and Infectious Diseases, Bethesda, MD,³Laboratory of Human Bacterial Pathogenesis, National Institute of Allergy and Infectious Diseases,Bethesda, MD, ⁴Univ of Maryland, College Park, MD, ⁵Univ Maryland, College Park, MD

Enhancing the host immune response at host-pathogen interface represents an advantageous alternative strategy to combat drug-resistant bacterial infections. One such intervention would be to enhance the activity of lysosomes, which are the ultimate degradation organelle for internalized bacteria. Here we report that increasing the levels of Activator of G-protein Signaling 3 (AGS3) augments lysosome activity, thereby limiting intracellular bacterial infections in macrophages. AGS3 is a guanine nucleotide dissociation inhibitor (GDI) that binds GDP bound G α subunits of the Gi/Go/transducin family of G proteins via its four G-protein regulatory (GPR/GoLoco) motifs. This stabilizes the G α subunit in its GDP-bound conformation. AGS3 has been implicated in a broad array of physiologic functions including neuronal differentiation, addiction and craving behavior, autophagy, membrane protein trafficking, metabolism, cardiovascular regulation, polycystic kidney disease, and leukocyte migration. We found that increasing the level of AGS3 in the human macrophage cell line, THP-1, led to an increased nuclear translocation of the transcription factor EB (TFEB), a known regulator of lysosomal biogenesis. This occurred as a consequence of enhanced mTOR activity and led to a significant increase in lysosomal mass. To test the impact of AGS3-induced lysosome enrichment on the response of macrophages to

bacterial infection, THP-1 cells with low or elevated levels of AGS3 (AGS3lo and AGS3hi) were infected with the intracellular pathogen, Burkholderia cenocepacia, an antibiotic-resistant gram negative bacterium that causes significant morbidity in cystic fibrosis and chronic granulomatous disease patients. THP-1 AGS3hi cells suppressed the intracellular replication of Burkholderia cenocepacia BC J2315 by enhancing lysosomal degradation and reducing bacterial escape from the endo-lysosomal pathway. Moreover, the infection of AGS3 deficient primary macrophages, which possessed a reduced lysosomal mass, resulted in a higher intracellular bacterial replication rate than was noted with wild type macrophages. Furthermore, the THP-1 AGS3hi macrophages better controlled two other bacterial infections. Mycobacterium tuberculosis replicated at a slower rate in THP-1 AGS3hi macrophages and Methicillin-resistant Staphylococcus aureus strain 252 induced a lower level of cellular apoptosis resulting in enhanced cell survival. Thus, by elevating their levels of AGS3 macrophages can upregulate lysosomal biogenesis decreasing their susceptibility to intracellular bacterial infection. Identifying the signals that control AGS3 expression may provide a mechanism to limit intracellular bacterial infections in macrophages and perhaps other cell types.

Autophagy is essential for the survival and regenerative potential of hematopoietic stem cells.

T.T. Ho¹, M.R. Warr¹, J. Debnath², E. Passegue¹;

¹Department of Medicine, University of California, San Francisco, San Francisco, CA, ²Department of Pathology, University of California, San Francisco, San Francisco, CA

While autophagy helps adult hematopoietic stem cells (HSC) to withstand metabolic starvation, its function in maintaining blood production remains unknown. Conditional inactivation of autophagy in the blood system results in myeloid expansion with mild anemia and lymphopenia, and maintenance of HSC numbers. However, autophagy-deficient HSCs show increased proliferation with enhanced myeloid differentiation, and rapidly become exhausted following transplantation with loss of self-renewal and regenerative potential. Electron microscopy analyses reveal increased numbers of usually deformed mitochondria, expanded endoplasmic reticulum and golgi compartments with excess of small vesicles, and misshaped nucleoli. Microarray gene expression analyses confirm significant changes in metabolic, membrane, nucleus, and mitochondria pathways. We are currently performing metabolic analyses to determine whether accumulation of mitochondria could drive increased oxidative phosphorylation and production of reactive oxygen species (ROS), thereby inducing HSC proliferation and functional exhaustion. Our results demonstrate that autophagy is essential for HSC survival and normal blood regeneration.

Role of Sop4, an ER membrane complex (EMC) member in protein quality control.

R. Lakshminarayan¹, E.A. Miller¹;

¹Biological Sciences, Columbia University, New York, NY

Protein biogenesis in the secretory pathway requires precise folding and targeting of nascent polypeptide-bound ribosome complex at the ER. Quality control is essential such that cells do not accumulate aggregates of misfolded and mislocalized proteins that are deleterious to the cell. Here, we studied the biogenesis of Yor1p, an ortholog of CFTR (Cystic Fibrosis Transmembrane Regulator) in yeast *S. cerevisiae*. Yor1p is an ABC transporter that confers oligomycin resistance to the cell and like CFTR, a single mutation (Yor1- Δ F670) causes misfolding and retention in the ER. A high throughput screen of Yor1- Δ F with the yeast gene deletion collection identified regulators of membrane protein biogenesis (Louie, RJ et al., *Genome Med* 2012). The ER membrane complex (EMC 1-6) family along with Sop4 was identified as one of the deletion enhancers (slower growth on oligomycin) which indicated that these factors might promote Yor1p biogenesis. Interestingly, deletion of *sop4* did not affect stability of Yor1- Δ F highlighting its' role in the early stages of protein translation. Biochemical studies using short pulses of S35 revealed that Yor1p levels were indeed reduced in a *sop4* Δ strain compared to wild-type (wt). Similar results were seen in a double delete *emc6* Δ *emc2* Δ strain but not with individual deletions indicating that the EMC members might be functionally redundant. Further, deletion of ribosomal proteins such as *rpl12a* but not the cytosolic E3 ligase (*ltn1*), or the ERAD member (*cue1*) rescued growth on oligomycin and Yor1p levels were restored in the *sop4* Δ strain. Interestingly, in a *sop4* Δ strain, reduction in Yor1p levels was concomitant with elevated levels of the GPI-anchored protein, Gas1. Under these conditions, synthesis of the tail anchored protein, Sec22 wasn't affected. We propose two models to explain our findings: 1) Sop4 is an ER membrane chaperone which co-translationally regulates the biogenesis of membrane anchored proteins and likely communicates with the ribosome through associated proteins like *bfr1*, *scp160* and *rpl12a*. 2) Sop4 and the EMC complex mediate targeting of the ribosome-mRNA complex to the ER ensuring appropriate localization and translocation through the ER.

P414**Board Number: B556****ER export of yeast plasma membrane proteins requires dual interaction with the COPII coat.**S. Pagant¹, E.A. Miller¹;¹Biological Sciences, Columbia University, New York, NY

Many polytopic membrane proteins that reside at the yeast plasma membrane require the cargo receptor, Erv14, for efficient ER export. We recently found that the yeast ABC transporter, Yor1, similarly requires Erv14 for traffic despite having its own diacidic ER export signal. We sought to ask why a membrane protein that directly interacts with the Sec24 subunit of the COPII coat to facilitate ER export also requires a dedicated cargo receptor. Here we present a detailed structure-function analysis of Erv14 in the context of both Yor1 and a comprehensive array of additional polytopic membrane clients. We show that Erv14 indeed functions as a receptor, with a cargo-binding site contained within its second transmembrane domain that recognizes a subset of clients. The COPII binding signal of Erv14 is essential for traffic of all of its clients, further supporting a role as a classical cargo receptor. However, Sec24 itself seems to be the primary driver of ER export since overexpression of Sec24 could rescue Erv14 defects, at least with respect to Yor1 traffic. We propose that for a large class of polytopic membrane proteins, Sec24 binds to a dual signal that forms from two independent COPII binding signals: one on the cargo protein and one on Erv14, which in turn binds to cargo via a TMD-TMD interaction. This added affinity for the coat may improve packaging efficiency of large, bulky proteins that could be difficult to capture into a spatially constrained vesicle.

P415**Board Number: B557****Analysis of a yeast strain with deletion of multiple genes encoding yeast COPII vesicle proteins.**Y. Noda¹, S. Fujii¹, K. Yoda¹;¹Department of Biotechnology, The University of Tokyo, Tokyo, Japan

How a variety of newly synthesized membrane and secretory proteins are correctly and efficiently sorted into the COPII vesicles remains incompletely understood. To gain new insights into selective transport mechanisms at the ER and the Golgi, we created a yeast strain whose multiple genes encoding abundant COPII vesicle proteins are deleted simultaneously. The eight genes, *SVP26*, *ERV41*, *ERV46*, *ERV14*, *ERV29*, *EMP46*, *EMP47*, *GOT1*, were deleted by pop-in-pop-out replacement of the target genes using the *URA3* marker. The deletion strain of 8 genes (the $\Delta 8$ strain) showed decreased growth rate at 30°C, and was not able to form colonies at 16°C and 37°C. Introduction of the *ERV14* or the *GOT1* gene rescued the temperature-sensitive growth of the $\Delta 8$ strain, suggesting that the double disruption of the *ERV14* and *GOT1* genes is responsible for the growth retardation at high temperature. Although

the function of Erv14 as a cargo receptor for ER exit of a number of membrane proteins was already established (1)(2), the function of Got1, which is a conserved tetra membrane-spanning ER-Golgi protein, was totally unknown (3). Based on the result of our genetic analysis, we hypothesized that the Got1 may function to facilitate the ER-Golgi traffic of the membrane proteins either as a cargo receptor similarly to the other abundant membrane proteins in the COPII vesicles or by previously unappreciated mechanisms. To identify proteins that may interact with Got1 specifically either at the ER or Golgi, alanine substitutions were introduced into the three inter-transmembrane regions predicted to face the cytosol. We found that the alanine substitutions in the second inter-transmembrane region caused accumulation of the mutated Got1 protein in the ER, suggesting that this region may contain the sequence necessary for the efficient incorporation of Got1 into the COPII vesicles. The triple HA-tagged version of either wild-type or the mutated Got1 with alanine substitutions were immunoprecipitated and two co-immunoprecipitated proteins were found, one of which was specific for the wild-type Got1 protein, and the other one was specific for the mutated protein accumulated in the ER. These two proteins were identified using TOF-MS and we are currently investigating whether or not they have physiological roles in the biological processes where the Got1 protein functions. Live cell microscopy of early ER export events underpins a new model for COPII function at the ER-ER exit site boundary.

O. Shomron¹, I. Nevo-Yassaf², T. Aviad¹, G.H. Patterson³, K. Hirschberg²;

¹Pathology, Tel Aviv university, Tel Aviv, Israel, ²Pathology, Tel Aviv University, Tel Aviv, Israel, ³NIBIB, NIH, Bethesda, MD

ER exit sites (ERESs) are tubular-vesicular high curvature membrane domains scattered over the ER. These domains orchestrate the anterograde trafficking of membrane proteins from the ER to the Golgi complex by facilitating the selection and concentration of transport competent cargo proteins. These processes and the subsequent budding of vesicles are mediated by the cytosolic ERES membrane-associated COPII heterocomplex. Isoforms of the COPII subunit Sec24p recognize a broad variety of targeting signals at the cytosolic tail of membrane cargo proteins. The mechanistic details of how the COPII complex mediates the selection and concentration of correctly folded transport-competent cargo are obscure. Treatment of intact cells with BFA and Nocodazole uncouples early cargo recognition, sorting and concentration from later vesicle formation steps. Under these conditions ERESs lose their tubular-vesicular curved structure and become dilated spherical membranes. Nevertheless, using high temporal resolution microscopy and quantitative analysis we demonstrated that these dilated ERESs retain their ability to select and concentrate membrane cargo proteins in a COPII-targeting signal interaction dependent manner. In this experimental system we demonstrate that COPII, bound to a stem-like membrane structure connecting ERES to the ER, generates a flow of cargo proteins and lipids

into the sphere shaped ERES membrane. High-resolution multifocal SIM analysis (improved X-Y and Z resolution) confirmed the cylindrical shape of COPII coated membranes. Furthermore, high-speed confocal microscopy analysis indicates that the COPII coat exerts a diffusion barrier for exchange between the ERES and the ER lumens. Site directed mutagenesis of Sec24p was used to modify and increase the interaction between the acidic motif of VSVG and the Sec24B isoform. We anticipated that rather than accumulation of COPII coated ERES membranes, ER export of VSVG will be blocked at an earlier stage. Indeed, in cells expressing the mutant COPII subunit Sec24B-V923R cargo accumulation within ERES was significantly reduced resulting in cargo being mostly retained in the ER. These data are consistent with the premise that the Sec24B-V923R remains coupled to its VSVG cargo thereby preventing its flow into ERESs membranes. Our data supports the hypothesis whereby the COPII coated short tubular structure on the ER-ERES boundary serves as a quality control and cargo sorting and concentration complex. The cargo protein and membrane flow, generated by this COPII apparatus is facilitated by three driving forces: (1.) dynamic weak interactions between the Sec24p-cargo proteins targeting signals. (2.) Interaction between the lipids and transmembrane domains of cargo proteins. (3.) Treadmilling towards the ERES of the membrane bound COPII-cargo complex due to the asymmetrical recruitment of COPII on the ER side.

Mutation in GAPDH that blocks endocytosis also arrests ER to Golgi transport.

E.J. Tisdale¹, N.K. Talati¹, C.R. Artalejo¹, A. Shisheva²;

¹Pharmacology, Wayne State Univ School of Medicine, Detroit, MI, ²Physiology, Wayne State Univ School of Medicine, Detroit, MI

Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) is required for ER to Golgi transport. GAPDH is also required for transport in the endocytic pathway; substitution of Pro236 to Ser rendered CHO cells defective in endocytosis. The objective of these studies was to determine if GAPDH (Pro236Ser) could inhibit ER to Golgi trafficking. To address this question, the recombinant mutant protein was evaluated in an in vitro trafficking assay. We found that the mutant protein efficiently blocked VSV-G protein transport suggesting that GAPDH (Pro236Ser) affected a factor(s) common to endocytosis and secretion. Permeabilized HeLa cells either incubated with mutant protein or ectopically expressing the mutant had fragmented Golgi. Moreover, Rab1 distribution was drastically altered in mutant treated/ectopically expressing cells, as assessed by indirect immunofluorescence. Immunoprecipitation and subsequent western blot analysis of cell lysates from wt and mutant transfected cells indicated that Rab1 associates with GAPDH but does not bind GAPDH (Pro236Ser). Importantly, the Pro236Ser mutation in GAPDH disrupted association between the enzyme and Akt. We propose that Rab1 requires GAPDH-Akt for ER-Golgi transport.

P418**Board Number: B560****Sar1b loss-of-function animal model explains diverse physiological roles of chylomicron traffic in morphogenesis.**E.W. Knapik¹, D.S. Levic², W. Wang¹, D.B. Melville¹;¹Medicine, Vanderbilt University Medical Center, Nashville, TN, ²Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

Anderson Disease (ANDD) or Chylomicron Retention Disease (CMRD) is a rare, hereditary lipid malabsorption syndrome associated with mutations in the SAR1B gene that is characterized by failure to thrive and hypocholesterolemia. Although the role of SAR1B in formation of coat protein II (COPII) coated carriers is well established, little is known about SAR1B loss-of-function in lipid absorption in vivo. Moreover, key questions regarding the pathogenesis of ANDD remain unanswered. To address this, we have developed a zebrafish model of Sar1b deficiency. Using pulse-chase lipid clearance assays and electron microscopy, we find that dietary fats accumulate in Sar1b-deficient enterocytes, consistent with ANDD symptoms of chylomicron retention. We also use in vivo imaging of dietary cholesterol analogs to reveal a novel requirement for Sar1b function in cholesterol uptake into enterocytes. ANDD patients present with a range of diverse symptoms, the pathogenesis of which is not known. Our study offers a model where specific symptoms and phenotypes can be tested. Using transgenic labeling, histology, and in situ analyses we show that Sar1b is required for exocrine pancreas and liver differentiation and growth. Furthermore, we find abnormal differentiation and maturation of craniofacial cartilage associated with defects in procollagen II secretion, as well as the absence of select, neuroD-positive neurons of midbrain and hindbrain. Our model of Sar1b-deficiency helps to systematically dissect developmental function of Sar1b and to discover molecular and cellular mechanisms leading to organ-specific ANDD pathology.

P419**Board Number: B561****Mechanism Regulating Synchronous Collagen Expression and Trafficking during Stem Cell to Chondrocyte Differentiation.**G. Unlu¹, E.W. Knapik²;¹Vanderbilt University, Nashville, TN, ²Medicine, Vanderbilt University Medical Center, Nashville, TN

Transition from the stem cell phase to a differentiated cell type is characterized by retooling cellular machinery, including regulatory molecules, structural proteins, and their transport machinery. To understand how the differentiation process provisions for synchronized changes in cellular functions during development, we used a robust in vivo model of zebrafish neural crest stem cells, which differentiate into chondrocytes and then produce, transport, and secrete procollagen II.

Although procollagen synthesis and trafficking are well studied, little is known about how collagen-specific transport machinery and collagen cargo are made synchronously available during vertebrate development and what mechanisms restrain this process from occurring in stem cells.

We have previously shown that procollagen transport requires COPII-inner coat components sec23a and Sec24D to promote collagen secretion (1,2), and a transcription factor, Creb3L2 to activate the expression of these COPII adaptors (3). We hypothesize that a stem cell factor temporarily restricts both collagen expression and trafficking machinery in the undifferentiated stem cell state; and its downregulation during chondrogenic differentiation allows for synchronous upregulation of collagen expression and secretion programs. Our in silico analyses suggested that a neural crest stem cell factor may bind to the promoter region of Creb3L2 to suppress collagen secretion as well as the promoter of a major chondrogenic factor Sox9 to inhibit collagen expression during cartilage development.

Using in vivo mosaic analysis, we find that overexpression of the stem cell factor in differentiated zebrafish chondrocytes and human fibroblasts downregulates both collagen expression and secretion. We demonstrate that overexpression of the stem cell factor leads to reduction in CREB3L2 promoter activity as detected by luciferase-based assays as well as decreased transcript levels of CREB3L2 and components of ER-to-Golgi (COPII) trafficking machinery, especially SEC23A and SEC24D. The changes at the transcript levels are matched by intracellular accumulation of type-I and type-II collagens. Our data support a model in which a neural crest stem cell factor acts as a master regulator of collagen expression and intracellular trafficking machinery; and its developmentally driven downregulation leads to synchronous upregulation of collagen cargo and its transport machinery during differentiation

SLY41 Suppresses the Loss of YPT1 through Regulation of Intracellular Calcium.

I. Mukherjee¹, C. Barlowe¹;

¹Dartmouth College, Hanover, NH

Newly synthesized secretory proteins and lipids are transported from the ER to the Golgi apparatus in a COPII-dependent pathway. This process can be separated into biochemically distinct stages:- of vesicle budding, tethering of vesicle to cis-Golgi membranes and ultimately SNARE-protein dependent membrane fusion. Genetic and biochemical approaches have been employed to identify the factors and characterize the mechanisms of each distinct stage. For vesicle tethering to Golgi membranes, the Rab GTPase Ypt1 functions by recruiting protein complexes important for vesicle recognition and tethering. Loss of *YPT1* gene function in yeast is lethal although a screen for suppressors of loss of *YPT1* identified a set of *SLY* genes that when overexpressed supported growth of *ypt1Δ* cells. Most of the *SLY* genes encode SNARE proteins or SNARE regulatory proteins that are thought to activate fusion and bypass the

Ypt1-dependent tethering stage. In contrast, *SLY41* encodes a multispanning membrane protein of the solute carrier (SLC) family and has no known function. In this study we characterize Sly41 and investigate the mechanism by which over-expression suppresses loss of Ypt1 function. Our findings show that Sly41 is efficiently packaged into COPII vesicles and actively cycles between the ER and Golgi compartments. A novel synthetic genetic interaction was identified between *SLY41* and the P-type ATPase Ca^{2+} transporter encoded by *PMR1*. Using aequorin-based techniques and inductively coupled plasma mass spectrometry, we detected elevated levels of intracellular Ca^{2+} in strains overexpressing Sly41. This effect of calcium is consistent with results showing that deletion of *PMR1* elevates intracellular Ca^{2+} levels and suppresses loss of Ypt1. Based on our data we are testing the hypothesis that Sly41 transports divalent cations such as Ca^{2+} and that overexpression increases intracellular Ca^{2+} levels to suppress tethering defects through activation of SNARE-dependent fusion of COPII vesicles with Golgi acceptor membranes.

Fast live super-resolution imaging of a synchronous Golgi-to-ER transport wave.

F. Bottanelli¹, E. Allgeyer¹, G. Lavieu¹, D.K. Toomre¹, J. Bewersdorf¹, J.E. Rothman¹;

¹Department of Cell Biology, Yale University School of Medicine, New Haven, CT

COPI vesicles mediate Golgi-to-ER retrograde transport. However, light microscopy has until recently been restricted to diffraction-limited structures (greater than ≈ 200 nm), making it impossible to follow COPI vesicles budding due to their small size and vicinity to the Golgi membranes. Here we generated a wave of COPI retrograde vesicles by recruiting a FKBP-KDEL (known to be contained in retrograde COPI vesicles) on a cis-Golgi localized FRB-tagged enzyme (ManII-FRB), taking advantage of the drug-induced FRB/FKBP dimerization system. We followed this wave of retrograde transport by Stimulated Emission Depletion (STED) microscopy on a custom built system, with lateral resolution better than 50 nm. Complete redistribution of ManII to the endoplasmic reticulum (ER) occurred within 1 hour after addition of the dimerizing drug. At earlier time points (10-30 mins) ManII-FRB/FKBP-KDEL dimers were incorporated into COPI-positive tubular-vesicular structures, which subsequently budded from the cis-Golgi side. Visualization of COPI vesicles budding from the Golgi in live cells at the nanoscopy level promises further insights in the mechanisms of formation of COPI in an intact living system.

P422**Board Number: B564****A role for a conserved domain within the Sec7 domain Arf guanine nucleotide exchange factor GBF1 in regulating dimerization, localization and function.**T. Busby¹, J. Bhatt¹, E.G. Viktorova², L. Newman³, G.A. Belov², R.A. Kahn^{3,4}, E. Sztul¹;¹Department of Cell, Developmental and Integrative Biology, University of Alabama at Birmingham, Birmingham, AL, ²Department of Veterinary Medicine, Virginia-Maryland College of Veterinary Medicine, University of Maryland, College Park, MD, ³Department of Biochemistry, Emory University School of Medicine, Atlanta, GA, ⁴Emory University School of Medicine, Atlanta, GA

Members of the large Sec7 domain Arf guanine nucleotide exchange factors (GEFs) appear to dimerize through their N-terminal DCB (dimerization and cyclophilin-binding) and HUS (homology upstream of Sec7) domains. However, the importance of dimerization for GEF function has not been assessed. In GBF1, a GEF functional at the ER-Golgi interface, the dimerization has been proposed to require the K91 and E130 residues within the DCB domain. Thus, we substituted both residues with alanines to generate a K91A/E130A (91/130) mutant and assessed its oligomerization status and function. We show that 91/130 is monomeric, that it targets to the Golgi in a manner indistinguishable from the wild-type dimeric GBF1, and that it rapidly exchanges between the cytosolic and membrane-bound pools. The monomeric 91/130 appears catalytically active as it integrates within the functional network at the Golgi, supports ARF activation and COPI recruitment, and sustains Golgi homeostasis and secretion. However, dimerization appears to stabilize GBF1 in cells and the 91/130 monomer is degraded faster than the dimeric GBF1. Our data support a model in which dimerization is not a key regulator of GBF1 catalytic activity, but impacts its function by regulating GBF1 cellular levels.

P423**Board Number: B565****Structure-function investigation of the C-terminal HDS domains of the Sec7 Guanine nucleotide exchange factor GBF1.**J.M. Bhatt¹, M. Mays¹, N.E. Kaushik¹, E. Sztul¹;¹Department of Cell, Developmental and Integrative Biology, University of Alabama at Birmingham, Birmingham, AL

Monomeric GTPases called ADP-ribosylation factors (ARFs) are critical for vesicular traffic. ARFs need to be activated by guanine nucleotide exchange factors (GEFs) that catalyze the GDP/GTP conversion on ARFs. Formation of COPI vesicles at the ER-Golgi interface has been shown to require the GEF GBF1. GBF1 is a multidomain protein consisting of a central Sec7 domain that catalyzes ARF activation and additional highly conserved domains with poorly understood functions. We hypothesized that the non-catalytic domains also play a role in GBF1 activity, and herein focus on the role of the HDS3 domain in modulating GBF1 function. Using multi-species and multi-member alignments of GBF1 orthologues we

identified a number of most highly conserved amino acids within the HDS3 domain and generated alanine replacements mutants: PLL1544AAA (PLL) and FPL1593AAA (FPL). Both mutants targeted to the Golgi, albeit with decreased efficiency. We assessed the role of the PLL and FPL motifs in "replacement assays" in which cells depleted of endogenous GBF1 by RNAi are 'replaced' with mutant GBF1. We show that the PLL and the FPL mutants are unable to support de novo Golgi synthesis as compared to wild-type GBF1. We investigated the folding of the proteins by limited proteolysis and found that the HDS3 mutants have altered folding patterns than wild-type GBF1. Our results suggest that the HDS3 domain plays a key role in the localization, folding and/or function of GBF1. Our future experiments are addressing two important questions: (1) what does the HDS3 domain interact with? And, (2) do the PLL and FPL mutations disrupt important GBF1 protein-protein interactions?

Board Number: B566

Regulation of the cis-Golgi Arf-GEFs Gea1 and Gea2 by their HDS3 domains and the Rab GTPase Ypt1.

M.A. Gustafson¹, J.C. Fromme¹;

¹MBG/WICMB, Cornell University, Ithaca, NY

The Golgi Arf GTPases control the sorting of membranes and proteins through all eukaryotic cells, recruiting adapters and cargo to sites of vesicle formation when in their activated GTP-bound form. Arf guanine nucleotide exchange factors (Arf-GEFs) are the master regulators of Arf activation and are conserved throughout eukaryotes. Two Arf-GEFs, Gea1 and Gea2, function at the *cis*-Golgi in *Saccharomyces cerevisiae*, but we know relatively little about how these GEFs are regulated. Recent work with their close relative at the *trans*-Golgi network, Sec7, has revealed that recruitment of Sec7 to the trans-Golgi network and relief of its autoinhibition are dependent on its C-terminal domains, as well as on positive feedback from Arf1 and other protein interactions. The Golgi Arf-GEFs share predicted domain architecture, suggesting that Gea1/2 may be regulated by mechanisms similar to those of Sec7. However, the specific proteins which orchestrate the activation and localization of Sec7 do not appear to act upon Gea1/2. *In vitro* biochemical studies, genetics, and live cell microscopy have revealed two contributing factors in Gea1/2 regulation: an interaction with the Rab GTPase Ypt1 and the regulatory roles of one of the domains of Gea1/2. Combined with structural studies, these results will define general features of Golgi Arf-GEF regulation and localization, as well as features specific to Gea1 and Gea2, providing fundamental insight into how Arf1 is regulated at the Golgi.

P425**Board Number: B567****Analyzing Polarized Protein Sorting at the Trans Golgi Network.**A. Treyer¹, F. Lazaro-Dieguez², M. Pujato¹, A. Muesch²;¹Albert Einstein College of Medicine, Bronx, NY, ²Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY

Transporting epithelial cells, such as those of the kidney, lung, gut, and liver, are situated at an interface between two different physiological environments in the body. To function, these cells rely on the generation of surface polarity, which includes initial segregation and continuous occlusion of large apical and basolateral surface domains. The protein and lipid identities of these domains have to be actively maintained throughout the lifespan of the epithelia due to constant turnover of these components in cellular metabolism. Polarized protein sorting and targeting is largely understood to be the function of the trans-Golgi network (TGN). Multiple studies in Mardin-Darby Canine Kidney (MDCK) cell lines, which both, exhibit polarized trafficking of apical and basolateral proteins, and are highly amenable to experimental manipulation, as well as in several other models have resulted in varying interpretations on how apical protein carriers are generated and on what basis are apical proteins segregated and targeted away from their basolateral counterparts. Since the TGN is a highly dynamic tubulo-vesicular structure, where the resident proteins are themselves subject to cargo-like cycling, no clear way exists to define this continuously transient organelle. In our studies, we are attempting to describe the properties of the TGN as a functional compartment by using temperature and pharmacological modulation of the secretory pathway to pulse chase fluorescent cargo to the TGN, while preventing its exit to the post-Golgi destinations, and thus attenuating the lifespan and function of the transient sorting domains. We have developed a fluorescence-based analysis protocol for membrane extracts that contain sorted cargo fractions, and we are proceeding to quantitatively describe the extent to which different cargo types become sorted in the TGN, as well as to further understand how the architecture of this compartment supports the observed sorting dynamics.

P426**Board Number: B568****PCAF is involved in acetylation and subcellular distribution of Sigma-1 receptors.**Y. Yasui¹, T. Su¹;¹NIDA, NIH, Baltimore, MD

Sigma-1 receptors (Sig-1Rs) are endoplasmic reticulum (ER) chaperon proteins that relate to a variety of cellular functions such as ion channel activities, ER-mitochondrial interorganellar calcium signaling, cellular survival and neuronal differentiation. Sig-1Rs predominantly reside at the ER subdomain-apposing the mitochondria (the mitochondria-associated ER membrane, MAM) and translocate to other compartments of the cell under certain conditions such as cellular stress and stimulation with the ligands including cocaine. We previously showed that cocaine-induced translocation of Sig-1Rs, which

intensifies the interaction between Sig-1Rs and Kv1.2 potassium channel, plays an important role in behavioral and neuronal responses to cocaine in mice. Thus, the dynamic shift of subcellular distribution is a critical step for Sig-1Rs to execute their functions at remote sites other than the MAM. However, the detailed mechanism on how the translocation is initiated is largely unknown.

In this study, we found that Sig-1Rs interact with a histone acetyltransferase, p300/CBP-associated factor (PCAF) and that cocaine affects the interaction. We found that the interaction between PCAF and Sig-1Rs occurs at the peri-nuclear area by using immunofluorescence studies. We also found that Sig-1Rs can be acetylated and the acetylation level is modulated by the overexpression or knockdown of PCAF. Protein acetylation on lysine residue(s) is known to usually play a key role in regulating protein functions that relate to nuclear and cytoplasmic events. However, recently it has been reported that acetylation of membrane proteins at the lumen of the ER regulates the protein translocation at the early secretory segment of the translocation pathway. Since Sig-1Rs have lysine residue(s) in the C-terminus that faces the lumen of the ER, we hypothesized that the acetylation of Sig-1Rs could be involved in Sig-1Rs' translocation. We therefore examined whether the PCAF expression level may affect Sig-1R's subcellular distribution by density gradient centrifugation. The results showed that overexpression or knockdown of PCAF changed the Sig-1Rs' subcellular distribution. We also confirmed that cocaine treatment changed the subcellular distribution of Sig-1Rs. However, the cocaine-induced distribution pattern of Sig-1Rs is not exactly the same as those caused by overexpression or knockdown of PCAF.

Together, our data show for the first time that PCAF is a molecular protein, which plays important roles in the acetylation and subcellular distribution of Sig-1Rs. Although cocaine affects the interaction between Sig-1Rs and PCAF, whether the PCAF-mediated acetylation of Sig-1Rs may fully explain cocaine-induced Sig-1R translocation remains to be clarified in the future.

Cbl-c: A Regulator of Golgi Organisation.

V. Lee¹, F.A. Bard¹;

¹IMCB, Singapore, Singapore

The Golgi apparatus plays a pivotal role in the secretory pathway through post-translational modification of secretory and membrane proteins and their subsequent sorting to appropriate destinations. Golgi organisation is dependent on a complex local signalling network. Src is a tyrosine kinase that controls Golgi structure and function. Src is regulated by various ubiquitin ligases, including Cullin-5 and Cbl family proteins. Here we find in a screen for Golgi regulators that Cbl-c depletion induces Golgi fragmentation, while c-Cbl, Cbl-b and Cullin-5 do not. This indicates Cbl-c is specifically involved in regulating Golgi organisation. Furthermore, the ubiquitin ligase activity of Cbl-c is required for its role in regulating Golgi organisation. Cbl-c protein is partially localised on Golgi membranes and this localisation is dependent on Src activity. We find that Cbl-c's regulation of Golgi organisation is dependent on Src, suggesting that Cbl-c regulates COPI dynamics. Cbl-c is self-ubiquitinated in the

presence of active Src. Overall, our results demonstrate a novel role of Cbl-c in regulating Golgi organisation.

Initial characterization of non-ER or -Golgi related nanotubes in protein transport.

L. Cai¹, L. Yao¹;

¹Fudan University, Shanghai, China

As written in the textbook, most protein transport within the cell relies on vesicular transport, which utilizes either small and spherical vesicles, or large and irregularly-shaped membrane-enclosed compartments. Through a specific labeling approach, we are able to show that there are extensive amounts of nanometer-scale tube-like structures (nanotubes) in the cytosol, participating in protein transport. Unlike linear fragments of ER or Golgi apparatus align along microtubules, these nanotubes have limited co-localization with either dynamic or stable populations of microtubules. Interestingly, some but not all of these nanotubes are regulated by dynamic actin filaments. Under stress conditions, the amount of nanotubes increases over time. It would be intriguing to know how these non-ER or -Golgi related nanotubes are generated, and why they exist. We postulate that these nanotubes function as tunnels to expedite protein transport.

BI-1 regulates insulin secretion through enhanced proinsulin synthesis and Glut2 glycosylation in ER.

H. Lee¹, H. Kim², H. Chae^{3,4};

¹Chonbuk National University, Jeonju, Korea, ²Department of Dental Pharmacology, Wonkwang University, Iksan, Korea, ³Department of Pharmacology, Chonbuk National University medical school, Jeonju, Korea, ⁴Department of Pharmacology, Chonbuk National University medical school, Jeonju, Korea

Type 2 diabetes mellitus (T2DM) is a metabolic disorder in which pancreatic insulin secretion does not meet the demands of insulin sensitivity. It is now accepted that elevated glucose levels are required to mediate the lipotoxic effects, including inhibition of glucose-stimulated insulin secretion (GSIS). Chronic hyperglycemia has been known to impair beta cell function. Glucose transporters (Gluts) are a family of integral membrane glycoproteins that transport saccharides across the cell plasma membrane by facilitative diffusion to supply metabolic energy. Pancreatic beta cell-surface expression of glucose transporter-2 (Glut-2) is essential for glucose-stimulated insulin secretion (GSIS), thereby controlling blood glucose homeostasis. N-glycosylation of Glut-2 is required for Glut-2 residency. In this study, Bax inhibitor -1 (BI-1) enhances Glut-2 expression on the β cell surface by regulating N-glycan

ligand for pancreatic lectin receptors. BI-1 enhanced Glut-2 cell surface half-life. The impairment of GSIS leads to metabolic dysfunction diagnostic of type 2 diabetes. Remarkably, the induction of diabetes by chronic ingestion of a high-fat diet is associated with attenuated Glut-2 glycosylation. Chronic hyperglycemia-induced insulin secretion impairment in human insulinoma (INS-1) cells and pancreatic beta islet cells, is regulated by BI-1. BI-1 highly maintains proinsulin synthesis in ER. In the presence of BI-1 insulin secretion is triggered by glucose after chronic hyperglycemia, most likely by enhanced glucose uptake through glycosylation. Ex vivo and in vivo study, we found a correlation between post-translational glycosylation of the Glut-2 and its associated chaperone, calnexin and calreticulin. These results indicate that BI-1 has a regulatory role in diabetes mellitus and can be a therapeutic target protein.

The COPI vesicle coat interacts with the Dsl1 tethering complex at polarized ER arrival sites.

S. Schröter¹, S. Beckmann¹, H. Schmitt¹;

¹Neurobiology, Max Planck Institute for Biophysical Chemistry, Göttingen, Germany

Retrograde trafficking from the Golgi apparatus to the endoplasmic reticulum (ER) is carried out by COPI vesicles. In order to fuse with the ER membrane, COPI vesicles must at least partially disassemble their coat to expose membrane and fusion machinery. However, to date it is still not known during which transport step the coat is removed, and which factors regulate the removal. The ER-resident Dsl1 tethering complex of *Saccharomyces cerevisiae* has recently been implicated in this process, as it was shown to interact with COPI coat components *in vitro*. Here, we provide *in vivo* evidence for the interactions between Dsl1 complex and COPI coat and cargo proteins under native expression conditions, using a bimolecular fluorescence complementation (BiFC) approach. By employing the BiFC system as a unique tool for *in vivo* crosslinking, we visualize the otherwise transient interactions between COPI vesicles and Dsl1 complex, and show that the interactions are substantial for cell viability. Our results carry two interesting implications: They provide evidence for COPI coat retention until arrival at the ER membrane, suggesting a targeting function of the coat complex. These results are complemented by our reports of genetic interactions between the Dsl1 complex and a set of p24 cargo receptors, which may in this context fulfill an additional regulatory role in vesicle uncoating. Furthermore, the visual detection of interaction sites between Dsl1 complex and COPI coat at the ER unveils the subcellular localization of ER arrival sites in *S. cerevisiae*. The ER arrival sites show a distinct localization with respect to ER exit sites, Golgi, and sites of secretion, and exhibit a growth-associated polarization pattern. These dynamics provide insights into the crosstalk between transport processes, suggest a function of COPI-mediated retrograde transport in cell budding, and conceivably play a role in organelle inheritance.

P431**Board Number: B573****Sac1 Phosphoinositide Phosphatase – Regulation of PI(4)P levels in the early secretory pathway.**S. Weiss¹, C. Barlowe¹;¹Biochemistry, Geisel School of Medicine, Dartmouth College, Hanover, NH

Phosphoinositides play multiple roles in intracellular trafficking and can act as intracellular signals, which recruit proteins to specific compartments. The restricted distribution of phosphoinositides is created by targeting of lipid modifying enzymes. PI(4)P is synthesized by multiple, separate PI(4)P-kinases and is therefore likely to have distinct intracellular pools. A previous study from our lab has shown that inhibition of PI(4)P levels on Golgi membranes results in decreased ER-to-Golgi transport efficiency (Lorente-Rodriguez and Barlowe, 2010). Based on these results, we proposed that Golgi-localized PI(4)P regulates fusion of COPII vesicles with Golgi membranes.

In this study, we investigate the role of the phosphoinositide phosphatase Sac1 in regulation of PI(4)P levels at *cis*- and *medial*-Golgi compartments. Localization of Sac1 was determined by sucrose gradient fractionation and live cell imaging experiments and compared to Sac1 localization under glucose starvation conditions. Endogenous Sac1 as well as Sac1-GFP remained ER-localized in the presence or absence of glucose starvation. In cell-free COPII-dependent vesicle budding assays we observed that Sac1 was not efficiently packaged into COPII vesicles. These results support a model in which Sac1 is ER-localized and fulfills its role in regulation of different PI(4)P pools through contact sites between the ER and other cellular compartments such as the Golgi or the plasma membrane. To understand which PI(4)P pools are targeted by ER-localized Sac1, we constructed different versions of the Sac1 protein. Overexpression of a soluble Sac1 protein, which lacks the two transmembrane domains (Sac1 Δ TM), rescues the cold sensitivity of *sac1* Δ cells, whereas the phosphatase dead mutants Sac1 C392S or Sac1 Δ TM C392S failed to rescue cold sensitivity. Furthermore, we observed that the Sac1 Δ TM C392S protein, which shows high affinity to PI(4)P but lacks the phosphatase activity was targeted to membranes compared to the soluble Sac1 Δ TM protein. GFP-tagged versions of Sac1 Δ TM C392S provide a new, powerful tool to analyze Sac1 function and intracellular localization in more detail.

P432**Board Number: B574****Congenital dyserythropoietic anemia type II reveals an interaction of the COPII coat component SEC23 with KIF23 and integration of cell cycle progression with membrane traffic.**F. Verissimo¹, k. schwarz², M. Gentzel³, R. Pepperkok⁴;¹EMBL, Heidelberg, Germany, ²Institute for Transfusion Medicine, University of Ulm and Institute of Clinical, Ulm, Germany, ³Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany,⁴Cell Biology and Biophysics, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

Congenital dyserythropoietic anemia type II (CDAlI) is caused by mutations in the Sec23b gene. Yet it's molecular mechanism and how mutations that span the complete gene cause the disease remains elusive. Here we propose that CDAlI is caused by the failure of the interaction of SEC23 with the mitotic regulator KIF23/MKLP1. The localization of these proteins at the mitotic spindle in metaphase is necessary for recruitment of KIF23 downstream effectors and successful completion of cell division. On the other hand localization of SEC23 to the mitotic spindle avoids its degradation and guarantees sufficient SEC23 for the reformation of the secretory pathway at the end of mitosis. Altogether, our results uncover a new role for the SEC23 protein in cell division, provide a mechanistic explanation for the congenital dyserythropoietic anemia type II (CDAlI) and describe a novel mechanism that integrates cell cycle progression with regulation of the early secretory pathway.

P433**Board Number: B575****Contact of cis-Golgi with ER exit sites executes cargo capture and delivery from the ER.**K. Kurokawa¹, A. Nakano²;¹Center for Advanced Photonics, RIKEN, Wako, Japan, ²Center for Advanced Photonics, RIKEN, Wako-shi, Japan

Protein transport from the endoplasmic reticulum (ER) to the Golgi apparatus is mediated by coat complex II (COPII) vesicles. Sar1-GTP recruits the inner shell complex (Sec23/24) to initiate COPII coat assembly and sorting of secretory cargo proteins, and then the outer cage complex (Sec13/31) promotes the polymerization of the whole coat and deforms ER membrane to drive COPII vesicle formation at the ER exit sites (ERES). It has been believed that COPII vesicles containing cargo are released from ERES into the cytosol and then reach and fuse with the first post-ER compartment, cis-Golgi or ER-to-Golgi intermediate compartment (ERGIC). However, it still remains elusive how cargo loading to vesicles, vesicle budding, tethering and fusion are coordinated in vivo. Here we show, using extremely high speed and high resolution confocal microscopy (which is named as Super-resolution Confocal Live Imaging Microscopy, SCLIM), that the cis-Golgi in the budding yeast *Saccharomyces cerevisiae* approaches and

contacts the ERES. The COPII coat cage then collapses, and the cis-Golgi captures cargo. The cis-Golgi, thus loaded with cargo, then leaves the ERES. We propose that this “hug-and-kiss” behavior of cis-Golgi ensures efficient and targeted cargo transport from the ERES to cis-Golgi.

Board Number: B576

Super-resolution imaging reveals anterograde and retrograde cargos in COPI vesicles.

L.K. Schroeder¹, E.S. Allgeyer¹, J. Bewersdorf¹, J.E. Rothman¹;

¹Department of Cell Biology, Yale University School of Medicine, New Haven, CT

COPI-coated vesicles play a central role in the secretory pathway. They have been strongly implicated in both anterograde and retrograde transport, though their role in anterograde transport remains controversial. COPI vesicles are approximately 70 nm in diameter and closely packed around the Golgi, which prohibits direct visualization of individual vesicles, or their cargo, with conventional light microscopy (limited to 250 nm resolution).

Recent advances in stimulated emission depletion (STED) and single molecule switching (SMS) super-resolution microscopy approaches now enable the examination of individual COPI vesicles. We have accordingly developed techniques to label endogenous proteins in COPI vesicles and use super-resolution microscopy to identify individual COPI vesicles in fixed cells. Using two and three-color imaging, we have determined that COPI vesicles contain the expected protein machinery such as the scaffold Scyl1 and the v-SNARE Bet1, while lacking Golgi cisternal tether proteins GM130 and GRASP65. We also confirm that COPI vesicles contain both anterograde and retrograde cargos (Orci *et al.* 1997, Cell 90: 335-349).

All roads lead to Rome- SRP independent translocation into the endoplasmic reticulum.

T. Ast¹, M. Schuldiner^{1,2};

¹Molecular Genetics, The Weizmann Institute of Science, Rehovot, Israel, ²Department of Molecular Genetics, The Weizmann Institute of Science, Rehovot, Israel

Translocation into the endoplasmic reticulum (ER) is an initial and crucial biogenesis step for all secreted and endomembrane proteins in eukaryotes. Even in the simple eukaryotic model organism, *Saccharomyces cerevisiae*, this is no simple task, as over a fifth of its proteome must translocate into the ER. It's been well established that several ER targeting pathways are present in *S. cerevisiae*, the best known of which relies on the signal recognition particle (SRP). We set out to shed new light on

alternative SRP-independent translocation pathways. To do so, we harnessed unbiased and systematic approaches to further our understanding of the mechanisms by which these pathways function, and what measures are in place if they are dysfunctional. By combining hydropathy-based analysis and high throughput microscopy, we uncovered that over 20% of the yeast secretome translocates without the aid of the SRP. Further investigation of these SRP-independent substrates revealed an additional motif for ER targeting and uncovered a network of cytosolic proteins that facilitate SRP-independent targeting and translocation. Finally, by employing a systematic microscopic screen, we revealed that SRP-independent substrates are subject to pre-translocational monitoring that clears the cytosol of proteins that have failed to translocate in a timely manner. These findings highlight the underappreciated complexity of SRP independent translocation and its central role in enabling the extensive flux of proteins into the ER.

Kismet affects synaptic transmission and endocytosis at the *Drosophila* Neuromuscular Junction.

K. Knoth¹, T. Delaney¹, F. Liebl¹;

¹Southern Illinois University Edwardsville, Edwardsville, IL

Efficient synaptic communication requires bidirectional signaling between the pre- and postsynaptic cells. This signaling depends on the localization of synaptic proteins to mediate endo- and exocytosis at appropriate synaptic locations. We have found that the trithorax group chromodomain helicase DNA binding (CHD) protein, Kismet (Kis), which regulates chromatin remodeling, influences synaptic transmission and, possibly secondarily, endocytosis. Animals with mutations in *kis* exhibit a significant decrease in the frequency and amplitude of spontaneous neurotransmission and in evoked amplitudes. The change in neurotransmission may be partly due to a reduction in endocytosis in *kis* mutants. Further, *kis* mutants exhibit a change in the localization of the postsynaptic glutamate receptor subunit, GluRIIC, relative to Brp, a protein localized to active zones. Our data suggests that Kis affects synaptic transmission and endocytosis by regulating distinct processes in both the pre- and postsynaptic cells. Based on these data, we hypothesize that Kis regulates synaptic transmission, possibly by influencing transcription of synaptic target genes involved in bidirectional synaptic signaling and/or endocytosis.

P437**Board Number: B580****Regeneration of Olfactory Epithelium from Horizontal Basal Cells.**R.E. Turn¹, C. Wall², H. Zhao²;¹Harriet L. Wilkes Honors Coll, Jupiter, FL, ²Department of Biology, Johns Hopkins University, Baltimore, MD

Due to environmental insult and natural turnover, olfactory neurons and the surrounding non-neural cells die and therefore need to be replaced to restore function. Two forms of progenitor cells facilitate the regeneration of neural tissue within the pseudostratified olfactory epithelium: globose basal cells (GBCs) and horizontal basal cells (HBCs). While GBCs regularly produce progeny which mature into olfactory neurons, HBCs only undergo mass regeneration after widespread loss of olfactory epithelium. HBCs are capable of producing all olfactory epithelium cell types. Furthermore, these pluripotent progenitor cells are found in adult mammals and are easily accessible via biopsy. These definitive characteristics of HBCs make them a promising population of adult neural stem cells that may be used for future medicinal applications. As a result, there is a push to better characterize HBCs and the mechanisms they employ to restore neural and non-neural tissue post-injury.

Recently, our lab has investigated different ways to activate HBCs and to characterize signaling after activation. To do so, we designed a Cre/LoxP mouse line that expresses the fluorescent marker protein, TdTomato, in members of the HBC lineage. Quantification of fluorescent and non-fluorescent cells in the olfactory epithelium was conducted subsequent to chemically-induced damage via intraperitoneal injections of the drug methimazole. We wish to define the relationship between administered dosage and resulting damage using flow cytometry, to identify the extent of regeneration after different modes of damage and recovery times, and to characterize HBC lineage protein expression at the time of activation (1-2 days post injury).

P438**Board Number: B581****Extracellular stimuli regulate cell differentiation and acquisition of functional properties in cultured embryonic chick olfactory neurons.**G. O'Neill¹, C. Musto¹, G. Gomez¹;¹Biology, University of Scranton, Scranton, PA

Cell differentiation is often governed by endogenous compounds, such as growth factors. However, sensory systems such as olfaction are unique because they are constantly exposed to external compounds as part of their normal function. Thus, our aim was to test if these external stimuli can exert similar effects on the differentiation of sensory cells. Olfactory turbinates were extracted from E-17 chick embryos, enzymatically dissociated, then grown on glass coverslips. Starting on day 2, cells were exposed to different odors for 12 hour periods, alternated with periods of no-odor exposure. On days 4,

5, and 6, cell odor sensitivity was tested using calcium imaging, and the expression of proteins characteristic of neuronal differentiation was quantified using immunocytochemistry. Our results show that a greater proportion of cells exposed to odors are odorant responsive. In addition, immunocytochemistry results showed that a higher proportion of treated cells were beta-tubulin+ and OMP+. Odor stimuli canonically activate signal transduction cascades mediated by cAMP. Our studies suggest multiple long-term roles of these signal transduction cascades that are traditionally thought to activate short-term signaling activities. This opens avenues for future investigations on the role of normal extracellular environments on directing neural cell development.

Uncovering a restrictive molecular mechanism that regulates dendritic spine formation in the developing brain.

T. Schaffer¹, J. Salogiannis², M. Greenberg², S. Margolis¹;

¹Department of Biological Chemistry, The Johns Hopkins University School of Medicine, Baltimore, MD,

²Department of Neurobiology, Harvard Medical School, Cambridge, MA

Within the brain, information is relayed across pathways of excitatory synapses. These excitatory synapses individually localize at specialized cellular compartments on neuronal dendrites called dendritic spines. Although dendritic spines are independently remodeled over an individual's lifetime, certain parameters of dendritic spine development are stereotyped in the early postnatal brain, including the locations, timing, and density of nascent spine formation. The restrictive molecular mechanisms defining these parameters to prevent aberrant dendritic spine formation are unknown.

The RhoA GEF Ephexin5 is a negative regulator of dendritic spine development that is ubiquitinated and degraded during events preceding dendritic spine formation. Ephexin5 localizes to dendritic spines and drives significant RhoA activation in the early brain, and I hypothesize based on this activity that the restrictive role of Ephexin5 is regulated by mechanisms enforcing where, when, and how often dendritic spines form during development.

By monitoring Ephexin5 expression over time, we have discovered that Ephexin5 is phosphorylated at N-terminal serines 107 and 109 during a developmental time course preceding synaptogenesis. This phosphorylation is required for Ephexin5-mediated RhoA activation and dendritic spine suppression in cultured neurons. Furthermore, Ephexin5 serine 107 and 109 phosphorylation appears to be mediated by a PKC isozyme that we are currently pursuing. The identification and characterization of Ephexin5-targeted kinase activity will ascribe a broadened role to the responsible enzyme in neuronal development, meanwhile enabling us to elucidate a restrictive molecular mechanism that parameterizes dendritic spine formation in the early postnatal brain.

P440**Board Number: B583****Transsynaptic protein alignment organized by a synaptic nanocolumn.**A. Tang¹, T.A. Blanpied^{2,3};¹Physiology, University of Maryland School of Medicine, Baltimore, MD, ²Department of Physiology, Univ of Maryland Sch of Med, Baltimore, MD, ³Program in Neuroscience, Univ of Maryland Sch of Med, Baltimore, MD

Accumulation of neurotransmitter receptors across from sites of synaptic vesicle fusion is the structural basis for synaptic transmission, and the molecular aspects of this organization are of great interest. Key critical elements are abundant and essential scaffold proteins that establish the architecture of the PSD; deletion or mutations in their human genes cause severe neuropsychiatric disorders including autism, mental retardation, and schizophrenia. Previously, by measuring the internal structure of single PSDs in live neurons using photoactivated localization microscopy (PALM), we have found that four major PSD scaffold proteins, PSD-95, GKAP, Shank and Homer1, were each organized in distinctive ~80 nm ensembles. Notably, PSD-95 ensembles were enriched for both GluA2-containing AMPARs and GluN2B-containing NMDARs. The functional influence of such an organization is predicted to be greatly amplified if postsynaptic receptor/scaffold ensembles lie very precisely across the synaptic cleft from sites of vesicle fusion within the active zone. However, whether such alignment exists has not been demonstrated.

Here, we used multiple-color 3D stochastic optical reconstruction microscopy (STORM) to examine the distribution of other synaptic constituents, including presynaptic proteins known to be involved in mediating vesicle fusion. Among these, RIM, a protein thought to link vesicles with Ca channels, was found organized in high-density ensembles within single active zones. These ensembles were of size similar to postsynaptic scaffold and receptor nanoclusters (76 ± 9 nm diameter). Critically, cross-correlation analysis showed that RIM nano-ensembles were highly correlated to the position of PSD-95. Furthermore, this correlation was reduced by picrotoxin treatment that enhances neuronal activity and is known to homeostatically weaken synaptic transmission. These results indicate that multiple proteins distributed along the axial extent of the synapse are co-enriched at specific domains across the face of the synapse. Further, this transsynaptic alignment is modulated by activity. This relatively compact, vertically oriented molecular organization within the bounds of the synapse suggests a “synaptic nanocolumn” that may be important for establishing and modulating synapse function.

P441**Board Number: B584****Distinct spatial distributions of evoked and spontaneous vesicle fusion sites.**H. Chen^{1,2,3}, T.A. Blanpied^{1,2},¹Program in Neuroscience, Univ of Maryland Sch of Med, Baltimore, MD, ²Department of Physiology, Univ of Maryland Sch of Med, Baltimore, MD, ³Medical Scientist Training Program, Univ of Maryland Sch of Med, Baltimore, MD

Healthy synapse function relies on precise structural alignment between the presynaptic active zone (AZ) and the postsynaptic density (PSD). A central question is whether localization of vesicle fusion sites influences the efficacy of synaptic transmission. The question is important because receptor activation at glutamatergic synapses is limited by both biophysical properties of the receptors themselves and their distance from vesicle release sites. Thus, release events can fail to activate all synaptic receptors. Recently, our lab found that PSD scaffolding proteins cluster receptors into nanometer-scale subregions. This organization is expected to increase the impact of fusion site organization: simulations show that EPSC amplitude at synapses with clustered receptor distributions is greatest when vesicle fusion is aligned with postsynaptic clusters. However, it has not been previously possible to precisely localize vesicle fusion sites, and so there is little information about where within the AZ vesicles fuse. The significance of this issue is emphasized by the growing list of diseases in which cognitive and behavioral deficits appear to stem from disruption of synapse function caused by mutations of genes such as RIM1 and Munc13 that encode synaptic proteins. To map vesicle fusion sites, I developed a novel technique to localize single-vesicle fusion with high spatial resolution, which I call "pHluorin uncovering sites of exocytosis" or pHuse. Using this approach, I mapped the pattern of evoked or spontaneous vesicle fusion at individual presynaptic terminals of cultured hippocampal neurons. Spontaneous release of neurotransmitter was previously thought to be biological noise but has recently been linked to distinct physiological functions. Interestingly, there is controversy over whether spontaneous and evoked release utilize different vesicle pools, involve different trafficking and fusion machinery, or activate different groups of receptors. All these factors suggest that spontaneous and evoked fusion could take place at spatially distinct regions of the AZ, but this has not been tested. My data using pHuse indicate that evoked and spontaneous fusion in fact occur over different subregions of the terminal. Specifically, when normalized to bouton area, we found that evoked fusion occurred over a significantly smaller proportion of the terminal (0.13 ± 0.02) than spontaneous fusion (0.20 ± 0.02 , Kolmogorov-Smirnov (K-S) test, $D=0.26$, $p < 0.01$). Thus, we propose that the spatial distributions of evoked and spontaneous vesicle fusion are differentially regulated by specific active zone proteins and activity. In sum, these data will help elucidate the organization and regulation of a key aspect of synaptic function.

P442**Board Number: B585****Disruption of Calcium Signaling Is Necessary for Ectopic Neuronal Cell Cycle Re-entry and Subsequent Neuron Death in Alzheimer's Disease.**E.J. Kodis¹, G.S. Bloom²;¹Department of Biology, University of Virginia, Charlottesville, VA, ²Departments of Biology and Cell Biology, University of Virginia, Charlottesville, VA

Alzheimer's disease (AD) is a neurological disorder characterized histologically by two types of lesions in the brain—extracellular plaques composed of amyloid- β ($A\beta$) peptides, and neurofibrillary tangles composed of the protein, tau. It has been demonstrated that $A\beta$ and tau aggregates have toxic effects on neurons, but less is understood about how the interaction of these two molecules leads to neuron dysfunction and death. $A\beta$ peptides act upstream of tau in AD pathogenesis, and it has been demonstrated that $A\beta$ peptides interact with multiple proteins and receptors at the cell surface. In particular, $A\beta$ oligomers ($A\beta$ Os) have been shown to bind and cause calcium influx through the N-methyl-D- aspartate (NMDA) receptor, increasing steady-state calcium levels and contributing to excitotoxicity in neurons vulnerable in AD. Although aberrant calcium influx and excitotoxicity due to $A\beta$ O exposure is well established, there is still little known about the downstream signaling consequences of how this calcium influx contributes to neuron death in AD. Neurons in adult brain are normally in a permanently post-mitotic state, but in AD they often exhibit ectopic cell cycle re-entry (CCR), which ironically leads to their eventual death. Our lab previously reported that neuronal CCR is initiated by $A\beta$ Os and requires tau (Seward, et al. J Cell Sci 126: 1278-1276). We now report that in addition to the NMDA receptor being an important mediator of excitotoxicity and synapse loss, it is also necessary for neuronal CCR. When primary neuron cultures are treated with $A\beta$ Os, they re-enter the cell cycle through G1 (as demonstrated by cyclin D1 expression) or S-phase (as demonstrated by nuclear BrdU incorporation), but treatment with the NMDA receptor inhibitor, MK-801, prevents CCR. Furthermore, $A\beta$ O treatment of primary neurons causes an early activation of CaMKII, a protein kinase known to be both dysregulated in AD and necessary for CCR. This $A\beta$ O-mediated CaMKII activation is prevented by shRNA knockdown of the NMDA receptor subunit NR1. This result suggests that $A\beta$ O toxicity at the synapse and excess calcium influx are directly connected to CCR and eventual neuron death in AD. Using this aberrant re-entry of post-mitotic neurons into the cell cycle as a read out of $A\beta$ O toxicity, signaling pathways connecting $A\beta$, tau, and calcium in AD are being further elucidated.

P443**Board Number: B586****Regulation of Low Voltage Activated Calcium Channels (Cav3) by Cyclin Dependent Kinase 5.**A. Calderon-Rivera¹, R. Gonzalez-Ramirez², A. Sandoval¹, R. Felix³;¹School of Medicine FES Iztacala, UNAM, Tlanepantla, Mexico, ²Department of Molecular Biology and Histocompatibility, Hospital General Dr. Manuel Gea González, Mexico City, Mexico, ³Department of Cell Biology, Cinvestav-IPN, Mexico City, Mexico

Low Voltage Activated (LVA) T-type calcium channels open in response to small membrane depolarization, and therefore represent an important source of calcium entry near the resting membrane potential. In neurons, these proteins significantly contribute to control relevant physiological functions including excitability, pacemaker activity and post-inhibitory rebound burst firing. Three subtypes of LVA channels (Ca_v3.1, Ca_v3.2 and Ca_v3.3) have been identified, and using functional expression of recombinant Ca_v3 channels diverse studies have validated the notion that T-type channels can be dynamically modulated by endogenous ligands as well as by second messenger pathways. In this context, the present study reveals a previously unrecognized role for cyclin-dependent kinase 5 (Cdk5) in the regulation of native T-type calcium channels in N1E-115 neuroblastoma cells as well as Ca_v3.1 channels heterologously expressed in HEK-293 cells. Cdk5 and its co-activators play critical roles in the regulation of neuronal differentiation, cortical lamination, neuronal cell migration and axon outgrowth. Our results show that overexpression of Cdk5 causes a significant increase in whole cell patch clamp currents through T-type calcium channels in N1E-115 cells, while knockdown of Cdk5 or the use of an inhibitor reduced T-type currents. Consistent with this, overexpression of Cdk5 in HEK-293 cells stably expressing Ca_v3.1 channels up-regulates macroscopic current. These results highlight a novel role for Cdk5 in the modulation of T-type calcium channels.

Anterograde and Retrograde Axonal Treatment**P444****Board Number: B587****Intra-Axonal Translational Control Mechanisms for ER Chaperone Protein mRNAs.**A. Pacheco¹, J.L. Twiss², G. Gallo³;¹Temple University, Philadelphia, PA, ²Dept of Biological Sciences, University South Carolina, Columbia, SC, ³Shriners Hospitals Pediatric Research Center, Temple University, Philadelphia, PA

Transport of mRNAs into distal nerve terminals and growth cones allows axonal processes to generate proteins autonomously from the cell body. Sensory neurons transport a complex population of mRNAs into their axons, including several encoding ER chaperone proteins. It remains largely unknown how

specificity is provided to the localized translational apparatus. Under cellular stress, protein synthesis can be regulated by both cap-dependent and cap-independent mechanisms (e.g., internal ribosome entry site [IRES]). We previously demonstrated that sensory axons have the capacity to translate mRNAs through IRES. For instance, axonal grp78/BiP but not calreticulin mRNAs' 5' untranslated regions [UTRs] have IRES activity. However, a simple binary choice between cap-dependent and cap-independent translation cannot explain the specificity for translation of individual mRNAs in distal axons. For calreticulin mRNA, one of its two 3' UTR elements can drive its localization to axons but its 5'UTR was shown to confer translational control through a mechanism that requires phosphorylation of eIF2 α in axons after stimulation of ER stress with LPA. This phosphorylation of eIF2 α typically blocks cap-dependent translation. Interestingly, the proximal 3'UTR localization element in calreticulin mRNA is essential for this phospho-eIF2 α -dependent translational control. Thus, 5' and 3' UTRs can perform concerted roles to achieve specificity for axonally localized mRNA translation. LPA is a physiological stress stimulus that induces growth cone collapse in DRG neurons and it is released after tissue injury. Since it has been shown that CNS inhibitory molecules can influence local translation in axons, we wondered if inhibitors molecules associated to injury response could regulate calreticulin expression. CSPGs (chondroitin sulfate proteoglycans) are extracellular matrix proteins produced by activated astrocytes in the injured CNS that stall the growth cone and forward movement of the axon. This effect extends to PNS sensory neurons that when plated onto substrates coated with CSPGs show extremely attenuated axonal outgrowth. We used immunostaining to detect axonal calreticulin of cultured DRG (dorsal root ganglion) neurons initially grown in CSPG coated coverslips. The results showed an increased signal in distal axons after 24h growing. Further experiments for local axonal translation regulation are being performed. We suggest that calreticulin mRNA elements could drive dual response to CSPGs vs other released stress signals after axonal injury.

Cytoplasmic dynein overrides other motors to transport axonal microtubules in a manner that establishes and preserves their uniform pattern of polarity orientation.

A. Rao¹, M. Black², P.W. Baas³;

¹Neurobiology and Anatomy, Drexel University, Philadelphia, PA, ²Anatomy and Cell Biology, Temple University, Philadelphia, PA, ³Department of Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA

We have proposed that the forces generated by cytoplasmic dynein are essential for the axon to maintain a nearly uniform plus-end-distal polarity pattern of its microtubules. The premise is that cytoplasmic dynein populates the axon with correctly oriented microtubules by transporting them with their plus-ends-leading from the cell body into the axon and down its length. Just as important, if minus-end-distal microtubules arise in the axon, we propose that cytoplasmic dynein would transport them back to the cell body to prevent them from accumulating. Such mal-oriented microtubules may

arise during plastic events such as branch formation, or as a result of disease or injury-related challenges. While the majority of microtubule transport in the axon is anterograde, a notable fraction is retrograde, which is consistent with the existence of such a clearing mechanism. However, the role of cytoplasmic dynein has proven technically difficult to investigate because previous methods for inhibiting or depleting this motor protein were only able to do so gradually, thus introducing the potential for compensatory changes in the levels of other motor proteins. Here, we used Ciliobrevin D, a novel small molecule inhibitor, to acutely inhibit cytoplasmic dynein in cultures of rat sympathetic neurons. Exposure of the neurons to the drug for various windows of time resulted in a dose-dependent appearance of greater numbers of minus-end-distal microtubules in the axon. In addition, and consistent with our hypothesis, microtubule transport events were severely reduced in frequency in both the anterograde and retrograde directions. The microtubule movements that did occur in the presence of the drug exhibited abnormalities including abrupt pausing or halting of movements and directional changes in the movements not observed in control axons, as well as abnormal transport rates. These data suggest that a variety of molecular motors are able to transport microtubules in the axon, but that cytoplasmic dynein overpowers the others to ensure that microtubule transport occurs predominantly or exclusively with plus-ends-leading. We conclude that the microtubule polarity pattern of the axon requires constant maintenance against corruption, and that dynein-driven microtubule transport ensures that mal-oriented microtubules do not accumulate in the axon. Pathogenic situations that may overwhelm or compromise this mechanism could permit corruption of the microtubule polarity pattern of the axon sufficient to cause problems such as organelle traffic jams.

Neuronal autophagosomes form via ordered assembly at transient DFCP1-positive ER subdomains in the distal axon.

S. Maday¹, E.L. Holzbaur²;

¹Department of Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA,

²Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

The highly polarized and complex morphology characterizing neurons poses a unique challenge to cellular trafficking pathways. Organelles and proteins must be transported across the axon with high fidelity over distances up to 1 meter. The vulnerability of the neuronal system is evidenced by the fact that mutations in axonal transport machinery lead to neuronal dysfunction and disease. While the degradative process of autophagy has been extensively examined in yeast and nonpolarized mammalian cells, less is known about the dynamics of this pathway along the axon of highly polarized neurons. We utilized live-cell imaging to investigate autophagosome biogenesis and maturation in primary dorsal root ganglion (DRG) neurons under basal conditions. Our results uncovered striking gradients of trafficking pathways along the axon, consistent with the compartmentalization of functions within the neuron. Markers for the biosynthetic pathway, such as ER exit sites, are enriched in the cell body, implicating the soma as the primary site of protein synthesis. In contrast, the formation of autophagosomes is spatially

enriched in the distal region of the axon; few autophagosomes are generated in the cell soma or mid-axon under basal conditions. Autophagosome formation proceeds via an ordered assembly of proteins recruited with stereotypical kinetics onto the developing organelle. Autophagosomes are generated from transient DFCP1-positive subdomains of the ER; DFCP1 biogenesis events are also enriched in the distal axon. Following formation, autophagosomes undergo robust transport toward the cell soma. As they move distally to proximally, autophagosomes mature into autolysosomes that more effectively catalyze cargo degradation. Delivery to the cell soma ensures efficient and rapid recycling of degraded components. This spatial and temporal regulation is not limited to actively growing DRG neurons. We also observed distal initiation followed by robust retrograde transport in synaptically-connected hippocampal neurons. Further, compartmentalization is also evident within dendrites; dendrites have few autophagosomes, which all exhibit bidirectional motility along the entire length of the process. Remarkably, autophagosome biogenesis is infrequent in dendrites suggesting that the mechanisms of autophagy in dendrites are fundamentally distinct from those in the axon. Together, our results are consistent with a highly compartmentalized pathway for constitutive autophagy along the axon of primary neurons. We propose that distal enrichment of autophagosome formation facilitates the degradation of damaged mitochondria and long-lived cytoplasmic proteins that reach the axon tip via slow axonal transport. Supported by NIH K99NS082619 to SM and NS060698 to EH.

A PIK3C3/Ankyrin-B/Dynactin pathway promotes axonal growth and multi-organelle transport.

D.N. Lorenzo^{1,2}, A. Badea³, J. Davis^{1,2}, J.D. Hostettler^{1,2}, J. He⁴, G. Zhong^{4,5}, X. Zhuang^{5,6}, V. Bennett^{1,2};
¹Department of Biochemistry, Duke University Medical Center, Durham, NC, ²Howard Hughes Medical Institute, Durham, NC, ³Radiology, Duke University Medical Center, Durham, NC, ⁴Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA, ⁵Howard Hughes Medical Institute, Cambridge, MA, ⁶Chemistry and Chemical Biology, Physics, Harvard University, Cambridge, MA

Axon growth requires long-range transport of organelles, but how these cargos recruit their motors and how their traffic is regulated is not fully resolved. Here we identify a new pathway based on the class III PI3-kinase (PIK3C3), ankyrin-B, and dynactin that promotes fast axonal transport of synaptic vesicles, mitochondria, endosomes and lysosomes. We show that dynactin associates with cargo through ankyrin-B interactions with both the dynactin subunit p62 and phosphatidylinositol 3-phosphate lipids (PtdIns(3)P) generated by PIK3C3. Ankyrin-B knockout results in shortened axon tracts in vivo and marked reduction in membrane association of dynactin and dynein, while did not affect the organization of spectrin-actin axonal rings imaged by 3D-STORM. Loss of ankyrin-B or of its linkages to either p62 or PtdIns(3)P, or loss of PIK3C3 all impair organelle transport and particularly retrograde transport in hippocampal neurons. Our results establish new functional relationships between PIK3C3, dynactin, and ankyrin-B that together promote axonal transport of organelles and are required for normal axon length.

P448**Board Number: B591****Elevated CDK5 Activity Leads to Dysregulated Axonal Transport in Neurons.**E. Klinman¹, E.L. Holzbaur²;¹Department of Neuroscience, University of Pennsylvania School of Medicine, Philadelphia, PA,²Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Cargo transport is essential for neuronal function and survival. Defects in cargo transport are associated with neurodegenerative diseases including Amyotrophic Lateral Sclerosis (ALS), wherein cargo builds up in the proximal axon as a result of transport failure. Increased activity of cyclin dependent kinase 5 (CDK5) and its stress-induced activator p25 has been observed in human patients with ALS and mouse models of the disease, as well as in other neurodegenerative diseases associated with cellular stress. CDK5 interacts with both anterograde (kinesin) and retrograde (dynein) motor proteins, but the differential regulation of CDK5 in healthy and stressed cells as well as the mechanism of regulation remain unknown. Here, we show that reducing CDK5 activity in healthy dorsal root ganglia neurons affects neither directionalities nor velocities of cargo transport. A wide range of cargo was examined, including lysosomes, mitochondria, and autophagosomes, none of which responded with changes in transport when CDK5 activity was lowered. However, introducing the stress-associated CDK5 activator p25 significantly increased the number of pauses and directional switches across all examined cargo, in both the anterograde and retrograde direction. This increase in nonproductive motion is consistent with changes observed in ALS neurons, and implies a link between increased CDK5 activity in diseased cells and disruption of transport. Next, we tested whether the effects of aberrant CDK5 activation on transport were dependent on the Lis1/Ndel1 complex. This complex binds and directly regulates the activity of dynein; Ndel1 contains 5 possible CDK5 phosphorylation sites. We determined that mutating the CDK5-dependent phosphorylation sites in Ndel1 blocked the effects of p25-dependent disruption of retrograde transport for both lysosomes and mitochondria. Together, these studies identify CDK5 as a regulator of cargo transport in stressed cells, and suggest that misregulated CDK5 activity may contribute to transport disruption in neurodegenerative diseases, in an Ndel1 and Lis1-dependent fashion.

P449**Board Number: B593****Functionally distinct roles for dynactin in regulating axonal transport initiation and microtubule dynamics in the distal axon.**J.J. Nirschl¹, E.L. Holzbaur²;¹Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

The dynactin complex activates cytoplasmic dynein by promoting efficient initiation of minus-end directed vesicular transport along microtubules. Dynactin also regulates microtubule dynamics as a neuron-specific anti-catastrophe factor. Mutations in the highly conserved CAP-Gly domain of the dynactin subunit p150^{Glued} disrupt both of these functions, leading to neurodegeneration. We wondered whether the transport initiation and anti-catastrophe activities of dynactin are separable, or instead are functionally linked. To address this question, we used siRNA to deplete endogenous p150^{Glued} from primary neurons and rescued cells with constructs lacking either the N-terminal CAP-Gly domain or a flanking basic domain that also binds microtubules but with a lower affinity. Previous work has shown that the CAP-Gly domain of p150^{Glued} is required for efficient retrograde transport initiation and that the tandem microtubule-binding domains are required for dynactin-mediated effects on microtubule dynamics. However, the role of the basic domain in axonal transport has not yet been tested. Using live-cell photobleaching assays, we show that expression of a p150^{Glued} construct lacking the CAP-Gly domain rescues the retrograde transport of LAMP-1-RFP vesicles along the mid-axon but not at the distal axon, consistent with an essential role for this domain in transport initiation. In contrast, a p150^{Glued} construct lacking the basic domain effectively rescued transport in both the mid- and distal axon, indicating that this domain is not required for either transport initiation or robust vesicular transport along the axon. Thus, we can effectively separate the functions of p150^{Glued} in regulating transport initiation and microtubule dynamics: the CAP-Gly domain of p150^{Glued}, but not the basic domain, is required for retrograde transport initiation whereas both the CAP-Gly and basic domains in tandem are required for regulating dynamics at the microtubule plus-end in neurons. Thus, dynactin has two functionally separable roles in the distal axon, both of which are disrupted by human mutations that cause Perry syndrome, a lethal form of parkinsonism.

P450**Board Number: B594****A molecular mechanism for the anterograde transport of dynein in the axon.**A.E. Twelvetrees^{1,2}, G. Schiavo², E.L. Holzbaur³;¹Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²Sobell Department of Motor Neuroscience and Movement Disorders, University College London Institute of Neurology, London, United Kingdom, ³Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Microtubules in the axon are uniformly orientated with their plus ends directed away from the soma and towards the axon terminal. Thus, the minus end directed microtubule motor, cytoplasmic dynein, has no ability to reach the axon terminal under its own ATP hydrolysis power and must be actively transported. This process is critical to neuronal function as without the presence of dynein in axon terminals there is no facility for essential retrograde trafficking events that are key to neuronal survival. In neurones cultured from DIC1-GFP knock in mice (which express a GFP tagged form of the neuron specific dynein intermediate chain subunit, DIC1, at endogenous levels) dynein accumulates in axon terminals. By live cell TIRF-M, imaging in axons of known polarity, we observe many dynein-GFP motile events in both anterograde and retrograde directions. Previous work in the lab had identified direct interactions between kinesin-1 and the DIC subunit. Building on this observation we find multiple points of protein-protein interaction between DICs and both the light chain and heavy chain subunits of kinesin-1. These direct interactions are consistent with activation of kinesin by dynein as well as being specific to neuronal spliceforms of the DIC subunits. Consistently, we find dynein and kinesin form an endogenous complex in vesicle free brain fractions. Using FRAP analysis we find that net rates of anterograde transport for dynein populations in the axon are the same as those that typically describe slow axonal transport. We propose that neuron specific isoforms of dynein subunits support the direct activation of kinesin by dynein in order to power the anterograde transport of dynein in the axon.

P451**Board Number: B594****The Dynein Inhibitor Ciliobrevin D Inhibits the Bi-directional Transport of Organelles Along Sensory Axons and NGF Induced Axon Growth and Branching.**R. Sainath¹, G. Gallo¹;¹Shriners Hospitals Pediatric Research Center, Temple University, Philadelphia, PA

The axonal transport of organelles is critical for the development, maintenance and survival of neurons, and its dysfunction has been implicated in several neurodegenerative diseases. Retrograde axon transport is mediated by the motor protein dynein. In this study, using embryonic chicken dorsal root ganglion neurons, we investigate the effects of Ciliobrevin D, a pharmacological dynein inhibitor, on the transport of axonal organelles, axon extension, nerve growth factor (NGF)-induced branching, growth cone expansion, and axon thinning in response to actin filament depolymerization. Live imaging of

mitochondria, lysosomes and Golgi derived vesicles in axons revealed that both the retrograde and anterograde transport of these organelles was inhibited by treatment with Ciliobrevin D. Treatment with ciliobrevin D reversibly inhibited axon extension and transport, with effects detectable within the first 20 minutes of treatment. NGF induces growth cone expansion, axonal filopodia formation and branching. Ciliobrevin D prevented NGF-induced formation of axonal filopodia and branching but not growth cone expansion. Finally, we report that the retrograde reorganization of the axonal cytoplasm which occurs upon actin filament depolymerization is inhibited by treatment with Ciliobrevin D, indicating a role for microtubule based transport in this process. This study identifies Ciliobrevin D as an inhibitor of the bi-directional transport of multiple axonal organelles, indicating this drug may be a valuable tool for both the study of dynein function and a first pass analysis of the role of axonal transport.

A novel role for huntingtin in the axonal transport of Rab4-containing vesicles in vivo.

J. White¹, S.D. Gunawardena¹;

¹Biological Sciences, SUNY-Buffalo, Buffalo, NY

Huntingtin (HTT), the Huntington's disease (HD) protein, has been implicated in axonal transport. Previous work showed that loss of HTT function caused axonal transport defects. Biochemical and genetic experiments indicated that HTT can associate with both kinesin-1 and dynein motors either directly or via accessory proteins. However, the vesicle type or the motor-cargo complex that HTT is contained in during axonal transport is unknown. Using *in vivo* motility analysis in *Drosophila* larval axons, we found that HTT influences the movement of particular Rab containing-vesicles. Interestingly, while reduction of HTT dramatically perturbed the bi-directional movement of Rab3 and Rab4 containing vesicles, only the retrograde movement of Rab7 and Rab19 containing vesicles were perturbed. Rab19 is proposed to be on recycling endosomes, while Rab3 is thought to be on synaptic vesicles. The identity of Rab4-containing vesicles is unknown. Using dual-color imaging we examined whether HTT is physically present on moving Rab-containing vesicles. While Rab4 is present on most of the HTT containing vesicles, not all Rab4 vesicles contained HTT. Further Rab4 is also present on synaptotagmine and synaptobrevin containing vesicles indicating that Rab4 is likely to be on synaptic vesicles. Both kinesin and dynein motors are also required for the movement of Rab4 containing vesicles. Collectively, our *in vivo* analysis provides compelling evidence for a moving HTT-Rab4 motor-complex during axonal transport and suggests that HTT may likely influence the motility of different Rab-containing vesicles. Moreover, expansion of polyQ repeats in the context of HTT dramatically perturbed the motility of Rab4-containing vesicles indicating that disruption of Rab transport mediated by mutant HTT could contribute to the neuropathology observed in HD.

P453**Board Number: B596****Directional actin turnover transports actin and associated proteins for early axonal outgrowth.**H. Katsuno¹, M. Toriyama², Y. Hosokawa³, K. Mizuno⁴, K. Ikeda⁵, Y. Sakumura^{6,7}, N. Inagaki⁷;¹Grad. Sch. Biol. Sci., Nara Institute of Science and Technology, Ikoma, Japan, ²Molecular Biosciences, University of Texas at Austin, Austin, TX, ³Grad. Sch. Mater. Sci., Nara Institute of Science and Technology, Ikoma, Japan, ⁴Tohoku Univ., Sendai, Japan, ⁵Grad. Sch. Inform.Sci., Nara Institute of Science and Technology, Ikoma, Japan, ⁶Sch. Inform. Sci. and Technol., Aichi Prefectural Univ., Nagakute, Japan, ⁷Grad. Sch. Bio. Sci., Nara Institute of Science and Technology, Ikoma, Japan

Intracellular transport is fundamental to cellular activities, supplying essential components to functionally specialized regions. Motor proteins, such as myosin and kinesin, walk along cytoskeletons to achieve directional transport of membrane organelles and protein complexes. Although actin and associated proteins at cellular leading edge are essential for cell protrusion and motility, how they are transported to the subcellular regions remain unclear. Previous report showed that an actin rich structure called “wave” moves along the axonal shafts or actin and associated proteins (Ruthel & Banker, *Cell Motil. Cytoskeleton*, 1998; Toriyama et al., *J. Cell Biol.*, 2006; Flyn et al., *Dev. Neurobiol.*, 2009)

Here we show that assemblies of F-actins migrating along axonal shafts are transported toward the growth cone of extending axons by means of their directional polymerization/depolymerization (treadmilling), a mechanism distinct from the motor-based ones. We found that the anterogradely migrating F-actins undergo treadmilling, with their polymerizing ends pointing toward the neurite tips. The lateral sides of F-actins were mechanically anchored to the plasma membrane and substrates through a linker protein shootin1 and a cell adhesion molecule L1-CAM. The velocity of actin transport positively correlated with the rate of actin polymerization and the degree of F-actin anchoring to the substrate. We also detected directional counter-force associated with the F-actin transport on the substrate through their anchorage. Actin interacting protein cofilin, cortactin and shootin1 co-migrated with F-actins in an actin-transport-dependent manner. Furthermore, blocking this transport by creating an adhesion gap along the axonal shaft inhibited axonal elongation. These findings present a novel mechanism for intracellular transport, which supplies actin and associated proteins toward cellular leading edge, thereby promoting its protrusive activity.

P454**Board Number: B597****Glucose Regulates Mitochondrial Motility via Milton Modification by O-GlcNAc Transferase.**G. Pekkurnaz¹, J.C. Trinidad², X. Wang³, D. Kong⁴, T.L. Schwarz^{1,5};¹The F.M. Kirby Neurobiology Center, Boston Children's Hospital, Boston, MA, ²Department of Chemistry, Indiana University, Bloomington, IN, ³Department of Neurosurgery, Stanford University, Palo Alto, CA, ⁴Department of Neuroscience, Tufts University School of Medicine, Boston, MA, ⁵Department of Neurobiology, Harvard Medical School, Boston, MA

Cellular homeostasis critically depends on the ability of cells to monitor nutrient levels that can be used for ATP generation by mitochondria. Among the many specialized cell types, neurons are particularly dependent on mitochondria due to their complex morphology and regional energy needs. Hence, abnormalities in mitochondrial distribution have been implicated in many neuropathologies including Alzheimer's, Parkinson's, and Huntington's diseases. Here, we report a molecular mechanism by which nutrient availability in the form of extracellular glucose regulates mitochondrial motility in neurons. We show that this mechanism requires the activity of O-GlcNAc Transferase (OGT), an enzyme whose activity depends on glucose availability, and that activation of OGT diminishes mitochondrial motility. We establish the mitochondrial motor adaptor protein Milton as a required substrate for OGT to arrest mitochondrial motility by mapping and mutating the key O-GlcNAcylated serine residues. We find that the O-GlcNAcylation state of Milton is altered by extracellular glucose, pharmacological inhibition of O-GlcNAcase or UDP-GlcNAc synthesis, and that OGT alters mitochondrial motility *in vivo*. Our findings suggest that, by dynamically regulating Milton O-GlcNAcylation, OGT tailors mitochondrial dynamics in neurons based on nutrient availability. Although in this study we took advantage of the polarized and regular arrays of microtubules in axons, the components of this pathway are present in all metazoan cells, and glucose, via OGT, may therefore be a widespread regulator of mitochondrial movement.

P455**Board Number: B600****Bidirectional cargo transport: Moving beyond tug-of-war.**W.O. Hancock^{1,2};¹Department of Biomedical Engineering, Pennsylvania State University, University Park, PA,²Interdisciplinary Graduate Degree Program in Bioengineering, Pennsylvania State University, University Park, PA

Bidirectional transport of vesicles, organelles and other intracellular cargo along microtubules is frequently described as a "tug-of-war" between oppositely-directed kinesin and dynein motors attached to the same cargo. A number of experimental and modeling studies support the tug-of-war paradigm, and it is the dominant model in the field. However, numerous knockout and inhibition studies in a variety of systems have found that inhibiting one motor leads to diminished motility in both directions.

This phenomenon can be defined as a “paradox of codependence” that directly challenges the tug of war paradigm. To resolve it, alternative models are needed that move beyond the tug of war paradigm. In an effort to resolve the paradox of co-dependence, I will describe three classes of bidirectional transport models, termed microtubule tethering, mechanical activation, and steric disinhibition (1). For each mechanism, experimental support from the literature will be presented, along with approaches for developing computational models that can be used to generate experimental predictions and interpret data. These proposed mechanisms and the development of models based on them will help to guide future experiments aimed at uncovering the fundamental mechanisms underlying bidirectional transport. (1) W.O. Hancock, Nature Reviews Molecular Cell Biology, September, 2014.

Is the axonal transport of neurofilaments a tug-of-war between opposing motors?

C. Johnson¹, J. Fenn², A. Brown², P. Jung¹;

¹Quantitative Biology Institute, Ohio University, Athens, OH, ²Department of Neuroscience, The Ohio State University, Columbus, OH

Neurofilaments are space-filling cytoskeletal polymers in nerve cells that function to increase axon caliber, thereby maximizing the rate of propagation of the nerve impulse. In addition of their structural role, these polymers are also transported along axons in a stop-and-go manner, exhibiting brief bouts of rapid bidirectional movement interrupted by prolonged pauses. The filaments move on microtubule tracks powered by kinesin-1 in the anterograde direction and dynein in the retrograde direction. To investigate the motile mechanism, we transfected primary cultures of cortical neurons from neonatal rat brains with GFP-tagged neurofilament protein M and then recorded neurofilament movement by epifluorescence microscopy at 30 frames per second using an EMCCD camera. We used kymograph analysis to track neurofilament movement, and edge detection algorithms to extract the paths of the leading and trailing ends of the moving filaments. We developed an unbiased noise-filtering algorithm to extract bouts of movement and pauses, and then used this method to obtain statistical distributions of pause times, run times and velocities. Remarkably, we found that the overall average velocities, the average velocities during a contiguous run, the run length distributions and the pause time distributions were all independent of neurofilament length across a range of lengths from 1-36 μm . To investigate whether the observed motile behavior can be generated by a tug-of-war, we developed a computational model in which dynein and kinesin motors attach to a single neurofilament cargo and interact through mechanical forces only. We then systematically varied the number of kinesin and dynein motors in the model and attempted to identify those combinations of motors that matched the neurofilament velocity, pause time and run length distributions in each kymograph trace. So far we have found no inconsistencies between the tug-of-war model and the experimental data, but distinct kinetic phases within individual traces suggest that the number of motors bound to the neurofilament cargo is not fixed and may change over time. The model predicts that the total number of active motors on each

neurofilament is relatively small and relatively independent of polymer length. Thus the motors may not be distributed uniformly along the filaments.

Witnessing microtubule-based transport in the living brain: Impact of the cargo-motor receptor, amyloid precursor protein, and Alzheimer's plaques.

F.L. Chaves¹, C.S. Medina¹, X. Zhang², R.E. Jacobs², E.L. Bearer^{1,3};

¹Department of Pathology, University of New Mexico, Albuquerque, NM, ²Beckman Institute, California Institute of Technology, Pasadena, CA, ³Biology, California Institute of Technology, Pasadena, CA

Most amyloid precursor protein (APP)-based Alzheimer's models overexpress mutant human APP resulting in Aβ plaques. Yet the relative contribution of this elevated APP and the presence of plaques to neurodegeneration remains a big question. APP's role as a cargo-motor receptor for axonal transport suggests that overexpression might lead to increased transport. Indeed we showed that transport is increased in Down's syndrome and decreased in APP knockout mice. Hence transport may be elevated in APP overexpressors and lead to either beneficial or deleterious consequences. Here we use high field microMRI with Mn²⁺, an MR contrast agent useful as a track-tracer, to pose this cell biological question within the whole living brains of wildtype and Alzheimer's model mice. Injection of Mn²⁺ into the CA3 region of the hippocampus results in measurable transport over time. Application of 3D unbiased whole brain image analysis detects all circuitry emanating from the hippocampus. By driving APP Swe/Ind transgene expression with a tetracycline-sensitive promoter, APPSwe/Ind expression can be decoupled from the presence of plaques with doxycycline (doxy). Three groups of mice were studied: group 'A' (no doxy, +plaques, +APP); group 'B' (doxy at 8 days before sacrifice, +plaques, no APP), and group 'C' (doxy prior to conception, and stopped 8 days before sacrifice, no plaques, +APP). Images were captured before and sequentially after Mn²⁺ injection into CA3 (1, 7, 25 hr). Images were aligned and analyzed by statistical parametric mapping to identify differential accumulation within the hippocampal projections. Histopathology revealed well-developed plaques in A and B, and Western blots showed human APP expressed five-fold over WT in in A and C. Our preliminary results show increased transport in A and C, with APP Swe/Ind expression when compared with B, where expression is suppressed. Cholinergic neurons in the medial septal nucleus were decreased as determined by anti-ChAT staining in Group C (p=0.0006 by one-way ANOVA, n=15). In conclusion, the effects of elevated APP expression are separable from consequences of plaque, and each may. Supported by NIGMS P50GM08273 and NINDS NS062184.

P458**Board Number: B603****Mobility of axonal neurofilaments in mature adult myelinated axons.**J. Fenn¹, P. Jung², J. Julien³, A. Brown¹;¹Department of Neuroscience, The Ohio State University, Columbus, OH, ²Quantitative Biology Institute, Ohio University, Athens, OH, ³Department of Psychiatry and Neuroscience, Laval University, Quebec, QC

Neurofilaments are the intermediate filaments of neurons and serve as critical structural elements that support the growth of axon caliber, which is an important determinant of axonal conduction velocity. Abnormal accumulations of neurofilaments are frequently manifested in neurological disorders such as amyotrophic lateral sclerosis, giant axonal neuropathy, diabetic neuropathy, Charcot-Marie-Tooth disease, Alzheimer's disease and others. For many years neurofilaments were thought to behave in a relatively static manner in mature neurons. Early electron microscopic evidence even suggested that neurofilaments may be immobile because they appeared to form a mesh-like network. We now know that neurofilaments are transported along axons, but there is still debate regarding what proportion of these polymers move. Some researchers have argued that most axonally transported neurofilaments are deposited into a permanently stationary network with less than 10% capable of movement. In contrast, we have argued that there are no permanently stationary axonal neurofilaments and that essentially all of these polymers are intermittently mobile, cycling repeatedly between moving and pausing states throughout their lifetime. Live cell imaging studies on cultured neurons from embryonic and neonatal animals support this more dynamic perspective, but it has been argued that this may not hold true for mature myelinated axons in vivo. To resolve this controversy, we have used a pulse-escape fluorescence photoactivation technique to analyze neurofilament transport in intact peripheral nerves of adult Thy1-paGFP-NFM mice, which express neurofilament protein M tagged with a photoactivatable GFP. Neurofilaments were activated in 5 μ m-long segments of myelinated axons (average diameter= 3.3 μ m) and the mobility of the polymers was determined by analyzing the fluorescence remaining in the activated window over time. Preliminary data show that 83 \pm 12% of the neurofilaments (n=21 axons) departed from the window within 3 hours after activation, indicating a highly mobile population. Thus, any permanently stationary neurofilaments cannot exceed 17% of the total population in these axons. Moreover, by extrapolation of the decay kinetics, we predict that all of the neurofilaments would have departed the activation window within 12 hours. We therefore conclude that most, if not all, axonal neurofilaments are mobile, even in mature myelinated axons of adult animals. We believe that this dynamic cytoskeletal architecture has important implications for the mechanism by which axon morphology is regulated during development and maturation, and by which neurofilaments accumulate in disease states.

P459**Board Number: B604****SMN functions as a chaperone for mRNP complex assembly.**P.G. Donlin-Asp¹, C. Fallini^{1,2}, J.P. Rouanet¹, K.R. Williams¹, G.J. Bassell^{1,3}, W. Rossoll^{1,3};¹Cell Biology, Emory University School of Medicine, Atlanta, GA, ²Neurology, University of Massachusetts Medical School, Worcester, MA, ³Neurology, Emory University School of Medicine, Atlanta, GA

Spinal muscular atrophy (SMA) is a neuromuscular disease characterized by a specific degeneration of motor neurons. SMA results from a reduction in the survival of motor neuron (SMN) protein, which is ubiquitously expressed with a well characterized role in promoting the assembly of spliceosomal small nuclear ribonucleoproteins (snRNPs). While underlying defects in splicing have been observed in SMA models, these defects are not unique to motor neurons, leaving their role in the selective motor neuron degeneration unclear. Studies from our laboratory and others have revealed impairments in axonal mRNA localization in SMA models. We have discovered specific defects in the axonal localization of mRNAs (*β-actin*, *Gap43*) and mRNA-binding proteins (HuD, IMP1) in axons and growth cones of primary motor neurons from SMA mice or depleted of SMN. We also observed that overexpression of both HuD and IMP1 can mitigate the effects of low SMN levels on axon outgrowth and GAP43 protein levels in growth cones. These findings led to the hypothesis that SMN plays a critical role in the assembly and/or trafficking of messenger ribonucleoproteins (mRNPs) in neuronal processes. However, the molecular function(s) of SMN in the biology of mRNPs remained unclear due to the lack of specific assays. To investigate the biological role of SMN and the effects of SMN deficiency in axonal mRNA regulation, we have established a trimolecular fluorescence complementation (TriFC) assay in motor neuron cultures as a sensor for mRNA and protein association, which permitted an analysis of the proposed role of SMN in mRNP assembly and localization. Our findings revealed a deficiency in the assembly of IMP1 protein / *β-actin* mRNA containing complexes in SMA motor neurons, which is consistent with SMN acting as a chaperone for mRNP complex assembly. These results are further supported by RNA immunoprecipitation experiments from SMA mouse tissue extracts, which show a substantial reduction in the levels of *β-actin* and *Gap43* mRNAs associated with IMP1. We further show that SMN-deficiency results in defects in axonal local translation, likely a downstream consequence of impaired mRNP transport complex assembly. Local translation of *β-actin* and *GAP43* are known to play an important role in axon outgrowth and branching. Our findings reveal a novel function for SMN in the assembly of axonally transported mRNP complexes, and uncover consequent effects on axonal mRNA localization and translation that may contribute to SMA pathology.

Determining the key residues within the MUC1 transmembrane domain dimer.

E. Li¹, T. Stachowski¹, C. Freeman¹;

¹Saint Joseph's University, Philadelphia, PA

Overexpression of the membrane protein mucin 1 (MUC1) has been linked to 75% of all human solid tumor cancers, including 90% of breast carcinomas. In cancer cells, MUC1 homodimerization has been associated with cell migration and adhesion. Furthermore, this interaction is necessary to form complexes with growth factor receptors targeting the nucleus, where MUC1 can interact with effector proteins regulating gene expression. Thus, understanding how MUC1 forms dimers is essential for developing novel therapeutic strategies to inhibit its oncogenic effects. Therefore, we are using site-directed mutagenesis and the ToxR assay to study certain residues within the transmembrane domain of MUC1 and their contribution to dimerization.

Proteomic and Functional Analyses of the Acidocalcisome, an Organelle Conserved from Bacterial to Human Cells.

G. Huang¹, P.N. Ulrich², M. Storey¹, D. Johnson³, J. Tischer¹, J. Tovar², S.N. Moreno¹, R. Orlando³, R. Docampo¹;

¹Center for Tropical and Emerging Global Diseases and Department of Cellular Biology, University of Georgia, Athens, GA, ²Department of Biology, Georgia State University, Atlanta, GA, ³Complex Carbohydrate Research Center, University of Georgia, Athens, GA

Acidocalcisomes are acidic organelles present in a diverse range of organisms from bacterial to human cells. In this study acidocalcisomes were purified from the model organism *Trypanosoma brucei*, and their protein composition was determined by mass spectrometry. The results, along with those that we previously reported, show that acidocalcisomes are rich in pumps and transporters, involved in phosphate and cation homeostasis, and calcium signaling. We validated the acidocalcisome localization of several proteins by expressing them fused to epitope tags in their endogenous loci or by immunofluorescence microscopy with specific antibodies. Knockdown of several newly identified acidocalcisome proteins by RNA interference (RNAi) revealed that they are essential for the survival of the parasites. These results provide the first comprehensive insight into the unique composition of acidocalcisomes of *T. brucei*, an important eukaryotic pathogen.

P462**Board Number: B608****Y1: a potential target of endocannabinoids.**A. Naeem¹, M.J. Khan¹, A. Khan¹;¹Department of Biosciences, COMSATS Institute of Information Technology Islamabad, Islamabad, Pakistan

NPY is 36 amino acid proteins having six receptors residing in hypothalamus. Y1 (Neuropeptide Y receptor 1) is a G-coupled transmembrane receptor that controls the regulation of feed intake thus playing a crucial role in obesity. Y1 is regulated by one of the neuropeptide protein NPY that is its natural ligand. Many drugs like BIBP3226, SR141716 and BIBO3304 have been introduced in the market as an inhibitor of Y1 to control feed intake. Another well-known system for appetite regulation is endocannabinoid system (ECS) that is regulated by endocannabinoids (ECs). The ECs are natural ligands of cannabinoid receptor 1 (CB1) located in hypothalamus. However, EC are reported to bind to Y1 and may potentially inhibit Y1 signaling. In this study, we have explored the interaction of thirty-five endocannabinoids with Y1 and CB1. For all the selected ECs, blood brain barrier (BBB) permeability was evaluated through their chemical properties. Docking analysis of the EC ligands showed that all ECs exhibit strong binding with CB1. Remarkably, ECs displayed high affinity towards Y1 as well and displayed binding energies that were comparable to CB1. On the basis of binding energy, interactions and ability to cross BBB, gamma-linolenoyl ethanolamide (BE -6.6 with Y1 and -4.4 with CB1), oleoyl-ethanolamide-d4 (BE of -5.3 with Y1 and -4.2 with CB1) and oleamide (BE of -5.6 with Y1 and -4 with CB1) were identified as most active ECs. Thus, endocannabinoids regulate appetite stimulation through CB1 signaling, potentially play the opposite role through Y1 signaling and provide the delicate balance between the two main pathways; that governs the energy intake regulation.

Keywords: NPY, Y1, Neuropeptide Y1, CB1, Endocannabinoids.

P463**Board Number: B609****B lymphocytes from lupus-prone mice are highly sensitive to LPS stimulation.**P. Eisenhauer¹, A. Kane¹, R.A. Roberts²;¹Ursinus College, Collegeville, PA, ²Biology, Ursinus College, Collegeville, PA

Systemic Lupus Erythematosus (SLE) is an autoimmune disease characterized by immune hyperactivity that produces a wide range of symptoms. Bacterial lipopolysaccharides (LPS) have been shown to initiate various immune responses and may play a role in SLE pathogenesis. This research sought to determine if LPS treatment has an effect on populations of splenic B lymphocytes, as well as an effect on the levels of MHC-II and B220 surface molecule expression, in control (C57BL/6) and lupus-prone (NZB/WF1) mice. Splenic B-lymphocytes were treated with 10 µg/mL or 20 µg/mL LPS for 18 hours in charcoal-treated phenol red-free fetal calf serum. Fluorescent Activated Cell Scanning (FACS) was

performed to measure B lymphocyte populations and surface protein expression. Compared to control, lupus-prone mice express a lower proportion of B lymphocytes per total cell population, as measured by B220 expression and confirmed by CD19 surface molecule expression. Further, a lower percentage of B lymphocytes express MHC-II in lupus-prone cell populations compared to control cell populations. However, lupus-prone cell populations appear to be more sensitive to LPS stimulation, showing increased blasting and increased MHC-II expression compared to control cells following LPS exposure. These results suggest that B lymphocytes in NZB/WF1 mice, while smaller in total cell proportion compared to control, may be more reactive to environmental stimulants such as LPS.

Is AMH signaling modulated by TGFB superfamily binding proteins?.

Y. Kawagishi¹, M.W. Pankhurst¹, I.S. McLennan¹;

¹Department of Anatomy, University of Otago, Dunedin, New Zealand

Anti-Müllerian hormone (AMH) is a gonadal hormone that induces part of the male phenotype. However, it is also present in the blood of both men and women, and is a putative local regulator of adult ovarian and testicular function. This suggests that AMH, like other members of the Transforming growth factor beta (TGFB) superfamily, is a pleiotropic regulator. The TGFB superfamily ligands share receptors and binding proteins (BPs), leading to context-dependent signaling. AMH is the only ligand to have a unique type 2 receptor (AMHR2), but it shares type 1 receptors with other TGFBs. Its ability to interact with other TGFB superfamily members through common BPs is unknown. AMH has a precursor form (proAMH) in blood, and also exists as a mature complex (AMH_{N,C}) that dissociates when AMH_C binds to AMHR2. We have therefore examined the influence of TGFB BPs on the various forms of AMH. Fourteen TGFB BPs were examined in two assays. The influence of BPs on AMH_C or AMH_{N,C} receptor binding was measured using a bone morphogenetic protein response element (BRE) luciferase reporter assay. Western blots were used to measure proAMH cleavage to AMH_{N,C} in the presence of BPs. Several of the BPs had subtle effects on receptor activation, with the follistatins increasing and endoglin decreasing EC₅₀, by 25-35%. These BPs were effective at AMH concentrations present in adult blood (50pM) but not at boy levels (1nM). The densities of the AMH_{N,C} westernbands generated by furin cleavage of proAMH were not altered by the addition of any of the fourteen BPs, suggesting that the activation of proAMH is not modulated by known TGFB BPs. In conclusion, AMH may share some of the BPs that modulate and integrate the activities of the TGFB superfamily. The physiological actions of the BPs may be limited to adults.

P465**Board Number: B611****HUMAN PLATELET ESTROGEN RECEPTORS: LOCALIZATION AND THEIR ROLE IN AGGREGATION.**N.H. Patel¹, R.A. Mitteer², J.M. Prakash², O. Borodevyc², G. Soslau³, H. Singh⁴;¹Department of Internal Medicine, Drexel University College of Medicine, Philadelphia, PA, ²Office of Professional Studies in the Health Sciences, Drexel University College of Medicine, Philadelphia, PA,³Office of Professional Studies in the Health Sciences/Biochemistry and Molecular Biology, Drexel University College of Medicine, Philadelphia, PA, ⁴Pharmacology and Physiology, Drexel University College of Medicine, Philadelphia, PA

Platelets are vital to thrombosis and the pathophysiology of coronary artery disease (CAD). Platelet membranes are dynamic structures involved in regulating aggregation and thrombosis. Agonists bind to surface receptors, activating second messenger systems that result in platelet aggregation.

Gender differences in CAD have been attributed to the effects of estrogen. Paradoxically, some in vitro studies report that estrogen upregulates platelet activity while others report the opposite. Using aggregometry assays, we found that exposure to physiologic levels (60-100nM) of 17- β -estradiol (E2) initially increased agonist induced activation; with prolonged E2 exposure this effect is reversed. E2 exposure alone did not induce any aggregation. Additionally, lipid rafts are necessary for this initial synergy to occur. Classically, steroids like E2 regulate nuclear gene transcription. Platelets are anucleate – thus there must exist a non-genomic mechanism of steroids. We tested the hypothesis that platelets possess membrane bound estrogen receptors (ERs) capable of modulating platelet activity.

Platelet rich plasma (PRP) was isolated by centrifugation of whole blood from donors at 400g. PRP was then diluted and fixed for immunofluorescent microscopy using 4% (w/v) paraformaldehyde. Using antibodies to 3 major ERs – ER α , ER β , and G Protein Coupled Receptor 30 (GPR30) – we showed that platelet membranes possess all 3 ERs by immunocytochemistry and western blots. Furthermore, GPR30 is present on the cytosolic membrane face, while ER α and ER β are exposed on the external surface.

PRP from males was incubated with E2 and slides again prepped with a focus on the colocalization of ERs to Glycoprotein IIb/IIIa (GPIIb/IIIa). GPIIb/IIIa is the most abundant protein found exclusively on the platelet membrane, and plays a crucial role in aggregation. On short (3 minutes) exposure to E2, ER colocalization with GPIIb/IIIa increases. This was most prominent with GPR30.

Platelets were then activated with Thrombin Receptor Activating Peptide-1 (TRAP1), a synthetic thrombin analog that acts via Protease Activated Receptor-1 (PAR1) to activate GPIIb/IIIa. TRAP1 activation in E2 treated platelets resulted in less colocalization of ERs with GPIIb/IIIa compared to resting E2 treated platelets.

Our results suggest that E2 upregulates aggregation by priming the GPIIb/IIIa complex. Lipid rafts may mediate migration of ERs towards GPIIb/IIIa. Upon activation, uncoupling of ERs from GPIIb/IIIa begins and may explain the time dependent decrease in aggregation, translating to a cardioprotective effect of

estrogen. In this study we have established that ER α , ER β and GPR30 localized in platelets play a direct role in platelet aggregation and can be used as therapeutic targets in CAD.

Ion channel formation by mouse prion protein; Effects on membrane permeability and cell toxicity.

A.T. Sabareesan¹, V. Bhardwaj¹, J.B. Udgaonkar¹, M.K. Mathew¹;

¹Biochemistry, NCBS, Bangalore, India

Prion diseases are a group of fatal neurodegenerative disorders which affect animals and humans. It is well accepted that the conversion of native monomeric cellular prion protein (PrPC) to an aggregated oligomeric form (PrPSc) elicits the pathological features in these diseases. It has been proposed that direct interaction between PrP and lipid membrane, apart from the GPI-anchor, might play a critical role in the PrPSc formation. Peptides derived from the PrP have been shown to interact with lipid membrane and many of these peptides elicit cell toxicity by perturbing the ionic balance inside the cell. In this study, we have shown that GPI- anchor less full length mouse prion protein (moPrP) bind to lipid membrane and causes calcium release from the lipid vesicles. Also, we have shown that, using a BLM technique, moPrP forms a cation selective channel which allows the transit of only potassium and calcium ions. Surprisingly, we have observed that the exogenous addition of moPrP into HEK 293T cells leads to the incorporation of moPrP into the membrane and forms ion channels. However, we have also observed an immediate increase in the intracellular calcium level. Importantly, this dynamic increase of the intracellular calcium level is followed a pattern which is similar to the typical calcium signaling. This observation suggests that prion protein is not only able to form ion channels on the membrane but could also activate calcium signaling through a group of receptor/s. Perhaps, these combinations of both the ion channel formation and signaling activity of moPrP might be sufficient to trigger the apoptotic pathways through the discharge of cellular membrane potential, specifically, mediated by the calcium influx. We have also shown that moPrP aggregates interact with the membrane and forms pores which can finally rupture the membrane.

Inhibition of ChLoride Intracellular Channel (CLIC) Proteins by IAA-94 Induce Reactive Oxygen Species Release from Cardiac Mitochondria.

J. Farber¹, D. Ponnalagu¹, S. Sukur¹, W. Xin¹, S. Gururaja Rao¹, H. Singh¹;

¹Pharmacology and Physiology, Drexel University College of Medicine, Philadelphia, PA

Reactive oxygen species (ROS) are known to play a key role in modulating cell signaling pathways and, when produced at high levels, they induce the development of disease states such as atherosclerosis,

ischemic injury, cardiac hypertrophy and hypertension and cell death. In mammalian cells, mitochondria are a major source of ROS. A small amount of leaked electrons from the generally efficient electron transport chain (ETC) participate in reduction of oxygen to superoxide mostly in complex III and, due to the back flow of electrons, in complex I. In cardioprotection, modulation of ROS production is controlled by activation of mitochondrial ion channels. Even though ChLoride Intracellular Ion Channel (CLIC) proteins are predicted to localize to the mitochondria, there is no evidence of involvement of CLICs in ROS modulation in cardiac mitochondria. In this study, we focus on the role of CLICs in mitochondrial ROS production. CLIC proteins are present in mammals (CLIC1-6) and are regulated by redox potential. R(+)-Indanyloxyacetic acid 94 (IAA-94), a known CLIC blocker is shown to play an inhibitory role in cardioprotection. Here, using specific antibodies, we demonstrate the expression and localization of CLICs in mitochondria of neonatal and adult cardiomyocytes isolated from rats and in cardiac tubes of *Drosophila* by Western blots and immunocytochemistry. To establish the role of CLICs in mitochondrial ROS production, we measured ROS production from isolated cardiac mitochondria using amplex red dye (Invitrogen). We found that, in the presence of the complex II/III substrate (3 mM, succinate) and complex I substrate (5mM, glutamate/malate), addition of 100 μ M IAA-94 resulted in a robust release of ROS from mitochondria. The EC₅₀ for IAA-94 was found to be 16.5 \pm 0.15 μ M (n=3) for ROS produced in presence of succinate. After an initial fast release (ROS spike) there was an 82.5% (n=3) reduction in rate of ROS production with succinate as a substrate; however there was an 18.1% increase (n=3) in rate of ROS production with glutamate- malate as a substrate for 100 μ M IAA-94. We also reconstituted mitochondrial membrane proteins in a planar lipid bilayer, and discovered that IAA-94 partially blocked channel activity that could arise from CLIC-like proteins. Furthermore, we found that CLIC5 is localized to the mitochondria of neonatal and adult cardiomyocytes. The molecular identity of an inner mitochondrial anion channel (iMAC) has not yet been established, and our results indicate that CLIC5 could be a putative candidate for an iMAC. The differential effects of mitochondrial ROS production by blocking CLICs, and its impact on cardiac mitochondrial physiology may help to determine specific therapeutic strategies for cardioprotection.

Manipulation of the luminal domain of IRE1 changes the quality of UPR signaling.

D. Eletto¹, D. Eletto², Y. Argon³;

¹Division of Cell Pathology, The Children's Hospital of Philadelphia, Philadelphia, PA, ²Division of Cell Pathology, The Children's Hospital of Philadelphia, Philadelphia, PA, ³The Children's Hospital of Philadelphia, Philadelphia, PA

In response to endoplasmic reticulum (ER) stress, the unfolded protein response (UPR) signals to re-adjusts the protein folding capacity of the ER. If the re-adjustment fails, the cells are committed to apoptosis. One of the major UPR signal transducers, the transmembrane kinase-endoribonuclease inositol-requiring enzyme 1 (IRE1), dimerizes and oligomerizes in response to ER stress, and depending on the magnitude of the stress IRE1 activates either pro-survival or pro-apoptotic signaling. However, it

is still unknown how IRE1 shifts from the dimer state to the oligomer, and whether the dimer is responsible for pro-survival UPR signaling and the oligomer for the apoptotic outcome. Here, we investigated how changes in the luminal domain of IRE1, which senses ER stress, underlie this molecular and/or functional transition. The substitutions D123P and K121Y, previously shown to inhibit signaling by IRE1, abrogate the clustering of IRE1 that is normally induced by chemical ER stress, but do not abolish XBP1 splicing. This suggests that splicing can be performed by oligomeric species of IRE1 that are not detectable by microscopy (perhaps dimers). The D123P mutant is also defective in the RIDD activity of IRE1 (the degradation of ER-bound transcripts). On the other hand, another mutation in the luminal domain of IRE1, C148S, which we previously showed prolongs XBP1 splicing, does not affect the capacity of IRE1 to form clusters. Therefore, D123P and K121Y display a selective phenotype. Expression of a N-terminal luminal domain (NLD) of IRE1 also inhibits IRE1 clustering, but in addition inhibits XBP1 splicing. The inhibitory effect of NLD expression relies on a physical interaction with full-length IRE1 and is observed already at a 1:1 expression ratio. A truncated NLD that does not contain the core stress-sensing region is still able to inhibit IRE1 and the inhibition is specific to IRE1, because expression of NLD does not impact the activity of the related UPR sensor, the kinase PERK. Taken together, these data suggest that: (1) Manipulation of the luminal domain affects the output of IRE1, which is mediated by the cytosolic domains. (2) XBP1 Splicing and RIDD activity can be differentiated and D123P IRE1 is able to perform the former but not the latter, perhaps because it dimerizes but does not oligomerize. We hypothesize that the precise manner by which IRE1 luminal domains interact upon ER stress determines whether the outcome of signaling is adaptive or pro-apoptotic.

Regulation of epithelial ion channels by the ER luminal chaperone ERp29.

Y. Bikard¹, Y. Grumbach¹, L. Suaud¹, J. Litvak¹, R. Rubenstein^{1,2};

¹Pulmonary Medicine, The Children's Hospital Philadelphia, Philadelphia, PA, ²Department of Pediatrics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

ERp29 is an endoplasmic reticulum (ER) 29 kD thioredoxin-homologous protein. Interestingly, ERp29 has only a single Cysteine instead of the usual C-X-X-C thioredoxins motif. ERp29 displays chaperone-like properties at both the biophysical and cellular levels and plays a role in regulating connexin 43 hemichannel biogenesis and assembly. Our group has also demonstrated that ERp29 promotes CFTR biogenesis. As the biogenesis of CFTR and ENaC share similar features, the present studies tested the hypothesis that ERp29 would also regulate ENaC biogenesis and functional expression, as well as further probed the mechanism by which ERp29 promotes both ENaC and CFTR biogenesis. In MDCK epithelial cells expressing $\alpha\beta\gamma$ -ENaC, overexpression of wt ERp29 increased the abundance of the active form of γ -ENaC, as well as ENaC functional expression in Ussing chamber experiments. In contrast, ERp29 overexpression of a mutant ERp29 lacking its single Cysteine (C157S ERp29) decreased ENaC functional expression. These observations were not associated with altered expression of β -ENaC at the apical

surface, suggesting that ERp29 may modulate ENaC open probability at the apical surface. Instead, ERp29 overexpression promoted the interaction of both ENaC and CFTR with the coat complex II ER exit machinery, whereas C157S ERp29 overexpression decreased this interaction. Finally, we also tested the hypothesis that ERp29's escape from ER retention is critical for its regulation of CFTR. We therefore designed a mutant containing a KDEL retention motif (ERp29 KDEL) and two mutants that would better escape the ER, by mutation and deletion (ERp29 KDEV and DKEEL, respectively). Together our findings suggest a key role for ERp29 in the biogenesis of ENaC and CFTR as well as emphasize ERp29 mechanism.

Exosomes as delivery vesicles for transferrin and lactoferrin into mammalian cells.

H. Malhotra¹, N. Sheokand², A. Chauhan¹, M. Kumar¹, P. Jakhar¹, C. Raje³, M. Raje¹;

¹Cell Biology and Immunology, Institute of Microbial Technology, Chandigarh, India, ²Cell Biology and Immunology, Inst Microbial Technology, Chandigarh, India, ³Biotechnology, National Institute of Pharmaceutical Education and Research, Mohali, India

Exosomes are vesicles of endocytic origin formed by invagination of cell membrane into endosomes to form multivesicular bodies (MVBs). These small vesicles (30-120nm) are released from the cells when MVBs fuse with cell surface. Exosomes are secreted by all types of cells in culture, and are also found in abundance in body fluids including blood, saliva, urine, and breast milk. They are concentrated carriers of genetic and proteomic information, and thus are believed to play important roles in intercellular communication. Exosomes are involved in numerous functions such as signaling, activation of the target cells, delivery of information via miRNA and delivery of proteins to different cells of body. Currently exosomes are being extensively studied for delivery of different molecules (siRNA and drugs). Iron is an indispensable element required by all organisms for vital metabolic processes. The properties that make iron essential also make it toxic as free iron has the ability to produce oxidative radicals. Almost all the iron present in body fluid is bound to either transferrin (Tf) or lactoferrin (Lf) and the controlled uptake of these proteins via cell surface receptors contributes significantly in maintaining iron homeostasis. The present study attempts to characterize the role of exosome's in Tf and Lf delivery. For this, exosomes from the culture supernatant of various cell types were purified and we found that not only were exosomes capable of capturing Tf & Lf but could also deliver these iron carrier proteins more efficiently into different mammalian cells. Enhanced uptake of Tf & Lf by internalization of exosomes into cells led to increased iron acquisition by cells. Uptake of exosome associated Tf and Lf was found to be both dose and time dependent. Previously, we have reported that the multifunctional Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) recruited onto mammalian cell surface as well as in a secreted form functions as a novel receptor for Tf & Lf leading to trafficking of these proteins into cells. Proteomic profiling of exosomes from different origins has demonstrated the presence of GAPDH. Here we also confirmed the presence of GAPDH in exosomes and demonstrated that exosomal GAPDH is involved in

interaction with Tf & Lf. Interaction of exosomal GAPDH with Tf & Lf was confirmed by co-immunoprecipitation and GAPDH supplemented exosomes had a higher loading of these proteins compared to control exosomes. This is the first report demonstrating, that exosomes functions as nano vesicle for the delivery of Tf & Lf into mammalian cells. Understanding of this pathway may provide a new insight into human disorders associated with iron deficiency.

Investigating the regulation of Notch activation at the cell surface: Single molecule tracking and ensemble imaging reveal membrane dynamics and spatial organization of the Notch receptor.

K. Southard¹, J. Farlow², Z.J. Gartner^{2,3}, Y. Jun⁴;

¹Chemistry and Chemical Biology, University of California, San Francisco, San Francisco, CA,

²Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, ³Center for Systems and Synthetic Biology, University of California, San Francisco, San Francisco, CA, ⁴Department of Otolaryngology, University of California, San Francisco, San Francisco, CA

Notch signaling is a highly conserved cell-to-cell communication mechanism throughout the metazoan. Notch plays a fundamental role in regulating cell response to developmental cues, apoptotic signals, and growth stimuli. Signals exchanged between neighboring cells via Notch amplify cellular differences, tipping the scales of cell fate determination and facilitating short-range pattern formation in development. Aberrant Notch signaling is linked to several developmental and adult onset disorders, as well as cancer.

Unlike many cell surface receptors, Notch, a type I transmembrane receptor, is activated by ligands presented as transmembrane proteins on apposing cells, rather than by soluble ligands. This unique aspect of Notch activation restricts signaling to cells that physically contact each other and is an example of Juxtacrine signaling. Because of the requirement for contact, spatial organization of the Notch ligands and receptors the cell has the capability to regulate activation by controlling the spatial arrangement of Notch and activation pathway components, including ligand and activating proteases. While the biochemical interactions of Notch activation pathway are fairly well understood, the mechanisms involved in spatial regulation and dynamic interactions of Notch are less well characterized despite many proposed models. As such, we are investigating the spatial organization and dynamics of Notch at the cell surface using both single molecule and ensemble imaging methods.

Previously, we developed monovalent quantum dot bioimaging probes for tracking the dynamics of transmembrane receptors on live cells (Farlow, 2013). With these probes we measured the diffusion dynamics of Notch revealing slow diffusion ($0.08\mu\text{m}^2/\text{s}$) in comparison to a generic type I transmembrane receptor ($0.29\mu\text{m}^2/\text{s}$), suggesting that Notch is interacting and/or confined prior to activation. Additionally, our static and live cell studies of the receptor on the ensemble level showed spatial organization of Notch at the cell surface on the micron length scale, including specific exclusion

from focal adhesions on the basal membrane. In order to narrow down possible interactions made by Notch, we generated truncated receptor constructs and imaged their spatial distribution and single molecule dynamics in live cells. We found that exclusion from focal adhesions seems to be mediated by the Notch extracellular domain. Single particle tracking revealed that the interactions made by Notch at the cell surface were context dependent, as the diffusion constant of Notch varied with specific truncations to the extracellular domains. Currently, studies are underway to characterize the effects of known Notch pathway regulators on membrane distribution, dynamics, and signal activation.

Molecular Anatomy of Early Events in STIM1 Activation; Oligomerization or Conformational Change?.

M.K. Korzeniowski¹, E. Wisniewski², D.A. Holowka¹, B. Baird¹, T. Balla²;

¹Chemistry and Chemical Biology, Cornell University, Ithaca, NY, ²NIH/NICHD, Bethesda, MD

A decrease in the luminal ER Ca²⁺ concentration triggers oligomerization and clustering of the ER Ca²⁺ sensor molecule, STIM1, to promote association of its CAD/SOAR domain with the plasma membrane Orai1 channels leading to increased Ca²⁺ influx. A key step in STIM1 activation is the release of the CAD/SOAR domain from the intramolecular clamp that it forms with the first coiled-coil region (CC1, 234-343) of the molecule. Here we used an approach that allowed studying the early molecular events controlling CC1-CAD/SOAR interactions for the first time in intact live cells. We used STIM1 mutants truncated within the CC1 domain and expressed them together with the isolated STIM1 CAD/SOAR domain. We found that the CAD/SOAR domain was bound to ER-localized STIM1(1-343) in quiescent cells but was rapidly released after ER Ca²⁺ depletion and re-associated upon store refilling. The CC1 domain truncated at residue 280 [STIM1(1-280)] was still able to bind the CAD/SOAR domain in a manner dependent on the ER luminal Ca²⁺ concentration. Importantly, CAD/SOAR was not released by artificial oligomerization of a STIM1 (1-343) construct containing FKBP12 in its luminal segment, even though it was released in response to ER Ca²⁺ depletion. Using bimolecular fluorescence complementation of YFP molecules, we also show that STIM1 (1-343) is minimally dimeric. Furthermore, using FRET measurements on a combination of tagged full length STIM1 constructs (with D76A or L251S mutations) and STIM1 molecules only containing the CC1 domain, we show that STIM1 CC1 is able to bind CAD/SOAR in trans. Artificial clustering of either the entire cytosolic domain [STIM1(238-685)] or STIM1(203-685), which lacks the Ca²⁺ sensing modules in the ER lumen, bypasses the early triggering events to fully activate the STIM1 and Orai1 proteins and generate Ca²⁺ influx. The liberated CAD/SOAR domain appears to be the major driver in clustering and activation of the Orai1 Ca²⁺ channels. We conclude, based on these experiments with live cells, that CAD/SOAR is not necessary for STIM1 dimer assembly, but that the release of CAD/SOAR from its CC1 interaction is likely controlled by a conformational change that occurs in STIM1 dimers upon Ca²⁺ unbinding and leads to STIM1-Orai1 clustering.

P473**Board Number: B619****Phosphatidylinositol-3,5-bisphosphate in vacuolar and lysosomal acidification.**S.C. Ho¹, C.H. Choy¹, C.A. Wattson¹, R. Botelho¹;¹Ryerson University, Toronto, ON

Lysosomes and the yeast vacuole are highly acidic and enriched in a variety of acid hydrolases. The acidic environment is required for the proper degradation of cell components and pathogens. Quinacrine, a fluorescent base that readily accumulates in acidic environments, such as the yeast vacuole, fails to accumulate in yeast vacuoles deficient in phosphatidylinositol-3,5-bisphosphate (PtdIns3,5P₂), which suggests that PtdIns3,5P₂ is necessary for acidification. PtdIns3,5P₂ is implicated in a variety of cellular processes such as endolysosomal trafficking, autophagy, and ion channel regulation. PtdIns3,5P₂ is synthesized by the PtdIns5-kinase, PIKfyve, or Fab1 in yeast. However, the role of PtdIns3,5P₂ in vacuolar acidification remains unclear. In addition, the quinacrine assay is not a quantitative measurement of pH. Thus, the actual vacuolar pH in PtdIns(3,5)P₂-deficient vacuoles is not known. Therefore, we developed a fluorimetric assay to measure vacuolar pH using cDCFDA. cDCFDA is a fluorescent base that accumulates in vacuoles irrespective of acidity but its fluorescent intensity is dependent on pH. Our findings indicate that both wild-type and PtdIns(3,5)P₂-deficient vacuoles are acidic, with pH <5.0. In comparison, the vacuolar pH of the V-ATPase mutants, vph1Δ and vph1Δ fab1Δ double mutants were both 6.1. These values were comparable across two background strains, SEY6210 and BY4241. Since these observations were unexpected, we employed a second method based on super-ecliptic pHluorin, a GFP whose fluorescence is very sensitive to acidic pH. Our data showed that the fluorescence signal of pHluorin fused to a methionine transporter, Mup1, is quenched in both wild-type and fab1Δ vacuoles when Mup1 is targeted to the vacuole for degradation. Forcing the alkalinization of the vacuolar pH with an ionophore increased the fluorescent signal of Mup1-pHluorin in both wild-type and PtdIns(3,5)P₂-deficient vacuoles by 5-fold. Overall, we have two independent and quantitative assays showing that vacuoles in fab1Δ cells acidify as well as wild-type cells. Finally, we also measured the lysosomal pH in mammalian cells inhibited for PIKfyve by ratiometric imaging. We labelled lysosomes by endocytosis of FITC-dextran, whose fluorescence intensity is also dependent on pH. The results were consistent with yeast, where lysosomal pH was <5 in control and cells treated with PIKfyve inhibitors, apilimod and MF4. Together, our findings indicates that PtdIns(3,5)P₂ may not be involved in maintaining the steady-state vacuolar/lysosomal pH.

P474**Board Number: B620****EXPRESSION OF GLUCOSE TRANSPORTER 8 IS ASSOCIATED WITH LACTOSE SYNTHESIS IN MAMMARY GLAND OF MICE.**M. Villagran¹, M. Muñoz¹, K. Muñoz¹, I. Ruminot¹, C. Venegas¹, R. Del Pozo¹, L. Mardones¹;¹Faculty of Medicine, Universidad Católica de la SSMA Concepción, CONCEPCION, Chile

Glucose uptake in mammary gland increases suddenly during pregnancy to supply energy for high proliferation rate, and in lactation to support increased metabolic activity for milk synthesis. Glucose transporter 8 (GLUT8) is a class III facilitative glucose transporter located mainly intracellularly. Although this transporter has been located in mammary gland of different species, its physiological role within this gland remains unknown. We hypothesize that GLUT8 is involved in lactose synthesis mediating glucose uptake into Golgi of alveolar cells. To study this issue, we analyzed the temporal expression and the cellular and sub-cellular localization of GLUT8 in murine mammary gland during pregnancy, lactation and early weaning by immunohistochemistry, RT-PCR and western blot. Different cell populations were identified with specific markers: adipocytes with GLUT4, alveolar epithelial cells with cytokeratin 18 (CK18), ductal epithelial cells with cytokeratin 14 (CK14) and mioepithelial cells with smooth muscle actin (SMA). We found GLUT8 transporter colocalized with CK18 and GLUT4 but not with CK14 nor SMA indicating that GLUT8 is constitutively expressed in alveolar epithelial cells and adipocytes but absent in mioepithelial and ductal cells. In alveolar cells, GLUT8 has an intracellular granular pattern shared with lactalbumin. Lactalbumin is an endogen protein of alveolar cells, located in the Golgi, which acts as regulatory subunit of lactose synthase enzymatic complex. Semi-quantitative analysis of peroxidase-stained formalin-fixed tissue samples revealed a progressively increment in GLUT8 expression in alveolar epithelial cells through the pregnancy and the lactation, increasing considerably in early lactation (2 days after birth) and reaching its highest expression at late lactation (10 days). Two days after weaning GLUT8 expression showed fall-down. The highest expression of GLUT8 (late lactation) was associated with the highest percentage of glands stained (80%), percent of cells stained for gland (90%) and intensity observed, meanwhile in virgin mice, only 20% of the glands were marked with less of 20% of cells stained in each gland with the lowest intensity observed. This expression pattern is also observed at mRNA level and in whole protein extracts, where the highest increase was of 10 and 3 fold, respectively. The location of GLUT8 in the Golgi of alveolar cells, its co-location with lactalbumin and its progressive expression through pregnancy suggest its possible association with lactose synthesis enabling glucose entrance to Golgi as a precursor necessary to synthesize this disaccharide.

Support Grand: FONDECYT 11121367 (Fondo Nacional de Desarrollo Científico y Tecnológico. Chile)

P475**Board Number: B621****Identification of a Calsequestrin-1 Mutation in a Human Vacuolar Myopathy.**D. Rossi¹, B. Vezzani¹, L. Galli¹, V. Barone¹, S. Spinozzi¹, V. Del Re¹, A. Gamberucci¹, S. Lorenzini¹, C. Paolini², F. Protasi², C. Reggiani³, V. Sorrentino¹;¹Molecular and Developmental Medicine, University of Siena, Siena, Italy, ²Neuroscienze e Imaging, Università G. d'Annunzio, Chieti, Italy, ³Biomedicine, University of Padova, Padova, Italy

Calsequestrin-1 (CASQ1) is the major calcium binding protein of the sarcoplasmic reticulum (SR) of skeletal muscle cells. It is mainly localized in the junctional domain of the SR where it is part of a quaternary complex, which includes the ryanodine receptor calcium release channel, junctin and triadin. Calsequestrin-1 can modulate Ca²⁺ release by either directly bind the ryanodine receptor and/or by binding to junctin and triadin. We recently identified a D244G mutation in CASQ1 in patients with a myopathy characterized by the presence of vacuoles containing aggregates of SR proteins. The mutation affects a conserved aspartic acid located in one of the high-affinity Ca²⁺ binding sites of CASQ1. We found that muscle fibers from patients carrying the CASQ1 mutation show alterations in the Ca²⁺ release kinetics, thus suggesting that the D244G mutation may alter the intracellular Ca²⁺ signaling in the affected fibers. Interestingly, mutations in the CASQ2 protein identified in patients affected by catecholaminergic polymorphic ventricular tachycardia (CPVT) were shown to alter either Ca²⁺ buffering or Ca²⁺ release properties of cardiac muscle cells and to reduce the ability of calsequestrin to bind junctin and triadin. In order to understand the cellular mechanisms responsible for alterations of Ca²⁺ release kinetics in skeletal muscle cells carrying the D244G mutation, interactions between mutated and wild type CASQ1 and the ryanodine receptor type 1, junctin and triadin are being investigated.

Signaling Receptors (RTKs and GPCRs) 1**P476****Board Number: B623****Optogenetic Control of Class A Orphan G-Protein Coupled Receptors.**M. Morri¹, J. Schwarz¹, H. Janovjak¹;¹IST - Austria, Klosterneuburg, Austria

G-protein coupled receptors (GPCRs) are the largest family of cell membrane receptors and involved in virtually every physiological process. The exact size and diversity of the GPCR superfamily is still unknown and approximately 800 seven transmembrane (7TM) receptors have been identified in the human genome. A large number of 7TM receptors express olfactory receptors (approximately 450 genes), while over 300 genes have functions other than olfaction and activate G-proteins upon stimulation by e.g. hormones, ions, fatty acids or even light. Notably, a considerable number of human 7TM receptors (appx. 150 genes) are considered by The International Union of Basic and Clinical

Pharmacology as orphan GPCRs as their native ligands, signaling pathways and physiological functions are yet to be determined. To understand the signaling function and physiological role of human orphan GPCRs, we combined optogenetics and high-throughput genetic engineering to create light-activated chimeric variants of 90 class A orphan GPCRs. In first experiments, chimeric receptor design and high throughput assays of G-protein activation were validated using well-studied class A GPCRs and their chimeric variants, for which activation by light was compared to activation by ligand. After validation, we used the methodology to test for the ability of all human orphan GPCRs to activate cellular signaling pathways, and to identify their downstream coupling specificity. In several cell types, we detected coupling to one or several G-proteins for a large number of orphan GPCRs. Our work demonstrates that many orphan GPCRs possess the ability to activate cellular signals and that a complete and original library of synthetic receptors can be created for use as optogenetic tools in vitro as well as in vivo.

Board Number: B624

Defining the rules of GPCR-G protein interaction.

R.U. Malik¹, S. Sivaramakrishnan¹;

¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

G protein-coupled receptors (GPCRs) are promiscuous signal transducers that bind to and activate multiple downstream G proteins or arrestins to communicate extracellular stimuli into the cell. Dysfunction in GPCR signaling is implicated in a wide range of disease states, including cardiac myopathies, neurodegenerative disorders, psychoses, retinal degeneration, and cancer. Despite large-scale efforts, the rules of GPCR-G protein interaction remain undefined. To complement the existing FRET/BRET methodologies, we have developed a modular system to control and visualize GPCR-G protein interactions. Using this technology, we characterized the basal association and functional interaction between the prototypical GPCR opsin, four distinct adrenergic receptors ($\alpha 1$, $\alpha 2$, $\beta 2$, and $\beta 3$ -AR), and adenosine type 1 receptor with Gs, Gi, and Gq. In general, while GPCRs bind G proteins with varying strengths, Gs always associates stronger than Gi or Gq. Despite binding preferences, GPCRs do maintain an inherent propensity for activating their canonical G protein pathway. Interestingly, the strength of the GPCR-G protein binding does not correlate with the efficacy of pathway activation. The functional implications of these observations, sequestration of G proteins, regulation by RGS proteins, and differential signaling by GPCRs are presented. Together, our studies provide a blueprint to broadly interpret GPCR-G protein interactions in the presence and absence of ligands.

P478**Board Number: B625****The increasing complexity of Wnt signaling at the cell surface.**A. Person¹, W. Xiong¹, K. Shields¹, B. Burroughs¹, C. Howe¹, V. Kalabokis¹;¹Bio-Techne, Minneapolis, MN

The complexity of Wnt signaling is apparent due to the large number of ligands, receptors, and secreted inhibitors that have been implicated in Wnt signaling. Recently, newly described adult stem cell markers, LGR5 and TROY, were shown to play prominent roles in the increasingly complex regulation of Wnt signaling at the cell surface. Over ten years ago, the secreted proteins, R-Spondins, were shown to enhance Wnt signal transduction, but only recently was the mechanism of R-Spondin-mediated Wnt activation uncovered. R-Spondins are now known to bind to the Leucine-rich repeat-containing G-protein coupled Receptors (LGR 4-6), the transmembrane ubiquitin ligase Ring Finger 43 (RNF43), and the related ubiquitin ligase Zinc/Ring Finger 3 (ZNRF3). RNF43 and ZNRF3 both negatively regulate Wnt signaling by ubiquitinating Frizzled receptors targeting them for internalization and degradation. R-Spondins bind to both LGR4-6 and RNF43/ZNRF3 with this complex formation initiating endosomal internalization of the negative Wnt signaling regulators RNF43/ZNRF3. In addition, the tumor necrosis factor receptor superfamily member 19 (TNFRSF19 or TROY) is a membrane protein that binds LGR receptors and negatively regulates Wnt signaling with an incompletely understood mechanism. R&D Systems is in a unique position to comprehensively investigate the physical interactions and the functional significance of these new cell surface Wnt pathway regulatory proteins as we have generated all of the necessary purified recombinant proteins for this analysis. Recombinant extracellular domain LGR4-6 proteins all bind R-Spondins, but show preferential binding to different R-Spondin family members. R-Spondin proteins bind to the extracellular domain of RNF43/ZNRF3 with high affinity, and the extracellular domain of TROY also interacts with LGR5. In Wnt reporter assays, addition of LGR4 and 6 extracellular domain proteins robustly enhance Wnt3a activity in HEK293 cells. Our data demonstrate that addition of the LGR proteins is sufficient to enhance R-Spondin mediated stimulation of Wnt signaling by inhibiting the negative regulators RNF43/ZNRF3. Interestingly, we also detect inhibition of R-Spondin activity when LGR4-6 proteins are added to Wnt reporter cells in the context of saturating doses of R-Spondins. Finally, addition of the RNF43 and ZNRF3 proteins inhibit R-Spondin-enhanced Wnt reporter activation. We present new binding and functional data describing these new Wnt pathway-related recombinant proteins, and we also describe the Wnt assay systems that have allowed us to better understand these complex new regulators of Wnt signaling.

P479**Board Number: B626****Evolutionarily Conserved Coupling of Adaptive and Excitable Networks Mediates Eukaryotic Chemotaxis.**C. Huang¹, P. Devreotes², P. Iglesias³, M. Tang⁴, M. Wang¹, C. Shi¹;¹Johns Hopkins University, Baltimore, MD, ²Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ³Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD, ⁴Johns Hopkins University School of Medicine, Baltimore, MD

Numerous models have been proposed to explain the remarkable ability of chemotactic cells to sense and migrate toward extremely shallow chemoattractant gradients independently of the ambient concentration. Recent studies indicate that the stochastic activity of an excitable signal transduction network involving Ras, PI3K, and Rac acts as a pacemaker that controls the cytoskeleton to drive motility. Here we show that blocking multiple signal transduction pathways simultaneously abrogated chemoattractant-induced actin polymerization and chemotactic motility but not directional sensing. We carried out experiments to distinguish the various models of gradient sensing in migrating cells. First, signaling activity was strongly suppressed toward the low side of cells in a gradient or following sudden removal of uniform chemoattractant. Second, signaling activities displayed a rapid shut off and, with stimulation of increasing duration, a slower adaptation during which responsiveness to subsequent test stimuli declined. Simulations of existing classes of models indicated that these observations can only be explained by the coupling between an adaptive module and an excitable network. Moreover, stimulation of cells lacking G-protein function suppresses downstream activities, while constitutive G-protein activation induced persistent responses. This indicates that chemoattractant sensing is mediated by a balance between G-protein dependent and independent signals. The salient features of the coupling between adaptive and excitable networks were observed for the chemoattractants cAMP and folic acid in *Dictyostelium* as well as fMLP in human neutrophils, suggesting an evolutionarily conserved mechanism for eukaryotic chemotaxis.

P480**Board Number: B627****An oncogenic c-KIT mutant can bypass SLAP-mediated negative regulation by phosphorylating SLAP.**J.U. Kazi¹, J. Sun¹, L. Rönnstrand¹;¹Translational Cancer Research, Lund University, Lund, Sweden

The stem cell factor receptor, c-KIT has been implicated in various malignancies including mastocytosis, some subtypes of acute myeloid leukemia, small cell lung carcinoma, malignant melanoma, colorectal cancer and gastrointestinal stromal tumors. Within the more than 500 mutations that have been found, the D816V mutation is the most abundant oncogenic mutation of c-KIT in human malignancies. Under

normal condition the receptor signaling is tightly regulated by regulatory proteins such as phosphatases, ubiquitin ligases and adapters or scaffold proteins. The SRC-like-adaptor protein (SLAP) has been shown to be a negative regulator of mitogenic signaling. In many cases SLAP expression overlaps with c-KIT expression and therefore we aimed to determine whether SLAP is involved in regulation of c-KIT downstream signaling. We observed that SLAP associates with both wild type c-KIT and the oncogenic mutant KIT-D816V. The SH2 domain of SLAP is involved in association with c-KIT through phosphotyrosine residues. SLAP induces ubiquitination and degradation of c-KIT resulting in negative regulation of downstream signaling. Unlike wild type c-KIT, SLAP did not block c-KIT-D816V-mediated phosphorylation of downstream signaling mediators such as AKT and ERK1/2. To understand the mechanism how c-KIT-D816V escapes SLAP-mediated controls, we studied localization and posttranslational modifications of SLAP in c-KIT-D816V expressing cells. We observed that c-KIT-D816V, but not wild type c-KIT, specifically phosphorylates SLAP on Y120, Y258 and Y273 residues. A mutant lacking the three phosphorylation sites can restore SLAP regulation on oncogenic c-KIT-D816V. Taken together, our data suggest that SLAP is an important regulator of c-KIT signaling and oncogenic c-KIT-D816V can bypass normal cellular regulation by phosphorylating SLAP and thereby enhanced oncogenic signaling.

PI 3 kinase is indispensable for oncogenic signal transduction by the V560D mutant of c-Kit.

J. Sun¹;

¹Translational Cancer Research, Lund University, Lund, Sweden

Oncogenic mutations of c-Kit are often identified in mastocytosis, gastrointestinal stromal tumors (GISTs) and acute myeloid leukemia (AML). The activation mechanism of the most often occurring mutation, D816V in exon 17 of c-Kit, has been well studied while other mutations remain fairly uncharacterized in this respect. In this study, we show that the constitutive activity of the exon 11 mutant V560D is weaker than the D816V mutant except that the phosphorylation of the Src family kinase binding site, Tyr568, is similar in both c-Kit mutants. The ligand for c-Kit, stem cell factor (SCF), induced phosphorylation of downstream signaling proteins, such as Akt and Erk, in c-Kit/V560D expressing cells was stronger than that in c-Kit/D816V expressing cells. Although cells expressing c-Kit/V560D showed increased ligand-independent proliferation and survival compared to wild-type c-Kit expressing cells, these biological effects were less than c-Kit/D816V expressing cells. In contrast to cells expressing wild-type c-Kit, cells expressing c-Kit/V560D are independent of Src family kinases for downstream signaling. However, this independence of Src family kinases is not due to a Src-like kinase activity of the mutant receptor that c-Kit-D816V holds. Blockage of the association of PI3 kinase with c-Kit/V560D by point mutation, but not inhibition of PI3-kinase with pharmacological inhibitors, totally blocked ligand-independent activation of the receptor, suggesting a key role of the non-lipid kinase activity of PI3 kinase in c-Kit/V560D mediated oncogenic signal transduction. Thus, PI3 kinase is an

attractive treatment target in c-Kit mutations induced malignancies independent of its lipid kinase activity.

Palmitoylation of EGFR attenuates receptor signaling.

K.B. Runkle¹, S. Terkowski¹, E. Stypulkowski¹, E. Witze¹;

¹Cancer Biology, University of Pennsylvania, Philadelphia, PA

Cellular signaling pathways important for tumor initiation and progression are regulated by a variety of well-studied post-translational modifications including phosphorylation, ubiquitination and acetylation. Recently, the reversible lipid modification; palmitoylation, has been demonstrated to control the localization and activity of a variety of proteins, thereby serving as a novel modification that has the ability to alter signaling pathways in cancer.

Palmitoylation is regulated by two classes of enzymes, the DHHC domain containing protein acyl-transferases (PAT) which mediate the addition of palmitate to target substrates, and the acyl-protein thioesterases (APT) which remove palmitate from proteins. Twenty-three DHHC PATs have been identified in mammalian cells and alterations in the expression and function of several PATs have been observed in neurodegenerative disorders and diseases such as cancer. Analysis of The Cancer Genome Atlas reveals a loss of expression of the PAT DHHC20 in a subset of breast, lung and prostate tumors suggesting a potential function for DHHC20 in cancer.

Using MDA-MB231, triple-negative breast cancer cells, we have determined that knockdown of DHHC20 increases chemotaxis which is blocked by the EGFR inhibitor Gefitinib. Closer examination of EGFR signaling in DHHC20 knockdown cells revealed elevated EGFR expression and amplified EGF-induced activation of EGFR and AKT. The expression and activation of EGFR are regulated by receptor mediated endocytosis and lysosomal degradation. Knockdown of DHHC20 impairs the endocytic trafficking of EGFR to lysosomes in response to EGF, which may contribute to the sustained signaling.

The specificity of DHHC enzyme-substrate pairs has not been well studied and little is known about specific targets of DHHC20. Our studies have identified EGFR as a novel substrate of DHHC20. Blocking palmitoylation by mutating intracellular cysteines on EGFR revealed putative palmitoylation sites that activate EGFR independent of EGF. These findings support the importance of palmitoylation in regulating EGFR activation. Finally, inhibiting EGFR activity is critical for treating cancers in which EGFR is highly expressed or constitutively activated. We found that pharmacological inhibition of protein depalmitoylation with the APT1 inhibitor Palmostatin B attenuates EGFR activation in a dose dependent manner, suggesting a potential treatment strategy to regulate EGFR signaling in cancer. Taken together, our findings identify palmitoylation as a novel modification of EGFR that regulates receptor activation. Maintaining EGFR in its palmitoylated form may serve as an innovative treatment approach to control EGFR activation in cancer.

P483**Board Number: B630****Na,K-ATPase function modulates EGFR signaling.**A. Litan¹, S. Lee¹, D. Wolle¹, Z. Li¹, S. Yoo¹, S.A. Langhans¹;¹A I duPont Hosp Children, Wilmington, DE

EGF regulates cell proliferation and migration by triggering molecular cascades, including Erk and PI3K/Akt signaling, that regulate cytoskeletal reorganization, cell cycle progression and gene expression. Aberrant expression/activation of EGFR is found in multiple human cancers, including medulloblastoma, the most prevalent pediatric brain cancer. Termination of EGF signaling is tightly regulated by endocytosis of the activated EGF receptor (EGFR) followed by trafficking of the receptor-ligand complex to specific endocytic compartments. Trafficking of EGFR relies on microtubule tracks that transport cargo vesicles to their intermediate and final destinations and can be modulated through posttranslational modification of tubulin. Using cultured medulloblastoma cells, we found that EGF-induced sodium influx regulates EGFR trafficking through increased microtubule acetylation. Increased sodium influx induced by sodium ionophores mimicked the EGF-induced effects on EGFR trafficking through histone deacetylase (HDAC) 6 inactivation and accumulation of acetylated tubulin. Furthermore, the cardiac glycoside, ouabain which specifically blocks the pump activity of Na,K-ATPase induced tubulin acetylation, suggesting that intracellular sodium homeostasis can modulate tubulin acetylation and may fine-tune tubulin function. Consistent with a role of intracellular sodium homeostasis regulating EGFR signaling, ouabain treatment modulated EGF-induced Erk1/2 and Akt signaling, blocked EGF-induced formation of actin stress fibers and cell motility, and modulated response to EGFR tyrosine kinase inhibitors. Together our data suggest that an increase in intracellular sodium is a component of an auto-regulatory loop that regulates termination of EGFR signaling through trafficking of the EGF-EGFR complex and includes HDAC6 and tubulin acetylation.

P484**Board Number: B631****The secreted LPR-1 facilitates LIN-3/EGF signaling during the development of the excretory system.**P. PU¹, M.V. Sundaram¹;¹Department of Genetics, University of Pennsylvania, Philadelphia, PA

LPR-1 facilitates LIN-3/EGF signaling during the development of the *C.elegans* excretory system Pu Pu, Meera V. Sundaram

The activity of signaling ligands such as Epidermal Growth Factor (EGF) must be tightly controlled in space and time to ensure that signaling is restricted to appropriate target cells. In the *C.elegans* excretory (renal like) system, the EGF/Ras/Erk signaling pathway plays multiple roles in specifying the

duct versus the pore cell fate and maintaining organ architecture. LPR-1 belongs to the large lipocalin family, which is a group of small secreted proteins functioning as carriers for lipophilic cargos. *lpr-1* loss-of-function mutants showed a highly penetrant L1 lethal excretory phenotype due to discontinuous lumen between the duct and pore, whereas this lethality was significantly suppressed by overexpressing a *lin-3*/EGF genomic fragment or by hyperactivating the downstream LET-60/Ras signaling pathway within the developing excretory duct and pore. By alternative splicing, *lin-3* generates at least 4 protein isoforms. In order to examine which one or more isoforms of LIN-3/EGF could function in the excretory system and rescue the *lpr-1* mutant excretory defect, 4 different LIN-3 isoforms were expressed under the control of its own promoter. All 4 LIN-3 isoforms could function in the excretory system and rescue *lin-3* and *lpr-1* mutant lethality, although at different efficiencies, with the predominant embryonic isoform showing relatively low signaling efficiency. Furthermore, *lpr-1* loss could suppress the excretory pore-to-duct fate transformation of *lin-15* SynMuv mutants, which have slightly elevated levels of *lin-3* expression. These epistasis results suggest that during excretory system development, LPR-1 facilitates efficient LIN-3/EGF signaling.

Induced proinflammatory signaling limits proliferative response to FGF.

A. Poole¹, E. Cooper¹, D. Kacer¹, I. Prudovsky¹;

¹Maine Medical Center Research Institute, Maine Medical Ctr, Scarborough, ME

We found that transient FGF1 or FGF2 stimulation of various cell types results in the novel phenomenon of “FGF memory” – a sustained blockage of efficient proliferative response to FGF, PDGF or EGF. FGF memory establishment requires HDAC activity, indicating its epigenetic character. FGF treatment stimulates the proinflammatory NFκB signaling, which is also critical for FGF memory formation. The search of potential FGF-induced mediators of FGF memory revealed that FGF stimulates a sustained expression of the inflammatory cytokine IL1α. Similarly to FGF, transient cell treatment with recombinant IL1α inhibits the proliferative response to further FGF stimulation, but does not prevent the FGF receptor-mediated signaling. Interestingly, cells pretreated with FGF1 or IL1α exhibit an enhanced restructuring of actin cytoskeleton and migration in response to FGF stimulation. IRAP, a specific inhibitor of IL1 receptor prevents the formation of FGF memory and rescues an efficient proliferative response to FGF restimulation. Thus, FGF1 memory is mediated by proinflammatory IL1 signaling. It may play a role in the limitation of proliferative response to tissue damage and prevention of wound-induced hyperplasia.

P486**Board Number: B633****Regulation of the "molecular brake" region in FGFR2 kinase.**J.M. Karp¹, D. Cowburn¹;¹Albert Einstein College of Medicine, Bronx, NY

Unregulated activity of tyrosine kinases (TK) is responsible for numerous developmental musculoskeletal diseases and cancers. The regulatory mechanisms of TKs and how they are affected by point mutations are still in need of elucidation. Fibroblast growth factor receptor (FGFR) kinase is a TK whose regulatory element, the "molecular brake," is thought to prevent constitutive activation of the receptor, despite not being near the kinase's active site. Germline mutations in this "molecular brake" region in FGFR cause musculoskeletal disorders such as craniosynostosis and dwarfism, while somatic mutations can lead to uninhibited cell growth, causing an array of cancers. Furthermore, it is thought that the majority of pathogenic activating mutations in protein kinases are in "molecular brake"-like regions. However, the mechanism through which the "molecular brake" of FGFR kinase is disengaged, allowing for signal transduction, is still unknown. Using path-based molecular dynamics (MD) simulations, we have shown that the inward motion of the kinase's activation loop upon tyrosine phosphorylation is correlated with disengagement of the "molecular brake." Results of the string method in collective variables, which finds the minimum free energy path connecting the loop-out and loop-in states, indicate found that inward motion of loop occurs within 1 frame of "molecular brake" disengagement. Furthermore, umbrella sampling shows that in loop-out conformations, the disengaged state of the "molecular brake" is less stable, while in loop-in conformations, the disengaged state becomes more stable. Our results suggest that the "molecular brake" is allosterically controlled by the activation loop motion. An understanding of the "molecular brake" disengagement mechanism will provide avenues for targeted therapies to counteract pathologic over-activation of FGFR kinase leading to uncontrolled signal transduction and uninhibited cell growth.

P487**Board Number: B634****Essential roles of Crk and CrkL in fibroblast growth.**T. Park¹, T. Curran¹;¹Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia Research Institute, Philadelphia, PA

Cytosolic proteins containing SH2 and SH3 domains, such as Crk and Crk-like (CrkL), are broadly expressed adaptors that interact with a variety of proteins to fulfill key roles in signal transduction pathways triggered by activation of receptor and non-receptor tyrosine kinases. Crk and CrkL are similar to each other in structure and biochemical function, and they provide both overlapping and distinct biological roles during development. We took a systematic approach to investigate Crk family functions at the cellular level by generating conditional knockout systems for ablation of Crk and CrkL in cultured

fibroblasts. Previously, we used lentiviral infection to induce ablation of Crk and CrkL in slowly growing fibroblasts and demonstrated that Crk and CrkL play critical roles in cell structure and motility by maintaining cytoskeletal integrity. Here we transfected rapidly dividing fibroblasts with modified RNAs synthesized in vitro using the Neon transfection system to study roles of Crk and CrkL in cell growth. Most cells became positive for green fluorescence 5 hours after transfection with GFP RNA, suggesting that RNAs are efficiently translated into proteins upon transfection. Loss of Crk and CrkL induced by Cre RNA transfection blocked cell proliferation in fibroblasts immortalized either by T antigen transfection or by culturing according to the 3T3 protocol. Western blot analyses indicated that transfection of Crk/CrkL double floxed cells with Cre RNA blocked expression of the three Crk family proteins, CrkII, CrkI and CrkL. In addition, expression of beta-actin protein and phosphorylation of both p130Cas and Akt were reduced in the absence of Crk and CrkL. Immunofluorescence staining revealed that the cytoplasm and nucleus became smaller in the absence of Crk and CrkL. Ablation of Crk or CrkL alone conferred a much more modest inhibition of cell proliferation suggesting that Crk and CrkL play overlapping functions in cell growth. Taken together, our results suggest that Crk and CrkL play essential roles in cell growth.

The role of EphA2 in regulating HGF-induced epithelial morphogenesis in three-dimensional culture.

K. Harada¹, M. Negishi¹, H. Katoh¹;

¹Laboratory of Molecular Neurobiology, Graduate School of Biostudies, Kyoto University, Kyoto, Japan

EphA2, a member of Eph family receptor tyrosine kinases, is overexpressed in various cancers derived from epithelial cells and promotes cancer cell migration and invasion. In contrast, its molecular mechanisms and functional roles in epithelial morphogenesis remain unclear. In this study, we show that EphA2 promotes extension formation, the first step of tubulogenesis, in three-dimensional cultured MDCK cysts in response to hepatocyte growth factor (HGF) stimulation. Interestingly, we also found that serine 897 phosphorylation, but not tyrosine kinase activity, of EphA2 is necessary for this morphogenesis. Moreover, ephrinA1 stimulation blocks HGF-induced extension formation. These observations suggest that ligand-independent activity of EphA2 is essential for epithelial morphogenesis.

P489**Board Number: B636****Sphingosine 1-Phosphate Mediates Epithelial-Mesenchymal Transition in Breast Cancer.**W. Wang¹, D. Herr¹;¹Department of Pharmacology, National University of Singapore, Singapore, Singapore

Epithelial-mesenchymal transition (EMT) is an essential process implicated in cancer metastasis, leading to cancer progression. Signaling pathways contributing to EMT are largely unknown. Sphingosine 1-phosphate (S1P), a bioactive lipid mediator, mainly exerts its effects by binding to a family of G protein-coupled receptors (GPCRs), namely S1P1-5. S1P signaling has been reported to regulate cell migration and motility in cancers; nevertheless, its role in EMT is not well established. Here we show that S1P signaling mediates EMT process via transcription factor Slug, which is one of the EMT master regulators. S1P treatment, particularly short term, can significantly up-regulate the level of Slug in breast cancer cell lines. A group of available ligands for S1P receptors have been validated using a novel tool (TGF α shedding assay) for the first time for their antagonistic and/or agonistic activities, as well as their specificity and potency. By pharmacological and genetic approaches, S1P2 and S1P3 are identified as two main receptors responsible for this signaling pathway, and most likely their downstream effectors Rho and Rac are also involved. Preliminary results suggest that S1P signaling up-regulates Slug expression level by promoting its transcription. Besides, efforts have been made to investigate the crosstalk between S1P-induced EMT and other known EMT pathways, such as TGF beta and EGFR/HER2. Taken together, our findings demonstrate that S1P signaling immediately up-regulates Slug level through S1P2 and S1P3, contributing to the initial stage of EMT. This study may provide new insights for therapeutic approaches in the early stage of cancer metastasis.

P490**Board Number: B637****Profibrotic upregulation of GLUT1 and Hexokinase 2 by transforming growth factor beta requires autocrine receptor tyrosine kinase mediation.**M. Andrianifahanana¹, X. Yin¹, Y. Wang¹, E.B. Leof¹;¹Thoracic Disease Research Unit, Division of Pulmonary and Critical Care Medicine, Departments of Internal Medicine and Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN

Defining the exact mechanisms by which transforming growth factor β (TGF β) exerts its profibrotic activity is critical for understanding the molecular basis as well as developing viable therapeutic strategies for disorders with a major fibroproliferative component, such as fibrosis and desmoplastic cancers. Here, we report that TGF β causes fibroblast cells to coordinately upregulate expression of the facilitated glucose transporter 1 (GLUT1/SLC2A1) and its downstream effector, hexokinase 2 (HK2), both at the mRNA and protein levels. Using pharmacological and genetic approaches we demonstrate that

GLUT1/HK2 induction occurs via the canonical Smad2/3 pathway and requires autocrine activation of the receptor tyrosine kinases, platelet-derived (PDGFR) and epidermal (EGFR/ErbB) growth factor receptors, whereby the MAPK/ERK (mitogen-activated protein kinase/extracellular signal-regulated kinase) module serves as a common effector. Of note, inhibition of GLUT1 activity is shown to prevent TGF β -driven anchorage-independent growth of fibroblasts on soft agar. Together, our results provide new insights into the mechanisms controlling upregulation of the glucose metabolic pathway and its role in profibrotic TGF β signaling. These findings may shed light on mechanisms associated with the pathogenesis of fibroproliferative diseases and contribute to the identification of novel therapeutic targets.

Fc ϵ RI Signal Propagation is Regulated Through Transient Binding of Syk.

S. Schwartz¹, D.S. Lidke¹, M.P. Steinkamp¹, C. Cleyrat¹, K. Lidke²;

¹Pathology, University of New Mexico, Albuquerque, NM, ²Physics, University of New Mexico, Albuquerque, NM

The high affinity IgE receptor, Fc ϵ RI, serves as the primary immunoreceptor on mast cells and basophils. Crosslinking of IgE-bound Fc ϵ RI via multivalent antigen induces phosphorylation of the immunoreceptor tyrosine-based activation motifs (ITAMs) followed by recruitment of the kinase Syk and further signal propagation. While the sequence of these signaling events has been well studied using biochemical techniques, the biophysical mechanisms that regulate Fc ϵ RI signaling are unclear. Using two-color single molecule imaging in live cells, we quantify how Fc ϵ RI aggregation influences Syk recruitment and mobility. We imaged the basal surface of RBL-2H3 cells expressing mNeon-Syk using TIRF microscopy and upon crosslinking of Fc ϵ RI observed an increase in the membrane localization of mNeon-Syk. Interestingly, while ensemble measurements showed that Fc ϵ RI and mNeon-Syk were co-localized over minutes, single molecule imaging revealed that mNeon-Syk clusters are in fact maintained through a continuous exchange of transiently bound mNeon-Syk. We quantify the residency time of individual mNeon-Syk molecules at Fc ϵ RI aggregates and explore the relationship between Fc ϵ RI aggregate size and Syk residency time. Previously, it has been shown that high concentrations of stimulating cross-linking antigen induce a drastic reduction in Fc ϵ RI mobility. However, when antigen is added at low concentrations, low valency, or presented from a mobile bilayer, this mobility change is less substantial. We use single particle tracking to characterize the mobility of mNeon-Syk and find a similar antigen dependence on mobility. We show that at high concentrations of crosslinking antigen, Syk is highly immobilized at the membrane, yet when antigen is presented at lower concentrations or from a mobile bilayer Syk remains mobile at the membrane while still exhibiting an increased residency time. These results demonstrate that mobile Fc ϵ RI are capable of recruiting Syk and that receptor immobilization is not a requirement for signaling.

P492**Board Number: B639****Autocrine Selection of Novel GABABR Agonists from Intracellular Combinatorial Libraries.**R.E. Turn¹, E. Sturchler², M. Stringhini², C. Rader², P. McDonald²;¹Harriet L. Wilkes Honors Coll, Jupiter, FL, ²Molecular Therapeutics Department, Scripps Research Institute, Jupiter, FL

Dysfunction of GABAB receptor (GABABR)-mediated synaptic transmission underlies various nervous system disorders including epilepsy, depression, schizophrenia, and addiction. Currently, only one GABABR orthosteric ligand namely Baclofen, is in clinical use. However, side effects such as sedation and tolerance limit its use. GABABRs are G-protein coupled receptors that have been shown to mediate their effects via multiple signaling pathways. Some receptor ligands have been shown to possess multiple efficacies depending on the specific down-stream signal transduction pathway being analyzed. This diversity is believed to be the result of conformational changes induced in the GPCR that are ligand-specific, a phenomenon known as 'functional-selectivity'. Hence, a dissociation of the therapeutic effects from the side effects of GABABR activation may be achievable with more pathway-selective GABABR drugs. In this study, we aim to identify novel positive modulators of GABABR by screening large combinatorial antibody libraries using purified extracellular domain of GABABR. 'Hits' identified in this primary screen will be further investigated in three distinct cell-based functional assays that monitor; 1) cAMP production, 2) intracellular calcium mobilization, and 3) MAP Kinase activation, using a GABABR-expressing CHO cell line, in an attempt to identify those that exhibit functional selectivity.

P493**Board Number: B640****Gene knockouts of two different constitutive GPCR activities produce opposite changes in the excitability of the unicellular ciliate *Tetrahymena thermophila*.**T.M. Hennessey¹, D. Zou¹;¹Biological Sciences, University at Buffalo, Amherst, NY

Tetrahymena are eukaryotic unicells that can move either towards an attractant or away from a repellent by modifying their swimming behaviors. These responses rely on alterations in the basal rate of changes in swimming direction. In bacterial chemotaxis, these changes are called "tumbles" but in *Tetrahymena*, we refer to it as PDC (the percent of cells showing direction changes). In general, attractants decrease basal PDC (allowing them to swim straighter towards the attractant) while repellents increase PDC (to send them in a new, random direction). For well regulated changes in PDC, there should be a relatively high basal PDC so that both increases and decreases are possible. What sets this basal PDC? How can stimuli regulate this PDC to cause changes in swimming behavior? The objective of our work is to try to answer these questions. Our current model (Lampert et al., 2011) is

that basal PDC is kept high in wild type by the constitutive activity of a pertussis-sensitive GPCR (*gpcr6*). This may act by modulating either Ca^{++} channel activity or by Ca^{++} regulation. Some attractants may work as inverse agonists to decrease this GPCR effect, decrease basal PDC and result in chemoattraction. Consistent with this model, we have described a GPCR knockout mutant in *Tetrahymena*, called G6 (Lampert et al., 2011), which has a low basal PDC and an inability to respond to chemoattractants because it can't lower the PDC further. It also under-responds to strong depolarizing conditions like high K^+ , possibly because of its effects on Ca^{++} channel activity. We have constructed another putative GPCR knockout in *Tetrahymena*, called G3, which dramatically over-responds to high K^+ . Analyses of the various behavioral responses of mutants and wild type and their effects on internal Ca^{++} concentrations suggest that the constitutive activity of the wild type GPCR3 gene product (*gpcr3*) may affect the voltage-dependent ciliary Ca^{++} channels to put them in a state that is more "reluctant" (Bean, 1989) to open and establish the basal PDC. We propose that the *gpcr3* knockout mutation puts the Ca^{++} channels in a more "willing" state and makes the G3 mutant more excitable. Together with the results from the G6 mutant, this suggests that the basal PDC is affected by both *gpcr3* and *gpcr6* to regulate the PDC. Attractants and repellents may act as "inverse agonists" to regulate the basal PDC through their effects on these GPCRs and their related Ca^{++} channel activities.

Role of RKTG, a novel Golgi localized receptor, in Gbetagamma regulated transport of secretory proteins from the Golgi to the Plasma Membrane.

T. Hewavitharana¹, P.B. Wedegaertner²;

¹Department of Biochemistry and Molecular Biology, Thomas Jefferson University, Philadelphia, PA,

²Department of Biochemistry and Molecular Biology, Thomas Jefferson University, Philadelphia, PA

Recent studies have revealed a role for G protein betagamma signaling at the Golgi via protein kinase D (PKD) regulating fission of plasma membrane (PM) destined secretory vesicles from the trans Golgi network (TGN). The mechanism by which the Gbetagamma subunits are recruited to and activated at the Golgi in this process remains elusive. Recent studies reveal that a newly characterized Golgi localized, membrane protein belonging to the Progestin and AdipoQ Receptor (PAQR) family, RKTG (Raf Kinase Trapping to the Golgi), interacts with the Gbeta subunit and sequesters Gbetagamma to the Golgi thereby regulating the functions of Gbetagamma. Here we show that over expression of RKTG causes vesiculation of the Golgi, while a Gbeta binding mutant of RKTG does not cause vesiculation. Also, the C-terminal fragment of GRK2 (GRK2ct), which interacts with, and inhibits Gbetagamma signaling, and Gallein, a small molecule inhibitor of Gbetagamma, were both able to inhibit Golgi vesiculation in the presence of RKTG. Furthermore, a dominant negative form of PKD (PKD-DN) and a pharmacological inhibitor of PKD, Go6976, also inhibited RKTG mediated vesiculation of the Golgi. Collectively, these results reveal a novel role for the newly characterized, Golgi localized RKTG receptor, in regulating Gbetagamma at the Golgi, thus controlling Golgi to PM protein transport via the Gbetagamma-PKD signaling pathway.

³Proteome Exploration Laboratory, Beckman Institute, California Institute of Technology, Pasadena, CA,

⁴Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom

JLP (JNK associated Leucine zipper protein) is a scaffolding protein, which has been shown to interact with and activate JNK/p38MAPK pathway. Its interaction with various signaling proteins is associated with coordinated regulation of cellular process such as endocytosis, motility, neurite outgrowth, cell proliferation and apoptosis. Here we identified a mitotic Serine/Threonine kinase, Polo like kinase 1 (Plk1), as a novel interaction partner of JLP through a mass spectrometry based approach. We show that the N-terminal domain of JLP interacts with the polo-box domain (PBD) of Plk1 in a phosphorylation-dependent manner. Our results indicate that, JLP is phospho-primed on Thr 351 residue on its N-terminus, which is recognized by the PBD of Plk1 leading to phosphorylation of JLP at additional sites. Moreover, treatment of cells with the Plk1 inhibitor, BI2536 affects the interaction demonstrating the importance of Plk1 kinase activity in this process. Since JLP is a scaffolding protein that recruits proteins to mediate specific cell signaling events, we hypothesized that the interaction of JLP with Plk1 might result in the recruitment of other proteins to this complex. To test this hypothesis, we carried out SILAC labeling of proteins in mitotic cells in the presence or absence of BI2536. Through mass-spectrometry we identified the transcription factor, FoxK1 as a Plk1-dependent JLP-interacting protein. Furthermore, we show that JLP, Plk1 and FoxK1 form a ternary complex, which occurs only during mitosis. Knockdown of Plk1 and not JLP, affected the interaction between JLP and FoxK1 indicating that the formation of the ternary complex is dependent on Plk1. FoxK1 has been previously characterized as a transcriptional repressor of cyclin dependent kinase inhibitor, p21/WAF1. We observed that knockdown of JLP in U2OS cells results in increased protein levels of FoxK1 and a reduction of p21 expression. Moreover, immunofluorescence studies in asynchronous cells showed that FoxK1 is excluded from the nucleus during mitosis. Based on our observations, we propose that formation of the ternary complex between JLP, Plk1 and FoxK1 regulates the stability and/or localization of FoxK1.

P496**Board Number: B643****The XB130/Tks5 Adaptor Protein Interaction Regulates Src-mediated Signal Transduction.**S. Moodley^{1,2}, M. Liu^{1,2};¹Institute of Medical Science, University of Toronto, Toronto, ON, ²Latner Thoracic Surgery Research Laboratories, Toronto General Research Institute, University Health Network, Toronto, ON

Adaptor proteins are signal transduction organizers that coordinate the formation of molecular complexes and translocation of molecules to relay signals from the extracellular environment to intracellular targets. The adaptor protein, XB130 regulates cell growth, survival and migration. Yeast-2 hybrid screening revealed that XB130 interacts with another adaptor protein, Tks5, which is highly involved in cell migration. We hypothesize that XB130 and Tks5 may act in conjunction to recruit and translocate proteins to initiate signal transduction cascades, leading to regulation of cell growth, survival or motility. Using co-immunofluorescence microscopy, XB130 and Tks5 were detected in the cytoplasm and peri-nuclear region of BEAS-2B human bronchial epithelial cells. Moreover, co-immunoprecipitation showed that XB130 and Tks5 interact endogenously and form a complex with Src-tyrosine kinase. Tks5 interacts with XB130 by binding to polyproline rich motifs in the N-terminal of XB130 and conversely, XB130 binds to the fifth SH3 domain of Tks5, as detected by immunoprecipitation of overexpressed XB130 deletion mutants and GST fusion protein pulldown of XB130 single amino acid substitution mutants or Tks5 SH3 domains. Cell motility studies showed that siRNA downregulation of XB130 inhibits lateral cell migration in a wound healing assay, whereas, downregulation of Tks5 inhibits cell invasion in a gelatin degradation assay. However, cell growth and survival studies showed that downregulation of XB130, Tks5 or both XB130 and Tks5 reduced cell proliferation, as assessed by BrdU incorporation, resulting in accumulation of cells in the G1 phase of the cell cycle and increased caspase 3 activity, as well as, apoptotic cell death, as assessed by PI/Annexin V flow cytometry. Interestingly, cell proliferation and survival were increased by overexpression of XB130 or Tks5 but decreased by overexpression of the XB130/Tks5 binding site mutants; XB130 deleted N-terminal and Tks5 W1108A fifth SH3 domain. Furthermore, overexpression of XB130 and Tks5 with Src enhances Src activation and total cell protein tyrosine phosphorylation but downregulation of XB130, Tks5 or both XB130 and Tks5 inhibited serum and growth factor-induced Src-activation. Our results suggest that XB130 and Tks5 interact endogenously with Src to form a putative protein complex to promote signal transduction. Moreover, the XB130/Tks5 interaction is required to mediate serum and growth factor-induced Src-activation, thereby promoting cell proliferation and survival, in lung epithelial cells.

P497**Board Number: B644****Screening and identification of dissociative inhibitors of ERK MAP kinase signaling pathway.**J. Ha¹, S. Park¹;¹Seoul National University, Seoul, Korea

The ERK mitogen-activated protein kinase (MAPK) pathway plays an essential role in the transduction of developmental and growth signals. The pathway involves kinases which relay phosphorylation to activate downstream kinases or effectors, and scaffold proteins which tether kinases to form a signaling complex. Because of its key function in cell proliferation, misregulation of the ERK pathway often results in uncontrolled cell growth that eventually leads to cancerous morphology changes. Many therapeutic approaches have targeted proteins in the pathway including ATP-competitive inhibitors to inactivate the enzymatic activity of kinases. In this study we attempt to suppress the ERK signaling using dissociative inhibitors that target the interactions between signaling proteins. The dissociative inhibitors can disrupt specific steps of signal transduction which may restore a precise regulation of the uncontrolled signaling. For the screening of dissociative inhibitors of ERK pathway, we utilized the bimolecular fluorescence complementation (BiFC) assay to monitor the interactions. We targeted the assembly of KSR1 scaffold complex, which is necessary for the transduction for proper signaling. The N-terminal or C-terminal fragment of a fluorescent protein is fused to a pathway kinase or KSR1, respectively, and the fluorescence is restored when the selected proteins interact to reconstitute a functional fluorescent protein. The fluorescence intensity was monitored from cells co-expressing these fusion proteins to screen chemical libraries for dissociative inhibitors. After the serial elimination of false-positives, we identified two chemicals as candidates which seem to inhibit the interaction between the kinase MEK and the KSR scaffold. The dissociative inhibitors are postulated to reduce the possibility of system-wide shutdown or perturbation of signaling which is often occurred when targeting receptors or kinases using competitive inhibitors. Specific Inhibition of designated interactions using dissociative inhibitors allows for a powerful means to control or fix the misregulated signaling in many diseases caused by signaling disorders.

P498**Board Number: B645****Csk-Binding-Protein mediates Thy-1 signaling and neurite retraction caused by astrocyte $\alpha\beta 3$ integrin in neuronal cultures.**H. Maldonado^{1,2}, L. Leyton^{1,2,3}, A. Quest^{1,3}, R. Herrera-Molina⁴;

¹Laboratory of Cellular Communication, Center for Molecular Studies of the Cell (CEMC), University of Chile, Santiago, Chile, ²Biomedical Neuroscience Institute (BNI), Cell and Molecular Biology Program, Biomedical Sciences Institute (ICBM), University of Chile, Santiago, Chile, ³Advanced Center for Chronic Diseases (ACCDiS), University of Chile, Santiago, Chile, ⁴Leibniz Institute for Neurobiology, magdeburg, Germany

Upon injury in the Central Nervous System, astrocytes migrate to the damaged area generating a non-permissive environment for neuronal regeneration. In general, this can be explained because glial cells possess in its cellular membrane or release outgrowth inhibitory molecules. Previously, we described that the astrocyte- $\alpha\beta 3$ Integrin binds to neuronal Thy-1 engaging pathway that involve Src inactivation leading to neurite retraction. However, how does Thy-1, a membrane GPI anchored protein, trigger intracellular signaling pathways is unknown. Csk Binding Protein (CBP) has been described as a Src-family scaffolding protein that precipitates with Thy-1 in other cellular lines. Thus, we propose the participation of this transmembrane-adaptor protein as a transducer of Thy-1 signaling to the cellular interior. Src inactivation can lead to an increase in ROCK activity, event that causes neurite retraction through actin cytoskeleton disruption by phosphorylation of Cofilin and Myosin light chain II (MLCII). Hypothesis: CBP and Thy 1 form a membrane complex that mediates Src inactivation, thus increasing phosphorylation of ROCK downstream effectors and neurite retraction caused by the addition of astrocyte $\alpha\beta 3$ integrin. Methodology: To study CBP participation we knock down CBP in neuron-like CAD cells. Recombinant $\alpha\beta 3$ integrin was used to stimulate transfected cells for 40 minutes and cells were then followed by phase-contrast microscopy to measure neurite length. We also evaluated MLCII, Cofilin and inactivating phosphorylation of Src (Y527) by Western blotting. To study CBP, Thy-1 and Src interactions we performed co immunoprecipitation and co localization assays using CAD cells and cortical rat neurons (E18, 14 days in vitro). Results: CBP knockdown prevented neurite retraction, the increase in inactivating phosphorylation of Src and the enhanced MLCII and Cofilin phosphorylation caused by $\alpha\beta 3$ integrin stimulation. CBP, Thy-1 and Src co precipitated in rat cortical neurons. The $\alpha\beta 3$ integrin addition enhanced co-localization, in the tip of neuronal processes, of CBP-Thy-1 and Thy-1-pSrcY527, as well as a decrease in co-localization of CBP with Src in both rat cortical neurons and CAD cells. Discussion: These results indicate that CBP and Thy-1 form a membrane complex that transduces $\alpha\beta 3$ Integrin-induced signals to the cell interior leading to Src inactivation and increase MLCII and Cofilin phosphorylation of thereby triggering neurite retraction. Finally, learning about Thy-1-associated signaling could be useful to identify therapeutic targets to assist neuronal regeneration. Supported by: FONDECYT 1110149(LL) and 1130250(AFGQ); BNI P09-015-F(LL) and Anillo ACT1111(AFGQ); Conicyt 24121665(HM), Becas Chile(HM).Conicyt-FODAP15130011 (AFGQ).

P499**Board Number: B646****Identifying a role for tetraspanin CD82 in cell cycle regulation of hematopoietic stem and progenitor cells.**C.A. Saito Reis¹, K.D. Marjon¹, K.L. Karlen¹, C.M. Termini¹, J.M. Gillette¹;¹Department of Pathology, University of New Mexico Health Sciences Center, Albuquerque, NM

Hematopoietic stem and progenitor cells (HSPCs) are specialized cells responsible for the continued production of new blood and immune cells. Cell signaling and adhesion within the bone marrow microenvironment tightly regulates the self-renewal and differentiation of HSPCs, which is critical for the function and maintenance of these cells. The tetraspanin, CD82, is a membrane scaffold protein shown to be highly expressed on HSPCs where it plays a role in modulating homing and engraftment to the bone marrow. Previous work in the lab showed that CD34+ cells in the G0 phase of the cell cycle were enriched in polarized CD82 domains critical for homing and engraftment to the bone marrow. Therefore, we hypothesize that CD82 expression and organization is a critical regulator of proliferation and cell cycle progression in HSPCs. To test this hypothesis we are utilizing the acute myelogenous leukemia progenitor-like cell line, KG1a, as a model for HSPCs. Taking a structure/function approach to evaluate the role of CD82, we generated CD82 knockdown (KD) (shRNA) and CD82 overexpressing (OE) cells (mCherry-CD82 vector). In addition, we generated a series of CD82 cell lines with mutations in N-glycosylation sites (NGLY: site directed mutagenesis Asp to Glu), palmitoylation sites (PALM: site directed mutagenesis Cys to Ser), and a C-terminal sort motif (YXX ϕ : amino acid change YSKV to ASKA). Next, we assessed the proliferation and cell cycle rate of these cell lines. Our data suggest that the CD82 PALM mutant and CD82 KD cells have increased proliferation when compared to control, OE, NGLY, and YXX ϕ cells. The proliferation rate of these cells did not change regardless of the presence of the ligand fibronectin or N-cadherin. In addition, we are utilizing the CD82 knock out (KO) mouse to evaluate changes in the HSPC population, which include the quantity of HSPCs, their localization, and also their self-renewal and differentiation potential. Preliminary data from these experiments indicate that the loss of CD82 expression does alter the HSPC population and self-renewal potential is likely to play a specific role. In combination, these data implicate CD82 expression and its membrane organization as a critical regulator of the cell signaling that occurs between HSPCs and the bone marrow microenvironment, which in turn can modulate the self-renewal potential of HSPCs.

P500**Board Number: B647****FRET biosensors reveal Ca²⁺/PKA crosstalk through AKAP targeting dynamics.**M.B. Schott¹, F.N. Thompson Gonowolo¹, B.D. Grove¹;¹Basic Sciences, University of North Dakota, Grand Forks, ND

A-Kinase Anchoring Proteins (AKAPs) play a critical role in cellular homeostasis by scaffolding cAMP-dependent Protein Kinase A (PKA) and other signaling enzymes in proximity to downstream effectors.

Although they are named “anchoring proteins”, some AKAPs do not assemble static enzyme complexes but form dynamic signalosomes that traffic to different subcellular compartments in response to stimuli. Gravin (AKAP12), a multivalent scaffold linked to a variety of cellular functions, anchors PKA and other enzymes to the plasma membrane but is known to undergo redistribution to the cytosol upon intracellular Ca^{2+} elevation. We postulate that gravin redistribution represents a novel crosstalk mechanism between Ca^{2+} -dependent and cAMP-dependent signaling pathways. To assess this, we measured the impact of gravin-V5/His expression on compartmentalized PKA activity using the PKA FRET biosensor AKAR3. In cultured AN3 CA cells which lack endogenous gravin, expression of gravin-V5/His caused an elevation in forskolin-stimulated PKA activity in AKAR3 constructs targeted to the plasma membrane compared to control cells lacking gravin or expressing a Δ PKA-gravin construct missing the PKA-binding domain. In contrast, gravin-V5/His expression caused a decrease in forskolin-stimulated PKA activity in cytosolic AKAR3 constructs compared to control cells lacking gravin or expressing Δ PKA-gravin. Interestingly, gravin localization at the cell periphery was dramatically impaired by the mutation of a calmodulin-binding consensus sequence within gravin’s CB4 domain. Similar to control cells, this mutant gravin construct had no effect on membrane and cytosolic PKA activity. Finally, pretreatment with the calcium-elevating agent thapsigargin caused the redistribution of gravin away from the plasma membrane and prevented gravin-mediated elevation in plasma membrane PKA activity in response to forskolin. These results reveal that gravin shapes the subcellular profile of PKA activity and support the hypothesis that gravin mediates crosstalk between Ca^{2+} and cAMP-dependent signaling pathways. Based on these results, AKAP localization dynamics may represent an important paradigm for the regulation of cellular signaling networks.

Phase-transitions of Multivalent Adapter Proteins.

S. Banjade¹, M.K. Rosen^{2,3};

¹University of Texas Southwestern Medical Center, Dallas, TX, ²Department of Biophysics, University of Texas Southwestern Medical Center, Dallas, TX, ³Howard Hughes Medical Institute, Dallas, TX

Heterogeneity of the plasma membrane in the form of clustering of proteins and lipids is well documented in many signaling pathways. However, the general mechanisms behind this organization remain unclear. Here, we report the in-vitro reconstitution of membrane clusters, using the adhesion protein Nephrin and its cytoplasmic partners Nck and N-WASP. We quantitatively determine that the clustering occurs due to a two-dimensional phase-separation process, induced by polymerization of the proteins through multivalent interactions. The clusters are sites of actin polymerization, supporting the hypothesis that clustering of nucleation promoting factors could be a general way to localize actin assembly on the plasma membrane. Furthermore, we show that an unstructured region of the adapter protein Nck self-assembles, and in cooperation with the multivalent interactions of the structured regions, induces phase-separation. Therefore, unstructured regions in adapter proteins may be specifically designed to provide additional energy for clustering of multivalent signaling proteins. Our

studies demonstrate that protein-protein interactions are sufficient to produce clusters on the membrane through phase-transition, and that cytoplasmic adaptor proteins can act as ligands to organize membrane receptors into signaling zones.

Megadalton nodes at cell cortex link cell growth and division.

L. Deng¹, R. Kabeche¹, N. Wang², J. Wu^{2,3}, J.B. Moseley¹;

¹Department of Biochemistry, Geisel School of Medicine at Dartmouth College, Hanover, NH,

²Department of Molecular Genetics, The Ohio State University, Columbus, OH, ³Department of Molecular and Cellular Biochemistry, The Ohio State University, Columbus, OH

Cell cycle progression is coupled to cell growth, but the mechanisms that generate growth-dependent cell cycle progression remain unclear. Fission yeast cells enter into mitosis at a defined size due to the conserved mitotic inducer Cdr1, which inhibits Wee1 and localizes to a set of cortical nodes in the cell middle. Through a large-scale protein interaction screen, we found that the conserved cell polarity protein Skb1 binds to Cdr1 and its inhibitory target Wee1. Skb1 inhibited mitotic entry through negative regulation of Cdr1 but localized to a novel set of previously unidentified nodes at the cell cortex. Through live-cell imaging, we demonstrated that Cdr1 nodes and Skb1 nodes are distinct structures at the plasma membrane, and artificial targeting experiments confirmed that spatial separation of these distinct node structures is required for proper entry into mitosis. Thus, Skb1 nodes operate as spatial cues for the signaling pathways that link cell size with mitotic entry. To understand the mechanisms of Skb1 node formation, we screened for interaction partners and identified the uncharacterized protein Slf1 as an Skb1 ligand. Skb1 and Slf1 colocalized in cortical nodes, and were mutually dependent for node assembly. Using quantitative fluorescence microscopy and in vitro assays, we discovered that Skb1-Slf1 nodes are megadalton structures that are anchored to the membrane by a lipid-binding region in the Slf1 C-terminus. Skb1 and Slf1 are present at a 1:1 molar ratio in nodes, and genetic epistasis experiments showed that these two proteins function in a linear pathway to control mitotic entry through Cdr1 and Wee1. Our combined experiments have identified a novel cortical compartment that assembles through defined molecular interactions. Further, the formation of distinct microdomains at the plasma membrane couples cell size to mitotic entry through spatial control of signaling pathways.

P503**Board Number: B650****Binding of different SH3 domain-containing proteins to the ubiquitin ligase Itch proline-rich region.**G. Desrochers¹, L. Cappadocia², M. Lussier-Price², J.G. Omichinski², A. Angers¹;¹Sciences Biologiques, Université de Montréal, Montréal, QC, ²Biochimie, Université de Montréal, Montréal, QC

Itch is a member of the C2-WW-HECT (CWH) family of ubiquitin ligases that also includes Nedd4 in humans and Rsp5p in yeasts. In addition to the WW substrate recognition domains common to all members of the CWH family, Itch contains a conserved proline-rich region (PRR) that enables it to interact with SH3 domain-containing proteins. The PRR of Itch is composed of 20 amino acids and contains four consensus class I and class II SH3-binding motifs. Although SH3 domain-containing partners of Itch have been identified, there is very little known about their binding preferences towards Itch.

In this work, we compare the binding of Endophilin, β -PIX, Pacsin, and Amphiphysin using isothermal titration calorimetry (ITC). We measured the dissociation constants of Itch's PRR for the isolated SH3 domain from the four proteins of interest. Based on these experiments, there is striking difference in the affinity of the isolated SH3s for Itch, with K_d 's varying over a thousand fold. In all cases, the binding stoichiometry is 1:1 except for the SH3 domain of β -PIX, which is 2:1 as previously reported.

In addition, we generated GST-fusion proteins with overlapping sections of the PRR of Itch and performed pull-down assays to determine if the SH3 domain-containing proteins display distinct binding preferences. We found that these proteins bind different yet overlapping motifs in the N-terminal region of the PRR, whereas β -PIX makes extensive contact with the central region of the Itch PRR. To further refine these findings, we generated point mutations at each of the five Arg residues within the PRR motif. GST pull-down assays using these mutants showed that the first three Arg residues all contribute to various extents to binding to the different SH3 domains.

Our findings show that although these proteins bind overlapping sequences, they display distinct preferences and affinities. Interestingly, these SH3 domain-containing partners are all readily ubiquitylated by Itch in cellular assays, except for β -PIX. Thus, in addition to their binding properties, there are important functional differences for their interaction with Itch. Taken together, these results expand our comprehension of the specific roles of Itch, and provide further knowledge of the interplay between protein ubiquitylation, cell signalling and protein trafficking.

P504**Board Number: B651****A physical explanation for protein partitioning in lipid membranes.**C.B. Carbone¹, X. Su¹, E. Hui¹, R.D. Vale^{1,2};¹Department of Cell and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA, ²The Howard Hughes Medical Institute, San Francisco, CA

Receptor-ligand binding across two plasma membranes is a recurrent phenomenon in cell biology. It has been theorized that the lipid membranes may be important in controlling how receptors and other proteins organize at the membrane interface. Specifically, the 'kinetic segregation' model, posits that proteins with large extracellular domains might be excluded from regions of close membrane apposition, and that receptor ligand pairs may organize based on intermembrane distance. Our recent development of an *in vitro* system using giant unilamellar vesicles (GUVs) and supported lipid bilayers (SLBs) has allowed us to test the effect of intermembrane distance on protein partitioning using a combination of timelapse, single molecule, and interference microscopy. Our ability to examine this biophysical phenomenon *in vitro* may provide important insights into how proteins organize in the immunological synapse.

P505**Board Number: B652****PLASMA MEMBRANE ORGANIZATION PROMOTES CD36 SIGNAL TRANSDUCTION IN ENDOTHELIAL CELLS.**J.M. Githaka¹, A. Vega², M.W. Davidson³, K. Jaqaman², N. Touret¹;¹Department of Biochemistry, University of Alberta, Edmonton, AB, ²Department of Biophysics, University of Texas Southwestern Medical Center, Dallas, TX, ³National High Magnetic Field Laboratory and Department of Biological Science, Florida State University, Tallahassee, FL

CD36 is a multiligand scavenger receptor that ligates Thrombospondin-1 (TSP-1) at the surface of endothelial cells and induces their apoptosis. Recent evidences have shown that clustering of CD36 is necessary for signal transduction in macrophages and is regulated by the architecture of the cortical actin cytoskeleton apposed to the plasmalemma. Here, we investigated the role of the cortical actin cytoskeleton and plasma membrane nanodomains in the control of CD36 activation in endothelial cells. Stimulation with multivalent ligands (TSP-1 and anti-CD36 IgM) resulted in the downstream phosphorylation of the Src Family kinase, Fyn. Disruption of the actin cytoskeleton or removal of cholesterol blocked this activation. To gain molecular details on the rearrangement of the receptors during TSP-1 binding, we conducted superresolution approaches (based on PhotoActivated Localization Microscopy or PALM) and quantitative spatial distribution analysis. Endothelial cell lines stably expressing CD36-PAmCherry were generated for that purpose. At steady state, CD36 receptors pre-exist in small clusters (average diameter of 100 nm), in which Fyn was also present. Upon TSP-1 binding, CD36 clusters increased in size (average diameter of 140 nm) and also became denser. The average distance

between CD36 molecules in these clusters was in the range of 8 nm compare to 11 nm in the control condition. F-actin depolymerization or cholesterol depletion reduced the capacity of the ligand to induce formation of larger clusters resulting in a decreased recruitment and activation of Fyn. Our data demonstrate cooperation between cholesterol-dependent domains and the cortical actin cytoskeleton in the organization of CD36 receptors and Fyn before and during TSP-1 stimulation.

Post-translational Modifications in Signaling

Maspin is phosphorylated in MCF-10A cells.

M.T. Longhi¹, N. Cella¹;

¹Department of Cell and Developmental Biology, Biomedical Sciences Institute, University of Sao Paulo, Sao Paulo, Brazil

Maspin (mammary serpin) is a 42 kDa tumor suppressor protein which belongs to superfamily of serpins due to sequence homology, however, its mechanism of action does not depend on protease inhibition. This protein was identified in 1994 during a search for genes expressed in normal mammary epithelial cells but absent in breast tumors. Among maspin biological effects are modulation of cell adhesion, inhibition of tumor growth, invasion and angiogenesis, a pro-apoptotic effect and control of oxidative stress response. This functional diversity reflects maspin numerous ligands and its subcellular localization, since it is found on the plasma membrane, in the cytoplasm, nucleus and in mitochondria. Several studies indicate that maspin is regulated by posttranslational modification, yet, little is known about how these alterations regulate its biological activities, subcellular localization and the intracellular pathways involved. Using the non-transformed mammary epithelial cell line MCF-10A as a model system, we identified four different maspin forms by 2D-SDS-PAGE followed by immunoblot with anti-maspin. Three of these forms were sensitive to acidic phosphatase treatment, suggesting that they are phosphorylated. Sodium peroxidovanadate treatment, a potent tyrosine phosphatase inhibitor, resulted in a rapid increase in maspin protein levels as well as its cytoplasmic accumulation. These data suggest that phosphorylation may be involved in maspin subcellular localization and regulation of its levels in the cell. Interestingly, we found that maspin is highly phosphorylated in a metastatic cell line which exhibits maspin predominantly in the cytoplasm. Thus, we verified a correlation between tyrosine phosphorylation, cytoplasmic localization and tumor progression. Searching for signaling pathways involved in maspin phosphorylation, we found that EGF-treatment increases maspin phosphorylation. This observation suggests that maspin may take part of the EGF signaling pathway. An association between EGF signaling, maspin phosphorylation and its subcellular localization is currently under investigation. Altogether, these results shed new light into the molecular mechanism underlying maspin biological activities and how this mechanism might be altered in tumor cells. This research was supported by CNPq and Fapesp.

P507**Board Number: B654****Possible role of UDP-GlcNAc 2-epimerase /ManNAc kinase (GNE) in cell apoptosis.**R. Singh¹, R. Arya¹;¹School of Biotechnology, Jawaharlal Nehru University, New Delhi, India

Sialic acids are nine carbon acidic amino sugars present at terminal end of monosaccharides on most mammalian glycoconjugates. Correct sialylation of glycoproteins is essential for normal cell function as they play crucial role in various biological, pathological and immunological processes. Genetically determined abnormalities of the glycosylation processes have been identified as a cause of severe skeletal muscle/neuromuscular disorders such as Hereditary Inclusion Body Myopathy (HIBM)/ Distal myopathy with rimmed vacuoles (DMRV). Still biological basis of pathogenesis is not known. Sialic acid synthesis is regulated by a rate limiting bifunctional enzyme, UDP-GlcNAc 2-epimerase /ManNAc kinase (GNE) that possess N-terminal epimerase and C-terminal Kinase domain. Homozygous missense mutations in either epimerase or kinase domain of GNE results in hyposialylation of glycoproteins in muscle cells of patients and primary defect in either N or O-linked glycosylation. However, it appears from some recent experiments including those from our laboratory that mutant GNE may also affect targets that are not directly related to sialic acid biosynthesis. In particular cytoskeletal network, sarcomere organization and apoptotic signaling are likely to be altered in muscle cells. In the present study, we have used HEK cell based model system for HIBM already established in the laboratory to understand cell apoptosis in presence or absence of functional GNE. We have used wild type GNE and pathologically relevant GNE mutations alongwith GNE knockdown stable HEK cell lines to study cell proliferation and apoptosis. We observed significant reduction in cell proliferation of GNE mutant and knockdown cells compared to vector control. Further staining with Annexin V-FITC and Tunel assay depicted significant increase in number of apoptotic cells and nuclear fragmentation of GNE mutant cells. In addition, changes in the structure and function of mitochondria were observed in GNE deficient cell lines. Our results clearly indicate that mutation in GNE affects cellular apoptosis and may contribute to the pathogenesis of the disease.

P508**Board Number: B655****Tubulin tyrosine ligase-like 4 is important for maintaining the structural integrity of erythrocyte plasma membrane.**F. Ijaz¹, K. Tsutsumi², Y. Hatanaka³, T. Hatanaka³, S. Asai-Akeida³, N. Zaima^{1,3}, K. Ikegami¹, M. Setou¹;¹Department of Cell Biology and Anatomy, Hamamatsu University School of Medicine, Hamamatsu, Japan, ²Division of Cell Biology, Department of Biosciences, School of Science, Kitasato University, Kanagawa, Japan, ³Mitsubishi Kagaku Institute of Life Sciences (MITILS), Tokyo, Japan

Glutamylation is a kind of post-translational modification in which multiple glutamic acids are added to gene-encoded glutamic acid residues in target proteins. Glutamylation occurs on tubulin and some non-tubulin proteins in various types of cells. This modification is catalyzed by some members of tubulin tyrosine ligases-like (TTL) protein family. TTL4 is a glutamylation-initiating glutamic acid ligase (E-ligase), and is known to glutamylate several non-tubulin proteins. In this study, we demonstrate the important role of TTL4 in red blood cells (RBCs) independent of tubulin glutamylation. We found nucleosome assembly protein 1 (NAP1) to be the sole protein in RBCs that was detected by a glutamylation-specific antibody, GT335. The glutamylated NAP1 was detected more strongly in plasma membrane than in cytoplasm of RBCs. The glutamylation of NAP1 completely disappeared in RBCs of TTL4-deficient mice. Hematological analysis showed larger diameters of RBCs in TTL4-deficient mice. Furthermore, the knockout mice showed increased hemolysis in mouse model of acute hemolytic anemia. Electron microscopy of RBC plasma membrane revealed significant decrease in spectrin-actin lattices in TTL4-deficient samples compared to wild-type samples. Taken together, our data suggest that the TTL4-mediated glutamylation of NAP1 is involved in maintaining RBC membrane structures.

P509**Board Number: B656****Poly(ADP-ribose) polymerase-1 (PARP-1) activity is regulated by a domain that locally unfolds when PARP-1 binds DNA damage.**J.M. Dawicki-McKenna¹, M.F. Langelier², J.E. DeNizio¹, A.A. Riccio², C.D. Cao¹, K.R. Karch¹, M. McCauley², B.E. Black¹, J.M. Pascal³;¹Department of Biochemistry and Biophysics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²Department of Biochemistry and Molecular Biology, Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA, ³Department of Biochemistry and Molecular Pharmacology, Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA

PARP-1 plays an important role in the cellular response to DNA damage. It rapidly localizes to DNA breaks where it couples damage detection to poly(ADP-ribosyl)ation (PARylation) of target proteins. The covalent attachment of PAR, primarily to PARP-1 itself, initiates the recruitment of several DNA repair factors to the sites of damage. Binding to DNA damage allosterically activates PARP-1 catalytic activity.

Despite valuable insight provided by the crystal structure of PARP-1 in complex with DNA damage (PDB ID 4dqy), the details of how DNA binding is coupled to increased PAR production that takes place more than 45 Å away in the active site remain unclear. Complementary approaches are now required to relate information provided by static structures to dynamic changes that occur in solution when PARP-1 is active. Here, we use hydrogen-deuterium exchange coupled to mass spectrometry (HXMS) to report differences in the structure and dynamics of full-length PARP-1 bound and unbound to a DNA single-strand break (PARP-1/DNA). Our HXMS results unexpectedly reveal a regulatory domain of PARP-1 that locally unfolds when PARP-1 is activated by DNA damage. The regulatory domain in PARP-1 is well folded prior to encountering DNA, but contains a large region that unfolds when PARP-1 recognizes DNA damage. We designed and tested mutants that revealed how allosteric activation of PARP-1 works. Unfolding of the regulatory domain is prevented in a PARP-1 mutant that cannot be activated by DNA binding. Further, we tested a mutant suspected of destabilizing the folding of the regulatory domain, and found that it is destabilized relative to the wild type protein and also has a higher basal activity. Using our HXMS data and existing crystal structures, we designed a mutation to disconnect the allosteric communication resulting from binding to damaged DNA. Indeed, this mutant no longer responds enzymatically to DNA damage. Taken together, our data support a simple and elegant model for connecting local protein unfolding to the allosteric activation of a major eukaryotic DNA repair enzyme. Our model provides a sophisticated view of the molecule in solution that is likely to be useful when targeting PARP-1 with small molecules, as is currently being done for several clinical trials.

Analysis of molecular mechanism for Gas ubiquitination.

T. Koimori¹, T. Kobayashi^{2,3}, H. Itoh^{2,3};

¹Grad. Sch. Biol. Sci., Nara Institute of Science and Technology, Ikoma, Japan, ²Nara Institute of Science and Technology, Ikoma, Japan, ³School of Medicine, New York University, New York, NY

G proteins consist of α , β and γ subunits and undergo an activation-inactivation cycle depending on the binding of guanine nucleotides. They function as molecular switches that turn on intracellular signaling cascades in response to the activation of G protein-coupled receptors (GPCRs) by extracellular stimuli including hormones, light and odorous chemicals. We have recently reported that Gas is degraded by the ubiquitin-proteasome pathway and its associated protein, Ric-8B, suppresses ubiquitination of Gas. These data raise a possibility that Gas is quantitatively controlled by ubiquitin-dependent degradation and Ric-8B stabilizes Gas by antagonizing ubiquitination. However, molecular mechanisms underlying ubiquitination of Gas are still unclear. We performed proteomic screening to identify Gas- or Ric-8B-binding partners that are involved in Gas ubiquitination. Flag-tagged Gas or Ric-8B were expressed in HEK293T cells and we analyzed by tandem mass spectrometry following immunoaffinity chromatography. Candidate proteins including one E3 ubiquitin ligases, GsAP (Gas-associating protein) - 1 and three deubiquitinases, GsAP-2, GsAP-3 and GsAP-4 were identified. We observed that ectopically expressed Flag-tagged GsAP-1, -3, or -4 and Gas in HEK293T cells were coprecipitated. To investigate

whether candidate proteins affect G α s ubiquitination, we expressed these proteins and G α s with His-tagged Ubiquitin in HEK293T cells, and performed pull-down assay using Ni-NTA agarose. We found that GsAP-3 suppressed G α s ubiquitination, but not GsAP-4. Knockdown experiments using siRNAs are currently ongoing and in this presentation we will discuss possible molecular mechanisms of G α s ubiquitination.

Ubiquitination and the control of Plasmodium falciparum cell cycle by melatonin.

C.R. Garcia¹, F.C. Koyama², G.T. Almeida³, W.R. Lima³, D. Chakrabarti⁴;

¹Departament Physiology, University of Sao Paulo, Sao Paulo, Brazil, ²Physiology, University of Sao Paulo, Sao Paulo, Brazil, ³Physiology, Univ Sao Paulo, SanPaulo, Brazil, ⁴Burnett School of Biomedical Sciences, University of Central Florida, Orlando, FL

The ubiquitin proteasome system (UPS) has several roles in eukaryotes including cell-cycle control, transcription regulation and signal transduction. Post-translational modifications such as ubiquitination are important modulator of signaling processes, cell cycle and many other cell functions. There are increasing evidences that melatonin and ubiquitin/proteasome system (UPS) interacts to regulate many cellular functions. We previously reported that melatonin-induced up-regulation of gene expression related to UPS in Plasmodium falciparum. Interestingly, the response to melatonin treatment is completely abolished in Pfk7 knockout of the parasites, and the response is restored when the parasites are complemented with Pfk7 gene, suggesting a link between modulation of intraerythrocytic differentiation of the parasite and this hormone. In this work we demonstrate by qPCR analysis, that melatonin induces gene up-regulation of nine out of fourteen genes from UPS. The induction of UPS gene expression occurs between 4 to 5 hours after hormone treatment, which leads to a time-dependent differential protein ubiquitination in parasites. We also performed deep sequencing (RNA-seq) polyA + extracted from trophozoites of Plasmodium falciparum (3D7 and Pfk7 knockout strains) treated with melatonin to identify possible targets and evaluate the role of protein 7 kinase (PK7). The results revealed that melatonin causes a temporally controlled gene expression of UPS members followed by a differential protein ubiquitination modulation. Finally, we identified two possible candidates for ubiquitination in response to melatonin: S-adenosylmethionine synthase and eIF4A-like protein. Importantly, the former is involved in cell growth and apoptosis in mammals and in developmental regulation in plants while the later is involved in P. falciparum proliferation suggesting that such substrates could be modulators of the parasite cell cycle and regulated by melatonin signaling.

P512**Board Number: B659****A 19S proteasomal subunit-PSMD9 enhances I κ B α degradation and NF- κ B activation by interacting with hnRNPA1.**I. Sahu¹, N. Sangith¹, M. Ramteke¹, R. Gadre¹, P. Venkatraman¹;¹Advanced Centre for Treatment, Research and Education in Cancer (ACTREC), Navi Mumbai, India

Background: PSMD9 is a PDZ-domain containing non-ATPase subunit of the 26S proteasome. Besides its well-studied role in proteasome assembly, the structure and functions of PSMD9 are largely uncharacterized. Till date a large number of protein-protein interactions have been identified by various proteomic methods and yet only a little of them turn out to be biologically significant. Using a novel structural bioinformatics method and peptide based screening we recently reported that, heterogeneous nuclear ribonucleoprotein A1 (hnRNPA1) is one among the novel interacting partners of PSMD9.

Results: We demonstrated in HEK293 and HeLa cells that, PSMD9 through its PDZ-domain interacts with the C-terminal motif of hnRNPA1. This domain-motif interaction is responsible for proteasomal degradation of I κ B α and consequently influences the NF- κ B activation. In accordance, overexpression of PSMD9 enhances both the basal and TNF- α induced I κ B α degradation as well as NF- κ B activation (upto 2-4 fold) while knock down of PSMD9 results in the opposite effect. Point mutations (Q181G and a triple mutation- L124G/Q126G/E128G) in PDZ domain of PSMD9 or 7-amino acid deletion from C-terminus of hnRNPA1 disrupt interaction between the two proteins. Consequently, overexpression of these mutants has no effect on either basal or TNF- α induced I κ B α degradation and NF- κ B activation. In addition, overexpression of WT-hnRNPA1 fails to modulate NF- κ B activation in PSMD9 knockdown background. These results emphasize the importance of interaction between PSMD9 and hnRNPA1 for this cellular function. In vitro interaction studies suggest hnRNPA1 interacts with I κ B α directly, whereas PSMD9 interacts only through hnRNPA1. Furthermore, hnRNPA1 shows increased association with the 26S proteasome upon PSMD9 overexpression and/or TNF- α treatment which however has no such effect in the absence of PSMD9. Endogenous and trans-expressed PSMD9 are found associated with the proteasome complex and this association is unaffected by PDZ-mutations or TNF- α treatment. Moreover, neither overexpression of the WT or mutant PSMD9 and hnRNPA1 nor the down-regulation of PSMD9 had significant effect on the Proteasomal activity in HEK293 cells as such.

Conclusion: Collectively, the tripartite interactions between I κ B α , hnRNPA1 and proteasome bound PSMD9 illustrates a potential mechanism by which ubiquitinated I κ B α are recruited on proteasome for degradation. In this process, hnRNPA1 may act as a shuttle receptor and PSMD9 as a subunit acceptor. The PSMD9 and hnRNPA1 interface/hot spot site may emerge as a vulnerable drug target in cancer cells which require consistent NF- κ B activity for survival.

P513**Board Number: B660****Arginylation affects G-protein signaling and visual processing in the retina.**D.W. Dong^{1,2}, M.E. Fina¹, S.S. Nikonov³, N. Vardi³, J. Wang¹, A.S. Kashina¹;¹Department of Animal Biology School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA, ²Penn Genome Frontiers Institute, University of Pennsylvania, Philadelphia, PA, ³Department of Neuroscience School of Medicine, University of Pennsylvania, Philadelphia, PA

Arginylation is a posttranslational modification that has been recently implicated in multiple key processes in development and physiology. Here we studied the effect of the neuron-specific knockout of arginyltransferase (Ate1) on visual processing in the retina using a conditional knockout model with Ate1 deletion driven by brain-specific Nestin (Nes) promoter. Electroretinography studies showed a thirty percent increase of the response of the dark-adapted retina bipolar neurons to dim light flashes in Nes-Ate1 mice compared to age-matched controls. Immunohistochemistry of retina sections showed an increase in one of the regulators of G-protein signaling (RGS) in Ate1 knockout, RGS11, likely due to inhibition of its arginylation-dependent degradation by the N-end rule pathway. Since the dim-light responses in rod bipolar neurons are facilitated by RGSs accelerating G-proteins' GTP hydrolysis rates, increased RGS protein levels leads to increased dim-light responses. Our data suggest that Ate1-mediated arginylation affects G-protein signaling in the retina by regulating RGS proteins, facilitating the proper balance of RGS family members in the healthy retina, and ensuring normal processing of visual stimuli in the healthy animals.

Protein arginylation is an emerging posttranslational modification that targets a number of metabolic enzymes, however the mechanisms and downstream effects of this targeting are unknown. Here we investigated arginylation of PRPS2, the key enzyme of purine biosynthesis, previously found in our proteomic screen to be arginylated at the N-terminus, unlike its close homolog PRPS1. We found that such selective arginylation of PRPS2 is regulated through a coding sequence-dependent mechanism that

combines elements of mRNA secondary structure with Lys residues encoded near the N-terminus in PRPS1 but not PRPS2. Lack of arginylation renders cells vulnerable to purine nucleotide synthesis inhibitors and affects related Gly and Ser metabolic pathways. Measurements of PRPS2 activity in cell extracts show that arginylation greatly facilitates the biological activity of this enzyme. This study is the first demonstration of a direct effect of arginylation on enzymatic activity, and the first implication of arginylation in nucleotide metabolism.

Identifying calpain-2 interacting proteins in endothelial cell lysates through affinity purification coupled with mass spectrometry.

D.E. Croall¹, J.R. Hoffman¹, C.P. Vary^{2,3}, S.L. Ashworth⁴, B.R. Chase¹;

¹Molecular and Biomedical Sciences, Univ Maine, Orono, ME, ²Center for Molecular Medicine, Maine Medical Center Research Institute, Scarborough, ME, ³Graduate School of Biomedical Sciences and Engineering, University of Maine, Orono, ME, ⁴School of Biology and Ecology, Univ Maine, Orono, ME

Calpain-2, a ubiquitous, calcium dependent proteolytic enzyme, is implicated in a variety of endothelial cell (EC) functions and responses including signal pathways downstream of flow/shear stress, VEGF, angiotensin II, and integrins. How calpain's presence, or activity, results in the measured responses/outputs is not yet described. An affinity capture-mass spectrometry strategy to screen for the proteins that bind to calpain-2 was utilized in order to begin to identify the individual protein substrates that calpain modifies, degrades or targets in ECs. This strategy required use of a catalytically incompetent variant of calpain-2 (C105A) that retains its native conformation and is also fused to a C-terminal peptide substrate for the biotin protein ligase BirA. The purified, biotinylated C105A-calpain-2 served as 'bait' and soluble extracts of bovine aortic endothelial cells (BAEC) were used as 'prey' after first removing endogenously biotinylated proteins and inactivation of endogenous calpains by reaction with a covalent inhibitor (suc-LLY-CHN2). Identifying proteins bound to calpain in the presence of calcium offered two key advantages: 1) the calpain-2 bait remained bound to the resin after EGTA elution of interacting proteins and 2) the capture of the well characterized calpain inhibitor, calpastatin, and/or other known putative substrates would provide proof of concept for the experimental approach. Calpain-protein complexes were captured with streptavidin-ultralink resin (Thermo-Pierce), washed with a series of buffers and proteins of interest recovered by elution with EGTA/EDTA. Proteins eluted from the biotinylated C105A-calpain-2 were compared with proteins isolated in a parallel control reaction containing non-biotinylated C105A-calpain-2 and free biotin. Of approximately 30 proteins initially identified by LC-MS-MS using Protein-Pilot™ software about 25% were also present in the control sample. Nonspecifically bound proteins were highly abundant in the lysates and included GAPDH, HSPs (D1,A9, A5,B1) and fetuin (AHSG). Not surprisingly calpastatin, calpains' nanomolar affinity inhibitor was the highest scoring calpain interacting protein. The selective capture of several annexins including ANXA1, ANXA2, ANXA6 and ANXA4 was of particular interest. ANXA1 was chosen to confirm calpain's ability to bind to it and we successfully demonstrated calpain-2 cleavage of it. Extension of these studies

and further analysis of proteins captured will allow design of future experiments aimed at defining calpain's mechanistic links to specific physiological and/or pathological events in ECs as well as other cell types

Identifying Wntless interaction domains required for its function in Wnt signaling.

S.S. Tektas¹, E.M. Selva²;

¹Biological Sciences, Univ Delaware, Newark, DE, ²Univ Delaware, Newark, DE

Wnt signal transduction plays important roles in numerous phases of organismal development and tissue homeostasis. When aberrant, can drive cell transformation that results in cancer and various developmental diseases. Over the years, it has become clear that Wnt activity is strictly regulated, not only in signal receiving cells, but also in signal producing cells at the level of Wnt production, transport and secretion. Posttranslational modifications of Wnts are critical for Wnt signal regulation at the level of intracellular trafficking, extracellular dissemination, and ligand-receptor interaction. Modified Wnts are escorted through the secretory pathway for extracellular release by Wntless (Wls), the dedicated Wnt chaperone protein. Wls directly interacts with lipid modified Wg (Drosophila Wnt) within the ER of the signal producing cells in order to assist its navigation through the secretory pathway for cell surface deployment, an indispensable step for downstream signal activation. Previous studies in our laboratory has shown that DWls (Drosophila Wls) forms homo-oligomeric structures required for Wg interaction, in which both its first transmembrane domain and amino acids between 137 to 223 play a role. While the presence of Wg binding region was not a requirement for DWls oligomers to form, DWls oligomerization was requisite for the Wg-DWls interaction; thus likely necessary for proper Wg intracellular transport. Recently, mutational studies in our lab revealed that cysteines, C50 and C72, within DWls are important for intermolecular disulfide bridges and oligomer formation. The effect of mutation of these cysteines in DWls-DWls and DWls-Wg interactions and overall DWls function remains to be determined.

Control of Nrf2 signaling by O-GlcNAc.

T. Smith¹, P. Chen², J. Chi², T. Meister¹, M. Boyce¹;

¹Dept. of Biochemistry, Duke University Medical Center, Durham, NC, ²Dept. of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC

O-GlcNAcylation is the addition and removal of β -D-N-acetylglucosamine (GlcNAc) to serine and threonine residues of nuclear and cytoplasmic proteins. Similar to phosphorylation, with which it often competes, O-GlcNAcylation is reversible. This dynamic cycling is managed by the enzymes O-GlcNAc transferase (OGT) and O-GlcNAcase (OGA) to control a multitude of cellular processes, including

transcription, nutrient sensing, and cell cycle progression. Despite being essential and previously implicated in several diseases including cancer, major aspects of O-GlcNAc regulation are still poorly defined. Here, we used DNA microarrays and global gene expression analysis to evaluate the transcriptional response to 5SGlcNAc, a small molecule inhibitor of OGT. We found that 5SGlcNAc caused marked upregulation of several canonical targets of the transcription factor nuclear factor erythroid 2-related factor (Nrf2), a crucial regulator of redox homeostasis and cell survival responses to endogenous and exogenous stresses. Microarray data were confirmed by real-time PCR for Nrf2 target genes glutamate-cysteine ligase, modifier subunit (GCLM), NADPH dehydrogenase, quinone 1 (NQO1), and heme oxygenase 1 (HO1). Further, Nrf2 and HO1 protein expression increased for 5SGlcNAc treated samples with effects similar to that of positive control tert-Butylhydroquinone (tBHQ), a known inducer of Nrf2. We propose that O-GlcNAc represses Nrf2 signaling under basal conditions by enabling proteasome-mediated degradation of Nrf2 protein, linking intracellular glycosylation to redox homeostasis and stress responses. Experiments are underway to identify relevant substrate(s) and underlying mechanism through which O-GlcNAcylation suppresses Nrf2.

RNF144A requires its transmembrane domain for E3 ubiquitin ligase activity.

S. Ho¹, Y. Lee², W. Lin^{1,2,3};

¹Section of Hematology/Oncology, Department of Medicine, Baylor College of Medicine, Houston, TX,

²Interdepartmental Program in Translational Biology and Molecular Medicine, Baylor College of Medicine, Houston, TX, ³Dan L. Duncan Cancer Center, Baylor College of Medicine, Houston, TX

RNF144A E3 ubiquitin ligase can ubiquitinate DNA-PKcs and promote DNA damage-mediated apoptosis (Ho et al, PNAS, 2014). It also regulates breast cancer cell migration and invasion. Here we characterize an important regulation of RNF144A through its transmembrane domain. The transmembrane domain of RNF144A is highly conserved among species. Deletion of the transmembrane domain abolishes its membrane localization and also significantly reduces its E3 ubiquitin ligase activity. Further evidence shows that the transmembrane domain is required for RNF144A self-association and may partially through a classic GXXXG interaction motif. A membrane localization loss mutant of RNF144A still keeps its self-association and E3 ligase activity, suggesting these functions are independent of RNF144A membrane localization. Therefore, our data demonstrate that the transmembrane domain of RNF144A has at least two independent roles, membrane localization and activation of its E3 ligase activity.

Micro-fabricated devices with stretchable silicone substrates and micro-patterned silicone gels for experiments on adherent cells with high-resolution imaging.

E. Gutierrez¹, B. Bober², E.V. Tkachenko³, S.B. Shah², A. Groisman¹;

¹Physics, University of California, San Diego, La Jolla, CA, ²University of California, San Diego, La Jolla, CA,

³University of California, San Diego, San Diego, CA

Flexible membrane substrates made of transparent silicone elastomers and experimental setups stretching those membranes unidirectionally or uniformly have been used for various experiments on different adherent mammalian cells. Stretching of the substrates, which can be one-time or periodic, can cause immediate and long-term mechanosensing cellular responses. However, in many of those experimental setups, cells on the flexible substrates cannot be accessed with short working distance (WD) high NA objectives, precluding high-resolution imaging of the cells in real-time. Moreover, when significantly stretched, large diameter membranes tend to move far out of focus, thus greatly complicating high-resolution imaging, even when the adherent cells are optically accessible. To address these problems, we have designed, built, and tested micro-fabricated devices, in which an ~100 μm thick, silicone membrane forms the bottom of an ~1mm wide micro-well. The membrane is stretched by the application of vacuum to two cavities flanking the micro-well. The design of the devices is optimized to limit the out-of-focus movement of the membrane to 5-10 μm , at lateral extensions as large as 12%, thus facilitating real-time high-resolution imaging. Using short WD, high NA oil-immersion and water immersion objectives and test fluorescent microparticles attached to the membranes, we demonstrated resolutions of ~0.3 μm . In a modified version of the device, with a high refractive index ($n = 1.46$) silicone membrane, 10% stretching was combined with total internal reflection fluorescence (TIRF) imaging. The setup has been used to stretch adherent neurons to study the effect of strain on axonal transport. In a separate project, we used micro-contact printing to generate micro-patterns of extracellular matrix (ECM) proteins on soft silicone gels with a high refractive index compatible with TIRF microscopy. To this end, we coated microscope cover glasses with 10-30 μm layers of TIRF-compatible gels and made microfabricated stamps with imbedded permanent magnets. The micro-patterned stamps were brought in a soft contact with the gel surfaces by activating an electromagnet, while monitoring the gel surfaces under a microscope. We used this technique to generate micro-patterns with ~8 μm wide strips on TIRF-compatible silicone gels with elastic moduli as low as 20 kPa. In a test experiment, we observed fibroblasts to exclusively attach to the ECM-patterned strips and to migrate along the strips for as long as 3 days.

P520**Board Number: B668****N-WASP/WIP mediated matrix adhesion site maturation drives 3D cancer cell migration through direct force coupling to the nucleus.**T. Zech¹, O. Chatzidoukaki^{1,2}, A. Charles-Orszag², S. Sender², L. Machesky²;¹Institute of Translational Biology, Dept of Cellular and Molecular Physiology, University of Liverpool, Liverpool, England, ²CRUK Beatson Inst Cancer Res, Glasgow, Scotland

The actin nucleation promotion factor N-WASP is up-regulated in breast cancer and is coupling pseudopod extension and matrix degradation to facilitate invasive cancer cell migration. Cells migrating through 3D matrices form hybrid adhesion structures termed “actin-hotspots”, which contain N-WASP and display hallmarks of both focal adhesions and invadopodia. We have identified a novel interaction between the N-WASP Interacting Protein, WIP, and the guanine nucleotide exchange factor ARHGEF7/bPIX. ARHGEF7 localises to actin-hotspots in 3D matrices. Loss of ARHGEF7 abolished cancer cell invasion, but increased matrix degradation and pseudopod extension in collagen matrices. These seemingly contradictory results can be explained by our finding that ARHGEF7 is part of a N-WASP/WIP↔ARHGEF7↔PAK2 signalling cascade that is required for adhesion site turnover and force coupling. Loss of ARHGEF7 leads to less tension being applied by actin on adhesion sites as well as the nuclear envelope, resulting in a loss of nuclear movement and subsequently cell motility. The nucleus can act as limiting factor in 3D cell migration. Migrating cells need to actively squeeze the nucleus through matrix pores. Knockdown of nuclear envelope actin binding proteins called Nesprin-1 and -2 severely affect 3D cell migration. We have found a reciprocal regulation of Nesprin-2 and ARHGEF7 function. We here show, using a novel nuclear membrane FRET/FLIM force biosensor, that direct force coupling from actin-hotspots to the nuclear membrane is required for 3D cell migration and we propose that this could be the mechanism to establish polarity during 3D cell migration.

P521**Board Number: B669****Extracellular mechanical cues drive vinculin mediated PI3-kinase signaling to enhance cell invasion in 3D.**M. Rubashkin¹, L. Cassereau¹, R. Bainer¹, C. DuFort¹, Y. Yui¹, G. Ou¹, M.J. Paszek^{2,3}, M.W. Davidson⁴, Y. Chen⁵, V.M. Weaver⁶;¹Bioengineering, University of California, San Francisco, San Francisco, CA, ²Field of Biophysics, Cornell University, Ithaca, NY, ³Kavli Institute at Cornell for Nanoscale Science, Cornell University, Ithaca, NY, ⁴National High Magnetic Field Laboratory and Department of Biological Science, Florida State University, Tallahassee, FL, ⁵Pathology, University of California, San Francisco, San Francisco, CA, ⁶Center for Tissue Engineering and Regenerative Medicine, University of California, San Francisco, San Francisco, CA

Extracellular matrix stiffness induces focal adhesion assembly to drive malignant transformation and tumor metastasis. However, it is unclear how force alters focal adhesions to promote tumor progression. We explored the role of the focal adhesion protein vinculin, a force-activated mechano-transducer, in mammary epithelial tissue transformation and invasion. We found that extracellular matrix stiffness stabilizes the assembly of a vinculin-talin-actin scaffolding complex that facilitates PI3-kinase mediated phosphatidylinositol (3,4,5)-triphosphate phosphorylation. Using defined two and three dimensional matrices, a mouse model of mammary tumorigenesis with vinculin mutants, and a novel super resolution imaging approach, we established that ECM stiffness promotes the malignant progression of a mammary epithelium by activating and stabilizing vinculin and enhancing Akt signaling at focal adhesions. Our studies also revealed that vinculin strongly co-localizes with activated Akt at the invasive border of human breast tumors, where the ECM is stiffest and mechano-signaling is enhanced. Thus, extracellular matrix stiffness could induce tumor progression by promoting the assembly of signaling scaffolds; a conclusion underscored by the significant association we observed between focal adhesion plaque proteins and malignant transformation across multiple types of solid cancer.

The local 3D microenvironment controls adhesion dynamics and cell motility by balancing forces at the leading edge.

A.D. Doyle¹, K.m. Yamada¹, K. Matsumoto¹;

¹NIDCR/NIH, Bethesda, MD

Integrin-based adhesions to the surrounding extracellular matrix (ECM) are sites of cellular mechanotransduction, where physical forces are propagated to and from the local microenvironment. It is well established that the physical attributes of simple two-dimensional (2D) ECMs, such as ECM rigidity and ligand density, can modify cell migration through control of cell adhesions; however, it remains unclear how local differences in a complex three-dimensional (3D) ECM can affect cell adhesion mechanics involved in migration. We generated 3D collagen gels with different matrix architectures to identify if ECM-dependent factors, such as matrix topography and rigidity, impact cell migration and adhesion dynamics. Gels ranged from a homogeneous highly reticular (HR) network of thin fibers to a heterogeneous fibrillar-bundled (FB) matrix of loose, parallel-bundled fibers. Atomic Force Microscopy (AFM) revealed that while overall global ECM stiffness was relatively similar between conditions, the parallel-bundled fibers in FB gels demonstrated a local 5-fold greater stiffness. Using live-cell 3D spinning-disk microscopy and automated tracking of EYFP-paxillin containing adhesions, we find that these local differences in matrix stiffness lead to increased 3D adhesion stability, reduced adhesion mobility, and slower adhesion protein turnover in matrices containing bundled fibers, indicating a higher degree of mechanical coupling between the cell and bundled fibers. Lower adhesion stability in HR gels is associated with an increased population of adhesions undergoing retraction at the leading edge, suggesting that cellular contractile forces are not balanced with the local ECM stiffness. By experimentally reducing cellular contractile forces or increasing integrin avidity for the ECM, cell/ECM

interactions become balanced, as shown by increased 3D adhesion stabilization and an increase in cell velocity. Besides establishing that local ECM stiffness is correlated with adhesion stability, we identify a unique process involving contraction of the actin cytoskeleton between adhesions at the leading edge and those proximal to the cell body, resulting in a “pinching” of the matrix. This pinching mechanism is common to all collagen gels and may be important to allow sensing of local matrix stiffness during 3D migration. These results establish that stiff elements of local ECM architecture can stabilize 3D adhesions, increasing the effectiveness of the mechanotransduction machinery required for efficient cell migration in 3D microenvironments.

Myosin II pulls the nucleus forward to increase intracellular pressure and drive 3D cell movement.

R. Petrie¹, H. Koo², K. Yamada¹;

¹NIH/NIDCR, Bethesda, MD, ²Department of Orthodontics, University of Pennsylvania School of Dental Medicine, Philadelphia, PA

Cells use actomyosin contractility to move through three-dimensional (3D) extracellular matrix. Contractility also governs the type of protrusions used during integrin-dependent 3D migration by controlling the switch between lobopodia and lamellipodia. To test the hypothesis that contractility controls intracellular pressure to dictate the mode of 3D cell migration, we directly measured the hydraulic pressure exerted by the cytoplasm in primary human fibroblasts migrating using either lamellipodial or lobopodial protrusions. We found that lobopodia are high-pressure protrusions, and inhibiting contractility switches cells to low-pressure lamellipodia-based movement. In lobopodial cells, the nucleus and associated intracellular membranes physically divide the cytoplasm into high and low pressure forward and rear compartments, respectively. The compartmentalized elevated pressure in lobopodial cells was associated with a polarized distribution of vimentin intermediate filaments and myosin IIA in front of the nucleus and the ability of the nucleus to accelerate periodically away from the trailing edge. Vimentin formed a contractility-dependent complex with actomyosin and the nucleoskeleton-cytoskeleton linker protein nesprin 3. Knocking-down nesprin 3 abolished the independent movement of the nucleus and slowed 3D migration in a manner similar to treatment with blebbistatin. Additionally, nesprin 3 knock-down reduced and equalized intracellular pressure between the front and back cytoplasmic compartments and switched cells to lamellipodia-based migration. Inhibition of myosin II in front of the nucleus by the local application of blebbistatin immediately reduced hydraulic pressure, whereas applying the drug behind the nucleus had no effect. Hence, the nucleus can act as a piston that is pulled forward by actomyosin contractility, acting on nesprin 3 to increase the hydrostatic pressure between the nucleus and the leading edge to drive lamellipodia-independent 3D cell migration. This mechanism is required for the efficient migration of primary human cells through physiological 3D matrix and highlights the importance of physical factors such as matrix microenvironment and pressure in mammalian cellular functions.

P524**Board Number: B672****Cytoskeletal integrity and acto-myosin contractility act by distinct pathways to regulate nuclear Yap1 localization and phosphorylation during mechanotransduction.**A. Das¹, C. Waterman²;¹Cell biology and physiology, National Institutes of Health/NHLBI, Bethesda, MD, ²National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD

Mechano-transduction is key to important biological processes such as gastrulation, vascularization and even cancer metastasis. Recent discoveries connect cellular mechanosensing to global transcriptional regulation, where the transcriptional co-activator Yap1/Taz induces transcription of target genes upon increased cellular tension induced by actomyosin contractility on stiff ECMs. Yap1/Taz regulation is also well-characterized in the context of contact inhibition-mediated Hippo signaling, where the dephosphorylation of S127 promotes its nuclear import and activity. However, the relationship between phosphorylation and nuclear import during mechano-regulation of Yap1/Taz is less clear. Here we sought to dissect the relationships between cytoskeletal integrity, contractility, Yap1 localization and Yap1 phosphorylation. We first examined the relationships between cytoskeletal integrity and either Yap1 localization or phosphorylation. We utilized the F:G actin ratio as a proxy for cytoskeletal integrity. Biochemical fractionation and single cell imaging assays showed that treatment with Latrunculin A (LatA) or plating cells on soft substrates decreased the F:G actin ratio, while either treatment with the actin stabilizer jasplakinolide (jasp), inhibition of myosin II with blebbistatin, or plating cells on stiff substrates increased the F:G actin ratio. We then examined the correlations between F:G actin ratio and either Yap1 localization or phosphorylation across these conditions. This showed that F:G actin ratio correlated positively with nuclear localization, but not with phosphorylation of Yap1. Specifically, compared to control, LatA and soft substrates reduced Yap1 nuclear localization and increased its phosphorylation, while Jasp, blebbistatin, and stiff substrates increased Yap1 nuclear localization compared to LatA, but had mixed effects on its phosphorylation. We then examined the relationship between contractility and Yap1 phosphorylation by utilizing the collagen gel contraction assay. This showed that LatA, Jasp, and blebbistatin, all of which induce Yap1 phosphorylation, also reduce contractility, indicating that contractility negatively correlates with Yap1 phosphorylation. Biochemical fractionation of nucleus and cytoplasm further revealed that conditions with high F/G actin ratio could even enrich phosphorylated Yap1 in the nucleus, indicating that cytoskeletal integrity is dominant in regulation of Yap1 nuclear localization, independent of its phosphorylation. Hence this study indicates a novel mechanism where cytoskeletal integrity and acto-myosin contractility act by distinct pathways to regulate nuclear Yap1 localization and phosphorylation during mechanotransduction.

P525**Board Number: B673****Actin dynamics and calcium signaling in B cells respond to surface topography.**C.M. Ketchum¹, X. Sun², H. Miller³, J. Fourkas⁴, W. Song³, A. Upadhyaya⁵;¹Biophysics Program, University of Maryland, College Park, MD, ²Department of Chemistry and Biochemistry, University of Maryland, College Park, MD, ³Department of Cell Biology and Molecular Genetics, University of Maryland, College Park, MD, ⁴Dept of Chemistry and Biochemistry, University of Maryland, College Park, MD, ⁵Physics and IPST, University of Maryland, College Park, MD

B cells become activated by membrane-bound antigen binding to the B cell receptor (BCR), inducing actin dynamics, reorganization of receptors into microclusters, and cell spreading. In vivo B cells gather antigen from a variety of sources which may have different physical characteristics such as mobility, stiffness or topography. However, the effect of these parameters on BCR clustering and signaling activation is not understood. Here we have studied the role of topography in cell spreading, actin polymerization and signaling activation. BCR ligand coated substrates presenting ridges of variable spacing were used to probe the interaction of B cells with non-planar surfaces. Using high-resolution TIRF and confocal microscopy of live cells, we followed the movement of BCR clusters and the dynamics of actin. Ridge separations of less than 1.5 μ m induced actin waves that travel parallel to the ridges, resulting in protrusions and retractions of the cell edge. Separations of 3 μ m or greater result in large-scale contractions of the actin network. B cells are known to exhibit periodic calcium enrichment after antigen engagement. On flat substrates we have measure the period to be \sim 30s, consistent with previously observed values. Interestingly, we found the period of the calcium enrichment was dependent on ridge spacing, with increasing time intervals on smaller spacings. Periodic calcium enrichment was also found to be slower on flat substrates when affected by actin-inhibiting drugs, such as latrunculin. Our results indicate that B cells are sensitive to topographical features, resulting in modulated actin dynamics and that calcium signaling is coupled to substrate-proximal actin dynamics.

P526**Board Number: B674****Traction Forces of Primary Human Macrophages.**L.E. Hind¹, M. Dembo², D.A. Hammer^{3,4};¹University of Pennsylvania, Philadelphia, PA, ²Boston University, Boston, MA, ³Department of Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA, ⁴Department of Bioengineering, University of Pennsylvania, Philadelphia, PA

Macrophages play a crucial role in our bodies as first responders in the innate immune system. In order to properly function they must migrate efficiently to sites of infection and inflammation. The signaling mechanisms underlying macrophage migration have been previously studied but to date no one has investigated the mechanical mechanism of macrophage migration. Using traction force microscopy, we have created the first traction maps of primary human macrophages migrating on compliant

polyacrylamide gels. We found that the force generated by macrophages is dependent on the stiffness of their underlying substrate with cells on stiff gels producing greater forces than cells on soft gels. Traction maps of motile macrophages have shown that macrophages produce their highest forces in the leading edge of the cell relative to cell motion indicating that they use a forward-towing mode of migration. This type of motility is common among mesenchymal cells and dendritic cells, another monocytic leukocyte, but the reverse of what was seen for neutrophils which propel themselves forward through a rearward squeezing mechanism. These varied results illustrate the importance of investigating the force profiles and signaling pathways for each individual cell type. We used a variety of chemical inhibitors to determine which signaling molecules are crucial for force generation in macrophages. The inhibitors Blebbistatin, Y27632, and LY294002 which block myosin II, the RhoA kinase ROCK, and PI3K signaling respectively all caused a significant reduction in macrophage force generation. This indicates that, like in most cells, myosin contraction through RhoA is necessary for force generation. PI3K is known to activate a variety of pathways at the leading edge of migrating cells so we decided to further investigate the necessity of one of its downstream effectors, Rac. We found that inhibition of Rac by NSC23766 which blocks signaling of the Rac GEF Tiam1 did not significantly change macrophage force generation. However, inhibition of Rac by 6-thio-GTP which blocks Rac binding to its GEF Vav1 leads to a significant reduction in force. This indicates that Rac is necessary for force generation downstream of some but not all Rac GEFs, illustrating the complexity of the signaling networks involved in force generation.

Investigating the role of type IV pili mechanics and force production in pathogenic *Neisseria gonorrhoeae* and commensal *Neisseria elongata* during their interaction with human host cells.

E.L. Munteanu¹, I. Spielman¹, N. Biais¹;

¹Biology, CUNY Brooklyn College, Brooklyn, NY

Type IV pili (Tfp) are long polymeric bacterial fibers produced on the surface of a wide variety of bacteria and archaea. In *N. gonorrhoeae* (Ng) and *N. elongata* (Ne) Tfp are involved in adhesion and motility, DNA uptake, and have essential roles in biofilm formation and virulence in the case of Ng. Tfp are dynamic and can generate pulling forces as high as 1 nN. We investigate the role of Tfp retraction and force production in the infection process using genetic methods, fluorescence microscopy and magnetic tweezers. We generated various mutant bacterial strains in both Ng and Ne with deleted components of the Tfp retraction machinery, i.e. pilT, the main protein responsible for Tfp retraction, and two other associated motors, pilT2 and pilU. We also generated Ng and Ne strains where the pilT gene, the pilT promoter, or both were switched with that of Ne and Ng, respectively. A431 human epithelial cells were directly infected with the mutant bacteria and actin recruitment at the infection site was monitored. We also simulated the infection by allowing Tfp-coated magnetic beads to interact with the human cells and subjecting the beads to variable magnetic forces to mimic Tfp pulling. Direct measurement of force

production by Tfp retraction in bacteria was also recorded using flexible polyacrylamide micro-pillar patterns. Preliminary results show that i) the Tfp retraction mechanics differs between Ng and Ne strains and it depends on pilT and pilT2 motors, ii) PilT2 deletion decreases Tfp retraction speed by half in *N. gonorrhoeae*, as previously reported, and has a similar effect in *N. elongata*, iii) actin recruitment in human cells at the infection site correlates with the pulling force. Our investigation promises to elucidate the role of the Tfp retraction machinery and the forces exerted by Tfp during bacterial interaction with human cells.

The dynamic interplay between cleavage furrow proteins as a model for cellular mechanoresponsiveness.

V. Srivastava^{1,2}, I. Chernysheva³, J. Van Eyk³, D. Robinson^{1,4};

¹Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, ³Cardiology, Johns Hopkins University School of Medicine, Baltimore, MD, ⁴Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine, Baltimore, MD

Cell shape changes associated with processes such as cytokinesis and motility take place on tens of seconds time-scale, but are derived from molecular events occurring much more quickly, such as dynamic protein-protein interactions, filament assembly and rearrangement, and force generation by molecular motors. While the local accumulation of cytoskeletal elements can often be driven by signaling pathways, mechanical stresses also direct protein accumulation. A myosin II-based mechanosensory system, which controls cellular contractility and cell shape change during cytokinesis and under applied stress, was previously identified in *Dictyostelium*. This system tunes myosin II accumulation by feedback through the actin network, particularly the actin crosslinker cortexillin I. The cortexillin-binding IQGAP proteins served as major regulators of the system. Here, we examine the dynamic interplay between these key cytoskeletal proteins using fluorescence recovery after photobleaching (FRAP) and fluorescence correlation spectroscopy (FCS), defining the short time-scale turnover characteristics of these players during cytokinesis or in response to mechanical stresses. We found that the actin network is highly dynamic, and turns over within 0.7 seconds post-bleach. Polar cortex enriched crosslinkers also show sub-second turnover at the cleavage furrow, while equatorially enriched proteins such as cortexillin I, IQGAP2 and myosin II turn over much more slowly on the 1-5 s time-scale. As compared to the interphase cortex, the mobility of the equatorial proteins is greatly reduced at the cleavage furrow, likely driving their accumulation at this region. This mobility shift does not arise from a single biochemical event, but rather from a global inhibition in protein dynamics by mechanical stress-associated changes in the cytoskeletal structure. We also expanded our genetic findings using a proteomics approach, which demonstrated that myosin II interacts with both cortexillin I and IQGAP2. This experiment was performed in the presence of Mg²⁺ and ATP to ensure that these proteins were not simply interacting through a common actin filament. We are now using two-color FCS

in tandem with in vivo biochemistry to further characterize the myosin II-cortexillin I-IQGAP2 interaction and determine how their molecular interplay leads to mechanosensation. Our results indicate that high crosstalk occurs between the different components of the mechanosensory system under stress. This mechanical tuning of contractile protein dynamics provides robustness to the cytoskeletal framework responsible for regulating cell shape, and contributes to the fidelity of cytokinesis.

In vivo monitoring of calcium signaling at the single-cell and tissue levels in the spermatheca of *C. elegans*.

J. Bouffard¹, A.R. Asthagiri^{2,3}, E.J. Cram⁴;

¹Bioengineering, Northeastern University, Boston, MA, ²Department of Bioengineering, Northeastern University, Boston, MA, ³Department of Chemical Engineering, Northeastern University, Boston, MA,

⁴Biology, Northeastern University, Boston, MA

The spermatheca is a stretchy and contractile tube in the reproductive system of the nematode *C. elegans* which is composed of a 24-cell tube and a 4-cell syncytial valve. The spermatheca is stretched by oocyte entry, remains stretched for a regulated period of time, then forcefully contracts to expel the fertilized egg. Previous work in the lab has examined calcium signaling at the tissue level during ovulation events, using widefield microscopy to image fluorescence from the genetically encoded calcium sensor GCaMP [1]. To further dissect the tissue level calcium signaling, and to develop an understanding of how calcium signaling in individual cells generates a tissue level response, we developed transgenic constructs to visualize the individual cells in the tissue. We utilized CRISPR genome editing [2] to generate stable lines of transgenic worms expressing an INX-12::mApple fusion protein that labels the junctions between the spermathecal cells in red. Combining these two fluorescent biosensors, we generated a worm strain where the spermathecae are labeled for calcium in green and cell boundaries in red.

Using a laser scanning confocal microscope to image ovulation events in live, intact animals, we optimized imaging parameters to enable fast, simultaneous acquisition of calcium signaling in the green channel and cell boundaries in the red channel. These fast acquisitions enable us to capture ZT stacks of the tissue, allowing the observation of cells in four dimensions during ovulation events. Preliminary evidence suggests that calcium signaling can differ markedly between adjacent spermathecal cells during ovulation events, with some individual spermathecal cells exhibiting very high levels of calcium signaling while adjacent cells exhibit considerably lower levels. These preliminary results indicate the utility of this strain for detailed investigation of calcium signaling in the spermatheca at the single-cell and tissue levels. This work will advance our understanding of how tissue level responses are generated in tubular arrangements of cells responding to stretch.

Cell migration in mechanically resistive environment.

N. Srivastava¹, A. Kabla¹, R. Kay²;

¹Department of Engineering, University of Cambridge, Cambridge, United Kingdom, ²Laboratory of Molecular Biology, MRC, Cambridge, United Kingdom

The mechanical environment of a cell influences its migration. It has been observed in particular that certain cell types such as *Dictyostelium discoideum* and cancer cells tend to migrate by forming blebs instead of pseudopodia/lamellipodia in mechanically resistive environments^{1–3}. However, very little is known about the mechanisms governing this transition between different modes of migration^{4,5}. In this work, we aim to disentangle the contributions of two key mechanical factors that might trigger this switch, the environment's stiffness (the extent of local deformation of extra-cellular matrix by the cell) and its state of stress (amount of pre-existing tension or compression). We use *Dictyostelium discoideum* as a model to study these questions. A custom built device, the "cell squasher", is used to compress an agarose gel of known stiffness against a glass cover slip under a dynamically controlled and uniform loading condition. A chemotactic gradient (using cAMP) is used to direct the cells under the agarose while monitoring cell's migration and recording its morphology and trajectory. Our preliminary results indicate that switching to bleb mode of migration can be triggered by an increase of either the external loading or the gel stiffness. This transition is also associated with a decrease of cell speed. Increasing the load even further triggers the rounding up of the cells and dramatically slows down the retraction of blebs; migration ceased in most of the cases. The setup is currently applied to study the dynamics of the lamellipodia/bleb transition. This work may be of significant importance in understanding the initiation of cancer metastasis where cells often migrate using blebs in environments often highly deformed by the growth of the tumour⁵.

Fibroblasts use Filopodia Extensions to Probe Substrate Rigidity before Occupying an Area.

S. Wong¹, W. Guo¹, Y. Wang¹;

¹Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

Rigidity sensing and durotaxis are thought to be important elements in wound healing, tissue formation, and cancer treatment. It has been challenging, however, to study the underlying mechanism due to difficulties in capturing cells during the transient response to a rigidity interface. We have addressed this problem by developing a model experimental system that confines cells to a micropatterned area with a rigidity border. The system consists of a rigid domain of one large adhesive island, adjacent to a soft domain of small adhesive islands grafted on non-adhesive soft gels. This configuration allowed us to test rigidity sensing away from the cell body during probing and spreading. NIH 3T3 cells responded to the micropatterned rigidity border similarly to cells at a conventional rigidity border, by showing a strong preference for staying on the rigid side. Furthermore, cells used filopodia extensions to probe substrate rigidity at a distance in front of the leading edge and regulated their responses based on the strain of the intervening substrate. Soft substrates inhibited focal adhesion maturation and promoted cell retraction, while rigid substrates supported stable adhesions and cell spreading. Myosin II was required for not only the generation of probing forces but also the retraction of probing structures in response to soft substrates. We suggest that a myosin II-driven, filopodia-based probing mechanism ahead of the leading edge allows cells to migrate efficiently, by sensing physical characteristics before moving over a substrate to avoid back-tracking.

P532**Board Number: B680****Dynamic tensile forces drive collective migration through three-dimensional extracellular matrices.**A. Piotrowski¹, N. Gjorevski¹, V. Varner¹, C. Nelson^{1,2};¹Chemical and Biological Engineering, Princeton University, Princeton, NJ, ²Dept. of Molecular Biology, Princeton University, Princeton, NJ

Collective migration drives a variety of biological processes, including wound healing, angiogenesis, branching morphogenesis, and cancer invasion. While collective migration is thought to be coordinated by soluble factors, it is also a fundamentally physical process. We used arrays of microfabricated tissues to elucidate the physical mechanisms by which epithelial cells move collectively through three-dimensional (3D) extracellular matrix (ECM). Cells undergo collective invasion predictably from specific locations within the microfabricated tissues, allowing for high-throughput analysis and manipulation of mechanical parameters. We examined the interactions between migrating cells and their surrounding ECM, as well as the dynamics of migrating cohorts. Using traction force microscopy, we found that cells exert tensile forces on their surrounding ECM while undergoing collective migration. In addition to serving a physical role in propelling cells forward, these forces also stimulated mechanotransduction signaling in the cells at the leading edge of the migrating cohort. Confocal reflectance microscopy revealed that the matrix ahead of the migrating cohort was remodeled into highly aligned fiber bundles along which the cohort preferentially migrated. Moreover, timelapse imaging showed that cohort extension was highly dynamic, and that variations in cohort length were highly correlated and in phase with deformations and tensile forces in the ECM. These results suggest both mechanical and signaling roles for dynamic tensile forces during collective migration.

P533**Board Number: B681****The dendritic cell cytoskeleton regulates ICAM-1 clustering and lateral mobility to promote T cell adhesion and activation.**W. Comrie¹, S. Li², S. Boyle², J.K. Burkhardt³;¹University of Pennsylvania, Philadelphia, PA, ²Children's Hospital of Philadelphia, Philadelphia, PA,³Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia Research Institute, Philadelphia, PA

Integrity of the dendritic cell (DC) actin cytoskeleton is essential for T cell priming, but the underlying mechanisms are poorly understood. We show that the DC F-actin network regulates the lateral mobility of ICAM-1, but not MHCII. ICAM-1 mobility and clustering is regulated by maturation-induced changes in the expression and activation of moesin and α -actinin-1, which associate with actin filaments and the ICAM-1 cytoplasmic domain. Constrained ICAM-1 mobility is important for DC function, since DCs

expressing a high mobility ICAM-1 mutant lacking the cytoplasmic domain exhibit diminished antigen-dependent conjugate formation and T cell priming. These defects are associated with inefficient induction of LFA-1 affinity maturation, consistent with a model in which constrained ICAM-1 mobility opposes forces on LFA-1 exerted by the T cell cytoskeleton. Our results reveal a novel mechanism through which the DC cytoskeleton regulates mechanotransduction at the immunological synapse.

F-actin flow drives affinity maturation and spatial organization of LFA-1 at the immunological synapse.

W. Comrie¹, A. Babich¹, J.K. Burkhardt²;

¹University of Pennsylvania, Philadelphia, PA, ²Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia Research Institute, Philadelphia, PA

Integrin-dependent interactions between T cells and antigen presenting cells are vital for proper T cell activation, effector function, and memory. Regulation of integrin function occurs via conformational change, which modulates ligand affinity, and receptor clustering, which modulates valency. Here, we show that conformational intermediates of LFA-1 form a concentric array at the immunological synapse. Using an inhibitor cocktail to arrest F-actin dynamics, we show that organization of this array depends on F-actin flow and ligand mobility. Furthermore, F-actin flow is critical for maintaining the high affinity conformation of LFA-1 and for enhancing valency through recruitment of LFA-1 to the cell-cell interface. Finally, we show that F-actin forces are opposed by immobilized ICAM-1, which triggers LFA-1 activation through a combination of induced fit and tension-based mechanisms. Our data provide direct support for a model in which the T cell actin network generates mechanical forces that regulate LFA-1 activity at the immunological synapse.

Biomechanical stress due to increased intraocular pressure (IOP) is associated with inner retinal pathology characterized by glial reactivity and retinal ganglion cell death. However, the

mechanotransduction mechanism by which resident cells respond to this stress is not understood. We have developed an *in vitro* model whereby controlled magnitudes of pathologically relevant stress are generated in retinal astrocytes to mimic the conditions that occur *in vivo* during the elevation of IOP. Proteomic analysis has identified Annexin A4, (ANXA4), a Ca^{2+} -dependent phospholipid binding protein, to be significantly elevated in this model. Relatively little is known about the function of ANXA4, but it plays a role in membrane interactions by contributing to their rigidity through calcium dependent translocation. We report that ANXA4 responds to Ca^{2+} and biomechanical stress in a way that can increase cell survival or inhibit pro-apoptotic pathways. Immunofluorescence microscopy was used to identify the pattern of ANXA4 protein in normal mouse, rat, and human retinas. Acute elevation of IOP was induced at the retina *in vivo* followed by quantitative RT-PCR. Live cell imaging of an astrocytic cell line was used to visualize ANXA4 localization and membrane dynamics in response to increased biomechanical stress and elevated intracellular Ca^{2+} . ANXA4 immunofluorescence staining revealed conserved localization to the ganglion cell layer and optic nerve head in normal mouse, rat, and human retinas. Furthermore, there was a 6-fold increase in ANXA4 mRNA expression by 18 hours following elevation of IOP *in vivo* ($p=0.039$). Live cell imaging showed evidence of ANXA4 localization to cellular and nuclear membranes upon increases in intracellular Ca^{2+} and dramatically reduced membrane blebbing. These results show that ANXA4 protein is localized to the cells lining the inner retina and optic nerve head and that it responds to biomechanical and Ca^{2+} stress. They further suggest that ANXA4 can increase cell integrity by inhibiting membrane blebbing when translocated to improve cell survival under conditions of biomechanical stress.

The CD2 isoform of protocadherin-15 is an essential component of the tip-links in mature auditory hair cells.

V. Michel¹, E. Pepermans², A. El Bahloul³, C. Petit⁴, R. goodyear⁵, G. richardson⁶, t. dupont⁷, P. avan⁸, C. Bonnet⁹, A. Zenati¹⁰, S. Marlin¹¹, M. Makrelouf¹²;

¹Neuroscience, Pasteur Institut - INSERM U1120, Paris, France, ²Institut Pasteur, Paris, France, ³CNRS/ Institut Pasteur, Paris, France, ⁴Coll De France-Inst Pasteur, Paris Cedex 15, France, ⁵university of sussex, Brighton, England, ⁶university of sussex, brighton, England, ⁷institut pasteur, paris, France, ⁸Faculté de Médecine, Clermont-Ferrand , France, ⁹INSERM UMRS 1120, Paris, France, ¹⁰Université des Sciences et de la Technologie Houari, Alger, Algeria, ¹¹Centre de référence des Surdités Génétiques, Paris, France, ¹²Faculté des Sciences Biologiques, Alger, Algeria

Protocadherin-15 (Pcdh15) is a component of the tip-links, the extracellular filaments that gate mechano-electrical transduction channels of the inner ear hair cells. There are three Pcdh15 splice isoforms (Pcdh15-CD1, Pcdh15-CD2, Pcdh15-CD3), which only differ by their cytoplasmic domains. These three isoforms are thought to function redundantly in mechano-electrical transduction during hair-bundle development, but whether any of these isoforms composes the tip-link in mature hair cells was still unknown. By immunolabeling we showed that Pcdh15-CD2 is correctly localized in mature auditory

hair cells to form the lower tip-link component. We generated postnatal hair cell-specific conditional knockout mice that lose only Pcdh15-CD2 after normal hair-bundle development. Electrophysiological analysis of these mice indicated that mechano-electrical transduction is lost from P21 onwards. Morphological analysis of the auditory hair cells of these mice proved that the loss of mechano-electrical transduction is due to the loss of tip-links. We conclude that this isoform is an essential component of the tip-links in mature murine auditory hair cells. This conclusion could be extended to humans, since a frame-shift mutation in PCDH15 (in the homozygous or compound heterozygous state) that only affects Pcdh15-CD2 was identified in profoundly deaf children from two unrelated families. These results provide key information for the identification of new components of the mature auditory mechano-electrical transduction machinery.

Morphodynamic analysis of T lymphocyte migration in confined microenvironments.

A. Reversat¹, F. Buggenthin², J. Merrin¹, A. Leithner¹, I. de Vries¹, F. Theis², C. Marr², M. Sixt¹;
¹IST Austria (Institute of Science and Technology Austria), Klosterneuburg, Austria, ²Helmholtz Center Munich, Institute of Computational Biology, Neuherberg, Germany

Leukocytes such as dendritic cells (DCs) or T lymphocytes are highly plastic and undergo a variety of molecular interactions with the substrate and morphological changes to efficiently move inside the organism. Although most leukocytes are able to migrate in the absence of integrins, they use, by default, the classical translocation mode: at the leading edge actin polymerization pushes forward, integrin-dependent adhesions couple the substrate to the retrograde actin flow, and actomyosin contraction allows the uropod to retract and push the nucleus forward. To decipher the role of adhesion in leukocyte locomotion, we set-up a PDMS device (Le Berre et al., 2014) that allows for real time microscopy combined with variable degrees of confinement between 2 parallel surfaces. In addition substrate micropatterning permits creation of defined adhesive domains. TIRF microscopy revealed that lamellipodia of confined DCs and T cells only occasionally and punctually contact the substrate and that these contacts are not associated with forward translocation. This indicates that actual force transduction occurs at the cellular mid-zone, while lamellipodial adhesions are dispensable for locomotion. Under non-adhesive (PLL-PEG-coated) conditions both T cells and DCs showed extensive retrograde actin flow. However, only DCs were able to migrate (Renkawitz et al., 2009), while T cells “ran on the spot”, indicating fundamental differences in the mechanisms how the two cell types generate friction with the substrate. In addition patterned structures alternating adhesive and non-adhesive areas induce almost instantaneous switch between polarized motility and loss of polarity associated with blebbing. Finally we are quantifying morphometric parameters from both the actin cytoskeleton and the nucleus together with velocity to decipher how migrating leukocytes can dynamically reorganize their actomyosin machinery in response to adhesive cues.

Repair cells activated in response to wound healing exhibit invasive function.

B.M. Bleaken¹, S. Menko¹, J.L. Walker¹;

¹Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA

Tumors are often referred to as “wounds that do not heal” because of their resemblance to a tumor cell environment that never resolves. This phenomenon suggests that tumor formation may reflect an aberrant wound healing process. In fact, fibrosis, a negative outcome of wound repair, is believed to increase susceptibility to tumor formation. Using a mock cataract surgery wound healing model in which we are able to follow the response of an epithelium to a physiologically relevant wounding, we have identified a subpopulation of vimentin-rich mesenchymal cells with repair function that are endogenous residents of an unwounded epithelium. Repair cells are activated to migrate to the wound edge immediately upon injury, serving as the directors of the wound healing process by guiding the collective movement of a wounded epithelium across the denuded (injured) basement membrane. It is not fully understood how the repair cells function to regulate healing of the epithelium; however, we have shown that vimentin function is central to their migration. Further elucidation of the migratory properties of repair cells and how these cells perform their role as the immediate responders to injury to coordinate the wound healing is important not only to understand their function in wound healing but also how they might contribute to disease states such as cancer. We now report that vimentin-rich repair cells at the wound edge are enriched for CD44, MMP-2, and MMP-9, molecules known to mediate interaction with, and/or remodeling of, the ECM microenvironment. These properties could provide repair cells with the ability to navigate their microenvironment. Furthermore, we discovered that vimentin-rich repair cells have innate invasive properties. These cells are able to invade through an extracellular matrix environment in both matrigel transwell and 3D matrigel invasion assays. Repair cell invasion appeared to occur in a vimentin-dependent manner since treatment with the vimentin inhibitor Withaferin A suppressed repair cell invasion. Understanding the wound healing process that results from a clinically relevant wounding can elucidate mechanisms that activate an invasive program where repair cells direct collective migration of epithelial cells, and is a pivotal step forward toward understanding how this repair cell function can become dysregulated and hijacked to promote disease.

P539**Board Number: B687****The Role of O-linked N-acetylglucosamine on Vimentin Function.**H.J. Tarbet¹, T. Smith², M. Boyce³;¹Department of Biochemistry, Duke University, Durham, NC, ²Duke University, Durham, NC, ³Dept. of Biochemistry, Duke University Medical Center, Durham, NC

Protein modification by O-linked β -N-acetylglucosamine (O-GlcNAc) is an essential intracellular signaling mechanism that affects diverse processes such as cell metabolism, cycle, and death. Aberrant signaling has been implicated in numerous human diseases, including cancer, diabetes, and neurodegeneration. However, major aspects of O-GlcNAc signaling are poorly understood, including the functional consequences of these modifications on proteins. Based on recent literature and our own preliminary results, our lab proposes that one important function of O-GlcNAc is mediating protein-protein interactions. In collaboration with the Kohler group at UT Southwestern, we previously developed a method of covalently capturing proteins that interact through O-GlcNAc using an analog with a diazirine photocrosslinking moiety. We used this approach to identify several proteins that engage in O-GlcNAc-mediated protein-protein interactions, including vimentin, an intermediate filament (IF) protein known to be O-GlcNAcylated. Vimentin is important in the integrity of mesenchymal cells and has been implicated in tissue movement and various cancers. Although vimentin glycosylation was identified in 2008, the purpose remains unknown. Due to vimentin's involvement in cell motility and the Epithelial to Mesenchymal Transition, we hypothesized that O-GlcNAc may be important in regulating vimentin function in these processes. Here we show that mutations in known O-GlcNAcylation sites drastically reduce O-GlcNAc-mediated protein-protein interactions of vimentin identified through our assay. In addition, we have characterized these mutants in an array of phenotypic assays such as wound healing, migration, and cell cycle transitions, and have examined how IF formation is regulated by O-GlcNAcylation. Many IF proteins besides vimentin are also glycosylated, so our work may provide broad insight into how O-GlcNAc regulates IFs in general.

P540**Board Number: B688****Vimentin is a key regulator of repair cell function in wound healing and fibrotic disease.**J.L. Walker¹, B.M. Bleaken¹, L. Zhang², S. Menko¹;¹Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA, ²Anatomy, Thomas Jefferson University, Philadelphia, PA

Wound healing of an epithelium involves the collective movement of the injured epithelium, directed at the wound edge by a population of mesenchymal leader cells. To study wound repair and regeneration of epithelial tissues we developed an ex vivo, clinically relevant wound model, which involves mock cataract surgery of isolated embryonic chick lenses. With this model we discovered that the

mesenchymal leader cells were, in fact, the progeny of an innate subpopulation of vimentin-rich repair cells. Vimentin was essential to the movement of the repair cells along the exposed basement membrane at the wound edge, as well as to the function of the repair cells in directing wound-healing of the epithelium. In the uninjured lens the vimentin-rich repair cell progenitors are located in niches among the epithelium. These cells respond rapidly to injury, quickly expanding in cell number and migrating to the leading edge of the wound where they extend vimentin-rich, actin-poor lamellipodial extensions, where it is the vimentin filaments that link to paxillin-containing integrin focal adhesion contacts in the lamellipodial tips. These findings highlight a key role for vimentin intermediate filaments rather than actin filaments in regulating migration and repair cell function during wound healing. Changes in vimentin detergent solubility, reflective of different vimentin assembly states, were found associated with migration. Non filamentous forms of vimentin, associated with detergent soluble fractions, were present near the tips of lamellipodia and an increase in the detergent soluble vimentin pool occurred in the migratory region. These results highlight a potential function for soluble vimentin in regulating migration. In addition to acting as directors of the wound healing process, we found that these vimentin-rich repair cells have a high potential to differentiate into myofibroblasts, the cell type associated with development of fibrotic disease, when they encounter a rigid microenvironment. Treatment with Withaferin A, for which vimentin is a druggable target, suppressed myofibroblast differentiation. Here too, vimentin function in the repair cells appears to be required for their acquisition of a myofibroblast phenotype. Vimentin has emerged as a key regulator of repair cell migration, their function in wound healing, as well as their potential to transition to disease-causing myofibroblast.

Microtubule-dependent transport and dynamics of vimentin intermediate filaments.

C. Hookway¹, L. Ding², M.W. Davidson³, J.Z. Rappoport^{1,4}, G. Danuser², V.I. Gelfand¹;

¹Department of Cell and Molecular Biology, Northwestern University, Feinberg School of Medicine, Chicago, IL, ²Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX,

³National High Magnetic Field Laboratory and Department of Biological Science, Florida State University, Tallahassee, FL, ⁴Center for Advanced Microscopy, Northwestern University, Chicago, IL

We studied two aspects of vimentin intermediate filaments dynamics, transport of filaments and subunit exchange. Using Structured Illumination Microscopy (SIM) of live cells, we directly observed transport of long intermediate filaments at the cell periphery. To study filament transport elsewhere in the cell, we used the photoconvertible protein mEos3.2 fused to vimentin. This technique enabled us to selectively label a subset of filaments within the dense vimentin network by photoconversion of green fluorescence to red in a small area of the cytoplasm. We then followed red filaments by time-lapse Total Internal Reflection Fluorescence Microscopy (TIRFM), which demonstrated that photoconverted filaments are rapidly transported along linear tracks. Filament transport was microtubule-dependent,

likely due to transport by microtubule-based motors. Transport was independent of microtubule dynamics and/or interaction of vimentin with the microtubule plus-tip binding protein APC. We also used mEos3.2-vimentin and photoconversion to study subunit exchange in vimentin filaments over the course of several hours. We found that even 17 hours after photoconversion, photoconverted (red) vimentin formed distinct patches and was not completely intermixed with green vimentin filaments. This pattern was also observed in cells that divided after conversion. These data show that vimentin filaments are stable and do not disassemble into individual subunits even during cell division. Instead, dynamics of intermediate filaments include severing and re-annealing. Together, these results contribute to the understanding of intermediate filament organization, which is important for maintaining mechanical integrity during cell migration. This work was supported by the Intermediate Filament Program Project Grant, NIGMS # P01GM09697.

Vimentin filament precursors exchange subunit in an ATP-dependent manner.

A. Robert¹, M. Rossow¹, C. Hookway², V.I. Gelfand²;

¹Department of Cell and Molecular Biology, Northwestern University, Chicago, IL, ²Department of Cell and Molecular Biology, Northwestern University, Feinberg School of Medicine, Chicago, IL

Unit-length filaments (ULFs) are non-polar oligomers formed by the lateral association of eight tetramers of vimentin polypeptides. These oligomers are the basic building blocks that form intermediate filaments by longitudinal annealing. Previous studies have shown that mature intermediate filaments can exchange segments along their length probably through severing and annealing. The long time scale for this process is indicative of the stability of the vimentin polymer as compared to the highly dynamic turnover of microtubules and actin filaments. Here we studied dynamic properties of ULFs using the vimentin mutant Y117L, which does laterally associate into ULFs but fails to longitudinally anneal and thus does not form vimentin filaments. By monitoring the fluorescence of Y117L mutant tagged with the photoconvertible protein EOS3.2, we found that ULFs are highly dynamic. Subunit exchange between ULFs occurred within seconds and is limited by diffusion of vimentin polypeptides in the cytoplasm rather than their association and dissociation from ULFs. Biochemical analysis and microscopy data demonstrate that cells expressing vimentin Y117L mutant contain a large pool of soluble vimentin that is in the rapid equilibrium with ULFs. Furthermore, our study demonstrated that subunit exchange between ULFs requires ATP; ATP depletion causes a dramatic reduction of the soluble vimentin pool. Therefore, this study shows that vimentin filament precursors can be present in two distinct states, the ULF vimentin oligomer and a soluble pool. The fast transition between these two states is an ATP-dependent active process that might play a critical role in the regulation of the first steps of the filament assembly in the cell.

P543**Board Number: B691****Lamellar tissue-specific expression of novel keratins and the effect of laminitis on keratin isoform expression.**

M. Modelski¹, J. Kopper², S.F. Colmer¹, C. Armstrong¹, R. Clark³, S. Brooks⁴, D. Lorom¹, J. Engiles⁵, H. Galantino-Homer⁶;

¹Clinical Studies, University of Pennsylvania, Kennett Square, United States, ²Large Animal Clinical Sciences, Michigan State University, EAST LANSING, MI, ³STEM and Health Division, Cumberland County College, Vineland, NJ, ⁴Department of Animal Sciences, University of Florida, Gainesville, FL, ⁵Pathobiology, University of Pennsylvania, Philadelphia, PA, ⁶University of Pennsylvania, Kennett Square, PA

Equine laminitis is a common and devastating disease that affects the hoof epidermis and its adhesion to underlying dermal connective tissues. Our previous quantitative proteomic analysis identified two novel equine keratins (K), K42 and K124 as the most abundant keratin pair in hoof lamellar tissue. We hypothesize that these unique keratins are lamellar tissue-specific and that laminitis alters keratin isoform expression patterns, thus altering the differentiation phenotype and mechanical properties of epidermal lamellae. The first objective of this study was to use qualitative PCR to determine the tissue expression of keratin isoform genes known to be expressed at the protein level in the equine hoof, skin, and cornea. Epidermal tissue-specific gene expression of the following keratin isoforms was determined by PCR: K42 and K124 are expressed only in hoof lamellar tissue, K3 is expressed only in the ocular cornea, and K10 is expressed only in skin. However, K10 has undergone a gene duplication in the equine genome and a second "K10b" gene copy was detected in all epidermal tissues. Our second objective was to relate keratin isoform protein expression and localization to laminitis histopathology.

Paraformaldehyde-fixed/sucrose dehydrated lamellar tissue cryosections from non-laminitic and laminitic horses were subjected to indirect immunofluorescence of the epidermal basal cell keratin, K14, confocal microscopy, and visual scoring by two independent evaluators. Semi-quantitative protein expression in laminitic and non-laminitic lamellar tissues was evaluated by K14 immunoblotting and image densitometry. K14 was predominantly localized to basal cells only of the secondary epidermal lamellae of non-laminitic tissues and to both basal and suprabasal cells of the secondary epidermal lamellae of tissues with histological evidence of laminitis. Moreover, K14 protein expression was increased in laminitic lamellar tissue. These results suggest that laminitis alters the keratin expression, and hence, differentiation phenotype of secondary epidermal lamellar cells. Ongoing studies include the investigation of K42 and K124 protein expression, localization, and utility as a tissue-specific laminitis biomarker.

P544**Board Number: B692****Phenotypic Assay Development Targeting Gigaxonin-mediated Intermediate Filament Aggregation associated with Giant Axonal Neuropathy (GAN).**M.G. Mendez¹, J. Inglese¹;¹Assay Development and Screening Technology (ADST) Laboratory, NIH/NCATS, Rockville, MD

GAN is a rare autosomal recessive disorder caused by mutations in gigaxonin (also *GAN*), a proposed E3 ligase substrate adaptor. GAN progresses rapidly from initial peripheral nervous system involvement that affects coordination and strength, to systemic central and peripheral motor and sensory deficits.

A hallmark of GAN is abnormally large caliber axons, which represent an increasingly greater proportion of axons as the disease progresses; their myelin sheaths are also greatly reduced. Giant axons contain abnormally densely packed, large masses of neurofilaments that can grow to fill the intracellular space. In astrocytes, fibroblasts and muscle fibers, cell-specific intermediate filaments – including vimentin in fibroblasts – form aggregates as well.

In order to screen large compound libraries for entities capable of reducing the effects of gigaxonin loss, a model gigaxonin-null cell line must be proliferative over many passages and exhibit a phenotype reliably distinguishable within the time, imaging and cell culture constraints of microtiter plate format. For many assays, high efficiency reverse transfectability is also desirable.

We used CRISPR/Cas9 genome editing techniques to generate frameshift mutations and isolated homozygous and heterozygous clones in U-2 OS cells. Mutations were confirmed by sequencing.

In contrast to the normal vimentin network distribution that radiates toward the cell periphery from a perinuclear cage, vimentin in homozygous *GAN* mutant U-2 OS cells organizes into a cluster apposed to one side of the nucleus. Vimentin in these cells is degraded by gigaxonin overexpression, as reported for other cell types. These phenotypes, coupled with factors such as proliferation rate, spread area, species, and amenability to processes such as transfection make these cells a useful model for quantitative high content screening (qHCS). Partial funding provided by Hannah's Hope Fund.

P545**Board Number: B693****NF68, a possible new player in pituitary plasticity.**A. Guardado¹, V. Ovando², T. Fiordeliso¹;¹Departamento de Ecología y Recursos Naturales, Facultad de Ciencias, UNAM, Mexico City, Mexico,²Instituto Nacional de Ciencias Medicas y Nutricion, Mexico City, Mexico

Being the systemic hormonal regulator, the anterior pituitary (AP) is exposed to a complex regulation system; endocrine cells identify and integrate signals from different origins, performing necessary

adjustments in secretion rates and endocrine cell population required to effectively respond to a different physiological condition. Intracellular endocrine cells in the AP respond, among others, with a series of cytoskeletal modifications controlling, hormonal synthesis and release, cell division, and other processes. In non-neuronal cells intermediate filaments intervene in the rearrangement of other cytoskeletal filaments, regulate vesicular transport, and DNA repair. In this work we used Western blotting and double immunofluorescence staining to quantify and study changes in the 68kDa neurofilament (NF68) expression in AP of two months old male and estrous female rats which were adrenalectomized, thyroidectomized, gonadectomized, or lactating (with and without suction stimuli) in order to provoke a physiological demand for certain hormones. Monoclonal mouse anti-NF68 and polyclonal rabbit antibodies for each AP hormone (GH, PRL, ACTH, TSH, FSH, LH) and actin were used for each experiment respectively. All images were analyzed with ImageJ. Our Western blot results show a twofold to threefold increase in total NF68 expression in all experimental condition (with the exception of lactating females without suckling stimuli); two different NF68 isoforms can be seen, one of them in the 68kDa band and the other near the 50kDa band, both sharing a common epitope recognized by our monoclonal antibody. Changes in NF50 and NF68 expression vary depending of experimental condition and sex. Double immunofluorescence staining results show NF68 expression in every endocrine cell population in the AP (with the exception of corticotropes) as well as an increase in NF68 expression in response to experimental condition, represented by an increase in the percentage of double positive cells (NF+/Hormone+). The increased total NF68 expression, NF50 and NF68 patterns of expression, as well as the increased NF+ cell proportions seen in our experimental conditions seem to suggest the presence of functionally different populations of NF+ endocrine cells in the AP. Considering all these evidence, we believe that NF may have a role in the regulation of NF+ cells' response to stimuli, contributing to AP plasticity. We will continue evaluating the possible effects in secretion and mitotic index of these NF+ cells in an attempt to determine if they are indeed functionally different from NF-cells.

Nuclear damage in highly constrained migration: from lamina defects to DNA breaks.

J. Irianto¹, A. Athirasala², R. Diegmiller², J. Swift³, D.E. Discher^{1,4};

¹Molecular and Cell Biophysics Lab, University of Pennsylvania, Philadelphia, PA, ²SEAS, University of Pennsylvania, Philadelphia, PA, ³University of Pennsylvania, Philadelphia, PA, ⁴Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA

Cells *in vivo* are sometimes required to migrate through tight spaces that are much smaller than the largest organelle, their nucleus. Micro-pore migration of lung cancer cells causes nuclear blebs with segregated lamins as well as DNA tethering and breaks. Nuclear blebs seen in the majority of cells are enriched in lamin-A and deficient in both lamin-B and DNA, but the cells are viable with a normal rate of post-migration proliferation. Phosphorylation of lamin-A, which relates to turnover under low stress,

decreases with migration, while phosphomimetic and progeria mutants of lamin-A exhibit distinct differences. Knockdown of lamin-A induced the frequent formation of DNA tethers that extrude from the main nuclear body through a gap in lamin-B and to the pore that the cell migrated through. Double strand breaks also increased and are consistent with subsequent cell death. The findings reveal a crucial role for the lamins in cell migration and survival, likely through DNA protection.

FAM83H regulates organization of the keratin cytoskeleton in colorectal cancer cells.

T. Kuga^{1,2}, Y. Saito¹, N. Yamagishi¹, T. Tomonaga², Y. Nakayama¹;

¹Department of Biochemistry and Molecular Biology, Kyoto Pharmaceutical University, Kyoto, Japan,

²Laboratory of Proteome Research, National Institute of Biomedical Innovation, Ibaraki, Japan

During invasion and metastasis, cancer cells lose, at least partially, properties of epithelial cells such as rigid cell-cell and cell-extracellular matrix adhesions. The keratin cytoskeleton is one of the important factors that maintain the epithelial properties. FAM83H, an essential protein for amelogenesis, was recently suggested to be involved in cancer. In this study, we show that FAM83H and casein kinase 1 α (CK-1 α) are novel proteins that modulate organization of the keratin cytoskeleton in colorectal cancer cells. We first performed proteomic analysis to search proteins that can interact with FAM83H, and we identified CK-1 α and keratins. This identification led us to hypothesize that FAM83H and CK-1 α are involved in organization of the keratin cytoskeleton. To investigate the role of FAM83H in organization of the keratin cytoskeleton, we performed experiments using knockdown and overexpression of FAM83H. The overexpression disassembled keratin filaments, whereas the knockdown thickened those, suggesting that the filamentous state of keratins is regulated by FAM83H. Next, to elucidate the involvement of CK-1 α in this FAM83H-governed organization of the keratin cytoskeleton, we used FAM83H mutants with alanine substitutions in their CK-1 α binding sites. These FAM83H mutants could not bind to CK-1 α and thus failed to recruit CK-1 α to keratin filaments. Importantly, these alanine mutants could not reorganize the keratin cytoskeleton, suggesting that CK-1 α binding is required for FAM83H to reorganize the keratin cytoskeleton. The important role of the CK-1 α binding was further supported by the results that FAM83H dominant negative mutants, which possess the ability to bind to CK-1 α but not to keratins, aggregated keratin filaments through sequestering CK-1 α from keratin filaments. In addition, we show that FAM83H is involved in formation of desmosomes, which are maintained by the keratin cytoskeleton. Lastly, we performed immunostaining of human colorectal cancer tissues to explore the role of FAM83H in vivo. Overexpression of FAM83H was observed in colorectal cancer cells that were invading through stromal cells. In fact, FAM83H-overexpressing cancer cells exhibited disassembled keratin filaments and characteristic features indicating loss of epithelial properties. Taken together, these results suggest that overexpression of FAM83H may impair the epithelial properties by disrupting the keratin cytoskeleton during invasion of colorectal cancer cells. (Kuga et al., J. Cell Sci. 2013; 126:4721-4731)

P548**Board Number: B696****The motile properties and distribution of mitochondria are altered in fibroblasts derived from Giant Axonal Neuropathy patients.**J. Lowery¹, N. Jain¹, R.D. Goldman²;¹Cell Molecular Biology, Northwestern Univ, Chicago, IL, ²Department of Cell and Molecular Biology, Northwestern University, Feinberg School of Medicine, Chicago, IL

Giant Axonal Neuropathy (GAN) is a rare inherited neurological disorder caused by mutations in the GAN gene, which encodes gigaxonin, a predicted E3 ligase adapter protein. Neurons and fibroblasts of GAN patients contain aggregates of intermediate filaments (IFs) caused by the improper degradation of IF due to dysfunctional gigaxonin. In GAN patient fibroblasts, mitochondria are abnormally distributed inside and surrounding vimentin IF (VIF) aggregates. Based on this observation, we used live cell imaging and quantitative fluorescence microscopy to compare mitochondrial motility in fibroblasts derived from GAN patients and normal human fibroblasts. By measuring the displacement and instantaneous velocities of individual mitochondria it was determined that mitochondrial motility was significantly reduced and altered in GAN. This reduction in the motility of mitochondria in GAN patient cells appears to be associated with the abnormal tethering of mitochondria to VIF which is also associated with abnormalities in the cytoplasmic distribution, morphology and membrane potential of mitochondria. In an attempt to mimic the disease phenotype, normal fibroblasts were treated with shRNA designed to lower the expression levels of gigaxonin by 75%. This reduction in gigaxonin induces aggregates of VIF which are similar to those seen in GAN patient cells. Mitochondrial motility was also significantly inhibited in these cells. Normal mitochondrial motility can be restored in GAN patient cells by transiently expressing wt gigaxonin. Furthermore, not all organelle motility is inhibited in GAN fibroblasts as shown by the detection of normal lysosome movements in GAN patient cells compared to control cells. Our results demonstrate that both the abnormal motility and the abnormal distribution of mitochondria in GAN patient fibroblasts are due to pathologically significant changes in VIF networks but not to changes in microtubule networks. Board Number: B697

Directional 3D cell migration is mediated by branching actin protrusions and matrix deformation.

C.K. Choi^{1,2}, S. Alimperti¹, D. Nguyen³, S.C. Stapleton³, C.S. Chen^{1,2};

¹Biomedical Engineering, Boston University, Boston, MA, ²Wyss Institute for Biologically Inspired Engineering, Harvard University, Boston, MA, ³Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA

Anchorage-dependent cells maneuver the extracellular matrix (ECM) by coordinated dynamics of actin and integrin-mediated adhesions that serve as major mechanical and signaling structures. Traditional 2D models have shown that cells on 2D substrates interact with the ECM on the basolateral side, exhibit relatively flat phenotype, establish apical-basal polarity, and migrate freely on a horizontal plane. However, most physiological processes in vivo are in a 3D microenvironment, where cells engage the matrix in all directions, adapt a spindle or stellate morphology, and cleave the matrix via metalloproteinase (MMP) to create physical migration paths. Taken together, the mode of cell migration in 3D, compared to 2D, is highly distinctive and not well-understood. In this study, we utilized an engineered microfluidic platform and high resolution image analysis to investigate how actin, adhesions, and cell mechanic are regulated during 3D chemotaxis.

Primary human endothelial cells were plated to form 3D perfusable endothelium imbedded in collagen, and directional chemotactic invasion and migration were induced by gradients of growth factors. Cellular morphometrics were measured over time to analyze 3D dynamics and structural reorganization. Fluorescent beads in the ECM were tracked over time to obtain the 3D ECM deformation field generated by cells. The role of cellular contractility in 3D migration was determined by measuring changes in the cytoskeleton and cell mechanics after perturbing myosin II.

Cells migrating directionally towards the gradient within 3D ECMs exhibit elongated actin protrusions. These pseudopodia, unlike broad lamellipodia generated by 2D cells, are highly dynamic and can branch out. Adhesions, identified by paxillin, form along the protrusions, and they remain relatively small. No well-delineated structural morphogenesis as observed in 2D cultures occurs in 3D. Quantifications of ECM deformation indicate that migrating cells exert 3D forces all around, including around the cell body and along the pseudopodia. The elongated actin structures become significantly disorganized when myosin-mediated contractility is inhibited. The persistence of pseudopodia is low, compared to lamellipodia, suggesting that multiple protrusions in one direction promotes synergy for migration efficiency. These findings reveal that chemotaxis in 3D matrices involves different and more complex cell mechanics and cytoskeletal organization, consisting of punctate adhesions and branching actin.

P550**Board Number: B800****Targeted Deletion of the Formin FMNL1 Suppresses the Macrophage Inflammatory Response.**M.R. Miller¹, S.D. Blystone²;¹SUNY Upstate Medical University, Syracuse, NY, ²Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Migration of macrophages to inflammatory loci or sites of injury mandates successful engagement and penetration of complex connective tissues. Specialized adhesion structures, termed podosomes, utilize integrin receptors in conjunction with signaling, adaptor and cytoskeletal proteins for traction during migration. We previously reported the functional and physical association between macrophage podosomes and FMNL1, a member of the formin family of actin binding proteins. In vitro, FMNL1 can affect actin filament dynamics through nucleation, elongation, bundling and severing. To determine the role of FMNL1 in podosome function and macrophage migration, we generated a murine deletion model system by introducing loxP sites to the FMNL1 allele. Murine macrophages deficient for FMNL1 were purified from progeny of FMNL1 floxed mice bred with mice expressing Cre recombinase via the macrophage specific promoter LysM (FMNL1^{-/-}). In a modified Boyden chamber we observed a 33.5 percent reduction in FMNL1^{-/-} macrophage migration across a porous barrier in comparison to wild type macrophages. FMNL1^{-/-} macrophages exhibit 47.8 percent reduction in cells developing podosomes and a 12.6 percent increase in cell spreading. Importantly, a 38.6 percent reduction in residential macrophages of the liver was observed. An in vivo inflammation model using thioglycollate induced peritonitis shows a 15.2 percent decrease in F4/80 (+) cells, a macrophage specific marker, in FMNL1^{-/-} mice. Interestingly, FMNL1^{-/-} macrophages show elevations of active GTPases including Rac1, CDC42, and RhoA with increases of 31.2, 20.4, and 38.6 percent, respectively, suggesting compensatory mechanisms responding to disrupted cytoskeletal dynamics. We have previously reported that human macrophages with reduced levels of FMNL1 through siRNA targeting exhibit deficient adhesion, migration, and loss of podosome stability. Our data support a model where FMNL1 affects the integrity of podosome structure and function necessary for macrophage immune-related migration events in vivo.

P551**Board Number: B801****Polarity mechanisms such as contact inhibition of locomotion regulate persistent rotational motion of mammalian cells on micropatterns.**B.A. Camley^{1,2}, Y. Zhang^{3,4}, Y. Zhao^{2,5,6}, B. Li^{2,5}, E. Ben-Jacob^{4,7}, H. Levine^{4,8}, W. Rappel^{1,2};¹Physics, University of California, San Diego, San Diego, CA, ²Center for Theoretical Biological Physics, San Diego, CA, ³Physics, Rice University, Houston, TX, ⁴Center for Theoretical Biological Physics, Houston, TX, ⁵Mathematics, University of California, San Diego, San Diego, CA, ⁶Mathematics, George Washington University, Washington DC, DC, ⁷Physics and Astronomy, Tel Aviv University, Tel Aviv, Israel, ⁸Bioengineering, Rice University, Houston, TX

Pairs of endothelial cells on adhesive micropatterns rotate persistently, but pairs of fibroblasts do not; coherent rotation is present in normal mammary acini and kidney cells but absent in cancerous cells. Why? To answer this question, we develop a computational model of pairs of mammalian cells on adhesive micropatterns and study the conditions under which persistent rotational motion (PRM) emerges. Our model couples the shape of the cell, the cell's internal chemical polarity (modeled by a reaction-diffusion process), and physical interactions between cells such as volume exclusion and adhesion. We show that PRM can emerge from this minimal model, and that the cell-cell interface shape may be influenced by the nucleus, which is often neglected in simulations. We study the effect of various mechanisms of coordinating polarity between cells on rotational motion, including contact inhibition of locomotion, neighbor-alignment, and velocity-alignment (where cells align their polarity to their velocity). These polarity mechanisms strongly regulate PRM: small differences in polarity mechanisms can create significant differences in collective rotation. We also show that an individual cell's persistence of direction can regulate PRM: cells with primarily random motility do not develop PRM. We argue that the existence or absence of rotation under confinement may lead to insight into the cell's methods for coordinating collective cell motility.

P552**Board Number: B802****Nanotopography induced guidance of actin polymerization waves and the underlying mechanisms in amoeboid neutrophil migration.**S. Das¹, C. Guven¹, X. Sun², M. Hourwit², J. Fourkas², W. Losert³;¹Dept of Physics and Institute for Physical Science and Technology, University of Maryland, College Park, MD, ²Dept of Chemistry and Biochemistry, University of Maryland, College Park, MD, ³Dept of Physics, University of Maryland, College Park, MD

Directional cell migration due to external chemical gradients is well established, and yet has limitations, especially over long distances. Topography induced contact guidance provides a ubiquitous alternative, for directional migration across long distances. In this study, we show that nanotopography can trigger

directional cell migration, opening up a broad range of possible applications. We found that actin waves are linked to this contact guidance process. Further, we investigate the mechanisms underlying this contact guidance in amoeboid migration using HL-60, neutrophil-like cell line. We find that cells are polarized with guided actin polymerization and cell migration on nanotopography. Tracking of the actin waves using the intensity differences of actin polymerization between successive frames allowed us to measure the distribution of actin-wave speeds and directions relative to the nanopatterned surfaces. Utilizing this technique we show that actin preferentially polymerizes to the nanotopography over a range of spatial periodicities and the velocity of actin polymerization waves is also increased along the nanotopography. Preliminary results show that nanotopography local protrusions spatially distribute the focal-adhesion associated actin regulator paxillin in polarized, migrating cells. We further demonstrate that the contact guidance efficiency, i.e., the degree to which a cell responds to nanotopography, depends on the local details in the nanotopographic features and is connected with the intrinsic actin dynamics in migratory amoeboid cells.

Exosomes mediate LTB₄ signal relay during neutrophil chemotaxis.

R. Majumdar¹, A. Tavakoli-Tameh¹, P. Kriebel¹, C.A. Parent¹;

¹NIH/NCI, Bethesda, MD

The secretion of secondary chemoattractants represents a powerful mechanism by which chemotaxing cells maintain robustness and sensitivity to highly diffusible primary chemoattractant signals. Once secreted, these secondary chemoattractants form a gradient to recruit neighboring cells, thereby dramatically increasing the range of detection. Leukotriene B₄ (LTB₄) has been shown to be such a secondary chemoattractant during neutrophil chemotaxis, although the secretion and the process by which such a small molecule maintains a stable long acting gradient remain to be determined. We hypothesize that in neutrophils, secreted LTB₄ is packaged into extracellular vesicles called exosomes that are periodically released to form a stable gradient. We now show that upon stimulation with the primary chemoattractant fMLP, neutrophils secrete extracellular vesicles that are enriched with the exosomal markers CD63 and HSP70 and contain LTB₄. Importantly, we also find that the enzymes involved in the synthesis of LTB₄, 5-lipoxygenase (5-LO), 5-lipoxygenase-activating protein (FLAP) and LTA₄ hydrolase, are present in purified exosomes, suggesting that active synthesis of LTB₄ occurs in secreted exosomes. Furthermore, we found that 5-LO-mCherry, which primarily associates with the nuclear membrane in resting neutrophils, redistributes into CD63-positive vesicles that coalesce at the back of chemotaxing neutrophils upon activation with fMLP. Exogenous addition of exosomes to resting primary neutrophils leads to a LTB₄ receptor-dependent polarization and migration and a concomitant activation of biochemical pathways known to be involved in migration. Finally, decrease of exosome secretion by inhibiting Rab27a and n-Sphingomyelinase-2 activity leads to reduction of neutrophil recruitment and LTB₄ relay, an effect that recapitulates the pharmacological inhibition of LTB₄ synthesis. Together, these findings strongly suggest that LTB₄ secretion is mediated by exosome release during

neutrophil chemotaxis and implicate this novel delivery mechanism to mediate signal relay in mammalian systems.

Mapping of motility behavior in neutrophil-like HL-60 cells using Linear Optimal Transportation (LOT) and dimensionality reduction techniques.

C. Chan¹, J.A. Theriot^{1,2};

¹Department of Biochemistry, Stanford University School of Medicine, Stanford, CA, ²Howard Hughes Medical Institute, Stanford University School of Medicine, Stanford, CA

Motile cells respond to changes in their environments, including temperature variations, changes in matrix structure, or the presence of chemoattractants. The change in motility is typically measured and characterized by changes in cell morphology, speed, shape, trajectory, or directional persistence. While these parameters can be readily obtained from microscopy data, only a subset of these parameters are normally used at the same time to analyze change in motility in a typical experiment, as it becomes increasingly difficult to visualize changes and interpret trends as the dimensionality of the data set increases. On the other hand, in order to investigate molecular mechanisms that underlie cell motility, it is necessary to connect changes in cell morphology, speed, shape, trajectory, and directional persistence to the underlying cytoskeletal dynamics by including data on subcellular structure movements as well as protein interaction and distribution, such as tracking the intensity and localization of nuclear DNA, actin/myosin, and focal adhesion markers over space and time. The resulting data set increases the dimensionality even further, and the complexity in analyzing such a high dimensionality data set also increases. Furthermore, changes in protein interaction and distribution often vary non-linearly over space and time, and traditional linear techniques such as Principal Component Analysis (PCA) may fall short on extracting critical trends in space, time, and frequency directly from these raw image data sets. However, by employing a technique called Linear Optimal Transport (LOT), which combines transportation-based metrics for image distance calculations while providing linear representations of the original data sets, intensity-based images can be transformed and embedded onto Euclidean space. This mapping thus enables the application of linear techniques such as PCA on high-dimensional, non-linear data sets for the study of motility behavior.

P555**Board Number: B805****Two different modes of collective cell movement.**A. Combedazou¹;¹University Paul Sabatier, LBCMCP CNRS UMR 5088, Toulouse, France

Collective cell migration is a central process during embryo morphogenesis, wound repair and cancer invasion. The hallmark of collective migration is that cells need to coordinate their behavior cooperatively in response to guidance signals. This coordinated migratory behavior is mainly referred as a polarized cell movement, in which chemoattractant gradients control the choice of leader cells from followers. However, this concept of leadership during collective chemotaxis is contradictory to a rotation or tumbling movement mainly reported in collective border cell migration during *Drosophila* ovary development. While the polarized non-rotational behavior has been extensively studied, the rotational phase is less understood notably because of a lack of tools to precisely quantify it and discriminate it from the polarized non-rotational phase in a 3D context. Consequently, the controlling mechanism and biological function of collective rotation are still completely unknown. To address these questions, we used *ex vivo* culture and time-lapse live cell imaging to monitor and measure different movements of border cell cluster, in WT and various genetic background. Using a mathematic approach to quantify the rotational behavior, we demonstrated that the cross-talk between the ROCK – Non-muscle MyosinII (NMII) signaling and the polarized activity of small GTPase Rac governs the transition between polarized non-rotational and rotational modes of collective migration. We found that the occurrence of rotation is mainly dependent on the activity of ROCK and NMII in collective cluster. Oppositely, the polarized Rac activity protrusion are correlated with the polarized non-rotational behavior. In order to confirm the switch control of collective polarized non-rotation vs. rotation by this signaling cross-talk, we used the genetic manipulation and an optogenetic tool called photoactivatable-Rac to change the ROCK/NMII activity and the Rac polarity respectively. We demonstrated that the ROCK/NMII activity and the Rac polarity antagonize each other. Thus this negative cross-talk efficiently governs a switch between these two modes of collective movement. Our further work indicated that the ROCK/NMII signaling negatively affects the Rac activity and protrusion formation locally, which thus leads to a global control of the polarized distribution of both Rac activity and protrusion within border cell cluster. In parallel, we confirmed this phenomenon in collective migration of different types of cancer cells, which have various collectively migratory abilities possibly through the adoption of different movement modes.

P556**Board Number: B806****Topography and stiffness of endothelial layers direct intraluminal crawling of T cells.**J. Doh¹, K. Song¹;¹Department of Mechanical Engineering, POSTECH, Pohang, Korea

Immune cells circulating in inflamed blood vessels undergo series of adhesion cascades to leave out of blood vessels to infiltrate into inflamed tissues. It has been shown that leukocytes crawl substantial amount of distances before they undergo transendothelial migration (TEM), but biochemical/biophysical cues directing the crawling of leukocytes have not been clear. While both endothelial cell (EC) junctions and flow can affect crawling direction of leukocytes, experimental settings currently widely used do not allow systematic examination on which factor has predominant roles on determining intraluminal crawling direction. To directly address this problem, we fabricated well-aligned EC layers by culturing ECs on nanogrooved surfaces and applied shear flow either parallel or perpendicular to the direction of EC orientation. Regardless of flow direction, T cells crawled along the EC orientation. Then, we further identified guiding cues on ECs and found out that T cells tend to crawl along the valleys of topographical landscapes of EC layers while avoiding nuclei of ECs. To directly test whether T cell crawling is guided by the topography of EC layers, EC layers were fixed, dried, and replicated with UV-curable resin poly(urethane acrylate) (PUA). T cells on PUA replicas coated with key adhesion molecules for crawling also crawled along the EC orientation, suggesting topography of EC layers is one of the major factors guiding T cell crawling. However, T cells on PUA replicas frequently crossed over nuclei of ECs, meaning that the tendency of avoiding nuclei of ECs by crawling T cells cannot be explained by topography effect. When lamin A/C of ECs were knocked down by siRNA to reduce nucleus stiffness of ECs, crawling T cells no longer avoided nuclei of ECs, meaning T cells sense stiff nuclei of underlying ECs during crawling. By using pharmacological inhibitors for arp 2/3 and cdc42, we found out that T cells utilize lamellipodia to sense topography of EC layers and invasive filopodia to sense stiff nuclei of ECs. Importantly, inhibitor-treated T cells crawled much longer distances than untreated T cells before they underwent TEM, suggesting that lamellipodia- and filopodia-mediated biophysical environments sensing of T cells are critical for optimal intraluminal path finding.

P557**Board Number: B807****Osmotic surveillance mediates rapid wound closure through nucleotide release.**W. Gault¹, B. Enyedi¹, P. Niethammer¹;¹Cell Biology, Sloan-Kettering Institute, New York, NY

While tissue intrinsic wound detection mechanisms exist (e.g. loss of contact inhibition or chemotactic guidance), little is known about the signals induced by an organism's extrinsic environment. Injury to wet epithelia (e.g. gastrointestinal/mucosal surfaces or fish skin) permits entry of environmental liquids

into the tissue and is associated with rapid wound closure. As osmotic cues from the environment promote wound detection by leukocytes in zebrafish, we tested the hypothesis that environmental osmolarity is a mediator of wound detection and closure by epithelial cells. Using time-lapse fluorescence microscopy and intravital luminescence imaging in a zebrafish larval tailfin model of wet epithelial wound closure, we found that an osmotic difference between the interstitial fluid and the external environment drives hypotonicity-induced ATP release, leading to long-range activation of basal epithelial cell migration and rapid wound closure. We determined that the spatiotemporal pattern of tissue velocity during wound closure is controlled by the extracellular nucleotide degrading ectonucleoside triphosphate diphosphohydrolase 3 (Entpd3). Our data supports that the larval zebrafish skin integrates two spatially distinct yet functionally interrelated modes of wound closure: an environmentally (hypotonicity)-induced lamellipodial sheet migration in the basal cell layer, and an environmentally independent purse-string contraction at the suprabasal wound margin. Overall, we define a novel environmental osmotic surveillance circuit, which is integrated with tissue intrinsic mechanisms to promote rapid, wet epithelial wound closure. These results support that extrinsic environmental exposure is an important master stimulus of the wound response for both leukocytes and epithelial cells in vivo.

Investigating electrotaxis within the confines of cell clusters.

M.L. Lalli¹, A.R. Asthagiri^{1,2};

¹Department of Chemical Engineering, Northeastern University, Boston, MA, ²Department of Bioengineering, Northeastern University, Boston, MA

Electrical signals arise naturally within the human body in multiple locations including blood vessels, the skin, and ducts. Externally applied electric fields have previously been shown to influence collective cell migration in cases such as wound healing. Additionally, it has been reported that cells within clusters are more sensitive to electric fields than their isolated counterparts. The purpose of this study was to quantify the properties of motion of non-transformed mammary epithelial cells (MCF-10A), isolated and within clusters, under an electric field. To do so, cells were seeded into an electrotactic chamber constructed with 0.15 mm glass coverslips attached to a polystyrene dish with silicon adhesive. Electric current was generated and maintained by an external potentiostat while cell movement was recorded in real time by time lapse microscopy. Highly metastatic breast cancer cells (MDA-MB-231) were confirmed to migrate towards the anode of an electric field, as reported previously. Surprisingly, MCF-10A cells were also found to migrate in a directed fashion towards the anode, with 51.8%, 57.0%, 73.8%, 83.8%, and 89.5% migrating towards the anode at field strengths of 0, .13, .26, .51, and 1.0 V/cm, respectively. The directedness of cell migration was defined as the cosine of the angle between the vector of the path length and a vector parallel to the electric field sharing the same origin. A directedness of 1 therefore indicates a cell moving directly towards the anode, 0 indicates random migration, and -1 indicates direct migration to the cathode. The directedness under these field strengths

were found to be .009, .113, .397, .600, and .705, respectively, indicating a linear dependence on the log of the electric field strength. Likewise, for cell clusters, 53.9%, 70.1%, 84.2%, 95.0%, 99.0% of cells migrated towards the anode under electric fields of 0, .13, .26, .51, and 1.0 V/cm, respectively, with corresponding directedness values of 0.081, 0.332, 0.560, 0.772, and 0.840. This increased sensitivity to the electric field within clusters is attributed to intercellular signaling rather than steric effects alone, as evidenced by analyzing the persistence of motion at these electric fields. Interestingly, isolated cells were found to achieve directedness of motion more quickly than their counterparts within clusters. Although cell-cell interactions afford cells within clusters a higher degree of sensitivity to electric fields, they also were found to dampen the dynamics of the associated electrotactic response.

Lipid Rafts Mediate Electric Field-induced Directional Migration.

S. Tsao¹, B. Lin¹, P. Chao^{1,2};

¹Institute of Biomedical Engineering, National Taiwan University, Taipei, Taiwan, ²Institute, National Taiwan University, Taipei, Taiwan

Endogenous electric fields arise during development, wound healing, and at epithelial interfaces. Cells respond to the electric fields with changes in directional migration, morphology, and gene expression. As such, these fields are involved in morphogenesis, healing, and metastasis. While the significance of bioelectricity is widely acknowledged, mechanisms behind electrosensing are not well understood. Previous studies proposed that electrophoretic and electroosmotic forces act on the charged molecules on the plasma membrane and result in redistribution of membrane molecules that lead to polarized intracellular signaling. Membrane proteins such as EGF receptors and integrins have been found to exhibit polarized distribution in direct current electric fields. However, due to the size, concentration, and diffusivity of these proteins, they are unlikely to be the primary response element to dynamic electric fields at relative high frequencies. Using alternating and direct current (AC and DC) fields, we demonstrate that lipid rafts are the primary response elements for directional migration in the field. Disruption of lipid raft integrity with M β CD and cholesterol eliminates polarized integrin distribution and cell migration directionality. Furthermore, caveolin-1 knockdown reduced polarized distribution of integrin and RhoA, which mediates migration directionality. Our results establish a new mechanism for cell electrosensing and provide a new role in lipid raft mechanotransduction.

P560**Board Number: B810****On the mechanism of durotaxis in motile cells.**M. Riaz¹, M. Versaevel¹, S. Gabriele¹;¹University of Mons, Mons, Belgium

Many dynamic processes, including cytoskeletal polymerization and cell-substrate interactions, determine morphological (e.g. shape and dimensions of cells) and directional (e.g. speed, direction and persistence) parameters of migrating cells. A large number of studies have characterized the mechanical behavior of stationary cells in response to matrix stiffness changes, however there have been no comprehensive efforts to elucidate the mechanisms by which matrix stiffness determines motile cell behavior. To this end, we have studied the mechanosensitive response of fish keratocytes, which are among the fastest moving animal cells. Based on a large population of cells, our results demonstrate that keratocyte morphological parameters (shape, aspect ratio, lamellipodial curvature, etc.) are significantly influenced by the matrix stiffness over a wide range of rigidities (from kPa to GPa). These observations suggest that matrix stiffness can be a valuable tool for controlling the natural phenotypic variability of keratocytes. Furthermore, migrating parameters (directionality, speed, motility coefficient) were also observed to be controlled by matrix stiffness, suggesting that the substrate rigidity dictates the level of polarization and directionality of motile cells. Surprisingly, motile cells were observed to maintain a constant spreading area during their polarization over seven orders of magnitude in rigidities, in contrary to previous reports on stationary cells. We further demonstrate that the physical linkage between the cytoskeleton and the substrate is significantly affected by the matrix stiffness and is required for cell polarization. On the whole, our results are consistent with a quantitative physical model in which the overall keratocyte behavior (shape, polarization and directionality) emerges from the impact of the matrix stiffness on the formation of focal adhesions that creates a frictional slippage, which, in turn, balances myosin-mediated contractile forces.

P561**Board Number: B811****Optogenetic control of chemokine receptor signal and T cell migration.**Y. Xu¹, M. Kim¹, Y. hyun¹;¹University of Rochester Medical Center, Rochester, NY

Adoptive cell transfer (ACT) of ex vivo generated immune-promoting or tolerogenic T cells to either enhance immunity or promote tolerance in patients has been used with some success. However, effective trafficking of the transferred cells to the target tissue sites is the main barrier to achieving successful clinical outcomes. Here, we developed a strategy for optically controlling T cell trafficking using a photoactivatable (PA) chemokine receptor. PA-CXCR4 transmitted intracellular CXCR4 signals in response to 505-nm light. Localized activation of PA-CXCR4 induced T cell polarization and directional migration ("phototaxis") both in vitro and in vivo. Directing light onto the melanoma was sufficient to

recruit PA-CXCR4-expressing tumor-targeting cytotoxic T cells and improved the efficacy of adoptive T cell transfer immunotherapy, with a significant reduction in tumor growth in mice. These findings suggest that the use of photoactivatable chemokine receptors allows remotely controlled leukocyte trafficking with outstanding spatial resolution in tissues and may be feasible in other cell transfer therapies.

Using a novel microfluidic device to define the role of TRIM9 in Netrin-based axon guidance.

S. Menon¹, C. Winkle², A.M. Taylor³, S.L. Gupton¹;

¹Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC, ²Neurobiology Curriculum, University of North Carolina, Chapel Hill, NC, ³Biomedical Engineering, University of North Carolina, Chapel Hill, NC

The functional network of neurons in the brain is established during development when extending axons are guided by extracellular guidance cues toward postsynaptic partners. One such cue, Netrin promotes axon branching and attractive axon guidance through its receptor DCC. We recently identified an interaction between DCC and the E3 ubiquitin ligase TRIM9. Using primary cortical neurons from *TRIM9*^{-/-} mice we found that TRIM9 is a novel regulator of Netrin-dependent exocytosis and axon branching in primary cortical neurons. Based on the well-established role of Netrin and DCC in axon guidance, we hypothesized that TRIM9 may be a novel regulator of axon guidance in response to Netrin. In support of this, cortical explants from wildtype mice grow preferentially toward an asymmetric Netrin source, however *TRIM9*^{-/-} explants fail to do so. Axon guidance has typically been investigated using low throughput needle-based assays to establish local gradients of axon guidance cues at the growth cone. Although these assays are useful, they are highly variable, time consuming, and difficult to analyze. We present here a novel PDMS-based microfluidic device in which we can establish a stable, long-lived gradient of Netrin specifically across aligned axons, without exposing neuronal cell bodies. This device is amenable to high resolution, live cell microscopy, long term neuronal viability, and because axons are aligned prior to exposure to Netrin, it also facilitates data analysis. With this device we observe that in wildtype neurons there is robust axon turning toward low concentrations of Netrin. Analysis of *TRIM9*^{-/-} axon turning is ongoing. Defects in outgrowth toward Netrin in vitro are associated with projection defects in vivo in *TRIM9*^{-/-} mice, and an overt spatial learning and memory deficit. We anticipate these defects will be associated with disrupted axon guidance in vitro as well. In conclusion we have identified a novel regulator of Netrin-dependent axon guidance and are using innovative new technologies to define changes in axon guidance in vitro.

P563**Board Number: B813****Collective Epithelial Cell Sheet Adhesion and Migration on Polyelectrolyte Multilayers with Uniform and Gradients of Compliance.**J.S. Martinez¹, T.C. Keller¹, J.B. Schlenoff²;¹Department of Biology, Florida State University, Tallahassee, FL, ²Chemistry, Florida State University, Tallahassee, FL

Polyelectrolyte multilayers (PEMUs) are tunable thin films, which could serve as coatings for biomedical implants. PEMUs built layer by layer with the polyanion PAA (poly(acrylic acid)) modified with a photosensitive 4-(2-Hydroxyethoxy) benzophenone (PAABp) and the polycation PAH (poly(allylamine hydrochloride)) are mechanically tunable by UV irradiation, which forms covalent bonds between the layers, increasing PEMU stiffness. Our study utilized uniformly charged PAH-terminated PEMUs (PAH-PEMUs) that were uncrosslinked, uniformly UV-crosslinked, or UV-crosslinked through a neutral density optical gradient filter forming a continuous compliance gradient to investigate how differences in PEMU stiffness affect the adhesion and migration of epithelial cell sheets underlying scales of the fish *Poecilia sphenops* (Black Molly) and *Carassius auratus* (Comet Goldfish). PAH-PEMUs containing a compliance gradient promoted durotaxis of the cell sheets but not of individual keratocytes. During the progressive collective cell migration, the leader cells in the sheets on the softer uncrosslinked PEMUs and less crosslinked regions of the gradient formed more robust stress fibers and vinculin-containing adherens junctions and focal adhesions, indicating higher levels of intracellular tension, than in the sheets on the stiffer PEMUs or glass. During sheet extension, the ratios of motility velocities between the leader cells and follower cells in the migrating sheets were two times greater on the softer PEMUs than on the stiffer PEMUs or on glass. On the softer, but not on the stiffer PEMUs, the region of leader cells in the sheets exhibited periods of retraction, during which the leader cells lost adhesion to the substrate and retracted toward the more adherent follower cell region. These retraction events were inhibited by blebbistatin (a myosin II inhibitor), which reduced the motility velocity ratios to those measured on the stiffer PEMUs and promoted loss of leader cell-cell connections. Blebbistatin also caused Myosin II disassembly of stress fibers, reorganization of focal adhesions, and increased cell spreading at the leading edge in epithelial cell sheets on glass. Interestingly, cells throughout the interior region of the sheets on uncrosslinked PEMUs conserved their actin and vinculin organization at adherens junctions. Like Blebbistatin, a Rho-kinase (ROCK) inhibitor promoted loss of cell-cell connections between leader cells, whereas a Rac-1 inhibitor altered the lamellipodial protrusion and ruffling patterns in both cell sheet leader cells and individual keratocytes. Investigating how PEMU surface compliance modulates cell sheet adhesion and motility will further our understanding of collective cell migration and durotaxis and suggest potential applications for PEMUs.

P564**Board Number: B814****A BioMEMS Device for Localized Manipulation of the Tumor Microenvironment.**L. Butt¹, J. Sanders¹, A. Clark¹, J.K. Williams¹, M.R. Padgen¹, P.J. Keely², J.S. Condeelis³, J.A. Aguirre-Ghiso^{4,5}, J. Castracane¹;¹SUNY College of Nanoscale Science and Engineering, Albany, NY, ²University of Wisconsin-Madison, Madison, WI, ³Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ⁴Black Family Stem Cell Institute, Manhattan, NY, ⁵Division of Hematology and Oncology, Mount Sinai School of Medicine, Department of Medicine, NY

The tumor microenvironment is a complex system which is not fully understood. New technologies are needed to provide a better understanding of the role of the tumor microenvironment in promoting metastasis. The Nano Intravital Device, or NANIVID, has been developed as an optically transparent, implantable tool to study the tumor microenvironment. Two etched glass substrates are sealed using a thin polymer membrane to create a reservoir with a single outlet. This reservoir is loaded with a custom hydrogel blend that contains selected factors for delivery to the tumor microenvironment. When the device is implanted in the tumor, the hydrogel swells and releases these entrapped molecules, forming a sustained concentration gradient.

In conjunction with the NANIVID technology, multiphoton-based intravital imaging has been used to perform in vivo migration experiments utilizing MDA-MB-231 cell-derived mammary tumors in SCID mice, with epidermal growth factor as a chemoattractant. Additionally, the induction of microenvironments implicated in metastasis including hypoxia and altered extracellular matrix composition have been explored using the NANIVID. Induction devices, or iNANIVIDs, were implanted into HEP3 tumors grown on the chorioallantoic membrane of chicken eggs to demonstrate the extent of the influence of the released chemicals. L-ascorbic acid released by the iNANIVID stimulated localized collagen deposition by hTERT fibroblasts. These projects demonstrate the flexibility of the NANIVID to be used as a tool for modifying and investigating tumor microenvironments in a localized and controlled manner.

P565**Board Number: B815****Control of Wnt5a signaling and cell polarity through organelle dynamics.**M. Connacher¹, N. Ahn¹;¹Biochemistry, University of Colorado Boulder, Boulder, CO

Wnt5a plays an emerging role in cancer malignancy and strongly enhances cell invasion in melanoma. We discovered a new intracellular structure, named the “Wnt5a-receptor-actomyosin polarity (WRAMP) structure”, which provides a novel mechanism to link Wnt5a, a signaling ligand that controls cell polarity, to rear-directed signaling and directional cell movement. This structure involves the formation of signaling endosomes, which interact dynamically with F-actin at the cell posterior to create the

WRAMP structure. Formation of the WRAMP structure induces a localized increase in cytoplasmic Ca²⁺, followed by membrane retraction and forward translocation of the cell body. Thus, the WRAMP structure explains how cells can integrate cell polarity with the mobilization of Ca²⁺ and subsequent membrane contractility, key steps needed for cell movement and invasion. It also explains how Wnt5a promotes Ca²⁺ signaling, observed years ago, but never explained mechanistically.

MCAM, a cell adhesion molecule, undergoes endosome internalization in response to Wnt5a and is our key marker for the WRAMP structure in melanoma cells. We have shown that the signaling endosomes contain both MCAM and Fzd3, a Wnt5a receptor Wnt5a. A new mass spectrometry approach, "Dynamic Organelle Trafficking by Signaling (DOTS-MS)" was used to identify other proteins that associate with the endosomes in the WRAMP structure. Several of these proteins were tested by immunofluorescence and confirmed to localize to the WRAMP structure.

The WRAMP structure links to the plasma membrane in a rear-polarized manner through the phosphoinositol binding protein, ezrin, and PI4,5P2. Ezrin, and another related protein moesin, are both required for the formation of the WRAMP structure and an enrichment of PI4,5P2 is found at the tail of the cell near the WRAMP structure in response to Wnt5a. In addition, rear polarity of the WRAMP structure requires the chemokine, CXCL12, which we suggest is responsible for setting up the rear polarity of PI lipids at the plasma membrane, while ezrin binds these lipids and forms a tether for the WRAMP structure.

A key function of the WRAMP structure is to elevate cytoplasmic Ca²⁺ in a highly localized manner, which in turn triggers actomyosin contractility. We have shown that the endoplasmic reticulum-bound Ca²⁺ sensor, STIM1, and the plasma membrane Ca²⁺ channel, ORAI1, localize near the WRAMP structure in response to Wnt5a and cortical ER is present at the WRAMP structure. We suggest that the highly localized Ca²⁺ elevation at the tail of the cells following WRAMP structure formation involves STIM-mediated opening of ORAI channels and demonstrates a potential mechanism beyond their conventional regulation of store-operated Ca²⁺ entry in response to Ca²⁺ depletion.

P-selectin Deletion Attenuates Immune Responses to Fat Overload in Visceral Fat Depots.

K. Preston¹, I. Rom², R. Scalia¹;

¹Cardiovascular Research Center, Temple University, Philadelphia, PA, ²Cardiovascular Research Center, Temple University, Philadelphia, PA

Infiltration of adipose tissue by immune cells is associated with insulin resistance in overweight and obesity. Studies have shown that deletion of the leukocyte-expressed P-selectin glycoprotein ligand-1 (PSGL-1) preserves insulin sensitivity in high-fat fed mice. PSGL-1 regulates trans-endothelial extravasation of leukocytes by binding endothelial expressed P- and E- selectin. Interestingly, recent

studies demonstrate that in fat fed mice infiltration of circulating neutrophils into visceral fat depots occurs very early, with peak values reached at 72 hours after consumption of high fat meals. Accordingly, we hypothesized that deletion of P-selectin, the early responder in endothelial inflammation, attenuates neutrophil invasion of the visceral fat following consumption of obesogenic high-fat meals. P-sel+/+ and P-sel-/- C57BL/6 mice were given either a low-fat (10% fat, 70% carbohydrate, 20% protein) or a high-fat (60% fat, 20% carbohydrate, 20% protein) meal by gavage. All groups of mice were then studied at 1, 2, 3, and 4 hours post gavage by intravital microscopy to measure postprandial kinetics of leukocyte rolling and leukocyte adhesion in the microcirculation of the visceral fat of the mesentery. Cell surface expression of P-selectin was measured by immunofluorescence techniques. The number of infiltrated leukocyte populations in visceral and subcutaneous fat depots was measured by FACS analysis. In wild-type mice, administration of high fat meals acutely increased leukocyte rolling and adhesion in the visceral fat microcirculation (p

Nuclear deformation and its consequences on cell function during cell migration through 3-D confining environments.

P. Davidson¹, C.M. Denais¹, P. Isermann¹, J. Lammerding²;

¹Weill Institute, Cornell University, Ithaca, NY, ²Department of Biomedical Engineering, Cornell University, Ithaca, NY

Cell migration and motility play a critical role in numerous physiological and pathological processes, ranging from development and wound healing to the invasion and metastasis of cancer cells. It is now becoming increasingly apparent that cell migration in 3-D environments imposes additional challenges and constraints on cells, which can have significant impact on cell migration. The deformation of the nucleus, the largest and stiffest organelle in most cells, is thought to be a limiting factor in cell migration through tight spaces smaller than the nuclear diameter. Reduced nuclear stiffness, as seen in lamin-deficient cells, may thus facilitate 3-D cell migration. Furthermore, lamins A and C, the major contributors to nuclear stiffness, are abnormally expressed in many tumors. Here we investigate the effect of lamin A/C expression on 3-D migration, as well as the consequences of nuclear deformation during the migration through tight spaces.

Since current methods to study the migration of cells confined in three dimensions (3-D) are limited by their physiological relevance and compatibility with available imaging techniques, we developed a novel polydimethylsiloxane (PDMS) microfluidic device that allows observation of cell migration along stable chemotactic gradients through precisely defined 3-D constriction channels. Using constrictions as small as 1 μm wide and 3 to 5 μm tall, we visualized the dynamic deformation of nuclei in cells migrating through the constrictions. We observed that the nuclear lamina deforms and buckles during migration through the smallest constrictions. While wild-type cells were substantially slower to migrate through 2 \times 5 μm^2 wide constrictions compared to 15 \times 5 μm^2 large channels, cells with reduced levels of lamins A and C displayed less or no slowdown in the narrow constrictions, demonstrating the important role of

nuclear stiffness in 3-D cell migration. To understand whether cells can adapt their nuclear or cytoskeletal organization to facilitate migration through narrow constrictions, we are currently studying the ability of cells to migrate through multiple constrictions in series. In addition, we are investigating whether cytoskeletal forces and nuclear deformation may induce nuclear rupture and DNA damage in cells migrating through narrow constrictions.

A better understanding of how cells overcome the mechanical confinement of their surroundings is highly relevant for a variety of physiological phenomena. The migration of cells through dense tissues is a hallmark of metastatic cancer spreading and understanding the factors that limit 3-D migration, as well as the functional consequences of cell deformation, will lead to avenues for cancer therapies.

The Role of Chemokines in Collective Cell Migration of Zebrafish Keratocytes.

K.A. Cho^{1,2}, C.K. Uppalapati³, K.E. Cooper², E.E. Hull², K.J. Leyva³;

¹AZCOM, Midwestern University, Glendale, AZ, ²Biomedical Sciences, Midwestern University, Glendale, AZ, ³Microbiology Immunology, Midwestern University, Glendale, AZ

The role of chemokines in explant zebrafish keratocytes is of interest for collective cell migration in epithelial wound healing models. Several studies have been conducted examining the specific role of chemokines in processes involving collective movement of epithelial cells. Stromal cell-derived factor-1 (CXCL12) is a chemoattractant that has been shown to activate various signaling pathways stimulating inflammation, homeostatic responses, angiogenesis and metastasis. CXCL11 is a chemokine acknowledged to have similar roles, though it has not been as extensively studied. To date, the role of these chemokines has not been examined in zebrafish keratocyte motility. Therefore, our focus was to determine the role of CXCL11 and CXCL12 in the collective migration of zebrafish keratocytes. The addition of exogenous CXCL11 to zebrafish explant cultures resulted in a decreased rate of migration, changes in cell morphology, accelerated expression of N-cadherin and disassociation of beta-catenin from E-cadherin over time when compared with untreated keratocytes. In contrast, the addition of exogenous CXCL12 resulted in an increased rate of migration when compared with CXCL11 and untreated keratocytes. CXCL12 treatment showed similar changes in cell morphology and N-cadherin expression as with CXCL11 treatment, but at later time points. We also analyzed changes in several biomarkers of EMT over time in chemokine-treated vs. untreated cells. Together, our results suggest that both CXCL11 and CXCL12 are playing significant, but likely different, roles in the collective cell migration of zebrafish keratocytes, and support the hypothesis that these chemokines are promoting an epithelial to mesenchymal transition (EMT) process.

P569**Board Number: B819****Production of Red Fluorescent CXCL12 Overexpressing Mesenchymal Stem Cells (MSC).**M. Reis¹, M.U. Maldonado², R.F. Stout Jr.³, L. Zamproni¹, R. Sessa⁴, P. Matsumoto⁴, S. Han⁴, D.C. Spray³, M. Porcionatto¹;¹Bioquímica, UNIFESP, São Paulo, Brazil, ²Dominick P Purpura, Albert Einstein College of Medicine, Bronx, NY, ³Dominic P. Purpura Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY, ⁴Biofísica, UNIFESP, São Paulo, Brazil

Neural stem/progenitor cells (NSC) migrate towards a CXCL12 gradient following activation of its receptor (CXCR4). In response to a brain injury, reactive astrocytes express and secrete the chemokine CXCL12, forming a gradient that attracts NSC from the subventricular zone. Our proposal is to generate red fluorescent CXCL12 overexpressing mesenchymal stem cells (MSC) to be used in mouse models for traumatic brain injury (TBI) and stroke. For this aim we constructed a lentiviral vector encoding a chimera formed by CXCL12 and mKate fluorochrome (CXCL12-mKate). The vector was transfected into Hek293 cells and the amount of chimeric CXCL12 secreted to the medium was quantified by ELISA. The concentration of CXCL12 in the conditioned medium of cells transfected with vector encoding CXCL12-mKate raised by 20X. In a transwell migration assay, Jurkat cells (CXCR4+) responded to the CXCL12-mKate chimera gradient increasing the number of cells in the lower chamber by 4.64X. Following the observation that CXCL12-mKate produced is biologically active, we produced viral particles using CXCL12-mKate and infected mouse bone marrow derived MSC, and selected infected cells with blasticidin, resulting in a population of 100% positive MSC for CXCL12-mKate. These cells will now be transplanted in a stroke mouse model, produced by electrocoagulation. In conclusion, we describe the production of mouse bone marrow derived MSC that express red fluorescent CXCL12 that can be used to study CXCL12 gradient formation by MSC, as well as, the dynamics of *in vivo* production and secretion of this chemokine.

P570**Board Number: B820****Cell Ratchets.**D. Riveline¹;¹Laboratory of Cell Physics ISIS/IGBMC, Strasbourg, France

Many physiological phenomena involve directional cell migration. It is usually attributed to chemical gradients *in vivo*. Recently, other cues have been shown to guide cells *in vitro*, including stiffness/adhesion gradients or micropatterned adhesive motifs. However, the cellular mechanism leading to these biased migrations remains unknown, and, often, even the direction of motion is unpredictable. In this study, we show the key role of fluctuating protrusions on ratchet-like structures in driving NIH3T3 cell migration. We identified the concept of efficient protrusion and an associated

direction index. Our analysis of the protrusion statistics facilitated the quantitative prediction of cell trajectories in all investigated conditions. We also varied the external cues by changing the adhesive patterns and topographical patterns. Our measurements for the motions are satisfactorily compared to a persistent random walk model. We show that the cell nucleus contributes to the strength of the trap, while cell protrusions guided by the adhesive gradients add a constant tunable bias to the direction of cell motion.

Persistent activation of signal transduction networks induces a novel mechanism of cell death.

M. Edwards¹, H. Cai², P. Devreotes²;

¹Cell Biology, Washington University School of Medicine, St. Louis, MO, ²Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

The directed migration of cells in response to chemical cues, known as chemotaxis, plays a critical role in normal physiology and disease pathogenesis. Knowledge of the molecular mechanism of chemotaxis is critical to our understanding of the process of metastasis and for developing new therapies to prevent it.

During chemotaxis ‘front’ proteins are recruited to extending pseudopods, which themselves are concentrated at the cell’s anterior. Conversely, ‘back’ proteins dissociate from nascent pseudopods. The Ras/TorC2 pathway has recently been shown to be important for chemotaxis in *Dictyostelium*. A similar conserved mTORC2 pathway has since been shown to play a role in neutrophil chemotaxis. The discovery of the importance of this pathway in chemotaxis challenges the conventional linear, PIP3-centric view of chemotaxis, in favor of a model involving a complex network of parallel pathways connected via feedback mechanisms. In an attempt to decipher the mechanism of chemotaxis we generated pairwise mutations activating front protein RasC, and inactivating back-protein PTEN. Here we report that this combination of RasC and PTEN perturbations trapped cells in a globally activated or ‘front-state’. Front-state “clamped” cells in *Dictyostelium* were extremely spread and flattened. Most surprising was the susceptibility of these altered cells to death by cytoplasmic fragmentation. Front state clamped cells displayed global elevations of front protein signaling at the cortex. Levels of actin-binding probe GFP LimE at the cortex of front-state cells were elevated, as they were at the peak of the chemotactic response at the tips of pseudopods in control cells. Activating Ras signaling whilst simultaneously inactivating PTEN signaling in mammalian cells led to cell spreading and cell death. These results suggest the mechanism of cell death observed in RasC/pten⁻ *dictyostelium* cells is conserved in mammalian cells.

P572**Board Number: B822****The direction of migration of T-lymphocytes under flow depends upon which adhesion receptors are engaged.**G.A. Dominguez¹, N.R. Anderson², D.A. Hammer^{1,2};¹Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, ²Department of Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA

T-lymphocyte migration is important for homing, cell trafficking, and immune surveillance. T-lymphocytes express lymphocyte function-associated antigen-1 (LFA-1) and very late antigen-4 (VLA-4), which bind to their cognate ligands, intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1). These adhesive interactions provide T-lymphocytes with the ability to withstand hemodynamic shear forces to facilitate adhesion and migration along the blood endothelium. This study investigated whether the identity of the receptor and the magnitude of its engagement affects the direction of T-lymphocyte migration under flow. Microcontact printed ICAM-1 and VCAM-1 PDMS surfaces allowed for control of the density, type of adhesion molecule, and blocking of non-specific adhesion. Using a laminar flow chamber, this study demonstrates that T-lymphocytes migrate either upstream or downstream dependent upon ligand type, ligand concentration, and shear rate. T-lymphocytes migrated upstream on ICAM-1 but downstream on VCAM-1 surfaces. This directed migration was also dependent on the type and concentration of ligand. At high shear stresses (8 dyne/cm²), T-lymphocytes favor upstream migration when any ICAM-1 is present, even in the presence of substantial VCAM-1. These results indicate that T-lymphocytes exhibit two different modes of motility depending on ligand composition and the shear rate.

P573**Board Number: B823****Mathematical modeling and data analysis strategies for tandem fluorescent protein timer microscopy screens.**J. Barry¹, A. Khmelinskii², E. Dona¹, B. Fischer³, D. Gilmour¹, M. Knop², W. Huber¹;¹EMBL, Heidelberg, Germany, ²ZMBH, Heidelberg, Germany, ³DKFZ, Heidelberg, Germany

Tandem fluorescent protein timers (tFTs) are optical probes that report on protein abundance and age in living cells. Each probe consists of a pair of fluorescent proteins that have different maturation kinetics. By comparing the intensities of fast- and slow-maturing fluorophores a quantitative measure of protein age can be attained; under steady-state assumptions a single ratiometric microscopy image is sufficient. The tFT approach presents many opportunities for multiple areas of biological research, including high-throughput microscopy and developmental biology. With these opportunities also come new challenges for data analysis. Here we present examples of data analysis methods used to analyse

high-throughput plate reader experiments of a proteome-wide library of yeast strains tagged with the protein timer, which are subject to different environments or genetic perturbations. We present a method for correcting for background autofluorescence that may skew ratiometric readouts for lowly abundant proteins, and also strategies for correcting for plate-to-plate variability that is technical in origin. As a second application, we demonstrate the efficacy of tFTs for quantifying receptor signaling activity, here in the case of the migrating posterior lateral line primordium in zebrafish. We use a mathematical model of time-dependent fluorophore maturation to characterize potential pitfalls for users of the timer, and show how it may be used to optimize experimental design, including the selection of the fluorophore pair in order to maximize the dynamic range of the readout for a given system.

A functional proteomic study identifies multiple novel regulators of epithelial cell-cell adhesion.

L.L. Gallegos¹, M.R. Ng², M.E. Sowa³, A. White¹, L. Selfors¹, I. Zervantonakis¹, S. Dhakal¹, P. Singh¹, J.W. Harper¹, J.S. Brugge¹;

¹Department of Cell Biology, Harvard Medical School, Boston, MA, ²Radiation Oncology, Massachusetts General Hospital, Boston, MA, ³Warp Drive Bio, LLC, Cambridge, MA

Although cell-cell adhesion is central to morphogenesis and maintenance of epithelial cell state, our understanding of the complex networks that regulate cell-cell adhesion is significantly less complete than that of cell-matrix adhesion. We previously identified a subset of 26 genes whose perturbation disrupts cell-cell adhesion as part of a large-scale siRNA screen for regulators of collective cell migration. In the current study, we undertook a proteomics approach to identify high-confidence protein interaction networks for the 26 potential cell-cell adhesion promoting proteins (CCAPPs) encoded by these genes. Specifically, we expressed tagged versions of the CCAPPs in MCF10A cells to serve as ‘baits’ in individual immunoprecipitation (IP)/mass spectrometry experiments, and then used a comparative proteomics analysis software suite (ComPASS) to assign confidence scores to the interacting proteins. The resulting networks (containing 432 high-confidence protein interactions) served as a ‘road-map’ linking novel CCAPPs to known adhesion proteins, connecting CCAPPs to each other, and identifying novel interactors for the canonical adherens junction proteins, α - and β -catenin. Specifically, 18 of the 26 CCAPPs co-precipitated with the α - and β -catenin adhesion complex or with other CCAPPs, and another 7 CCAPPs could be connected through interaction with one or more of the 28 shared interacting proteins (SIPs) amongst the baits within our networks. Novel SIPs for α - and/or β -catenin (DUSP23, ERBB2IP, NEK8, ARVCF, CDH4, PKP4, PLEKHA6) were further validated by immunofluorescence and co-IP studies, and the phosphatase DUSP23 was found to support cell-cell adhesion by promoting dephosphorylation of β -catenin at position Tyr 142 to enhance the interaction between α - and β -

catenin. An additional siRNA-based functional analysis of the 28 SIPs is underway to determine whether more of these proteins play a role in promoting cell-cell adhesion; preliminary data has pinpointed a role for one of the SIPs, PPP6C, in promoting strong cell-cell adhesion. Our study characterizes a network of interconnected, functionally validated cell-cell adhesion regulatory proteins as a resource for further investigations of this important process.

Remodeling of cell-cell junctions during cytokinesis.

T. Higashi¹, T.R. Arnold¹, R.E. Stephenson¹, A.L. Miller¹;

¹Department of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI

Cell-cell junctions are required for maintenance of mechanical integrity and barrier function in epithelial tissues. During cytokinesis, the dividing cell and its neighbors undergo major changes in shape and tension as the contractile ring pinches the cell in two. Junctional integrity and barrier function are thought to be preserved even during cell division. However, our understanding of how junctions are maintained and remodeled during cytokinesis in epithelial cells is lacking. In this study, we investigated the behaviors of three types of cell-cell junctions, tight junctions (TJs), adherens junctions (AJs), and tricellular tight junctions (tTJs), during cytokinesis in the *Xenopus* gastrula by immunofluorescence microscopy and live-imaging of fluorescently-tagged junction proteins. Using a small fluorescent tracer molecule, we demonstrated that the barrier function of TJs remained intact throughout cell division. We found that both TJs and AJs invaginated together with the cleavage furrow; this is in contrast to reports in the *Drosophila* epithelium indicating that AJs are locally disengaged at the division site. Notably, the invagination of AJs preceded that of TJs. Furthermore, we observed that two nascent tTJs were formed at the end of cytokinesis, one on each side of the midbody. LSR/angulin-1, a protein unique to tTJs, was recruited to the newly formed tTJ first and was quickly followed by a second tTJ component, tricellulin. Our data provide the first in-depth characterization of dynamic cell-cell junction remodeling during vertebrate cytokinesis and show for the first time how nascent tTJs are formed following cell division.

Critical roles for the apical extracellular matrix and EGF-Ras signaling in building, maintaining and remodeling tiny tubes in *C. elegans*.

J. Parry¹, J. Cohen¹, M.V. Sundaram¹;

¹Department of Genetics, University of Pennsylvania, Philadelphia, PA

Unicellular tubes are formed from single cells that create an internal lumen. Such tubes are found in the microvasculature of mammals and in simple tubular organs of invertebrates. We use the *C. elegans* renal-like excretory organ as a model system to study unicellular tube development. The excretory

organ is composed of three tandemly-connected unicellular tubes, the canal, duct, and pore, which form through de novo epithelialization coupled either to hollowing or wrapping modes of single-cell tubulogenesis. Through forward genetic screening, we found several families of apical transmembrane or secreted proteins (including leucine-rich repeat proteins, zona pellucida domain proteins and lipocalins) that are required for lumen integrity and junction maintenance. Our results point to a critical role for the apical extracellular matrix in maintaining the integrity of narrow bore tubes.

We also showed that EGF-Ras signaling plays multiple roles in building and remodeling the excretory organ; one important role is to permit G1 pore tube delamination. During normal development, the initial pore cell, G1, delaminates from the organ to become a neuroblast and is replaced by a new cell, G2. G1 delamination and G2 intercalation involve cytoskeletal remodeling, interconversion of autocellular and intercellular junctions and migration over a luminal matrix, followed by G1 junction loss. EGF-Ras signaling acts cell non-autonomously in the duct cell to permit G1 junction loss and delamination. In humans, aberrant EGF-Ras signaling promotes tumorigenesis and metastasis. Our results demonstrate that Ras signaling in cells that remain in an epithelium can create a microenvironment that is permissive for neighboring cells to detach.

Repositioning and restructuring of adherens junctions in response to mechanical tensions.

M. Weng¹, E. Wieschaus²;

¹Dept. of Molecular Biology, Princeton University, Princeton, NJ, ²Department of Molecular Biology, Princeton University/HHMI, Princeton, NJ

Although adherens junctions are traditionally thought to maintain tissue integrity by passively resisting disruptive forces, they have increasingly been recognized to actively respond to mechanical cues in cell culture systems. This study uses ventral mesodermal cells of gastrulating *Drosophila* embryos as an *in vivo* system to explore the role of mechanical force in re-positioning, remodeling and maintenance of adherens junctions. Using live imaging and quantitative image analysis we tracked individual junction clusters during gastrulation and found that they persist and move apically while being restructured to enhance intensity and density. Importantly the changes in intensity and position are temporally correlated with pulsed myosin activity both at the level of a whole tissue and at the resolution of individual junctional clusters. Consistent with the correlation study, loss of function analysis indicates myosin is required for the remodeling of adherens junctions. Genetic analyses suggest that tension generated by the apical myosin contraction temporarily protects adherens junctions from a Snail-dependent disassembly mechanism that ultimately occurs when the mesoderm has completed its invagination and begin an epithelial mesenchymal transition. Dual-color live imaging shows that changes of junctional clusters in response to tension precede that of the polarity protein Par3/Bazooka. Our results present *in vivo* evidence that adherens junctions are repositioned and restructured in response to mechanical force and polarity proteins follow the change. We also reveal an unexpected role of Snail

in disassembling adherens junctions at post-transcriptional level which can be suppressed by tension-dependent mechanism.

Compartmentalized 3D colocalization analysis – a method to quantify epithelial adherens junction assembly.

L.A. Cruz¹, P. Vedula¹, N. Gutierrez¹, R. Abramczyk¹, M. Ocegueda¹, R.J. Petrie², A.J. Rodriguez¹;

¹Federated Department of Biology, Rutgers University, Newark, NJ, ²NIDCR, NIH, Bethesda, MD

Epithelial adherens junctions are multi-protein complexes composed of the transmembrane adhesion molecule – E-cadherin, which in turn binds to the plaque/adaptor proteins – p120-catenin, β -catenin and a-catenin. This complex is further anchored to the actin cytoskeleton. It has been recently shown that for de novo assembly of adherens junctions, the localization and translation of β -actin mRNA to initial cell-cell contacts is required. In the current work we describe a Pearson's Correlation-based method to measure adherens junction assembly. We reasoned since the adherens junction complex is anchored to the actin cytoskeleton, there must be an increase in the spatial correlation of the adherens junction proteins (E-cadherin, p120-catenin, β -catenin, and a-catenin) and the actin cytoskeleton at the cell periphery during junction assembly. Using the calcium switch approach to initiate de novo junction assembly in MDCK cells, we found the indirect immunofluorescence signals detecting the adherens junction proteins and fluorescent Phalloidin signal detecting F-actin were indeed correlated at the cell periphery. In order to track junction assembly with respect to time, we hypothesized that the correlation of these signals in the cytoplasm of the cell would decrease as the junctions are assembled owing to recruitment of the components of the complex. Setting the lower bound of correlation to 0.1 and carrying out a log transformation of the ratio of correlation at the cell periphery to that in the cytoplasm yielded a metric – Peripheral Asymmetric Index (PAI) – which faithfully tracked assembly of adherens junctions across time. RhoA activation is required for the localization of β -actin mRNA which led us to investigate if RhoA signal at the cell periphery correlated temporally with adherens junction assembly. We show that using a RhoA FRET biosensor, RhoA activation at the cell periphery followed similar temporal scales as adherens junction assembly. We then applied this metric to adherens junction assembly with accumulation of active Src protein at the cell periphery. Since activation of Src at the periphery is required for the translation of β -actin mRNA and hence adherens junction assembly, we hypothesized that recruitment of active Src will spatially and temporally correlate with junction assembly. Indirect immunofluorescence for active Src revealed its accumulation at cell periphery as cells assembled adherens junctions. Upon further quantifying PAI for junction assembly we found cell periphery accumulation of active Src and adherens junction assembly were in fact correlated in both space and time. We thus show a new method based on spatial correlation of immunofluorescence signals to quantify adherens junction assembly across time.

P579**Board Number: B830** **α -Catenin coordinates epithelial migration and tissue morphogenesis through a dual-kinase/phosphorylation mechanism.**

The cadherin-catenin adhesion complex is a key contributor to epithelial tissue stability, mechanotransduction, and dynamic cell movements during animal development and tissue renewal. How cadherins and catenins are regulated to accomplish these functions is not fully understood. Here we examined the role of phosphorylation of α -catenin (α -cat), a multi-domain scaffolding protein that links the cadherin/ β -catenin complex to the actin cytoskeleton and is a mechano-sensor for the cadherin/catenin complex. Phospho-proteomic screens and our mass-spectrometry analysis identified several phosphorylation sites in a flexible linker located between the central M-region and the C-terminal actin-binding domain of mammalian α -E-cat and *Drosophila* α -cat. Our data show that this 'P-linker' is phosphorylated hierarchically by casein kinase (CK) 2 and 1 and comprises the main phosphorylated region in α -E-cat. Assessment of α -cat phosphorylation in *Drosophila* and mammalian cells indicate that the P-linker and its phosphorylation and dephosphorylation are required for normal cadherin-catenin complex function. Although P-linker mutations did not interfere with cadherin-catenin complex assembly and epithelial integrity in flies, fewer embryos reached adulthood indicating a required role during later developmental stages. In mammalian cells, phosphorylation within the P-linker is required for epithelial sheet integrity, coordinated migrations during scratch-wound repair, and mechano-sensing using Magnetic Twist Cytometry. Together, these data show that α -cat phosphorylation is required for strong intercellular adhesion and tissue morphogenesis, and suggest that dynamic cycles of phosphorylation and dephosphorylation are required for the mechano-sensing properties of α -cat.

P580**Board Number: B831****Tumor Necrosis Factor induces a biphasic change in claudin-2 expression in tubular epithelial cells: potential role in barrier functions and proliferation.**Y. Amoozadeh^{1,2}, Q. Dan^{1,2}, J. Xiao^{1,2}, F. Waheed^{1,2}, K. Szaszi^{1,2};¹Keenan Research Center for Biomedical Science, St Michael's Hosp, Toronto, ON, ²Department of Surgery, University of Toronto, Toronto, ON

Tubulointerstitial inflammation is a condition associated with acute and chronic kidney disease. It is triggered by harmful stimuli including ischemia-reperfusion, albuminuria, toxins and infectious agents. The inflammatory cytokine Tumor Necrosis Factor- α (TNF- α) is now recognized as a key mediator of kidney injury. We have previously shown that TNF- α induces cytoskeleton remodeling in tubular epithelial cells, and alters their permeability. To gain insight into the mechanisms of this latter effect, we used the proximal tubule cell line LLC-PK1 to explore changes in tight junction protein expression. We show that short-term (1-3h) TNF- α treatment induced an increase in the total and cell surface levels of the channel forming claudin-2. In contrast, long-term (>8h) TNF- α treatment induced a marked downregulation of claudin-2, which was accompanied by an increase in claudin-1, 4 and 7 expression. Interestingly, the early increase and the late decrease in claudin-2 expression differed both in the mechanisms and the signaling pathways involved. The late decrease involved changes in mRNA levels and promoter activity, suggesting reduced synthesis of claudin-2. In contrast, the early increase was independent of these, suggesting a decrease in protein degradation. As Epidermal Growth Factor (EGF) has been shown to reduce claudin-2 expression in tubular cells, and our previous results indicated that TNF- α transactivates the EGF receptor, we asked whether EGF receptor signaling might play a role in the effect of TNF- α on claudin-2. We found that the early increase but not the late decrease in claudin-2 expression required the EGF receptor and its downstream effectors ERK, Rho and Rho kinase. Next we asked whether TNF- α -induced changes in paracellular permeability and cell proliferation could be linked to altered claudin-2 expression. We measured Transepithelial Resistance (TER) using Electric Cell-substrate Impedance Sensing (ECIS). TNF- α exerted a biphasic effect on TER causing an initial decrease (corresponding to increased permeability) and late increase (corresponding to reduced permeability). In line with its role as a high permeability protein, claudin-2 silencing with an siRNA elevated TER, and mimicked the effect of long-term TNF- α treatment. Importantly, long-term TNF- α treatment did not induce further TER increase when claudin-2 was silenced. Finally, claudin-2 siRNA also prevented the proliferative effect of TNF- α . Taken together, our findings suggest that altered claudin-2 expression during inflammation not only impacts on barrier functions, but also changes proliferative responses of tubular cells. Claudin-2 expression could be a key factor affecting epithelial cell fate and tubular regeneration following injury.

P581**Board Number: B832****Characterization of RhoA-GTP flares in the *Xenopus laevis* epithelium.**R.E. Stephenson¹, T.R. Arnold¹, T. Higashi¹, A.L. Miller¹;¹Department of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI

Precise regulation of the small GTPase RhoA is important for the proper formation and maintenance of cell-cell junctions in epithelial cells. While active RhoA (RhoA-GTP) is known to rapidly and transiently accumulate during processes like cytokinesis and wound healing, the population of active RhoA at cell-cell junctions was previously thought to be relatively stable over time. Recent work from our lab has demonstrated that knockdown of the scaffolding protein Anillin in the epithelium of gastrula-stage *Xenopus laevis* embryos results in loss of cell-cell junction integrity, which is accompanied by acute, local accumulations, or flares, of RhoA-GTP at cell-cell junctions. Despite the dramatic nature of the RhoA-GTP flares, their cause and the consequence for the cell remain unclear. Here we show that perturbation of the RhoA regulator Guanine nucleotide Exchange Factor-H1 (GEF-H1) by injection an antisense morpholino or by overexpression of a dominant negative form of GEF-H1 results in similar RhoA-GTP flares. We examined tight junction behavior during RhoA-GTP flares using live imaging of mRFP-ZO-1, a fluorescently tagged tight junction plaque protein, and found that RhoA-GTP flares are preceded by discontinuities in mRFP-ZO-1. Following the flare, mRFP-ZO-1 signal becomes continuous again, suggesting that RhoA-GTP flares serve to repair junctions. RhoA-GTP flares are accompanied by protrusions of the plasma membrane and accumulations of filamentous actin in the protruding cell and its neighbor. We are currently working to characterize the molecular events surrounding these RhoA-GTP flares, which may give us insight into how junctions are maintained and repaired during dynamic processes like epithelial cell division and morphogenesis.

P582**Board Number: B833****Diurnal variations in matrix metalloproteinase expression and tight junction integrity in *Xenopus laevis* corneal epithelium.**A.F. Wiechmann¹, B.P. Ceresa², E.W. Howard¹;¹Department of Cell Biology, Univ Oklahoma Hlth Sci Ctr, Oklahoma City, OK, ²Pharmacology and Toxicology, University of Louisville School of Medicine, Louisville, KY

Introduction: The corneal epithelium (CE) provides a permeability barrier largely due to the presence of tight junctions between neighboring surface CE cells. As the surface CE cells mature, they must actively desquamate to maintain tissue homeostasis. Matrix metalloproteinases (MMPs) are expressed in the CE, and are known to target junctional proteins in other systems. The objective of this study was to investigate the potential temporal and spatial inverse relationship of MMP expression and tight junction integrity in the *Xenopus laevis* CE.

Methods: Corneas were obtained from adult *Xenopus laevis* frogs during the light or dark period of the day/night cycle and examined by double label confocal immunohistochemistry.

Results: Expression of MMP-2, tissue inhibitor of MMP-2 (TIMP-2) and membrane type 1-MMP (MT1-MMP) and the tight junction proteins occludin and claudin-4 were present in the CE. Occludin and claudin-4 expression was generally intact on the lateral membranes during the light period, but was frequently disrupted in small clusters of cells during the dark period. MMP-2 expression was often elevated in a mosaic pattern at night and associated with clusters of desquamating surface cells. The MMP-2 binding partners, TIMP-2 and MT1-MMP were also localized to surface corneal epithelial cells during both the light and dark phases, with TIMP-2 tending to be elevated during the daytime.

Conclusions: MMP-2 protein expression is elevated in a mosaic pattern in surface corneal epithelial cells during the nighttime in *Xenopus laevis*, and may play a role in homeostatic surface cell desquamation by disrupting intercellular junctional proteins.

Regulation of fibrotic signaling by desmosomal armadillo proteins in cardiac tissue.

A.D. Dubash¹, D. Patel¹;

¹Pathology, Northwestern University, Chicago, IL

The process of fibrosis, described as accumulation of myofibroblasts and excessive deposition of extracellular matrix components, is a key development in the progression of multiple different types of cardiac disease. Nevertheless, little is known about the molecular mechanisms which cause the onset of fibrosis in cardiac disease. Fibrosis is a significant component of arrhythmogenic cardiomyopathy (AC), a genetic disorder characterized by replacement of healthy cardiomyocytes (CMs) with fibrous tissue, leading to arrhythmia and in certain cases, sudden death. AC is often characterized as a “disease of the desmosome”, as mutations for all obligate desmosome proteins have been found in cases of AC, including the desmosome armadillo proteins Plakophilin-2 (PKP2) and Plakoglobin (PG). PKP2 and PG are multi-functional proteins involved in both mechanical stabilization of the cardiac area composita, as well as mediation of desmosome-related signaling pathways. We have determined that loss of PKP2 or PG in neonatal CMs causes an aberrant increase in gene expression of pro-fibrotic stimuli such as transforming growth factor beta 1 (TGF-beta1) and Interleukin-6 (IL-6). In addition, p38 MAPK, a known mediator of inflammatory fibrosis, is activated upon loss of PKP2/PG. We hypothesize that mutation or loss of PKP2 or PG cause the recruitment and activation of cardiac fibroblasts via pro-fibrotic TGF-beta and p38MAPK signaling, resulting in pathological fibrosis characteristic of AC. Indeed, conditioned media from PKP2-silenced CMs causes an increase in fibronectin gene expression by freshly isolated cardiac fibroblasts. Our future experiments will investigate whether inhibition of TGF-beta or p38MAPK signaling can alleviate fibrotic gene production. By highlighting a novel link between desmosome armadillo proteins and pro-fibrotic signaling in cardiac tissue, this study provides mechanistic insights into the pathogenesis

of AC, as well as advances our knowledge of potential therapeutic targets for combating fibrosis in multiple different types of heart disease or injury.

Regulation of epithelial morphogenesis by a tight junction (TJ)-apical complex.

S. Tsukita¹, T. Yano², H. Kanoh², A. Tamura¹;

¹Graduate School of Frontier Bioscience and Graduate School of Medicine, Osaka University, Osaka, Japan, ²Osaka University, Suita, Osaka, Japan

Epithelial cells adhere to each other by tight junctions (TJs) to form cell sheets, which is a critical step in epithelial morphogenesis. We recently discovered that a network of microtubules exists just below the apical membrane of the epithelial cell sheet. Because this apical microtubule network appears to be connected to TJs and associated with actin and keratin filaments, we defined the TJ and its associated membrane and apical structures as the "TJ-apical complex." The TJ-apical microtubules represent one of the layered cytoskeletal networks within the TJ-apical complex. Gel overlay assays of isolated TJ fractions on microtubules in the presence of taxol revealed four TJ-associated microtubule-binding proteins (TJ-MAPs): TJ-MAP1, TJ-MAP2 (cingulin), TJ-MAP3, and TJ-MAP4. A knockdown (KD) analysis for cingulin revealed that cingulin-KD partially disrupted the association between microtubules and TJs. More recently, we found a similar effect of knocking out TJ-MAP3. We further found that TJ-MAP3 critically influences the TJ-actin organization by regulating the phosphorylation of myosin, suggesting a functional link between the microtubules and the actomyosin ring at TJs. In addition, we found that TJ-MAP3 contributes to the apical constriction mediated by Rho/ROCK signaling and functionally regulated by microtubules.

Based on these findings, we propose the novel idea that the planar network of apical microtubules is linked to circumferential actin rings at the TJ-apical complexes. Future studies will explore the role of the TJ-apical complex in the general context of all cytoskeletons, including those based on microtubules, actin, and keratin filaments. We propose that the TJ-apical complex is critical for organizing the TJ and apical membrane systems, including the location and function of membrane proteins that play essential roles in epithelial cell sheet functions, and thus in the regulation of biological systems.

P585**Board Number: B836****Bidirectional crosstalk between retinal pigment epithelium (RPE) and endothelial cells regulates RPE tight junctions.**I. Benedicto¹, G. Lehmann-Mantaras¹, M. Ginsberg², D.J. Nolan², S. Rafii³, E. Rodriguez-Boulan⁴;¹Department of Ophthalmology, Weill Cornell Medical College, New York, NY, ²Angiocrine Biosciences, New York, NY, ³Department of Genetic Medicine, Weill Cornell Medical College, New York, NY,⁴Department of Ophthalmology, Dyson Vision Research Institute, Weill Medical College of Cornell University, New York, NY

In the eye, the retinal pigment epithelium (RPE) separates the neural retina from the fenestrated choroid endothelium. RPE tight junctions (TJs) are key for the correct maintenance of the outer blood-retinal barrier. Whereas it has been shown that RPE TJs are affected by factors secreted by the neural retina, it is not known whether RPE TJs are also regulated by choroid endothelial cells (ECs). Recent studies have demonstrated that ECs play key instructive roles in the differentiation and maintenance of parenchymal cells in several body organs. Thus, we studied whether ECs regulate RPE TJ function.

We performed co-culture experiments on Transwell inserts using human fetal RPE (hFRPE) and either human umbilical vein ECs (HUVECs) or mouse primary choroid ECs, both expressing the adenoviral protein E4. E4-expressing ECs are able to survive in the absence of endothelial factors or serum. hFRPE were seeded on top of the filter and ECs were seeded on the bottom chamber of the insert. The effect of ECs on hFRPE transepithelial electrical resistance (TER) was assessed at different time points during both de novo TJ formation and TJ recovery after disruption by TNF α treatment. As controls, several cell lines were used instead of ECs. Alternatively, co-cultures were carried out with ECs that had been previously exposed to polarized hFRPE conditioned medium. Expression levels of the TJ-associated proteins claudin-1, -2, -3, -9, -10b, -12, -15, -16, -19 and occludin were analyzed in hFRPE at different time points by real time PCR. The effect of the epidermal growth factor receptor (EGFR) inhibitor AG1478 on hFRPE TER and claudin levels was also evaluated.

hFRPE co-cultured with ECs presented a significantly increased TER both in the presence or absence of serum. This effect was not detected when other cell types were used instead of ECs. The increase in TER was faster when ECs had been previously primed with hFRPE. We also observed that the presence of ECs induced a specific decrease in hFRPE claudin-2 mRNA levels. EGFR inhibition significantly reduced EC-mediated changes in hFRPE TER and claudin-2 levels.

Our results suggest that choroid endothelium modulates RPE TJ function. In addition, the fact that the effect on TER was faster when ECs were previously primed with hFRPE suggests a bidirectional communication model in which ECs receive a signal from RPE which in turn enhances their ability to modulate RPE TJs. Our inhibition assays suggest that EGFR could participate in such crosstalk. This model fits well with the observed synchronized development of RPE and choroid endothelium.

P586**Board Number: B837****The scaffolding protein Anillin contributes to epithelial cell-cell junction protein dynamics.**T.R. Arnold¹, R.E. Stephenson¹, T. Higashi¹, A.L. Miller¹;¹Department of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI

Intact cell-cell junctions and proper cell division are critical for both tissue development and homeostasis, while failures in these processes contribute to disease. Anillin is a well-characterized scaffolding protein that recruits and stabilizes components of the contractile ring during cell division. We recently discovered that a population of Anillin localizes to epithelial cell-cell junctions and is important for their proper organization and function, though the mechanism is still unclear. We investigated the dynamics of junction proteins when Anillin was perturbed in the intact epithelium of *Xenopus laevis* gastrula-stage embryos. Using fluorescence recovery after photobleaching (FRAP), we found that the tight junction protein ZO-1 recovers faster when Anillin is knocked down and slower when Anillin is overexpressed, suggesting that Anillin stabilizes ZO-1 protein dynamics and may contribute to junction structure and function by regulating the dynamics junctional proteins. Further, we observed that knockdown of Anillin leads to local, acute discontinuities in ZO-1, followed by localized flares of active RhoA, and then re-establishment of ZO-1. This suggests that the increased frequency of active RhoA flares we previously reported in Anillin knock down embryos is likely a response to loss of junction integrity and may indicate that transient localized activation of RhoA serves to repair or remodel junctions. Additionally, Anillin is enriched at the cytokinetic contractile ring, a site of high junctional tension. Because changes in tension and Anillin levels can alter junction protein dynamics, we hypothesize that junction proteins near the furrow may exhibit altered FRAP. We are currently investigating whether cell-cell junction proteins in dividing cells have altered dynamics at the cleavage furrow relative to polar regions. Our studies provide evidence that Anillin contributes to normal junction protein dynamics and that local activation of RhoA precedes re-establishment of junctions when Anillin is knocked down.

P587**Board Number: B838****The organophosphate pesticide methamidophos disrupts de blood testis barrier by inducing the phosphorylation of the tight junction proteins occludin and ZO-2.**J. Ortega-Olvera¹, B. Chávez², B. Quintanilla-Vega³, L. Gonzalez-Mariscal⁴;¹Physiology, Biophysics and Neuroscience, CINVESTAV, Mexico City, Mexico, ²Infectomics and Molecular Pathogenesis, CINVESTAV, Mexico City, Mexico, ³Toxicology, CINVESTAV, Mexico City, Mexico,⁴CINVESTAV, Mexico City, Mexico

Methamidophos (MET) is an organophosphate pesticide widely used in agriculture in developing countries. MET has been associated with male reproductive alterations including a decrease in sperm quality and fertilization ability, as well as sperm DNA damage. The blood-testis barrier (BTB) plays a crucial role in spermatogenesis, since it seals the paracellular route between Sertoli cells and protects post meiotic germ cells from the immune system present in the systemic circulation. The BTB is constituted by several types of junctions including tight junctions (TJ) that may be targets of MET. Here we have explored if MET disrupts the BTB by targeting TJ. To explore this, CD1 mice were treated for 4 consecutive days with MET (5 mg/kg body weight) and sacrificed one day later. We observed that MET treatment induced the appearance of a leaky BTB by using a biotin tracer and that the paracellular space between Sertoli cells is widened as observed by transmission electron microscopy. These results prompted us to analyze the effect of MET on TJ proteins that form the BTB: claudin 11, occludin and ZO-2. In frozen testis sections from control and MET treated animals, claudin-11, occludin and ZO-2 circumscribed each Sertoli cell near the basement membrane. However, when seminiferous tubules were isolated we observed that the ZO-2 chicken fence pattern was disturbed by numerous breaks in the network. Since MET induces the addition of phosphate-adducts to proteins, we then explored if the treatment with MET increased the amount of phosphorylated proteins in the testis. We observed that this is the case, and further demonstrated by using a phosphate affinity SDS-PAGE that ZO-2 and occludin become hyperphosphorylated after MET treatment. In conclusion, our results indicate that MET induces the rupture of the BTB probable by increasing the phosphorylation of the TJ proteins ZO-2 and occludin.

Using microfluidic approaches to study gap junction intercellular communication.

B. Waxse^{1,2}, A.J. Hughes¹, M. Wojcik¹, D. Feliciano¹, S. van Engelenburg^{1,2}, J. Lippincott-Schwartz^{1,2};

¹Physiology Course at Marine Biological Laboratory, Woods Hole, MA, ²Cell Biology and Metabolism Program, NICHD, NIH, Bethesda, MD

Intercellular communication is vital for multicellular life. In addition to endocrine and paracrine signaling, gap junctions mediate direct metabolic and electrical coupling between cells. The disruption of these junctions brings drastic consequences. Without gap junction intercellular communication (GJIC), the contraction of the heart becomes uncoordinated, Schwann Cells fail to maintain peripheral nerves and macrophages no longer impart signals upon tissues, for example. With such diversity in roles, it follows that GJIC is tightly regulated both by gating and by downregulation from the plasma membrane.

To date, a variety of techniques have been used to assay GJIC. While valuable, some established assays (e.g., microinjection, patch clamping or gap-fluorescence recovery after photobleaching) are technically difficult or only measure single-cell effects – a laborious route for obtaining rigorous, well-powered conclusions. While the preloading assay offers an opportunity to easily study many cells, this technique requires proper gap junction formation and there is evidence for nonspecific calcein transfer between

cells. Lastly, the population-level scrape loading assay is confounded by the fact that the cells studied must be torn apart for loading.

When met with these difficulties at the 2014 MBL physiology course, we established a microfluidics assay to measure GJIC and the effects of two different drugs: carbenoxolone (purported to gate gap junctions) and phorbol 12-myristate 13-acetate (PMA) (a PKC activator thought to remove gap junctions from the plasma membrane). Using a t-shaped microchannel, we specifically loaded a fraction of cells with Calcein AM and measured its diffusion through gap junctions (obtaining a diffusion coefficient similar to that measured by other implementations of this technique). As expected, carbenoxolone-mediated gap junction gating led to a drastic inhibition of GJIC, while PMA-mediated gap junction downregulation led to an intermediate effect. Also while at the course, we met a TA who recently published how to adapt a commercially available CellASIC system to study GJIC by hydrodynamic focusing. Considering the reproducibility of our findings using microfluidic approaches and the ease of assessing the extent of GJIC over many cells at once, we argue that microfluidics serves as an ideal method to measure GJIC in living cells.

Development of an angulin binder and its tricellular tight junction-modulating activity.

D. Iguchi¹, S.M. Krug², T. Hayaishi¹, A. Watari¹, M. Nagahama³, M. Fromm², K. Yagi¹, M. Kondoh¹;
¹Graduate School of Pharmaceutical Sciences, Osaka University, Osaka, Japan, ²Institute of Clinical Physiology, Charité – Universitätsmedizin Berlin, Berlin, Germany, ³Graduate School of Pharmaceutical Sciences, Tokushima Bunri University, Tokushima, Japan

Epithelial cell sheets and tissues possess a tight junction (TJ) which almost perfectly seal the intercellular space against uptake of unwanted large solutes, but also of large drug molecules. The TJ between two adjacent cells is named bicellular TJ (bTJ) while that at the meeting point of three cells is the tricellular TJ (tTJ). One strategy for oral drug delivery is to modulate the TJ seal and by this to enhance the permeation of drugs. Several classes of TJ modulators have been identified so far including chelators, bile acids, fatty acids, and an enterotoxin fragment. All of them modulate the bTJ, but permeation enhancers targeting the tTJ have not been fully developed so far. The tTJ comprises a tetra-transmembrane protein, tricellulin, and lipolysis-stimulated lipoprotein receptor (also known as angulin-1), a transmembrane protein of the angulin family which consists of three members: angulin-1, -2, and -3. Angulin-1 is a receptor for *Clostridium perfringens* iota toxin (Ib). This suggests that a receptor-binding component of Ib might modulate the epithelial barrier by interaction with the tTJ. Here, we investigated whether angulin may be a target for modulation of the tTJ seal using the putative receptor-binding domain corresponding to amino acids 421–664 of Ib (Ib421–664). Ib421–664 bound to angulin-1-expressing cells without causing cytotoxicity and colocalized with angulin-1. Ib421–664 interacted with angulin-1 and -3, but not with angulin-2 and decreased epithelial integrity in angulin-1- or -3-expressing, but not in angulin-2-expressing cells. Thus, Ib421-664 appears to act as an angulin-1 and -3 binder. Two-

path impedance spectroscopy showed that Ib421-664 decreased the electrical resistance of the TJ pathway in the intestinal monolayer-forming cell line HT-29/B6. Ib421-664 enhanced the permeation of solutes across these cells and immuno-fluorescence data indicated that the angulin binder may allow solutes to pass through the tTJ. Solute absorption was enhanced by Ib421-664 also in rat jejunum. In conclusion, Ib421-664 is the first compound shown to bind to tTJs and to act in vitro and in vivo as an tTJ modulator providing a new mechanism for enhancing drug delivery.

Cadherins and Cell–Cell Interactions

Quantifying the time-dependent strengthening of cell-cell adhesion using a monolayer cell-binding assay.

P. Shrestha¹, P. Vo¹, P. Nguyen¹, A. Azodi-Kazeroony¹, P. Chataigne¹, S. Teo¹, W.A. Thomas¹;
¹Colby-Sawyer Coll, New London, NH

Cell adhesion affects the development and maintenance of tissue integrity. Quantification of cell adhesion is important in biomedical research because of the importance of cell adhesion in a number of cellular processes, including tumor metastasis. We have designed a novel monolayer cell-binding assay yielding data comparable to, but more rapid and less expensive than, the dual pipette assay previously used in this work. Unlabeled cells are centrifuged in 25mm wells at 5000 rpm to form a confluent monolayer. Fluorescently-labelled probe cells are then brought into contact with the monolayer for defined periods of time, at the end of which the monolayers are subjected to a gyratory shear. Adhesion is quantified in terms of the number of labeled fluorescent probe cells still bound after the gyratory shear. Here, we compare two methods to quantify bound probe cells: 1) a densitometric method using iVision software to count fluorescent pixels in multiple fields of view from monolayers photographed using fluorescence microscopy, and 2) a fluorimetric approach using a Synergy HT fluorimeter and KC4 software to quantify fluorescence solubilized directly from the test wells. Both methods showed strong correlations between the measured fluorescent signal and the actual number of fluorescent cells present ($R^2 = 0.99629$ and 0.9145 , respectively), and are thus comparably accurate. However, the fluorimetric method is faster and allows us to collect more data in less time.

P591**Board Number: B842****Cellular distribution and expression of cell adhesion molecules (CAMs) in pancreatic islet cells of obese and diabetic mice.**V.T. Falcão¹, R.B. Oliveira², D.A. Maschio², C.P. Carvalho³, C.B. Collares-Buzato²;¹College of Nursing, University of Pernambuco, Recife - PE, Brazil, ²Department of Biochemistry and Tissue Biology, University of Campinas (UNICAMP), Campinas - SP, Brazil, ³Department of Biosciences, Federal University of São Paulo (UNIFESP), Santos - SP, Brazil

Intercellular junctions (IJs) and their CAMs participate in important cellular processes such as cell adhesion, growth/death and signaling. In the endocrine pancreas, IJs play a role in regulating islet cytoarchitecture, insulin biosynthesis and secretion. In this work, we investigated the islet histology and cellular distribution and content of CAMs (i.e., E-, N-, VE-cadherins, ZO-1, α - and β -catenins) in the endocrine pancreas of C57BL/6/JUnib mice fed a high-fat (HF) diet (21% lipids, w/w) for a prolonged time period (8 months). After HF diet exposure, mice became obese and displayed marked metabolic disturbances indicative of establishment of type 2 diabetes mellitus (T2DM), such as marked peripheral insulin resistance and hyperglycemia (in fasted and fed states), and moderate postprandial hyperinsulinemia in comparison with the control mice (fed on regular diet containing 4.5% lipids, w/w). Isolated pancreatic islets of HF-fed mice showed a significant impairment of glucose-stimulated insulin secretion in comparison with control islets. Histology of the endocrine pancreas revealed no marked changes in islet morphology and cytoarchitecture between animal groups, although HF-fed mice showed a 57% increase in the relative islet volume (per total pancreas) in comparison with controls, indicative of beta-cell mass expansion. As shown by immunohistochemistry and Western Blot, E-, N-cadherins, ZO-1, and catenins, were expressed at the intercellular contact site of endocrine cells while VE-cadherin was restricted to the islet vascular compartment. A cellular redistribution of N- and E-cadherins and α -catenin (from the contact region to the cytoplasm) in pancreatic endocrine cells and a significant increase in VE-cadherin islet content were seen in diabetic mice as compared to controls. No significant differences in islet immunoreaction for the other CAMs were observed between the experimental groups. In conclusion, CAMs are expressed by endocrine and endothelial cells of pancreatic islets and, in particular, the distribution and content of N-, E- and VE-cadherins as well as α -catenin are significantly altered in islet cells of obese and diabetic mice, that may have a relevance in the T2DM pathogenesis. This research was approved by the Ethics Committee of Experimental Animal IB/UNICAMP (# 3122-1) and financially supported by FAPESP/Brazil (# 2010/50789-1).

P592**Board Number: B843****Regulation of Cadherin-Mediated Cell Adhesion and Lumen Formation by the Tyrosine Phosphatase, PTPN14.**P. Dimarco¹, A. Gladden¹;¹Univ Texas M.D. Anderson Cancer Ctr, Houston, TX

Cell-cell adhesion is mediated through dynamic regulation of cell junctions including adherens junctions (AJ). The AJ comprises the E-cadherin/ β -catenin protein complex that is assembled in the Golgi and transported to cell-cell contacts. Multiple regulatory mechanisms, including tyrosine phosphorylation, influence how the E-cadherin/ β -catenin complex promotes adhesion. The non-receptor tyrosine phosphatase, PTPN14, is a member of the Band 4.1, Ezrin, Radixin, Moesin (FERM) family of proteins that plays a critical role in linking membrane proteins to the cell cytoskeleton, thereby aiding in the communication of extracellular signals to the cytoskeleton. PTPN14 is mutated or deleted in several human cancers, including colorectal cancer, suggesting that PTPN14 activity may be involved in tumor development and/or progression. Previous work identified β -catenin as a PTPN14 substrate, but how PTPN14 regulates β -catenin-mediated adhesion or signaling is not known. The observations that PTPN14 is altered in cancer, coupled with its potential role in AJ regulation, led us to examine the function of PTPN14 in the non-malignant intestinal cell line, Caco-2BBE. We found that endogenous PTPN14 co-localizes with E-cadherin during initial cell junction formation and with both E-cadherin and the tight junction (TJ) protein ZO-1 in both mature cell contacts and in 3D cysts. PTPN14 knockdown (kdPTPN14) disrupted ZO-1 localization, actin cytoskeleton organization and formation of functional AJ and TJ. Furthermore, kdPTPN14 cells were unable to form lumens in 3D cultures. To determine how PTPN14 regulates cell contacts and lumen formation, we examined the levels of phosphorylation at β -catenin tyrosine residues known to be phosphorylated by upstream kinases. Notably, kdPTPN14 cells displayed increased levels of β -catenin Y654 phosphorylation, but no change in Y142 or Y489 phosphorylation. Src kinase phosphorylates β -catenin Y654, triggering disruption of the β -catenin/E-cadherin complex. Live-cell imaging revealed that whereas control cells displayed primarily intramembranous movement of E-cadherin at cell:cell contacts, PTPN14 depleted cells showed a significant increase in E-cadherin movement on and off of the membrane at cell:cell contacts. FRAP analysis confirmed increased E-cadherin movement and recovery after photobleaching, indicating that PTPN14 stabilizes E-cadherin complexes at cell:cell contacts. E-cadherin movement can be restored by expression of full-length PTPN14 or treatment with a Src inhibitor, thus providing evidence that PTPN14 activity opposes Src-mediated disruption of the AJ. These results suggest that PTPN14 promotes cell adhesion, tissue organization and could be utilized therapeutically to prevent tumor progression.

P593**Board Number: B844****Twist1-induced epithelial dissemination requires E-cadherin and is regulated by heterotypic cell-cell dynamics.**E. Shamir¹, E. Pappalardo², P. Tran³, J. Bader², A. Ewald¹;¹Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Department of Biomedical Engineering, Johns Hopkins University, Baltimore, MD, ³Radiation Oncology and Molecular Radiation Sciences, Johns Hopkins University School of Medicine, Baltimore, MD

Dissemination of epithelial cancer cells represents the first step in metastatic spread. One postulated mechanism for dissemination is activation of an epithelial to mesenchymal transition (EMT), in which repression of the cell adhesion gene E-cadherin (E-cad) is considered the driving molecular event. We sought to test the sufficiency of single gene perturbations to induce dissemination out of primary mouse mammary epithelium. Deletion of E-cad disrupted simple architecture and morphogenesis but, contrary to expectation, rarely resulted in dissemination. In contrast, expression of the EMT transcription factor Twist1 induced rapid dissemination of cytokeratin+ epithelial cells. A core concept in EMT is that cells lose epithelial characteristics, such as tight cell-cell adhesion, and acquire mesenchymal characteristics to invade as single cells. However, we found that Twist1 did not significantly regulate epithelial-specific genes, such as E-cad. Rather, Twist1 induced dramatic transcriptional changes in extracellular compartment and cell-matrix adhesion genes. Surprisingly, we observed Twist1+ disseminating cells with membrane-localized E-cad, and complete knockdown of E-cad strongly inhibited Twist1-induced single cell dissemination. Dissemination can therefore occur through an innately epithelial migratory program.

In clinical management of ductal carcinoma in situ, focal disruptions in the myoepithelium, the basal mammary epithelial layer, serve as a negative prognostic indicator. Interestingly, we found that constitutive Twist1 expression induced dissemination of both inner luminal and outer myoepithelial cells and abnormal ingression of myoepithelial cells, resulting in gaps in myoepithelial coverage at the basal surface. We next developed mouse models to restrict Twist1 to distinct mammary lineages. Twist1 expression in the myoepithelial compartment induced cell autonomous myoepithelial dissemination. In contrast, Twist1 expression in the luminal compartment resulted in almost no dissemination. Using fluorescent reporters to distinguish Twist1+ and Twist1- cells, we observed that normal myoepithelial cells appear to contain Twist1+ luminal cells protruding into the extracellular matrix. Myoepithelial cells display a similar response to invasive E-cad- luminal cell behavior. Taken together, our data supports the hypothesis that normal myoepithelial cells dynamically block luminal cell escape. We now seek to test the molecular basis of myoepithelial barrier function and have validated shRNAs to knock down myoepithelial-specific genes important for contractility, cell-cell adhesion, and the intermediate filament network. We expect that perturbation of myoepithelial function will enable E-cad- and Twist1+ luminal cell dissemination.

P594**Board Number: B845****Nanoscale organization of cadherin-mediated adhesion complexes formed on planar cadherin-coated surfaces.**C. Bertocchi¹, T. Sailov¹, M. Baird², R. Mege³, B. Ladoux^{3,4}, M.W. Davidson⁵, P. Kanchanawong^{1,6};¹MBI, National University of Singapore, Singapore, Singapore, ²Florida State University, Tallahassee, FL,³Institut Jacques Monod, Université Paris Diderot CNRS, Paris, France, ⁴Mechanobiology Institute,National University of Singapore, Singapore, Singapore, ⁵National High Magnetic Field Laboratory andDepartment of Biological Science, Florida State University, Tallahassee, FL, ⁶Department of Biomedical

Engineering, National University of Singapore, Singapore, Singapore

Cadherin-mediated junctions are of fundamental importance for multicellularity and tissue homeostasis. Although cadherins are part of a supramolecular complex that performs diverse functions such as mechanotransduction, signaling and dynamic regulation and linkages to the actin cytoskeleton, still much remains unknown about the ultrastructural basis of these functions. Although superresolution microscopy offers a potential avenue for dissecting the nanoscale organization within these complexes, the highly variable 3-D geometry of the native cell-cell junctions is sub-optimal for high resolution optics. Therefore, we employed a planarized substrate which presents uniformly oriented cadherin extracellular domains that mimic many attributes of true cell-cell junctions such as cadherins clustering, recruitment of canonical cadherin associated proteins, and importantly the connection to the actin cytoskeleton. To elucidate the nanoscale architecture underlying distinct cadherin-mediated complexes, we applied superresolution microscopy techniques to determine proteins position and orientation in C2C12 myoblast (N-cadherin) and MDCK cells (E-cadherin) cultured on respective cadherin biomimetic surfaces. We observed that distinct proteins within the cadherin-mediated complexes appear to be differentially partitioned along the vertical (z) axis at the nanoscale. Proteins that reside in close proximity to the cadherin cytoplasmic tails (N-cadherin: $z = 47.4 \pm 5.9\text{nm}$; E-cadherin: $z = 46.9 \pm 4.7\text{nm}$, relative to the substrate) include p120-catenin ($z = 47.9 \pm 8.3\text{nm}$ in C2C12; $45.0 \pm 4.3\text{nm}$ in MDCK) and α -catenin (n-terminal probe) ($z = 47.0 \pm 10.3\text{nm}$ in C2C12; $41.5 \pm 7.5\text{nm}$ in MDCK). The actin cytoskeleton is distinctly separated from the cadherin-associated partition by $\sim 30\text{nm}$, and is closely associated with actin-binding proteins such as α -actinin, eplin, VASP, and zyxin. Interestingly, vinculin was observed to span between these two vertical partitions, suggesting that it is oriented in a polarized manner, and likely in an open and active conformation. Similar hierarchies of nanoscale protein organization between the two different cell types suggest a commonality between the nature of the physical links between actin and E-/N-cadherin. However, we observed a greater extent of vertical stratification in N-cadherin-based complexes. In particular, vinculin appears to be highly extended, with at least $\sim 30\text{nm}$ contour length, consistent with the large and elongated morphology of the cadherin clusters in the more contractile myoblast cells. Our results suggest how cadherins and associated proteins are assembled at the nanoscale level on a planar format, which likely recapitulates how they are organized in native cell-cell contacts to interface with the actin cytoskeleton.

P595**Board Number: B846****Actin dynamics modulate mechanosensitive immobilization of E-cadherin at adherens junctions.**V. Viasnoff^{1,2}, W. Engl¹, J. Thiery^{3,4}, X. Gao¹;¹MBI/DBS, Mechanobiology Institute, Singapore, Singapore, ²UMI3639, CNRS, Singapore, Singapore,³Biochemistry, NUS, Singapore, Singapore, ⁴IMCB, Astar, Singapore, Singapore

Mechanical stress is increasingly being shown to be a potent modulator of cell–cell junctional morphologies in developmental and homeostatic processes. Intercellular force sensing is thus expected to be an important regulator of cell signalling and tissue integrity. In particular, the interplay between myosin contractility, actin dynamics and E-cadherin recruitment largely remains to be uncovered. We devised a suspended cell doublet assay to quantitatively assess the correlation between myosin II activity and local E-cadherin recruitment. The single junction of the doublet exhibited a stereotypical morphology, with E-cadherin accumulating into clusters of varied concentrations at the rim of the circular contact. This local recruitment into clusters derived from the sequestration of E-cadherin through a myosin-II-driven modulation of actin turnover. We also show the similarities between E-cadherin recruitment induced by internal contractions or external mechanical stimuli. We exemplify how the regulation of actin dynamics provides a mechanism for the mechanosensitive response of cell contacts.

Cell-cell and cell-matrix adhesions transduce mechanical signals from the extracellular environment to regulate fundamental cellular processes. While it is well established that cell-matrix adhesions stimulate cell cycling, the effect of cadherin-based cell-cell adhesion on proliferation is not as well understood. We now demonstrate that matrix stiffness controls the crosstalk between cell-matrix and cell-cell adhesion complexes by promoting expression of N-cadherin through a FAK-Cas-Rac signaling pathway. In vivo mouse studies reveal a strong upregulation of N-cadherin in injured arteries that have undergone tissue

stiffening. Complementary in vitro studies examining vascular smooth muscle cells (VSMCs) cultured on polyacrylamide hydrogels matched to the elastic moduli of healthy and injured arteries demonstrate that N-cadherin protein expression increases with stiffness, and that this effect requires stiffness-regulated activation of FAK which in turn selectively activates Cas and ultimately Rac. To determine the functional importance of stiffness-induced expression of N-cadherin, we examined the consequence of N-cadherin engagement on cell proliferation. Using micropatterned islands to control cell shape and cell-cell contact, we show that N-cadherin-mediated contact overrides the spreading requirement for VSMC cycling in vitro. Conditional knockout of N-cadherin in mouse VSMCs also demonstrates that N-cadherin is essential for proliferation after arterial injury. Furthermore, in vivo deletion of FAK in VSMCs phenocopies the effect of N-cadherin deletion on cell proliferation in response to injury. Therefore, we conclude that N-cadherin is an essential downstream effector of FAK during stiffness-induced cell cycling in vivo. Overall, our studies demonstrate that matrix stiffness is an important regulator of N-cadherin expression and that, in turn, N-cadherin-dependent signaling is essential for stiffness and FAK-dependent proliferation.

A positive feed-back loop between N-cadherin and FGFR regulates cell-cell cohesion and cell migration.

T. Nguyen¹, L. Duchesne², R. Mege³;

¹Institut Jacques Monod, University Paris Diderot CNRS, Paris, France, ²Institut de génétique et développement de Rennes, CNRS, Rennes, France, ³Institut Jacques Monod, Université Paris Diderot CNRS, Paris, France

In addition to its known function in adhesion, N-cadherin initiates signal transduction by interacting with several signaling proteins. A functional interaction between Ncad and Fibroblast Growth Factor Receptor (FGFR) during tumor cell migration and neurite outgrowth has been reported. How this interaction occurs, how the signal is transduced and what are the consequences for the cell remain open questions. We show that FGFR1 expression reduces the migration of Ncad expressing cells on Ncad-Fc and promotes their collective migration on fibronectin. Both proteins are co-recruited at cell-cell contacts supporting a crosstalk between Ncad and FGFR signaling in regulating cell adhesion and migration. Biosensor and co-immuno-precipitation analyses revealed an interaction between Ncad and FGFR ectodomains. Analysis by FRAP of the mobility of FGFR and Ncad at cell-cell contacts shows that the dynamics of FGFR closely follows that of Ncad when they are co-expressed. The appearance of an immobile fraction of FGFR at cell-cell contacts is specific of Ncad and was not observed in FGFR/E-cad expressing cells. In turn the expression of FGFR increases the immobile fraction of Ncad and cell-cell contacts strength. These effects were blocked by inhibitors of the catalytic activity of the receptor, suggesting that Ncad recruits FGFR at cell-cell contact, the activity of which strengthens Ncad adhesions by stabilizing junctional cadherins. Cell surface biotinylation followed by cell fractionation and western blot analysis shows that FGFR stabilizes Ncad at the cell membrane by decreasing its internalization.

FGFR expression also increases the recruitment and the level of phosphorylated p120. As p120 is a well-known regulator of cadherin trafficking as well as a substrate of Src, a kinase involved in FGFR signaling, we suggest that the increased phosphorylation of p120 is a consequence of the mobilization of Src by FGFR. Accordingly, the inhibition of Src decreases the phosphorylation of p120 and its recruitment at the plasma membrane. This leads to an increase of the mobile fraction of junctional Ncad as well as of cell migration on Ncad-Fc. Based on these findings we propose a positive feed-back loop between Ncad and FGFR1 at adhesion sites controlling cell migration. FGFR recruitment by Ncad adhesions is activated then activates Src. Src phosphorylates p120 which stabilizes Ncad at the cell-cell contacts by blocking its endocytosis. This stabilization strengthens cell-cell interactions, limiting cell migration on Ncad substrates and promoting collective cell migration on fibronectin. Ongoing experiments aim at understanding the link between this regulatory loop and the mechanocoupling of cadherins to the actomyosin network instrumental in cell migration.

How P-cadherin induces collective cell migration? Analysis of mechanical forces and their regulation by Rho GTPases.

C. Gauthier-Rouviere¹, C. Plutoni¹, E. Bazellières², F. Comunale¹, S. Bodin¹, D. Planchon¹, X. Trépat²;
¹CNRS-CRBM, Montpellier, France, ²IBEC, Barcelona, Spain

Collective cell movement is relevant for many processes in morphogenesis, tissue repair, and cancer invasion and metastasis. Both mechanical and chemical cues have to be integrated at the cellular level to allow collective behaviors. Physical interactions in multicellular populations are guided by adhesion between neighboring cells and between cells and the extracellular matrix. Cell-cell adhesion molecules, and in particular cadherins, are important for collective cell migration *in vitro* and *in vivo* and are critical for coordinating cell movement and force transmission. However, the precise mechanistic pathways through which cadherins contribute to CCM remain to be examined. We analyzed the impact of P-cadherin expression, a protein associated with tumor invasion and metastasis formation, on the migratory behavior of normal mesenchymal cells. We expressed P-cadherin in mouse C2C12 myoblasts and analyzed their migration using a “wound-healing like assay” in which migration is analyzed after removal of a physical barrier. We showed that P-cadherin expression increased the speed, polarity, persistence and directionality of migration toward the free space of both cells at the multicellular leading row and cells into the multicellular layer. We concluded that P-cadherin expression induces collective cell migration. Using traction force and monolayer stress microscopy, we demonstrated that P-cadherin expression i) increases the traction forces anisotropy at the leading edge and ii) increases inter-cellular stresses and force transmission across the cell sheet. To better understand how these mechanical signals induce collective cell migration, we studied the spatio-temporal activity of Rho GTPase. We showed that P-cadherin expression activates Rac1 and Cdc42 at cell-cell contact sites and at the leading edge of the migrating multicellular layer. The knockdown of Rac1 and Cdc42 impacted both on intercellular stresses and traction forces generation demonstrating that P-cadherin-dependent

induction of collective cell migration requires Rac1 and Cdc42 activation. In conclusion, our analysis, combining a detailed measurement of the parameters of cell migration with physical measure of the intercellular stresses and traction forces, allowed to provide evidences for a mechanical role of P-cadherin during collective cell migration.

Forced-dimerization and membrane targeting of α -catenin impacts epithelial sheet migration.

M.N. Novak¹, D. Escobar¹, C. Gottardi^{2,3};

¹Driskill Graduate Program, Northwestern University, Chicago, IL, ²Department of Medicine, Northwestern University, Chicago, IL, ³Department of Cell and Molecular Biology, Northwestern University, Chicago, IL

Intercellular adhesion is mediated by transmembrane cadherin receptors and their associated catenins, which together integrate the recognition of an identical molecule on a neighboring cell with their coupling to the actomyosin cytoskeleton. While forced oligomerization of a cadherin lacking the catenin-binding region is known to be sufficient to enhance adhesion to recombinant cadherin ectodomains in a flow-based assay (Yap et al., 1997), the consequences of forced lateral dimerization or higher order clustering of the full cadherin/catenin complex for F-actin recruitment, junction morphology, adhesion and collective cell migrations is not known. Towards this end, we have used the iDimerize system to force α -catenin (α -cat) interactions in the context of full-length (FL) α -cat, which exists in both cadherin/ β -catenin-associated and -free forms, as well as a truncated α -cat that cannot bind β -catenin using the α -cat negative R2/7 variant of the DLD1 colon carcinoma cell line. We find that forced lateral dimerization of FL- α -cat within the cadherin complex enhances actin recruitment to the plasma membrane and increases rate of epithelial sheet migration post-wounding, while decreasing the persistence and connectivity of individual cells within the wound front. Remarkably, targeting FL α -cat to the membrane with a myristoylation sequence fails to enhance the rate of sheet migration and cell persistence despite evidence that its forced oligomerization enhances detergent insolubility and intermediate connectivity between adjacent cells. These data suggest that mechanisms that control lateral dimerization and higher order clustering of the cadherin/catenin complex may differentially contribute to epithelial sheet migrations. (Supported by NSF to MNN and NIGMS to CJG).

P600**Board Number: B851****Loss of the cardiac cell adhesion protein alpha-T-catenin increases sensitivity to toluene-diisocyanate-induced asthma.**S. Folmsbee¹, C. Gottardi^{2,3};¹Medicine - Pulmonary, Northwestern University, Chicago, IL, ²Department of Medicine, Northwestern University, Chicago, IL, ³Department of Cell and Molecular Biology, Northwestern University, Chicago, IL

α -T-catenin (α -T-cat) is an essential mediator of cell-cell adhesion through linking the β -catenin/cadherin complex to the cytoskeleton, and α -T-cat is almost exclusively described in cardiac muscle cells. It plays an important role in maintaining cardiomyocyte hybrid junctions, which are composed of desmosomes, cadherin junctions, and gap junctions. Surprisingly, a genome-wide association study (GWAS) identified single nucleotide polymorphisms (SNPs) in α -T-cat that correlated with the incidence and severity of toluene diisocyanate (TDI) occupational asthma, which is a subtype caused by exposure to environmental irritants in the workplace. Furthermore, another GWAS has identified SNPs in α -T-cat that correlated with changes to lung function in a healthy pediatric cohort. Despite these strong clinical data, a mechanism by which a dysfunction in the cell junctions of cardiomyocytes could contribute to changes to lung function and TDI-asthma has been unclear. We have found, however, that α -T-cat is indeed expressed in lung within the cardiomyocyte sheath of pulmonary veins (PV). How PV and cardiac dysfunction might underlie asthma is not known, but α -T-cat knockout (KO) mice manifest enlarged hearts with disrupted junctions and decreased contractility. To examine changes in lung physiology due to α -T-cat, we mechanically ventilated α -T-cat KO mice. There was no difference in resistance, compliance, or elasticity in the KO mice when compared to wild-type (WT), but KO mice had a significantly increased pressure-volume curve area, which suggests loss of α -T-cat may confer a mild obstructive phenotype. To test α -T-cat's role in TDI-asthma, we used a murine model of TDI-asthma with intranasal sensitization and nebulized challenge. From this, TDI-exposed α -T-cat KO mice show increased airway hyperresponsiveness to methacholine by plethysmography when compared to WT mice. Interestingly, bronchoalveolar lavage revealed only a mild macrophage-dominant inflammation that was not significantly different between WT and KO mice. Further analysis of histological sections by H&E revealed no difference between WT and KO mice in airway inflammation. Based on these data, we suspect α -T-cat dysfunction may contribute to asthma through a mechanism independent of inflammation, specifically decreased cardiac cell electrical coordination that leads to decreased contractility and increased airway edema. This process may occur because α -T-cat connects hybrid junctions through its binding to the desmosomal protein plakophilin-2 (PKP2), but the cellular function of this interaction is unknown. In future studies, we will examine the role of PKP2 binding in junction formation and gap junction coupling in cardiac cells in vitro.

P601**Board Number: B852****Force-dependent binding of vinculin to α -catenin constitutes the core mechanosensing machinery of cadherin adhesions.**R. Seddiki¹, B.R. Sarangi², G. Peyret², E. N'Guyen³, R. Mege², B. Ladoux^{2,3};¹Institut Jacques Monod, University Paris Diderot CNRS, Paris, France, ²Institut Jacques Monod, Université Paris Diderot CNRS, Paris, France, ³Mechanobiology Institute, National University of Singapore, Singapore, Singapore

Tissue-scale mechanics is important in morphogenesis, homeostasis and wound healing. Cells exert mechanical force on each other at sites of cell-cell adhesion, typically through cadherins. We demonstrated previously that cadherin adhesions transmit and adapt to mechanical stress. Here we aim at understanding how mechanical stress regulates the formation and strengthening of cell-cell contacts and at identifying the molecular mechanosensor involved. We focus here on the role of α -catenin which links cadherins to the acto-myosin network. We recently demonstrated that α -catenin reversibly unfolds upon physiologically-relevant forces allowing the binding of another actin binding protein, vinculin (Yao et al, Nature Communication, 2014), suggesting that the tension-dependent binding of vinculin to α -catenin is essential for tension-dependent cell-cell contact strengthening. By plating epithelial MDCK cells on micro-patterned, fibronectin-coated, substrates of controlled rigidities, we first showed that the stability of E-cadherin and α -catenin at cell-cell contacts, as analyzed by FRAP, as well as the extent of recruitment of vinculin and actin increases with stiffness. We then generated GFP-tagged mutated α -catenin constructs: one bearing a point mutation in the vinculin binding α -helix (L344P) and the other deleted of the MI and MII domains masking the vinculin binding domain (Δ mod), not able to bind and constitutively binding vinculin, respectively. Both constructs expressed in α -catenin-depleted MDCK cells restored the formation of E-cadherin-mediated cell-cell contacts, although L344P did not allow vinculin recruitment. We further show that the binding of vinculin regulates the stiffness-dependent stabilization of α -catenin at cell-cell contacts. The analysis of cell-cell cohesion dynamics, by Particle Imaging Velocimetry, and force transmission, by micro-force sensor array, of mutants and wt α -catenin expressing cells plated on confined fibronectin-coated substrates revealed that cell-cell contact stability, cell-to-cell mechanical coupling and collective movement correlation length increase from L344P to wt and Δ mod, i.e. with the ability of α -catenin to bind vinculin. Thus the interaction between α -catenin and vinculin is crucial for cells to develop stable cell-cell contacts and long-range interactions as well as coordinated motions. The fact that the association between the two proteins, manipulated here by mutagenesis, has a direct incidence on adhesion complex stability and complex collective cell behavior put this interaction at the center of the cadherin mechanosensing machinery. Further studies will allow to decipher how this interaction stabilizes α -catenin and the recruitment of the acto-myosin network in force-dependent manner.

P602**Board Number: B853****Alpha-T-catenin is constitutively-active actin-binding protein that couples the cadherin complex to the actin cytoskeleton.**A.V. Kwiatkowski¹, E. Wickline¹, I. Dale¹, C. Merkel¹;¹Cell Biology, Univ Pittsburgh Sch Med, Pittsburgh, PA

The core component of the adherens junction, the cadherin-catenin complex, organizes the actin cytoskeleton to regulate cell-cell adhesion and tissue organization in metazoans. The primary link between the cadherin-catenin complex and actin is α -catenin, a multifunctional actin-binding protein that regulates cell adhesion, movement and signaling. Mammals possess three α -catenins – α E(Epithelial), α N(Neural) and α T(Testes)-catenin. In contrast to the widely studied and well-defined mammalian α E-catenin, little is known about the molecular properties of α T-catenin, a protein unique to amniotes and expressed predominantly in cardiomyocytes where it localizes to cell-cell junctions. Notably, mutations in α T-catenin have been linked to arrhythmogenic right ventricular cardiomyopathy (ARVC). However, it is not clear how these mutations affect the biochemical properties of α T-catenin or impact α T-catenin functions in cardiomyocyte adhesion. We hypothesized that α T-catenin is specialized to meet the demands of cardiomyocyte adhesion. To test this, we analyzed the molecular properties of mouse α T-catenin and found that it has key functional differences from mouse α E-catenin. Size exclusion chromatography and native PAGE revealed that α T-catenin is primarily a monomer in solution, unlike α E- and α N-catenin that can readily form homodimers. α T-catenin monomer bound to filamentous actin with K_d of 0.2 μ M in cosedimentation assays, roughly twice as strong as α E-catenin homodimer (0.5 μ M). The β -catenin/ α T-catenin heterocomplex bound to F-actin with a K_d of 0.7 μ M. Addition of β -catenin lowers the affinity of α T-catenin for F-actin only slightly, unlike the dramatic decrease in F-actin binding observed with the β -catenin/ α E-catenin complex (>10 μ M). Finally, we examined how a mutation in α T-catenin linked to ARVC – V94D – affected protein function. Strikingly, the α T-catenin V94D mutant protein eluted as a homodimer in size exclusion chromatography and failed to bind β -catenin in pulldown assays. Thus, the V94D mutation creates an α T-catenin homodimer that cannot bind β -catenin, and we predict this mutation impairs α T-catenin function in cardiomyocytes. Our data demonstrate that α T-catenin is a constitutively-active actin-binding protein that can functionally couple the cadherin-catenin complex to F-actin, properties that make it unique from mammalian α E-catenin. These studies begin to define the molecular mechanisms underlying α T-catenin function in cell-cell adhesion and how disruptions in α T-catenin properties can lead to cardiomyopathies.

P603**Board Number: B854****Arp2/3 mediated membrane activity induces membrane fusion at self-contacts.**G. Sumida¹, S. Yamada¹;¹Biomedical Engineering, Univ California-Davis, Davis, CA

Actin assembly is required for membrane activities that drive cell adhesion and migration. The Arp2/3 complex, a potent actin nucleator, binds to the side of actin filaments and recruits additional actin monomers to generate a new branching actin filament. While Arp2/3 complex-mediated actin polymerization plays a critical role in membrane dynamics at the leading edge of migrating cells, the roles of the Arp2/3 complex is not limited to cell adhesion and migration. Interestingly, recent studies implicate the roles of actin dynamics in cell-to-cell fusion. Using micron-sized obstacles to induce the formation of self-contacts in epithelial cells, we showed that the efficiency of such self-adhesion depends on E-cadherin, a calcium dependent cell-cell adhesion molecule, but is distinct from cell-to-cell adhesion in that self-contacts are eliminated by membrane fusion. At self-contacts, while the concentration of E-cadherin diminished, the intensity of GFP-tagged Arp3 rapidly fluctuated, then decreased and stabilized after membrane fusion. Furthermore, the Arp2/3 complex inhibitor prevented Arp3 from localizing near self-contacts and reduced self-contact induced membrane fusion. We identified Rac1 as a potential upstream regulator of the Arp2/3 complex in membrane fusion, as both dominant-negative Rac1 and a Rac1-specific inhibitor decreased membrane fusion at self-contacts. Taken together, these data suggest that the Arp2/3 complex induced actin polymerization likely brings two opposing membranes into close apposition by excluding E-cadherin, thus promoting membrane fusion at self-contacts. Our analysis extends the roles of actin dynamics in self-contact induced membrane fusion, and provides new insights into the elimination of self-junctions during phagocytosis or the formation of seamless, single-cell capillaries.

P604**Board Number: B855****Dual role of Src in regulation of endothelial barrier.**J.E. Brinks Klomp¹, M. Patel¹, A.V. Karginov¹;¹Pharmacology, University of Illinois - Chicago, Chicago, IL

Adherens junctions (AJs) mediate cell-cell interactions, crucial for regulating endothelial cell permeability. The role of Src tyrosine kinase in the regulation of AJs is controversial. It can stimulate AJ disassembly, but its activity is required for AJ formation, suggesting a dual function of Src in regulation of endothelial barrier. We hypothesized that the specific effect of Src on AJ depends on the duration and the level of kinase activity. To test this we employed a recently developed technology for engineered activation of Src that provides specificity and tight temporal control of kinase activity in living cells. Our studies demonstrate that Src activation causes a distinct biphasic temporal effect on endothelial permeability. Initially Src induction leads to strengthening of endothelial barrier and then later increases

barrier permeability. This suggests that sustained elevated Src activity increase endothelial permeability, whereas transient activation of Src promotes barrier function. To gain insight into the mechanism of these effects we analyzed how Src activation affects phosphorylation and interactions of AJ proteins (VE-cadherin, β -catenin and p120-catenin), and AJ morphology. Src activation was sufficient to induce phosphorylation of VE-cadherin at the early time points, but it did not disrupt VE-cadherin association with catenins. Following Src activation VE-cadherin initially stayed in the cell-cell junctions, but underwent morphological rearrangement. Only at the later time points it was internalized to the perinuclear region. Src activation also altered the arrangement of F-actin. F-actin initially formed actin foci and was enriched within lamellipodia following Src activation. However, at later times F-actin became arranged in centripetal actin bundles at the edge of the cell. Interestingly, the morphological changes in AJs, VE-cadherin re-localization and F-actin reorganization temporally correlated with Src-induced biphasic changes in endothelial permeability. Our studies also show that the Src-mediated changes associate with an increase in Rac1 GTPase activation, suggesting that Rac1 activation is possibly the driving force for the temporal changes in VE-cadherin localization and F-actin arrangement which in turn alter endothelial cell permeability. Currently, we are expanding the inducible kinase system to other SFKs and analyzing their role in regulation of endothelial permeability.

dGirdin supports cell-cell adhesion and maintains epithelial tissue integrity.

E. Houssin¹, U. Tepass², P. Laprise¹;

¹BMBMP, Centre de Recherche sur le Cancer de l'Université Laval - CRCHU de Québec, Québec, QC, ²Cell and Systems Biology, University of Toronto, Toronto, ON

Introduction: The human Girdin protein is overexpressed in various cancers, and promotes cell migration and invasion. This suggests that Girdin contributes to tumor progression. Recently, it was shown that Girdin directly interacts with Par-3. This interaction is essential for cell polarization associated with directed cell migration. Par-3 and its Drosophila ortholog Bazooka (Baz) are also known for their role in the establishment and maintenance of epithelial cell polarity and adherens junction formation. Epithelial polarity, which is characterized by the asymmetric distribution of many cellular constituents, is necessary for epithelial tissue function and homeostasis. Indeed, loss of several epithelial polarity regulators leads to epithelial to mesenchymal transition (EMT).

Hypothesis: We hypothesized that Girdin plays a role in epithelial polarity and/or cell-cell adhesion, as reported for its binding partner Par-3. In order to test this premise *in vivo*, we generated null alleles of *dgirdin* (*dgir*), which encodes the Drosophila ortholog of Girdin, and established specific anti-dGir antibodies.

Results: First, we demonstrated that dGir is mainly expressed during embryogenesis. In embryonic epithelial cells, it is predominantly associated with the plasma membrane and enriched at adherens junctions. Besides, we found that phosphorylation of dGir increases its association with the

cytoskeleton. *dgir* mutant embryos show dorsal closure failure caused by impaired collective cell migration. Thus, dGir is important for cell motility, as reported for its mammalian counterpart. We also observed that some cells detach from the ectoderm in the absence of dGir. This individualization of epithelial cells is sometimes accompanied by an opening of the ventral midline, suggesting that loss of dGir weakens cell-cell adhesion. Consistent with this phenotype, the association between adherens junction components, including Armadillo (β -catenin) and DE-Cadherin, and the cytoskeleton decreases in *dgir* mutant animals. These results suggest that dGir participates in junction stability by favouring attachment to the F-Actin network. Finally, we noticed the presence of ectopic epithelial cell cysts in *dgir* mutant embryos. These cysts originate from ectopic invagination of ectodermal cells. Cyst cells show expansion of the apical membrane, indicating polarity defects.

Conclusion: Together, our data identify dGir as a novel regulator of epithelial cell polarity and cell-cell adhesion. These results thus reveal unsuspected roles for Girdin related proteins. Comprehensive analysis of Girdin/dGir function is essential to evaluate whether it is an appropriate target to treat cancer.

ARF6 activation in response to Wnt stimulation leads to increased endocytosis and mitotic spindle defects in epithelial cells.

J. Clancy¹, C. Tricarico², S. Jayman², C. D'Souza-Schorey¹;

¹Biological Sciences, University of Notre Dame, Notre Dame, IN, ²University of Notre Dame, Notre Dame, IN

Regulation of surface proteins, from growth factor receptors to cell adhesion components, is critical to the development and maintenance of epithelial tissues. ADP-ribosylation factor 6 (ARF6) is a member of the Ras-related GTPases with well-documented roles in controlling endocytosis of cell surface components. For example, stimulation of epithelial cells with hepatocyte growth factor leads to the activation of ARF6 and subsequent internalization of both c-Met (the HGF receptor) and E-cadherin. Here we demonstrate that ARF6 activation during canonical Wnt signaling leads to the intracellular accumulation of β -catenin, c-Met and E-cadherin in endosomal compartments along with robust activation of the extracellular signal related kinase (ERK). Disassembly and endocytosis of adherens junctions is dependent on Wnt induced ERK activation, as treatment with the MEK inhibitor PD98059 blocks the internalization of E-cadherin while having no effect on the accumulation of internal pools of c-Met. These findings suggest that Wnt-induced endocytosis of c-Met and E-cadherin likely occurs via distinct pathways. Wnt stimulation also leads to a defect in mitotic spindle orientation with cells dividing in a manner that leaves one daughter cell growing out of the epithelial monolayer. Misorientation of the mitotic spindle appears to be independent of ERK activation and E-cadherin endocytosis. Thus, canonical Wnt signaling can effect multiple cellular changes which have profound impact on epithelial architecture.

P607**Board Number: B858****Functional E-cadherin is required for translation-dependent beta-actin cytoskeleton remodeling at epithelial cell-cell contact sites.**L.A. Cruz¹, A.J. Rodriguez¹;¹Federated Department of Biology, Rutgers University, Newark, NJ

Epithelial adherens junction complexes are composed of a single pass transmembrane glycoprotein, E-cadherin, and juxta-membrane localized catenin family members (ρ -120, β - and α -catenin) that anchor to the actin cytoskeleton. In addition, adherens junction complexes are prominent sites for regulated phosphorylation and dephosphorylation events including Src activation by E-cadherin homophilic binding. Moreover, E-cadherin homophilic binding activates RhoA to localize β -actin mRNA at cell-cell contacts sites. The active Src at cell-cell contacts then releases the translational repression of the β -actin mRNA allowing localized β -actin monomer synthesis at cell-cell contact sites driving the anchoring of the adherens junction complex to the actin cytoskeleton during adherens junction maturation. Using Madin-Darby Canine Kidney (MDCK) cells and E-cadherin function blocking antibodies we demonstrate E-cadherin homophilic binding regulates spatially localized β -actin monomer synthesis during de novo adherens junction assembly in Ca^{2+} switch experiments using the β -actin translation site imaging method. The effects of blocking E-cadherin homophilic binding were quantified as the ratio of colocalization between adherens junction markers and F-actin at the cell periphery to that in the cytoplasm. Preliminary experiments using function blocking antibodies confirm blocking E-cadherin homophilic binding perturbs de novo adherens junction assembly. In addition, assembly of circumferential actin belts 3-hours post-contact are perturbed characterized by radial arrays of F-actin at cell-cell contacts sites in E-cadherin blocking antibody treated cells. We hypothesize E-cadherin homophilic binding activates Src at cell contacts that in turn is required to initiate β -actin mRNA translation. β -actin translation site imaging studies support this hypothesis because β -actin translation sites appear to be present throughout the whole cell with a decrease in β -actin synthesis observed at cell contacts in E-cadherin blocking antibody treated cells. These results demonstrate E-cadherin homophilic binding is required for contact localized β -actin translation, which is required to remodel the actin cytoskeleton providing linear filaments used to anchor and stabilize adherens junction complexes at epithelial cell-cell contact sites.

P608**Board Number: B859****Size Exclusion Chromatographic Assay of Dimerization by Epithelial Cadherin.**C.S. Fox¹, S.D. Pedigo²;¹Chemistry and Biochemistry, University of Mississippi, Oxford, MS, ²Chemistry and Biochemistry, The University of Mississippi, Oxford, MS

The classical cadherin family is an extensively studied family of calcium- dependent homophilic cell adhesion proteins, which includes epithelial cadherin (ECAD) and neural cadherin (NCAD). ECAD plays essential roles in the formation and maintenance of epithelial tissues. The adhesive interface lies in the first of five similar tandemly repeated extracellular domains (EC1-EC5) and requires exchange of the N-terminal A-strand. The purpose of the experiments presented here is to develop a simple assay for dimerization using purified recombinant protein. A chromatographic assay has been developed for NCAD, which essentially involves trapping the protein in a dimeric state thus significantly reducing the exchange rate between states. This allows resolution of monomer and dimer peaks using size exclusion chromatography. No equivalent assay for the study of ECAD dimerization has been established until now. The K14E mutant of ECAD experiences slow exchange between monomer and dimer, although the dimerization affinity is unchanged by the mutation. Studies presented here establish a chromatographic assay for ECAD dimerization affinity using the K14E mutant. Control experiments demonstrate that equilibration requires 4 hours and dimerization occurs in a calcium and protein dependent manner. This assay is useful for determining the effect of microenvironmental factors that will influence dimerization by ECAD in vivo. NSF MCB 0950494 and DOEd GAANN P200A120046-13

P609**Board Number: B860****Nickel reduces calcium-dependent dimerization by Neural Cadherin.**M. Dukes¹, R.K. Rowe¹, S.D. Pedigo¹;¹Chemistry and Biochemistry, The University of Mississippi, Oxford, MS

Cadherins are the primary transmembrane component in adherens junctions, structures that link the actin cytoskeleton in adjacent cells within tissue. Adherens junctions occur in most solid tissues including neurological synapses, epithelium and endothelium. Cell-cell adhesion by cadherins requires the binding of calcium ions to specific sites in the extracellular domain. Requirement of calcium binding beckons the question of whether other divalent cations might substitute for or compete with calcium for site occupancy. The studies reported herein characterize the biophysics of nickel binding to neural cadherin. Based on results from thermal-denaturation studies, it was clear that neural cadherin was stabilized by the presence of nickel in solution. Furthermore, we attempted to determine the K_d for nickel binding by direct titrations of neural cadherin monitored by circular dichroism. The K_d was unable to be determined due to the absence of a saturated baseline. Subsequent experiments tested whether the presence of constant low levels of nickel affected calcium binding affinity and calcium-induced

dimerization. Interestingly, there was a significant effect upon the apparent calcium binding affinity and on adhesive dimer formation as a function of nickel concentration, suggesting that detrimental competition for site occupancy occurs between these divalent cations.

An assay to study cellular responses to simultaneous mechanical and chemical gradients.

S. García¹, R. Sunyer¹, J. Atencia², X. Trepas¹;

¹Institute for Bioengineering of Catalonia, Barcelona, Spain, ²biochemical Science Division, National Institute of Standards and Technology (NIST), Gaithersburg, MD

Cell response to chemical cues is at the core of a myriad of fundamental biological processes that range from angiogenesis to cancer metastasis. Most of these biological processes are also influenced by mechanical cues from the extracellular matrix. How chemical and mechanical cues act in synergy to drive biological function is unknown, however. Here we present a robust microfluidic device that combines the precise diffusion of chemical factors together with well-defined stiffness profiles. The device generates a stable, linear and purely diffusive chemical gradient over a biocompatible hydrogel with a well-defined and perpendicular stiffness gradient. Device fabrication relies on a recently developed technique based on patterned PSA (Pressure Sensitive Adhesive) double side tape stacks that can be implemented with minimal cost and lab equipment. This technique is suitable for long-term observation of cell migration and the application of traction force microscopy. We validate our device by testing MDCK cell scattering in response to perpendicular gradients of HGF and substrate stiffness.

FilGAP, a Rho/ROCK-regulated GAP for Rac controls adherens junctions in MDCK cells.

K. Tsutsumi¹, S. Nakahara¹, T. Zuinen¹, Y. Ohta¹;

¹Division of Cell Biology, Department of Biosciences, School of Science, Kitasato University, Kanagawa, Japan

Cell-cell adhesion is essential for epithelial tissue integrity and functions. Adherens junctions (AJs) are responsible for epithelial cell-cell adhesions and are composed of a transmembrane protein E-cadherin that is connected to actin cytoskeleton via catenins. Rho family small GTPases are essential for the formation of adherens junctions of epithelial cells. We found FilGAP, a Rac specific Rho GTPase-activating protein, promotes the formation of adherens junctions of Madin-Darby canine kidney (MDCK) cells. Knockdown of FilGAP by siRNA stimulated the disassembly and migration of MDCK cells induced by Hepatocyte-growth factor (HGF). Conversely, forced expression of FilGAP induced accumulation of E-

cadherin at adherens junction and suppressed HGF-induced scattering. Reduction of medium Ca^{2+} disrupted the cell-cell adhesion and restoration of Ca^{2+} re-established the cell-cell adhesion. Depletion of FilGAP by siRNA prevented cell-cell adhesion induced by Ca^{2+} . The Rac GAP domain of FilGAP is necessary for suppression of scattering. In agreement with this observation, knockdown of endogenous Rac by siRNA suppressed disassembly of MDCK cells induced by HGF. Forced expression of Rho kinase (ROCK) induced accumulation of E-cadherin at adherence junction and depletion of FilGAP by siRNA prevented the accumulation of E-cadherin. Moreover, phospho-mimic FilGAP mutant but not non-phosphorylatable FilGAP mutant stimulated accumulation of E-cadherin at cell junctions. These results suggest that FilGAP may regulate cell-cell adhesion through inactivation of Rac downstream of Rho/ROCK-signaling in MDCK cells.

Histatin 1, a histidine-rich peptide in human saliva, promotes cell adhesion and plays a role in mesenchymal-epithelial transition.

I.A. Van Dijk¹, K. Nazmi¹, J. Bolscher¹, E. Veerman¹, J. . Stap²;

¹Oral Biochemistry, Academy of Dentistry Amsterdam, Amsterdam, Netherlands, ²Cell Biology / Van Leeuwenhoek Center for Advanced Microscopy, Academic Medical Center, Amsterdam, Netherlands

Histatins are histidine-rich peptides produced by the salivary glands of higher primates. This study explores the effects of histatins on cell-substrate adhesion and cell-cell adhesion of epithelial cells and fibroblasts.

We found that single cells seeded in serum-free medium attach and spread significantly faster in the presence of histatin 1 (Hst1). This effect was specific for Hst1, since other tested histatins did not stimulate cell-substrate adhesion. Hst1 causes a more than 2-fold increase in the ability of cells to attach and spread, even under conditions that impair cell adhesion. Rapid cell-substrate adhesion is particularly important for junctional epithelium, an intermediate cell type between gingival tissue and tooth enamel acting as a protective seal against microbial and physical stresses.

The effect of Hst1 on cell-cell adhesion was investigated using trans-epithelial resistance (TER) measurements in Caco-2 cells, a widely used model system for the epithelial layer. Hst1 causes an over 20% increase in TER compared to control cells. A role for Hst1 in both cell-substrate and cell-cell adhesion is highly conceivable, because these two modes of adhesion are closely related via connected signaling pathways and shared components.

Using confocal microscopy we observed that Hst1 induced a more than 2-fold increase in the amount of active E-cadherin, a cell-cell adhesion protein, and a 50% increase in the amount of the tight junction protein ZO-1 in Caco-2 cells. Our results indicate that Hst1 is involved in maintaining the epithelial architecture and barrier function. This barrier is not only important in the mouth, which is a challenging environment where food, heat, cold and acidic compounds all induce stress to the soft tissues of the

oral cavity, but also for the total of epithelial layer covering the cavities and surfaces throughout the body.

E-cadherin activation is recognized as a hallmark for mesenchymal-epithelial transition (MET), a process important during embryogenesis, development, cell differentiation and cancer metastasis.

Immunochemical staining of Hst1 revealed the presence of Hst1 in several layers of the oral epithelium of 16-20 weeks old fetuses. Hst1 was not present in fetal salivary glands, which are not yet functional at this age, indicating that oral epithelial cells produce Hst1 during fetal development. Together our results suggest that Hst1 promotes MET.

VE-cadherin is proteolytically processed upon endocytosis to remove the beta-catenin binding domain.

W. Su¹, A. Kowalczyk¹;

¹Emory Univ Sch Med, Atlanta, GA

Regulation of endothelial cell adhesion is essential in many biological processes including wound healing, angiogenesis, inflammation and cancer metastasis. VE-cadherin trafficking to and from the plasma membrane has emerged as a critical mechanism for regulating surface levels of VE-cadherin and adherens junction adhesion strength. Despite the fact that VE-cadherin trafficking has been under extensive investigation, little is known about the role of proteolytic processing in regulating VE-cadherin trafficking. To investigate this process further, endothelial cells were treated with chloroquine to inhibit lysosomal degradation. This treatment resulted in the accumulation of a 95kD VE-cadherin fragment, suggesting that VE-cadherin is cleaved during the process of internalization and trafficking to endosomal compartments. Using biochemical and fluorescent imaging of internalized and surface pools of cadherin, we found that the b-catenin binding domain of VE-cadherin is removed upon internalization. Further analysis suggests that this cleavage occurs between the juxtamembrane domain and the catenin-binding domain of the VE-cad tail. To determine if endocytosis is required for cleavage, we utilized pharmacological inhibitors of clathrin-mediated endocytosis as well as VE-cadherin point mutants resistant to internalization. Both of these approaches indicated that endocytosis of the cadherin is required for proteolytic processing. Furthermore, over-expression of p120-catenin, which inhibits VE-cad endocytosis, blocked VE-cadherin cleavage. These findings suggest that VE-cadherin is proteolytically processed upon endocytosis to remove the beta catenin binding domain, raising the possibility that this cleavage event is critical in regulating both VE-cadherin trafficking and adhesive function.

P614**Board Number: B865****Quantitative Real Time Imaging of Protein Secretions from Single Cells.**M.P. Raphael¹, J.A. Christodoulides¹, J.B. Delehanty¹, J.P. Long¹, J.M. Byers¹;¹Naval Research Laboratory, Washington, DC

Cell-to-cell signaling often involves the secretion of proteins, which creates spatial and temporal concentration profiles in the extra-cellular environment for the receiving cells to detect and interpret. Real-time measurements of secreted protein concentrations at the single cell level are thus fundamental to understanding these communications pathways but have proven difficult to realize in practice. Here we present a label-free technique based upon nanoplasmonic imaging and high-affinity binding which enabled the measurement of individual cell secretions in real time. When applied to the detection of antibody secretions from individual hybridoma cells, the enhanced time resolution revealed two modes of secretion: one in which the cell secreted continuously and another in which antibodies were released in concentrated bursts that coincided with minute-long morphological contractions of the cell. From the continuous secretion measurements we determined the local concentration of antibodies at the sensing array closest to the cell. The technique is incorporated on to a wide-field microscope which enables real-time transmitted light and fluorescence imaging of the cells as well. We anticipate this technique will be broadly applicable to the real-time characterization of both paracrine and autocrine signaling pathways.

Structure and Function of the Extracellular Matrix**P615****Board Number: B866****Hydraulic fracture during epithelial stretching.**L. Casares Garcia^{1,2}, R. Vincent¹, D. Zalbidea¹, N. Campillo², D. Navajas^{1,2,3}, M. Arroyo⁴, X. Trepats^{1,2,5};¹Institute for Bioengineering of Catalonia (IBEC), Barcelona, Spain, ²University of Barcelona, Barcelona, Spain, ³Ciber Enfermedades Respiratorias, Bunyola, Spain, ⁴LaCàN, Universitat Politècnica de Catalunya-BarcelonaTech, Barcelona, Spain, ⁵Institució Catalana de Recerca i Estudis Avançats (ICREA),, Barcelona, Spain

The epithelium is a cohesive cell sheet adhered on a soft hydrogel matrix that covers free surfaces and cavities throughout the body. During development and adult life, the epithelium performs a broad diversity of functions including morphogenesis, wound healing, tissue compartmentalization, and protection against environmental pathogens. Epithelial sheets carry out these functions in a dynamic mechanical environment characterized by elevated levels of cell and tissue stretching. Failure to withstand stretching leads to epithelial fracture, which is associated with impaired development and severe pathological conditions. Epithelial fracture is commonly attributed to excessive tension in key stress bearing elements of the epithelium such as the cytoskeleton, the plasma membrane, and cell-cell

junctions. We developed a new experimental approach to study fracture dynamics of micropatterned epithelial monolayers adhered to soft hydrogel substrates. Using this approach, we demonstrate epithelial cracks caused by tissue stretching but independent of epithelial tension. We show that the origin of these cracks is hydraulic; they form to release a transient buildup of pressure in the hydrogel substrate during stretch/unstretch maneuvers. Shortly after stretch cessation, transepithelial pressure equilibrates and cracks seal through an acto-myosin dependent mechanism. We demonstrate this behavior in a variety of synthetic and physiological hydrogel substrates including polyacrylamide, matrigel, and decellularized animal tissue. The theory of poroelasticity successfully captures the observed phenomenology and allows us to predict the size and healing dynamics of epithelial cracks as a function of the stiffness, geometry, and composition of the hydrogel substrate. Thus, coupling between tissue stretching and matrix hydraulics determines epithelial integrity in a tension-independent manner.

Extracellular Matrix Remodeling Regulates Age-Associated Cardiomyocyte Function.

A.O. Sessions¹, G. Kaushik², A. Cammarato³, A.J. Engler²;

¹Biomedical Sciences, University of California, San Diego, La Jolla, CA, ²Bioengineering, University of California, San Diego, La Jolla, CA, ³Medicine, Johns Hopkins University, Baltimore, MD

Increased deposition of extracellular matrix (ECM) is observed in all advanced age heart failure patients, but current model systems are complex and slow to age. To investigate the effect of extracellular remodeling on mechanical function in genetically tractable, rapidly aging, and simple model organisms, we employed *Drosophila melanogaster*, which has a bilayered heart tube. We found that two common wildtype strains of *Drosophila*, i.e. *yellow-white (yw)* and *white-1118 (w¹¹¹⁸)*, exhibit different cytoskeletal and ECM remodeling with age. Using a recently developed nanoindentation method to measure cardiomyocyte stiffness and high speed optical imaging to assess contractility of intact *Drosophila* hearts, we found that *yw* flies had stiffer intercalated discs (ICD) and exhibited diastolic dysfunction with age. On the other hand, *w¹¹¹⁸* flies did not exhibit ICD stiffening, exhibited a less severe diastolic dysfunction, and showed an increase in ECM layer thickness between ventral muscle (VM) and cardiomyocyte (CM) layers of the heart tube. To modulate ECM and assess its effect in the aged *w¹¹¹⁸* flies, we knocked-down ECM genes LamininA (Laminin 3,5) and Viking (Collagen IV) and found no effect on cardiac performance in juvenile flies, but in aged flies, it decreased cardiomyocyte stiffness and increased contractile irregularity. This suggests that the cell-ECM contacts in the basement membrane are intimately tied not only to the coupling of the cardiomyocytes of the *Drosophila* heart tube but also to cytoskeletal remodeling. These data may also have larger implications for elderly patients suffering from extensive age-related myocardial remodeling and fibrosis who experience cardiomyocyte decoupling and resultant arrhythmias.

P617**Board Number: B868****Synergistic activation of fibroblasts by a modest increase in stiffness in combination with serum cytokines in a 3-D model of the tumor stroma.**J.S. McLane¹, L.A. Ligon¹;¹Biology, Rensselaer Polytechnic Inst, Troy, NY

Activated fibroblasts have been shown to enhance the progression of metastatic disease. These cancer-associated fibroblasts are found in the transformed extracellular matrix (ECM) that surrounds tumors such as those of the mammary gland. One important property of the transformed ECM is an approximately ~3-4 fold increase in stiffness in comparison to normal mammary tissue. This increase in stiffness is conserved among multiple tumor types, leading us to hypothesize that differences in 3-D matrix stiffness can cause fibroblast activation. To test this, we developed an in vitro model in which fibroblasts were grown in a collagen-I based 3-D hydrogel system where the stiffness is controlled independently of collagen concentration by chemical crosslinking. We generated collagen-I hydrogels representing both normal breast stroma (~200 Pa) and tumor associated stroma (~800 Pa). Our results indicate that this modest (~600 Pa), but physiologically relevant, increase in matrix stiffness, leads to a partial activation of fibroblasts toward a myofibroblast phenotype, but that full activation requires the contribution of serum factors. We conclude, therefore, that the activation of fibroblasts in the tumor microenvironment involves the synergistic activity of increased matrix stiffness and chemokine signaling.

P618**Board Number: B869****Interplay of Extracellular Matrix Stiffness and Tethering in Regulating Stem Cell Fate.**J.H. Wen¹, L.G. Vincent¹, A. Fuhrmann¹, Y. Choi², K.C. Hribar³, H. Taylor-Weiner¹, S. Chen³, A.J. Engler¹;¹Bioengineering, University of California, San Diego, La Jolla, CA, ²Kolling Institute of Medical Research, Sydney, Australia, ³Nanoengineering, University of California, San Diego, La Jolla, CA

Stem cells “feel” and differentiate in response to the surrounding extracellular matrix (ECM) properties integrating signals such as stiffness and ligand type, by binding to and contracting against the matrix. Recently, the degree of fibrous protein coupling to the surface of the underlying substrate, i.e., tethering and matrix porosity, has also been proposed to mechanically regulate differentiation. In order to further investigate how these factors and substrate mechanics contribute to cell fate, we modulated substrate stiffness, porosity, and surface ligand tethering density of polyacrylamide hydrogels to investigate how these factors collectively or independently regulate cell fate. Varying substrate porosity while maintaining constant stiffness did not significantly change collagen protein tethering observed by atomic force microscopy (AFM), substrate deformations observed by traction force microscope (TFM), or osteogenic and adipogenic differentiation of sub-confluent human adipose-derived stromal cells (ASCs)

or marrow-derived mesenchymal stem cells. Adjusting protein-substrate linker sulfo-SANPAH density while maintaining constant porosity changed tethering, but did not affect osteogenesis or adipogenesis, surface protein unfolding by cells detected via FRET, and underlying substrate deformations determined via TFM. To eliminate the possibility of surface protein deformations altogether, the short cell-adhesive peptide RGD was incorporated into the substrate; differentiation of ASCs and MSCs was unaffected by the absence of fibrous protein tethering or peptide density as only softer substrates prevented sub-confluent osteogenesis, and stiffer substrates prevented adipogenesis. Careful investigation of the elastic mechanical properties of PDMS and polyacrylamide using AFM further supports that these conclusions extend to other systems. Together, our data imply that cell-generated deformations of planar matrices of a specific stiffness regulate stem cell differentiation independently of protein tethering and porosity.

IL-1 β promotes mesenchymal stem cell migration by inducing the expression of MMP-1.

M. Chen¹, P. Tsai², H. Wang¹;

¹Anatomy and Cell Biology, Natl Yang-Ming Univ, Taipei, Taiwan, ²Surgery, Veteran General Hospital, Taipei, Taiwan

Mesenchymal stem cells are known to “homing” to areas of injury in response to signals of cellular damage. However, the characteristics, mechanisms, and significance of how cytokines can directly influence the stem cells and recruit it to the target tissue are still unclear. In this study, we found that the pro-inflammation cytokine interleukin-1 β (IL-1 β) promotes mesenchymal stem cells migration. The cDNA microarray data shows that IL-1 β induces matrix metalloproteinase-1 (MMP-1) expression. We then used quantitative real-time PCR and MMP-1 ELISA to verify the results. Pre-treatment with IL-1 β inhibitor interleukin-1 receptor antagonist, MMP-1 inhibitor tissue inhibitor of metalloproteinases, and protease activated receptor 1 inhibitor SCH79797, the results showed that PAR1 protein signaling pathway leads to cell migration. In conclusion, IL-1 β promotes the secretion of MMP-1 which then activate the PAR1 and by a G-protein-coupled signal pathway to promote mesenchymal stem cells migration.

P620**Board Number: B871****ECM Geometry Promotes Directed Cell Migration by Regulating Leading Edge Dynamics.**G.R. Ramirez-SanJuan¹, P.W. Oakes², M.L. Gardel²;¹James Frank Institute, Institute for Biophysical Dynamics and Physics Department, University of Chicago, Chicago, IL, ²James Franck Institute, Institute for Biophysical Dynamics and Physics Department, University of Chicago, Chicago, IL

During development and tissue morphogenesis dynamic changes in cell motility and shape can be regulated by extracellular matrix (ECM) physical cues. Fibrillar ECM geometries are a hallmark of several developmental processes, however *in vivo* it is difficult to assess the influence of ECM geometry in directing cell migration and promoting tissue rearrangements. Furthermore, the physical parameters and cytoskeletal organelles that control geometry sensing in cells are unknown. Here we use UV micropatterning to mimic aligned ECM fibrils and study the influence of subcellular changes in ECM geometry in 3T3 cell shape and migration. We pattern 2 μ m thick Fibronectin parallel lines onto an elastic substrate, varying the spacing between lines at a subcellular lengthscale (0-10 μ m). On uniformly coated substrates, cells migrate in a random direction, however in linear geometries cells acquire an elongated morphology and migrate preferentially along the direction of the ECM lines. As we increase the spacing between lines, we find that migration directionality and shape elongation increase monotonically as a function of distance between lines. Since the shape of a migrating cell is regulated by its protrusive and contractile organelles, we investigated their contribution to ECM geometry sensing. We find that inhibition of Myosin II has a modest effect on the ability of cells to sense geometry changes. In contrast, upregulation of lamellipodial protrusion, by expression of a constitutively active form of Rac, impairs the ability of cells to migrate along axis of the ECM lines. Further analysis of the protrusive dynamics in cells migrating on uniform and linear substrates reveals that lamellipodial protrusions are concentrated in the direction of the ECM axis in linear substrates. These protrusions are longer lived as compared to protrusions perpendicular to the ECM axis, thus biasing the direction of cell migration and promoting an elongated cell morphology. Finally, we tested the relevance of ECM geometry sensing in individual cells in a multicellular context. To this end we grew MDCK cell monolayers on micropatterns with linear ECM geometries, similar to single cells, in these monolayers cells elongate and exhibit directional motion in line spacings as small as 2 μ m. Thus we propose a model where ECM fibrillar geometries influence the direction of cell migration in a multicellular assembly, by acting at an individual cell level to increase the persistence of protrusive activity along the axis of the fibrils. Our work demonstrates that ECM geometry can provide an asymmetry that influences migration dynamics both in single cells and multicellular assemblies, highlighting the importance of physical properties of the ECM for development and tissue morphogenesis.

P621**Board Number: B872****Induction of Kidney Fibrosis by Fibronectin Synthesis via WNT Signaling.**A. Kuma¹, M. . Tamura², S. Yamada³, H. Ueno¹, N. Ishimatsu¹, Y. Fujimoto¹, K. Bando², R. Serino², Y. Otsuji¹, K. Kohno⁴;¹Second Department of Internal Medicine, University of Occupational and Environmental Health, Kitakyushu, Japan, ²Kidney Center, University Hospital of Occupational and Environmental Health, Kitakyushu, Japan, ³Department of Pathology and Cell Biology, University of Occupational and Environmental Health, Kitakyushu, Japan, ⁴The President Laboratory, University of Occupational and Environmental Health, Kitakyushu, Japan

Background: Acute interstitial nephritis (AIN) induces kidney fibrosis after acute kidney injury (AKI). We previously reported WNT10A as a novel angio/stromagenic factor useful in wound healing. However, the relationship between WNT10A and kidney fibrosis is not completely clear. Here we investigated the role of WNT10A in the fibrotic process in AIN. **Methods:** Kidney samples from 20 male patients (≥ 60 years) diagnosed with AIN by kidney biopsy at our hospital were analyzed by immunohistochemistry (IHC) for WNT proteins, α -SMA, and fibronectin. The relationship between estimated glomerular filtration rate (eGFR) and WNT protein expression was evaluated. COS-1 cells (obtained from kidney fibroblasts of African green monkey) were transfected with a WNT10A expression plasmid (WNT10A overexpressing cells; COS-1-10A). Protein expressions of cell lysates were detected by western analysis and cytotoxicity was analyzed by WST-8 assay. **Results:** Of the 20 patients, 10 with WNT10A expression in biopsy tissue had significantly lower eGFR values (median, 11.12 mL/min per 1.73 m²) than the remaining 10 with no detectable WNT10A expression (median, 34.70; $p=0.0002$). The relationship between eGFR and the expression level of any other WNT protein examined (WNT-1, -3, and -4) was not significant. IHC WNT10A positive samples showed a positive correlation with fibronectin positive ($p = 0.0062$) and α -SMA-positive ($p = 0.0005$) samples. Furthermore, compared with control COS-1 cells, COS-1-10A enhanced the expression of fibronectin around 3- to 5-fold. COS-1 10A increased the level of peroxiredoxin (PRDX) 5 expression and rendered fibroblasts resistant to hydrogen peroxide (15-62.5 μ M). However, downregulation of PRDX 5 expression by siRNA sensitized COS 1 10A cells to hydrogen peroxide. **Conclusion:** WNT10A expression may promote kidney fibrosis following severe kidney dysfunction. WNT10A-expressing fibroblasts may induce fibronectin synthesis against oxidative stress via PRDX 5 expression.

P622**Board Number: B873****CD47-SIRP α interactions mediate MMP expression.**J.B. Slee^{1,2}, K.A. Clarke^{2,3}, R.J. Levy^{2,3}, S.J. Stachelek^{2,3};¹Department of Pediatrics - Division of Cardiology, The Children's Hospital of Philadelphia, Philadelphia, PA, ²University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ³Pediatrics - Cardiology, The Children's Hospital of Philadelphia, Philadelphia, PA

Implanted medical devices and materials trigger an inflammatory reaction resulting in adsorption of blood proteins and platelets, monocyte/macrophage adhesion, and the release of pro-inflammatory cytokines, all of which contribute to clinical complications. Our lab has focused on appending recombinant CD47 to implanted polymers as a way to prevent material-induced inflammation and increase the long-term biocompatibility of medical devices. CD47 is a ubiquitously expressed transmembrane protein with a role in immune evasion and shows promise at conferring biocompatibility when appended to polymeric surfaces. SIRP α , the cognate receptor for CD47, is an immunoreceptor tyrosine-based inhibitory motif (ITIM)-containing transmembrane protein expressed on cells of myeloid origin. Recent work from our laboratory showed that the anti-inflammatory capacity of CD47-SIRP α interactions extend beyond its canonical role as an inhibitor of phagocytosis. Specifically a microarray analysis of whole blood exposed to immobilized CD47 surfaces showed a 100-fold increase in select matrix metalloproteinase (MMP) transcription. MMPs are ubiquitously expressed endopeptidases involved in degrading extracellular matrix, a process involved in the later stages of material-induced inflammation. In these studies, we test the hypothesis that CD47-SIRP α interactions increase MMP expression at the protein level. Whole human blood exposure to immobilized CD47 surfaces results in increased expression of MMP7 in plasma as determined by western blotting compared to control. The increase in MMP7 protein levels corresponded to increased enzymatic activity assessed by zymography compared to control. To validate the role of the CD47/SIRP α signaling pathway in mediating the increase in MMP7 expression and activity, THP-1 cells (monocyte-derived macrophage cells) transduced with SIRP α shRNA were used. SIRP α shRNA THP-1 cells failed to exhibit the increased MMP7 expression characteristic of exposure to polymeric tubing, establishing the necessity of SIRP α . Lastly, a rat sub-dermal implant model showed increased MMP7 staining in tissue surrounding CD47-modified implants after 7 days. Collectively, these data support the role of MMP7 activation downstream of the CD47-SIRP α interaction in preventing implanted biomaterial-induced inflammation.

P623**Board Number: B874****Proteolysis of Decellularized Extracellular Matrices Generates a Significant Amount of Fibronectin Fragments.**A. Ramanathan¹, N.W. Karuri¹;¹Chemical and Biological Engineering, Illinois Institute of Technology, Chicago, IL

Fibronectin degradation has been closely associated with a number of pathologies ranging from periodontal disease, to wound repair and cancer. Excessive inflammation in the wound is believed to result in increased fibronectin proteolysis and impaired wound healing. We studied the impact of fibronectin degradation on decellularized extracellular matrices. These were treated with alpha chymotrypsin and proteolysis stopped at different time points. The content of the protease solution as well as that of the immobilized matrices was examined by immunoblotting and Bicinchoninic Acid assays. Fibronectin was 5.0% of the total decellularized matrix but was extremely susceptible to proteolysis; after 15 minutes of protease treatment 74.5% of the fibronectin in the decellularized matrix was degraded while there was an 11.1% decrease in the total protein content in the extracellular matrix. A cell adhesion assay was used to quantify NIH3T3 mouse fibroblast adhesion, spreading and actin extensions when seeded on the decellularized extracellular matrices and on coverslips incubated with solutions of the proteolyzed extracellular matrices. Cell number, cell area and actin extensions within the extracellular matrix decreased with increased proteolysis time. Interestingly, cell adhesion and spreading positively correlated with proteolysis time in cells cultured on coverslips coated with extracellular matrix fragments. This study demonstrates that in a high protease environment, fibronectin in the extracellular matrix is more susceptible to degradation than the total extracellular matrix protein content and places weight on bioengineering strategies to stabilize it against proteolysis as a therapeutic strategy.

P624**Board Number: B875****A PROTEOLYTICALLY STABLE FIBRONECTIN THAT BINDS CELLS AND GELATIN.**N.W. Karuri¹, A. Ramanathan¹, C. Zhang¹;¹Chemical and Biological Engineering, Illinois Institute of Technology, Chicago, IL

Excessive proteolysis of fibronectin (FN) has been implicated in impaired poor wound healing, periodontal disease and tumor invasion. We previously reported two strategies for stabilizing soluble FN against proteolysis; the first conjugated polyethylene glycol (PEG) through cysteine residues and the second conjugated PEG chains of varying molecular weight on lysine residues. Cysteine PEGylation of FN increased proteolytic stability, did not perturb cell binding activity but resulted in poor gelatin binding. On the other hand, PEGylation of FN via lysine residues resulted in increased resistance to proteolysis

with increasing PEG size, but an overall decrease in biological activity, as characterized by cell and gelatin binding. Our latest method to stabilize FN against proteolysis screens the gelatin binding domain during lysine PEGylation. FN is PEGylated while bound to gelatin Sepharose beads with 2, 5 and 10 kDa PEG precursors. This results in partially PEGylated FN molecules with higher stability than native FN and whose proteolytic stability increases with PEG molecular weight. Unlike completely PEGylated FN, partially PEGylated FN has cell adhesion, gelatin binding and matrix assembly responses that are comparable to native FN. This is new evidence of how PEGylation variables can be used to stabilize FN while retaining its activity. The conjugates developed herein can be used to dissect molecular mechanisms mediated by FN stability, and address the fundamental problem of FN degradation in a number of pathologies.

Tenascin-C regulates macrophage behavior during tissue repair after myocardial infarction in mouse model.

T. Kimura¹, K. Tajiri¹, M. Hiroe², T. Yoshida³, K. Imanaka-Yoshida³;

¹Cardiovascular Medicine, Tsukuba University, Tsukuba, Japan, ²National Center for Global Health and Medicine, Tokyo, Japan, ³Mie Univ Sch Med, Mie, Japan

Tenascin-C (TN-C) is a matricellular protein generally expressed at high levels during embryonic development and tissue remodeling in response to injury. It is sparsely detected in normal adults but transiently upregulated in pathological heart closely associated with tissue injury and inflammation such as acute myocardial infarction. The aim of this study was to investigate the effects of TN-C on ventricular remodeling after myocardial infarction and elucidate the molecular mechanism. Eight to 10 weeks old male wild type (WT) and TN-C knock-out (KO) mice were divided into 4 groups of WT+Sham, KO+Sham, WT+myocardial infarction (MI) and KO+MI. In WT+MI, the expression of TN-C was highly up-regulated at day 3, peaked at day 5 and then down-regulated at day 7. Fluorescence activated cell sorting (FACS) analysis showed that deletion of TN-C significantly increased that the ratio of M2 macrophage (CD45+/ F4/80+/ CD206 high) at 7 day, while the ratio of M1 macrophage (CD45+/ F4/80+/ CD206 low) were significantly decreased at day 5 compared with that of WT+MI group. RT-PCR analysis showed that the expression of IL-10, an anti-inflammatory cytokine, was significantly higher in KO+MI than WT+MI. In chronic phase, 12 weeks post-MI, although the survival rate of both WT+MI (48.3%, 14 of 29 mice) and KO +MI (55.6%, 15 of 27 mice) groups had no significant difference, TN-C KO group had the significantly better cardiac function than WT had (LVEF, 19.02±6.31% vs 10.63±4.43%; p

P626**Board Number: B877****Antagonistic effects of platelets and erythrocytes on blood clot contraction.**V. Tutwiler^{1,2}, R.I. Litvinov³, T. Lebedeva³, C. Nagaswami³, D.B. Cines³, J.W. Weisel³;¹Department of Cell and developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA, ²Drexel University, Philadelphia, PA, ³University of Pennsylvania School of Medicine, Philadelphia, PA

Blood clot contraction plays a critical role in stopping bleeding (hemostasis), wound healing, and restoring blood flow past obstructive thrombi. Contraction results in volumetric shrinkage of the clot, redistribution of platelets and fibrin polymer to the surface of the clot, and deformation of naturally biconcave erythrocytes into compressed, tightly packed, polyhedral erythrocytes (polyhedrocytes). To examine the role of blood cells in clot contraction, reconstituted blood was clotted through the addition of Ca^{2+} and thrombin. Reconstitution allowed for the platelet and/or erythrocyte levels to be varied while keeping other blood components constant. Microstructure of the clots was examined by scanning electron microscopy. Dynamic viscoelastic properties and the contractile force of the clot were determined using high precision rheology. Kinetics of contraction was quantified using an optical analyzer system, which continuously monitors changes in clot size by tracking clot-induced light scattering with time. Morphologically contracted clots revealed a packed core of polyhedrocytes surrounded by a platelet-fibrin meshwork. The mechanical nature of this cellular deformation was confirmed through the formation of polyhedrocytes when blood was centrifuged without clotting. The platelet-fibrin meshwork was able to generate the forces needed to compact the erythrocytes; the rate and degree of clot contraction depended linearly on the platelet count ($R^2=0.99$). Platelet levels $>500\text{k}/\mu\text{l}$ and $250\text{-}300\text{k}/\mu\text{l}$ resulted in more than a significant 30% and 15% increase in clot contraction, respectively, when compared to the lowest platelet concentration (40% resulted in a 30% decrease (p60% increase in the contractile forces generated by the platelet-fibrin meshwork when compared to samples without erythrocytes. These results reveal a complex effect of cellular composition on the course and degree of contraction, mechanical properties of the clot, and the contractile force. Notably, erythrocytes turned out to dampen the platelet-driven clot contraction, which may affect the formation and properties of a hemostatic plug in pathophysiological conditions with varying levels of erythrocytes, such as anemia and polycythemia.

P627**Board Number: B878****A lectin counterstain for immunofluorescence studies of equine hoof lamellar tissue and cultured keratinocytes.**R. Linardi¹, R. Clark², H. Galantino-Homer³;¹Clinical Studies, University of Pennsylvania, Kennett Square, PA, ²STEM and Health Division, Cumberland County College, Vineland, NJ, ³University of Pennsylvania, Kennett Square, PA

Equine laminitis is a common, painful, debilitating condition affecting the extensively interdigitated epidermal-dermal lamellar interface that suspends the distal phalanx bone within the hoof capsule and is a leading cause of disability in horses, often necessitating euthanasia. The objectives of this study were to develop a counterstain to facilitate histological and histopathological studies of the complex, multi-layered epidermal and dermal lamellae and to characterize this counterstain in cultured lamellar keratinocytes. A panel of seven tetramethylrhodamine isothiocyanate (RITC)-conjugated lectins (Lectin kit RLK-2200; Vector Laboratories, Inc., Burlingame, CA) was used to stain paraformaldehyde-fixed/sucrose-dehydrated lamellar tissue cryosections and paraformaldehyde-fixed cultured lamellar keratinocytes, which were then visualized by confocal microscopy. Of the seven lectins investigated, RITC-conjugated wheat germ agglutinin (WGA) displayed the most potential for utility as a counterstain. It selectively labels dermal extracellular matrix fibers and epidermal cell membranes/perimembranous regions in tissue sections of horse hoof lamellae, thereby facilitating the visualization of secondary dermal lamellae and individual epidermal lamellar keratinocytes. RITC-WGA also localizes to the cell membrane/perimembranous region of cultured keratinocytes. RITC-WGA was next applied to tissue cryosections and cultured keratinocytes to test its utility as a counterstain following indirect immunofluorescence staining for subcellular markers. As a counterstain, RITC-WGA is compatible with indirect immunofluorescence of tissue cryosections and cultured keratinocytes and augments interpretation of indirect immunofluorescence antigen localization. RITC-WGA can serve as a rapid, simple, economical counterstain for indirect immunofluorescence studies of the equine hoof and cultured keratinocytes.

This study was supported by the Bernice Barbour Foundation, Inc., the University of Pennsylvania Fund for Laminitis Research, and the Raymond Firestone Trust. RLL was supported by the USDA-National Institute of Food and Agriculture (NIFA) postdoctoral fellowship (#2012-67012-19994).

P628**Board Number: B879****The Influence of Suspended and Aligned Fibrous Environment on Mesenchymal Stem Cell Behavior.**T.L. Popielarczyk¹, A.S. Nain², J.G. Barrett³;¹Biomedical and Veterinary Sciences, Virginia-Maryland College of Veterinary Medicine, Leesburg, VA,²Department of Mechanical Engineering, College of Engineering, Virginia Tech, Blacksburg, VA,³Department of Large Animal Clinical Sciences, Virginia-Maryland College of Veterinary Medicine, Leesburg, VA

Tendon injury occurs through cumulative damage to naturally aligned extracellular matrix (ECM) causing cellular repair mechanisms to be overwhelmed. Compared to conservative management, recent advances in cell therapy have demonstrated some improvement in tendon healing. Optimization of mesenchymal stem cell (MSCs) therapy requires a better understanding of how these cells are influenced by their aligned topographical environment. We are investigating cellular response of equine bone marrow MSCs on specifically designed nanofiber scaffolds fabricated using a non-electrospinning technique (STEP). We hypothesize that equine bone marrow MSCs will differentiate into tenocytes on scaffolds that mimic native tendon ECM dimensions and alignment, through use of suspended scaffolds composed of nanofibers. MSCs were grown on 4 different designs including suspended nanofibers in parallel and intersecting orientation and supported nanofibers in parallel and suspended orientation acting as controls. Endpoints of MSC differentiation and ECM production (collagen and glycosaminoglycan) were determined through quantitative PCR and biochemical analysis respectively over 14 days. Results have shown that equine bone marrow MSCs exhibited tenocyte-like characteristics when interacting with nanofibers of suspended and parallel orientation. It was observed that cells elongated along parallel fibers in a tenocyte-like morphology, expressed upregulation of scleraxis on day 14 and expressed an upregulation of type I collagen by day 7. These cells also showed an increase production of both collagen and glycosaminoglycan content in culture media over 14 days of cell culture. These findings provide evidence of tenogenic differentiation on fibers of suspended and parallel orientation. Further modifications to the STEP platform and the study of MSCs in topographical environments may help to elucidate the parameters needed to stimulate tenogenesis.

P629**Board Number: B880****Investigating the B-LINK: an adhesion system that links neighboring basement membranes.**D.P. Keeley¹, M. Morrissey¹, D.R. Sherwood¹;¹Biology Department, Duke University, Durham, NC

Basement membranes (BM) are specialized extracellular matrices that surround most tissues in metazoans. While adhesion systems that mediate cellular attachment to basement membranes (BMs) are well known, how juxtaposed BMs associate with one another, as happens between the glomerular and endothelial BMs in the kidney and astrocyte and pericyte BMs in the blood brain barrier, is unclear. Work from our lab has recently identified a complex, termed the B-LINK, that functions to connect juxtaposed BMs together in *C. elegans* during uterine-vulval morphogenesis. The core components of this complex are integrin, plectin, and hemicentin. All these proteins are highly conserved in mammals, suggesting this may be a conserved system for attaching neighboring tissues through their adjacent BMs.

In *C. elegans*, the B-LINK connects the uterine utse cell and the epidermal seam cells by linking their juxtaposed BMs. This connection is necessary for maintaining integrity of uterine tissue during uterine muscle contractions. Perturbation of B-LINK components results in failure of the utse-seam cell attachment and expulsion of uterine and other internal tissues through the vulval opening following the start of uterine muscle contraction, this is known as the 'Ruptured vulval' phenotype (Rup). Through a GO search, we have identified 23 genes that exhibit a Rup phenotype when mutated or knocked down by RNAi. We are employing a compound microscope screen of RNAi mediated knockdown of these genes to determine if the utse-seam cell junction remains intact. If the Rup phenotype appears to be caused by separation of the utse-seam cell junction, this would indicate a potential B-LINK component. Candidates identified by this screen will then be assayed for localization of the gene product either in the utse cell or in the BMs at the utse-seam cell junction. Using this approach, we have already identified an additional B-LINK component, fibulin-1, which is also highly conserved in mammals. When knocked down by RNAi, fibulin exhibits the Rup phenotype and a translational reporter shows fibulin localization to the BM at the utse-seam cell junction. Given that fibulin assembles in a hemicentin dependent manner, we hypothesize that fibulin reinforces hemicentin, serving as an extracellular anchor for the B-LINK. Together, our work aims to identify proteins that are key regulators of the B-LINK in *C. elegans* and determine if they play conserved roles in attaching neighboring tissues in other metazoans.

Dependence receptors and retrograde neuronal death after spinal cord injury.

J. Chen¹, C. Laramore¹, M. Shifman¹;

¹Temple University School of Medicine, Shriners Hospitals Pediatric Research Center, Philadelphia, PA

Following injury, axons in the mammalian spinal cord do not regenerate and functional recovery is further impeded by retrograde neuronal death. The retrograde cell death appears to be apoptotic, but little is known about its specific mechanisms. Recently, a new type of apoptosis-inducing mechanism, so-called “dependence receptors”, was described. Dependence receptors induce apoptosis when unoccupied by their ligands, but block apoptosis when bound by their ligands. Unlike in mammals, spinal cord injury (SCI) in the lamprey is followed by axon regeneration, but only about 50% of the severed reticulospinal (RS) axons regenerate, while the fate of unregenerated neurons is unknown. We reported previously that in animals allowed to survive 16 weeks after SCI, many of those neurons were TUNEL and activated caspase – positive, suggesting that cells were dying by apoptosis. The majority of these neurons also expressed Neogenin (axonal guidance receptor for RGM) and simultaneously, expression of RGM was downregulated near the transection site. Thus we hypothesized that after SCI, Neogenin function as “dependence receptor,” inducing delayed apoptotic neuronal death. To test this hypothesis, we downregulated Neogenin expression by in vivo delivery of antisense morpholino oligonucleotides (MOs) to RS neurons by retrograde transport at the time of spinal transection. Downregulation of Neogenin expression in lamprey RS neurons enhance their survival and prevent caspase activation. However, not all neurons where Neogenin expression was downregulated, survive after SCI. Inability of Neogenin downregulation alone to rescue all axotomized RS neurons may be explained by the fact that majority of apoptotic RS neurons co-expressed Neogenin and UNC5. Therefore, in our future experiments we will inject the combination of MOs for Neogenin and UNC5. Conclusions • Spinal cord injury lead to retrograde neuronal death of spinal-projecting brain neuron that apoptotic by nature.

- Activation of dependence receptors (UNC5 and Neogenin) might induce apoptosis of reticulospinal neurons.
- Inhibition of Neogenin expression by antisense MOs rescue some RS neurons from apoptotic death.

P631**Board Number: B883****RhoA proteolysis: A novel mechanism for RhoA regulation in cell stress and apoptosis.**M. Girouard¹, M. Pool¹, A. Fournier¹;¹Neurology and Neurosurgery, Montreal Neurological Institute, Montreal, QC

RhoA, a member of the Ras-related family of GTPases, is ubiquitously expressed in eukaryotic cells and is involved in many cellular functions, including regulation of the cytoskeleton. As such, it promotes the assembly of actin-myosin filaments known as stress fibers, limits actin depolymerization and stabilizes microtubules. RhoA regulates numerous cellular processes such as cytokinesis, adhesion and migration. RhoA is tightly regulated by a variety of mechanisms such as GTP-binding, phosphorylation and prenylation. Our laboratory has found that RhoA is processed through proteolytic cleavage to generate a 10kDa stable amino terminal fragment (NTF-RhoA), suggesting a novel regulatory mechanism for this protein. Our studies revealed that RhoA proteolysis is activity-dependent, and is regulated by both phosphorylation and prenylation. Furthermore, it is promoted following oxidative stress induced by hydrogen peroxide treatment and following initiation of apoptosis with Staurosporine. Investigation of the proteases involved in RhoA processing using specific protease inhibitors revealed that Calpain and Caspase activity result in degradation of NTF-RhoA. Introduction of NTF-RhoA into serum-starved Swiss 3T3 fibroblasts leads to mild stress fiber formation while introduction of the C-terminal fragment promotes the formation of nuclear actin rods, a hallmark of cell stress observed in some neurodegenerative diseases. Thus, our findings describe a novel mechanism of RhoA proteolysis occurring in conditions of cell stress and apoptosis. Future work will investigate RhoA proteolysis in neurons and its effects on growth cone collapse and neurite retraction. We are seeking to determine how this mechanism may impact neuronal regeneration following central nervous system injury.

P632**Board Number: B884****Ionizing radiation injury of the skin: Histologic and metabolomic evaluation in the pig as a model for testing the potential benefits of topical treatments for cutaneous radiation injury.**

M. Tytell¹, M.B. Robinson², J.E. Dorand³, A.R. Gabard⁴, J.K. Hurt⁴, A.M. Anderson⁵, J.D. Bourland⁶, L.R. Burnett⁴;

¹Wake Forest Univ Sch Med, Winston Salem, NC, ²Neurobiology and Anatomy, Wake Forest Univ Sch Med, Winston-Salem, NC, ³Physics, Wake Forest University, Winston-Salem, NC, ⁴KeraNetics, Winston-Salem, NC, ⁵Biostatistics, Wake Forest Univ Sch Med, Winston Salem, NC, ⁶Radiation Oncology, Wake Forest Univ Sch Med, Winston Salem, NC

Destruction of the normal replacement capacity of the epidermis and loss of its barrier function after skin exposure to ionizing radiation is a major concern following a radiological event, such as a nuclear accident or “dirty” bomb. Current treatments are mainly palliative and do not reduce damage or promote repair. We have developed a model using the full-sized pig (*Sus scrofa*) to assess the responses of the skin to a range of β and x-ray radiation doses (18-48 Gy) over time. For β -ray radiation, a custom irradiation device was designed using strontium-90. For x-ray radiation, a conventional 300 kV orthovoltage x-ray device was modified to deliver the required, localized doses. Radiation was delivered to six, 4 cm diameter circular sites on each flank of ~30 kg female pigs (n=12 sites for 18 pigs). Dose and treatment sites were randomized on each pig, and the sites were visually graded and photographed every 3 or 4 days for up to 70 days. An equal number of pigs were euthanized on days 15, 35 and 70. Four 1-cm biopsies were collected from each of the 12 sites for histological processing and one 5-mm biopsy was frozen for metabolomic analysis. Visual grading revealed dose-related early and late erythema and moist desquamation. These observations correlated with histologic changes that included epidermal atrophy and dermal invasion by inflammatory cells, edema, and vascular pathology. Abnormal regenerative changes occurred at the higher radiation doses and longer post-irradiation intervals. Metabolomic analysis revealed dose-related increases in oxidative damage, prostaglandin-related molecules, mitochondrial breakdown, and bacterial penetration. These pathologic changes provide a greater understanding of the skin’s response to ionizing radiation and serve as a foundation from which potential treatments for this injury can be evaluated. Supported by the Biomedical Advanced Research and Development Authority, HHS, contract HHSO100201200007C.

P633**Board Number: B885****Caffeine inhibits angiogenesis via induction of endothelial cell apoptosis.**H. Li¹, L. Zhang², H. Jin³, S. Jin¹;¹Research Center, Affiliated Hospital of Yanbian University, Yanji, China, ²Department of anesthesiology, Meihekou Central Hospital, Meihekou, China, ³Department of Thoracic surgery, Yanbian University Affiliated Hospital, Yanji, China

Purpose: Numerous studies have shown that adenosine, adenosine receptor agonists, and/or adenosine transport inhibitors can stimulate angiogenesis. Recent study indicated that stimulation of adenosine receptor increased angiogenesis by down-regulating production of thrombospondin-1 (TSP-1). However, the effects of caffeine, as adenosine receptor antagonist on angiogenesis has not been studied yet. It is the aim of this study to determine the effect of caffeine on angiogenesis and to clarify the mechanism by which caffeine elicits such a response. **Methods:** To investigate the effects of caffeine on angiogenesis, chick embryonic chorioallantoic membrane (CAM) assay was performed, and data was analysed using image analysing program. Proliferation, migration and differentiation assays using human umbilical vein endothelial cells (HUVECs) were performed, to identify that caffeine affects on the specific step of angiogenesis. Apoptosis of HUVECs by caffeine was detected by FACS and DAPI staining. Expression of TSP-1, caspase-3 and Bcl-2 were examined through Western blotting. Immunofluorescence and DAPI staining were performed to identify the morphological change of HUVECs. **Results:** CAM assay showed that caffeine inhibited formation of blood vessels in dose-dependent manner. Caffeine had no effect on migration and differentiation of HUVECs. However, caffeine inhibited proliferation of HUVECs in both time- and dose-dependent manner. FACS analysis and DAPI staining showed that inhibitory effect of caffeine on the proliferation of HUVECs might be attributed to the induction of apoptosis. Caffeine increased the expression of TSP-1, which was abrogated by adenosine A2A/B agonist, but not affected by specific adenosine A2A agonist. These data indicate that caffeine regulates TSP-1 expression through blocking adenosine A2B receptor. Caffeine also increased caspase-3 expression and decreased Bcl-2 expression in HUVECs. **Conclusion:** We conclude that caffeine appears to block angiogenesis and that these effects may be mediated through increasing expression of TSP-1 via inactivation of adenosine A2B receptor.

P634**Board Number: B886****Developing a Model for Slow Hypoxic Injury and Vascular Degeneration in Amyloid Burdened Brains.**C.M. Floruta¹, F.L. Chaves¹, C.S. Medina¹, E.L. Bearer^{1,2};¹Department of Pathology, University of New Mexico, Albuquerque, NM, ²Biology, California Institute of Technology, Pasadena, CA

The breakdown of neurovascular systems may play a crucial role in the pathogenesis of Alzheimer's disease. However whether this breakdown initiates a degenerative mechanism or is the consequence of some other deleterious process remains unknown. We examined hippocampal pathology in double transgenic mice overexpressing a human mutant gene encoding the amyloid precursor protein (APP^{Swe/Ind}) using a combination of histochemistry and stereologic techniques. Expression of APP^{Swe/Ind} in these mice is driven by a tetracycline-sensitive promoter. Tetracycline transcriptional activator (tTA), the second transgene, is driven in turn by a CAM KIIa promoter that is only active in neurons. Thus this double transgenic construct allows us to control expression of APP^{Swe/Ind} with doxycycline. Utilizing this characteristic, we created three distinct experimental groups: A, display abeta plaque pathology and express APP^{Swe/Ind} at time of sacrifice; B, display abeta plaque pathology but do not express APP^{Swe/Ind} at time of sacrifice; and C, do not display abeta plaque pathology but do express APP^{Swe/Ind} at time of sacrifice. Stereologic investigation revealed decreased hippocampal volume in groups A(n=5) and B(n=5) when compared to group C(n=5) and age-matched wildtype (n=9) (p

P635**Board Number: B887****Real-time visualization of intracellular potassium dynamics in mouse macrophages during inflammasome-associated processes.**J.R. Yaron^{1,2}, L. Zhang¹, X. Kong¹, C.P. Ziegler¹, F. Su¹, S. Gangaraju¹, Y. Tian¹, H.L. Glenn¹, D.R. Meldrum¹;¹Center for Biosignatures Discovery Automation, The Biodesign Institute at Arizona State University, Tempe, AZ, ²School of Biological and Health Systems Engineering, Arizona State University, Tempe, AZ

Inflammasomes are caspase-1-activating, multiprotein platforms that mediate processing and secretion of pro-inflammatory cytokines and cell death in macrophages in response to host danger signals and pathogen invasion. It is well recognized that potassium efflux from the cell is a critical step for caspase-1 activation by inflammasomes in response to most stimuli. However, existing methods for directly investigating potassium in live cells are limited and most studies focus on bulk cell biochemical measurements or indirect indicators of pathway inhibition. Using novel intracellular potassium sensors and laser scanning confocal microscopy we demonstrate visualization of real-time potassium dynamics in live mouse macrophages. Specifically, we describe the kinetics of potassium efflux via the P₂X₇

purinergic receptor stimulated by exogenous ATP (active pathway) as well as the potassium ionophore nigericin (passive pathway). Further, we describe the mobilization of the mitochondrial potassium pool in response to exogenous ATP, suggesting a previously unobserved effect of P₂X₇ engagement beyond effecting solely cytosolic potassium efflux. These observations support a broader inflammasome-associated potassium response and demonstrate the applicability of an improved intracellular potassium sensor.

Age Dependent Loss of α (E)-catenin Potentiates Cisplatin-induced Apoptosis in Renal Tubular Epithelial Cells.

X. Wang¹, E.A. Borgmann¹, A.R. Parrish¹;

¹Medical Pharmacology and Physiology, University of Missouri, Columbia, MO

Cisplatin is a well-known anti-cancer drug used for the treatment of numerous solid tumors. A frequent side effect which limits the use of cisplatin therapy is nephrotoxicity. Previous studies in our lab have shown that aging is associated with loss of α (E)-catenin in aged kidney and aged kidney is more susceptible to cisplatin injury. We hypothesize that the loss of α (E)-catenin could increase susceptibility to cisplatin injury. To study the effects of reduced α (E)-catenin, a cell line with stable knockdown of α (E)-catenin (C2 cells) was used; NT3 is non-targeted control. C2 cells exhibited a significant loss of viability as determined by MTT assay compared with NT3 cells after cisplatin challenge, but showed no difference in lactate dehydrogenase (LDH) leakage. Increased caspase3/7/8/9 activation and PARP cleavage was observed in C2 cells after cisplatin treatment. Furthermore, blocking apoptosis using caspase 8, caspase 9, or pan-caspase inhibitors can completely abolish the difference in susceptibility between NT3 and C2 cells. The expression of α (E)-catenin was further decreased after cisplatin treatment, both in C2 and NT3 cells. Importantly, increased *in situ* apoptosis were detected in aged kidney after cisplatin challenge. In conclusion, loss of α (E)-catenin increases apoptosis of tubular epithelial cells which contributes to the increased nephrotoxicity induced by cisplatin in aged kidney.

Characterization of Novel Stress Granule Components in Cancer Cells.

H. Mahboubi¹, M. Kodiha¹, O. Moujaber¹, U. Stochaj¹;

¹Physiology, McGill University, Montreal, QC

The exchange of macromolecules between the cytoplasm and nucleus is essential for the viability of all eukaryotes. Nuclear transport relies on soluble factors, in particular adaptors and carriers, as represented by members of the importin- α and importin- β families. In addition to their well-established roles in nuclear transport, importin- α proteins also serve other functions. These range from

transcriptional regulation to control of proliferation in cancer cells. Some of these diverse functions are related to the stress response and in particular to the biology of stress granules (SGs). SGs are cytoplasmic compartments formed when cells are exposed to stress; they contain RNA-binding proteins and translationally arrested mRNAs. SGs play a protective role in cells, and a growing number of studies link SGs to various human diseases, such as cancer.

Here, we evaluated the response of soluble transport factors to different stressors in tumor cells. Since humans synthesize seven importin- α members that belong to three subfamilies with different cargo preferences, we focused on one representative of each group. We demonstrate that stress targets members of all three importin- α subfamilies, importin- α 1, importin- α 4, importin- α 5, as well as their binding partner importin- β 1 to SGs, but not to P-bodies. This SG association is specific and not a general property of nuclear carriers, as the nuclear exporter CAS did not concentrate in SGs. The physiological relevance of nuclear carriers in SGs is currently not understood. To address this question, we assessed their interaction with poly(A)-RNA, a major constituent of SGs. Our results establish, for the first time, that importin- α 1, but not importin- α 4 or α 5, specifically associates with poly(A)-RNA. This association occurs in a stress-depending fashion.

Taken together, we identified essential nuclear transport factors as novel SG constituents. Our work therefore sheds new light on the expanding functions of the nucleocytoplasmic transport apparatus. Moreover, it emphasizes the links between transport factors, the stress response and RNA biology. We propose that importin- α proteins, through their association with SGs, promote the survival of cancer cells under the stressful conditions they encounter in their hosts.

BH3-in-groove dimer interface that initiates mitochondrial Bax oligomerization rearranges to form a pore complex with an additional helix 9 dimer interface.

J. Lin¹, Z. Zhang¹, S. Subramaniam², J. Kale³, A. Senes², D.W. Andrews³;

¹Biochemistry and Molecular Biology, Univ Oklahoma Hlth Sci Ctr, Oklahoma City, OK, ²Biochemistry, University of Wisconsin-Madison, Madison, WI, ³Biological Sciences, Sunnybrook Research Institute, Toronto, ON

Proapoptotic Bax induces mitochondrial outer membrane permeabilization (MOMP) by forming oligomeric pores in the MOM. The assembly process and structure of the pores are largely undefined. Here, we revealed the key structural features of the pore using site-specific crosslinking and compartment-specific labeling approaches combined with mutational analysis. The BH3-in-groove dimer interface that was previously observed in crystals was indeed formed on the MOM surface by the activated integral Bax. After helix 5, a part of the groove, was released into the MOM, the remaining interface with helices 2, 3 and 4 was rearranged to another conformation. Another dimer interface was formed inside the membrane by two helices 9 that were either intersected or aligned in parallel. Large oligomers were generated by combinations of a dimer interface on the MOM with a dimer interface in

the MOM. A mutation in the groove that disrupted the BH3-in-groove interface inhibited not only the formation of other three interfaces but also the MOMP by Bax, suggesting that the formation of BH3-in-groove interface initiates a process resulting in the other three interfaces and an oligomeric pore in the MOM. In contrast, a mutation in helix 9 that disrupted the helix 9 dimer interfaces affected neither the BH3-in-groove and helices 2-3-4 dimer interfaces nor the MOMP, indicating that the helix 9 interfaces are dispensable.

Gas phase extract of cigarette smoke and its cytotoxic components induce cell death via protein kinase C and NADPH oxidase.

T. Higashi¹, Y. Mai¹, T. Horinouchi¹, K. Terada¹, E. Elmeligy¹, A. Hoshi¹, P. Nepal¹, T. Harada¹, S. Karki¹, M. Horiguchi¹, C. Hatate¹, S. Miwa¹;

¹Hokkaido University, Sapporo, Japan

Cigarette smoking is a major risk factor for several diseases, such as cardiovascular diseases, chronic pulmonary obstructive diseases, and several forms of cancer. Cigarette smoke is reported to contain more than 4,000 chemical compounds. Recent studies indicate that cigarette smoke contain stable components which have the potential to stimulate cellular reactive oxygen species (ROS) production. Cigarette smoke consists of two phases: tar phase containing nicotine and gas phase. In view of human health, the gas phase is more important, because it can pass through the lung alveolar epithelium to reach the circulation, and induces cytotoxicity in tissues remote from the lung. However, the chemical compounds responsible for cytotoxicity in the gas phase of cigarette smoke and molecular mechanism of their cytotoxicity have not been elucidated. The purposes of this study are identification of cytotoxic compounds in cigarette smoke gas phase and elucidation of molecular mechanisms for their cytotoxicity. The gas phase extract of cigarette smoke (nicotine- and tar-free cigarette smoke extract, CSE) was prepared by passing the main stream of cigarette smoke through Cambridge filter to remove tar phase containing nicotine and bubbling it in phosphate-buffered saline. For determination of cytotoxicity of CSE, MTS reduction assay, lactate dehydrogenase (LDH) leakage assay, propidium iodide (PI) uptake assay, and DNA fragmentation assay were used. The CSE induced protein kinase C (PKC)- and NADPH oxidase (NOX)-dependent ROS production, cell membrane damage, and cell death. Intracellular Ca²⁺-dependent PKC activation was induced by CSE. To identify the cytotoxic components in the CSE, the CSE was fractionated into nine fractions by reverse-phase HPLC, each fraction analyzed for cell membrane damage by PI uptake assay, and two positive fractions were obtained. Using LC/MS and GC/MS in combination with functional assays, the unsaturated carbonyl compounds such as acrolein (ACR), methyl vinyl ketone (MVK) and 2-cyclopentene-1-one (CPO) were identified as the major compounds responsible for the cytotoxic activity in these two fractions of the CSE. Incubation for a short period of time (4 h) with ACR and MVK but not CPO induced both cell membrane damage (determined by PI uptake and LDH leakage assays) and cell death (determined by MTS reduction and DNA fragmentation assays) in rat C6 glioma cells in a PKC- and NOX-dependent manner. In contrast,

CPO induced cell death alone without cell membrane damage in a manner independent of PKC and NOX only after incubation for a longer period of time (24 h). These results show that ACR and MVK are responsible for acute cytotoxicity of the CSE through PKC- and NOX-dependent mechanism, whereas CPO is responsible for delayed cytotoxicity of the CSE through PKC- and NOX-independent mechanism.

Cytoplasmic translocation of DGKzeta exerts a protective effect against p53-mediated cytotoxicity.

K. Goto¹, T. Tanaka¹;

¹Department of Anatomy and Cell Biology, Yamagata University School of Medicine, Yamagata, Japan

The transcription factor p53 plays a crucial role in various stress responses, such as DNA-damage, hypoxia, hyperproliferation, and oncogene activation. In response to cellular stresses, p53 triggers various cellular reactions that engender DNA repair, cell cycle arrest, apoptosis, senescence, differentiation, and inhibition of angiogenesis. Therefore, p53 protein levels and activity need to be kept under tight control. Diacylglycerol kinase (DGK) consists of a family of isozymes that metabolize a lipid second messenger diacylglycerol. Of the family, DGKzeta, containing a nuclear localization signal (NLS), localizes primarily to the nucleus in various cell types and is involved in a variety of pathophysiological cellular responses through the metabolism of DG. Recently, we have reported that excitotoxic stress induces DGKzeta nucleocytoplasmic translocation in hippocampal neurons. Although p53 activation is implicated in the apoptotic cell death under stress conditions, it remains unclear how DGKzeta nucleocytoplasmic translocation is involved in p53-mediated stress response mechanisms. In this study, we examined a pathophysiological link between DGKzeta cytoplasmic translocation and p53-mediated cytotoxicity after doxorubicin (DOX)-induced DNA damage. For this purpose, using cellular and organismal models, we investigated the effect exerted by DGKzeta on p53, i.e., how increased cytoplasmic pool of DGKzeta and attenuated nuclear DGKzeta affect p53 function after apoptotic stimuli. We show here that cytoplasmic DGKzeta attenuates p53-mediated cytotoxicity against DOX-induced DNA damage by facilitating cytoplasmic anchoring and degradation of p53 through a ubiquitin-proteasome system. Concomitantly, decreased levels of nuclear DGKzeta engender down-regulation of p53 transcriptional activity. Consistent with these in vitro cellular experiments, DGKzeta-deficient brain exhibits high levels of p53 protein after kainate-induced seizures and even under normal conditions. These findings suggest that 1) DGKzeta serves as a sentinel to control p53 function under normal and stress conditions and 2) its cytoplasmic translocation is a protective stress response and attenuates p53-mediated cytotoxicity under stress conditions. This study provides a novel molecular basis for the regulation of p53-mediated apoptotic pathway.

P641**Board Number: B893****Med13p anchors cyclin C in the nucleus to prevent stress-independent mitochondrial fragmentation and stress hypersensitivity.**K. Cooper¹;¹RowanSOM, Stratford, NJ

The budding yeast cyclin C has two roles in the cell. First, in combination with Med12p, Med13p and Cdk8p, cyclin C forms a subcomplex (Cdk8 module) of the mediator that represses transcription initiation of several gene types including stress responsive loci. In its second role, cyclin C translocates to the cytoplasm in response to oxidative stress. In the cytoplasm, cyclin C associates with the mitochondria to promote extensive fission and programmed cell death. Therefore, releasing cyclin C from the nucleus represents a critical decision point in the cellular response to stress [1]. We demonstrate that Med13p represents the nuclear anchor that retains cyclin C in the nucleus in unstressed cells. Deleting MED13 allows cyclin C relocation to the cytoplasm in the absence of stress. This event has three important consequences for the cell. First, the mitochondria undergo constitutive extensive fission. Second, since this fragmentation prevents mitochondrial DNA repair, large deletions occur in the mitochondrial genome resulting in loss of organelle function. Finally, mitochondrial hyper-fission hypersensitizes cells to programmed cell death [2]. Further studies revealed two independent mechanisms that dissolve the Med13p-cyclin C interaction. First, cyclin C is phosphorylated by the Slr2p MAP kinase [3]. This modification causes partial release of cyclin C from Med13p. However, final dissolution of the interaction requires Med13p proteolysis. Med13p destruction requires Cdk8p kinase activity and the 26S proteasome. Taken together, this study defines a complex molecular switch controlling cyclin C subcellular localization and ultimately mitochondrial shape, function and sensitivity to cytotoxic agents. This study reveals a new role for Med13p in maintaining mitochondrial maintenance and preventing aberrant activation of the programmed cell death pathway by restricting cyclin C to the nucleus in non-stressed cells.

P642**Board Number: B894****Complexes of platelet factor 4 with pathogenic anti-platelet factor 4/heparin antibodies induce platelet activation, apoptosis, and release of microparticles.**T.A. Nevzorova¹, E.R. Mordakhanova¹, I.A. Andrianova¹, L. Rauova^{2,3}, R.I. Litvinov²;¹Department of Biochemistry, Kazan Federal University, Kazan, Russia, ²University of Pennsylvania School of Medicine, Philadelphia, PA, ³Children's Hospital of Philadelphia, Philadelphia, PA

Platelets are blood cells that have many important functions, including their well-known role in stopping bleeding (hemostasis) and thrombosis. Platelet functionality is affected in (patho)physiological conditions by a number of bioactive blood components, such as a self-secreted chemokine platelet factor 4 (PF4) and its complexes with heparin and anti-PF4/heparin antibodies. A subset of these antibodies cause heparin-induced thrombocytopenia (HIT), a severe immunological complication of heparin therapy, in which platelets aggregate and cause thrombotic obstruction of the microvasculature; however, the mechanisms and functional cellular consequences of such platelet activation remain largely unclear. To get insight into the link between autoimmunity and platelets in HIT, we incubated resting platelets in vitro with either purified recombinant human PF4 (10 µg/ml) or isolated pathogenic monoclonal mouse anti-human-PF4/heparin antibodies (named KKO) (50 µg/ml) or the immune complexes between PF4 and KKO formed by mixing them at the same final concentrations. Gel-filtered platelets isolated from the blood of healthy donors were treated during 15-60 min followed by flow cytometry using apoptotic markers Annexin V-FITC and MitoTracker Red CMXRos. Annexin V binding characterize the exposure of the procoagulant phosphatidylserine on the outer platelet membrane during activation and apoptosis, while lowering of intensity of the MitoTracker reflects a decrease of the mitochondrial membrane potential during early stages of apoptosis. We revealed that in the presence of the KKO/PF4 complexes the number of Annexin V-FITC-positive signals increased with a concurrent shift of the particle size towards smaller structures, likely representing formation of platelet-derived microparticles. Staining of platelets with the MitoTracker revealed that the KKO/PF4 complexes significantly reduced the mitochondrial membrane potential, which is indicative of platelet apoptosis. Compared to the KKO/PF4 complexes, PF4 by itself induced qualitatively similar but substantially less pronounced changes in the platelet status. KKO alone had no detectible effects on the platelets. The results suggest that immune complexes of the pathogenic anti-PF4/heparin antibodies with PF4 induce platelet activation and apoptosis accompanied by release of platelet-derived procoagulant microparticles, which may contribute to the thrombotic component of HIT. In addition, the data suggest that PF4 released at the sites of inflammation and injury by activated platelets promotes their programmed death and maybe subsequent scavenging. (Research supported by the Program of Competitive Growth of Kazan Federal University)

P643**Board Number: B895****Estrogen improves osteocyte viability by inhibiting apoptosis and enhancing autophagy in alveolar process of ovariectomized rats.**R.F. Silva¹, G.R. Sasso¹, E. Sasso-Cerri², M.J. Simões¹, P.S. Cerri²;¹Morphology and Genetics, Federal University of São Paulo (UNIFESP), São Paulo, Brazil, ²Morphology, Univ Estadual Paulista - UNESP, Araraquara, Brazil

Osteocyte viability is influenced by several factors, such as estrogen status and ageing. Autophagy, a cell survival mechanism, has also been shown to maintain osteocyte viability by preventing accumulation of cellular stress. However, it is not known whether estrogen improves osteocyte survival by promotion of autophagy. Thus, we aimed to investigate whether estrogen influences osteocyte survival by regulating autophagy. Sixty-six adult female rats were sham-operated (SHAMG) or ovariectomized (OVXG). After 21 days, the rats received daily subcutaneous injection of 30µg/Kg of body weight of estrogen (OVXEG) or vehicle solution (OVXG) for 15, 30 and 45 days. Twelve non-estrogen-treated SHAM and OVX female rats were used as baseline groups. Afterwards, the rats were euthanized and the maxillae containing the alveolar processes of the first molars were fixed and embedded in paraffin. Sagittal sections were subjected to immunohistochemistry for detection of apoptosis (cleaved caspase-3, bcl2 and TUNEL method) and autophagy (beclin1, LC3II and p62). Some fragments of maxilla were also fixed and embedded in araldite for transmission electron microscopy. Significant increase in the incidence of caspase-3, TUNEL and p62-positive osteocytes was observed in the OVX baseline group in comparison to SHAM baseline. On the other hand, the frequency of beclin-1 and LC3II-positive osteocytes was significantly lower in the OVX baseline group. In all periods, a significant increase of TUNEL-positive osteocytes was observed in the OVXG in comparison to OVXEG. In addition, high incidence of caspase-3-immunolabeled osteocytes was also found in the OVXG at 15 and 45 days. In these periods, a significant reduction in the incidence of beclin1-positive osteocytes was found in the OVXG in comparison to OVXEG. At 45 days, a significant increase in the incidence of p62-positive osteocytes and significant reduction in the incidence of LC3II was observed in the OVXG in comparison to OVXE. Significant differences were not verified in the frequency of bcl2-immunolabeled osteocytes among the groups. Ultrastructural analysis revealed osteocytes containing peripheral condensed chromatin; some abnormal osteocytes exhibiting cytoplasmic protrusions were also found. Occasionally, some bone lacunae contained apoptotic bodies derived from osteocytes. Our findings point to a possible correlation between autophagy reduction and apoptosis increase in osteocytes, under estrogen deficient condition. On the other hand, estrogen replacement improved osteocyte survival by stimulating autophagy and inhibiting apoptosis in the alveolar process of ovariectomized rats. These findings indicate that autophagy plays an important role in osteocyte survival.

(Support by FAPESP nº 2012/19428-8 and CNPq)

P644**Board Number: B896****Neutrophils of Patients with Chagas Positive Serology in Autologous Culture.**F.M. Rodriguez¹, A.D. Orquera¹, M.R. Maturano¹, N.S. Infante¹, I.T. Novak^{1,2};¹Institute of Cell Biology, Faculty of Medical Sciences, National University of Cordoba, Cordoba, Argentina, ²Institute of Cell Biology, Natl Univ Cordoba Fac Med, Cordoba, Argentina

Neutrophils or polymorphonuclear (PMN) leukocytes play a crucial role in protecting against infections and recent evidence suggests that they are involved in a key role in effector and regulatory mechanisms of the innate and adaptive responses (Mantovani et al., 2011; Phillipson and Kubes, 2011). Currently there is controversy about the half life of these cells (Kolaczowska and Kubes, 2013). In inflammatory conditions, PMN can release neutrophil extracellular traps (NETs) (Brinkmann et al, 2004, Kolaczowska and Kubes, 2013) composed of chromatin, histones and granule proteins, which sometimes lead to NETosis. Objectives: perform an ultrastructural study to observe the morphology of PMN in relation to characteristics of viability, apoptosis, or NETosis, at different times of autologous culture in healthy people and with positive serology for Chagas who donate blood to the blood bank of the UNC. From healthy human blood samples (n = 10) and with positive Chagas serology (n = 6), anticoagulated with heparin (donated by the blood bank, UNC, in anonymity, with serology data) autologous leukocyte cultures were performed in TC199 medium (SIGMA, St. Louis, MO). Samples of cell culture to 1, 3, 20, 24 and 48 h were subjected to stains standard, H/E, ATO, Giemsa microscopy and processing techniques for ultrastructural study with an electron microscope MET: Zeiss LEO-neoi. Results: in culture samples with positive serology for Chagas PMN were observed ultrastructural features of viability at all times even at 48h; in one case it was observed an NETosis-compatible image. In healthy people, after 3 h of culture were observed images of apoptosis. Most of PMN after 20 h showed apoptotic characteristics. We open questions for further study: what stimuli contribute to increase the half-life of PMN in Chagas? which stimuli induce to NETosis?, is this NETosis "vital" or "suicide"?

P645**Board Number: B897****Effect of Regular and Light Cigarette Smoke Extract on Human Lung Epithelial Cells.**A. Madabushi¹, A.R. Gbemafu¹, L.Y. Kougang¹;¹Baltimore City Community College, Baltimore, MD

Cigarette smoking continues to be a leading preventable cause of morbidity and mortality worldwide. Cigarette smoke mediates oxidative as well as inflammatory events directly effecting airway and alveolar linings. This eventually leads to smoking related pulmonary diseases and disorders. One such chronic disorder of unknown etiology is idiopathic pulmonary fibrosis (IPF). The complete disease biology of IPF is an area of active research; however one of the key determinant of initiation and progression of IPF is believed to be based on the response of alveolar epithelial cells type II (AEC II) to the wound healing

process post injury. The purpose of this study is to acquire a better understanding of how short term exposure of cigarette smoke from regular or light cigarette impacts AEC II and contributes to the initiation of IPF. Out of the two popular brands tested in the study, morphology studies and cell viability assays in AEC II cells have shown similar cell death upon treatment with smoke extract from light or regular cigarettes for the brands tested. The wound healing assays have also shown that wound healing is substantially reduced, if the cells are treated with cigarette smoke extracted media regardless of the type (regular or light) and brand used. This indicated loss of function and viability on AEC II post cigarette smoke treatment holds the key to unravelling the initiation of IPF and similar pulmonary disorders.

Investigation of intrinsic cell death using different inducers reveals differences in cell death pathways upon lysosomal leakage.

G.N. Joshi¹, D. Knecht²;

¹Department of Molecular and Cell Biology, Univ Connecticut, Storrs, CT, ²Department of Molecular and Cell Biology, Univ Connecticut, Storrs Mansfield, CT

Cell death is necessary to maintain homeostasis; however, under several conditions this homeostasis is disturbed resulting in adverse physiological and pathological outcomes. Apoptosis, the most commonly studied form of cell death can be divided in to intrinsic and extrinsic pathways. The intrinsic pathway can be activated by lysosomal leakage. Various compounds can be designed to specifically target lysosomes to activate this death stimulus, which can be used for therapeutic purposes. We were therefore interested in understanding the underlying molecular machinery leading up to cell death post lysosomal leakage.

Three different compounds were chosen to stimulate lysosomal leakage: silica particles that cause lung fibrosis and the disease silicosis; staurosporine (STS), a protein kinase inhibitor; and Leu-Leu-O-Me (LLOMe), a lysosmotropic agent. Alveolar macrophages were chosen as a cell line of choice due to their relevance to the development of silicosis. According to literature, lysosomal leakage can activate protein Bid that can further activate cytoplasmic Bax resulting in its relocalization to mitochondria and formation of pores in the outer mitochondrial membrane resulting in mitochondrial outer membrane permeabilization (MOMP). This leads to release of Smac and Cytochrome-c causing activation of Caspase-9 and -3. Activation of the latter is a point-of-no return in apoptosis. MOMP results in disruption of mitochondrial function by causing mitochondrial membrane depolarization.

Spectrally distinct genetically encoded fluorescent probes for Bid, Bax, Smac and caspase were expressed in macrophages individually or in combination. Both Bid and caspase were Förster Resonance Energy Transfer (FRET) based probes. Multiple compounds and parameters were tested utilizing a semi-throughput imaging scheme. With all three compounds, lysosomal leakage occurred within one hour and continued over time. Bax activation preceded mitochondrial membrane depolarization for both silica

and STS treatment where as for LLOMe treatment Bax activation follow mitochondrial membrane depolarization. Surprisingly for STS treated cells, Smac release from mitochondria was observed a minute prior to Bax localizing into mitochondria rather than later. FRET based Bid activation was observed post caspase activation rather than following lysosomal leakage for both silica and STS treatment. Our data therefore does not support the role of Bid in Bax activation but rather shows Bax activation to occur by yet an unknown trigger. Caspase activation and cell blebbing, a morphological characteristic of apoptosis was shown to occur simultaneously with mitochondrial depolarization in staurosporine treated cells or with mitochondrial hyperpolarization in silica treated cells.

The effect of aflatoxin B1 on Jurkat T-cell growth, viability, and activation.

L. Sutherland¹, T. Laakko Train²;

¹Department of Chemistry, Elon University, Elon, NC, ²Department of Biology, Elon University, Elon, NC

Aflatoxins develop from two common mold species, *Aspergillus flavus* and *Aspergillus parasiticus*, known for the contamination of animal feeds as well as staple foods such as groundnuts, corn, rice, spices and seeds. This contamination is common in animal feed as well as food supplies in developing countries, where food-production technology is not developed enough to avoid the conditions conducive to mold growth. The metabolite aflatoxin B1 (AFB1) has been identified as a carcinogen known to cause liver cancer. Animal studies have suggested that AFB1 may also have a negative impact on immune function and clinical studies on humans exposed to aflatoxin have also shown immunosuppression. However, the direct effects of exposure to aflatoxin on human immune cells and the mechanism behind immunosuppression have not been thoroughly studied. This study investigated the effect of AFB1 on T lymphocyte activation, growth and viability. After treatment of the Jurkat T-cell line with 10 μ M AFB1 for 48 hours, microscopic viability counts and flow cytometric analysis showed that cell concentrations decreased by 50%. A 7-day treatment with 10 μ M AFB1 showed a decrease in cell concentration to 42% of the control. In order to investigate the decrease in cell concentration, Propidium Iodide (PI) and BrdU staining and flow cytometric analysis were used in order to identify alteration of the cell cycle. In Jurkat cells treated for 24 hours with AFB1, no change in the cell cycle was observed. Western Blot analysis of extracts obtained from cells pre-treated with or without AFB1 followed by stimulation with phorbol myristate acetate and phytohemagglutinin (PMA/PHA) showed the ERK MAP Kinase activation pathway was not significantly modulated by AFB1, thus suggesting that changes in cell activation were not responsible for immunosuppression. Additionally, the potential induction of apoptosis was studied using Annexin-V/PI staining and flow cytometric analysis. After a 48 hour treatment with 10 μ M AFB1 the t-cell line showed a significant increase in Annexin V+/PI- cells (early and late apoptotic cells) of approximately 50% (from an average 8.14% to 12.5%) from the untreated control. After a 7 day treatment with the same conditions, the proportion of apoptotic cells increased by 83%. These results suggest AFB1 might promote immunosuppression by significantly reducing T-cell concentrations, at least in part, by inducing apoptosis.

P648**Board Number: B900****The study of BAX oligomerization kinetics using live-cell imaging.**M. Maes¹, C. Schlamp¹, R. Nickells¹;¹Ophthalmology and Visual Sciences, Univ Wisconsin-Madison, Madison, WI

BAX, a pro-apoptotic *BCL2* gene family member, regulates the committed step of the intrinsic apoptotic pathway. Once activated, BAX forms oligomers at the mitochondrial outer membrane, which facilitate the release of cytochrome c. To date, the mechanism of BAX activation has been a primary focus of study, while the mechanism of BAX oligomerization has been secondary, and predominantly described using biochemical methodology. We propose that by studying the kinetics of BAX oligomerization using live-cell imaging, we can provide a better understanding of the underlying mechanisms of BAX oligomerization and function.

To monitor BAX oligomerization kinetics *in vitro*, HCT116^{BAX^{-/-}/BAK^{-/-}}, D407 and neuronally differentiated 661W cells transiently expressing fluorescently labeled wildtype BAX or non-oligomerizing BAX mutant protein were challenged with apoptotic stimuli, staurosporine or HDAC3 overexpression. Cells were imaged every minute for 60-75 minutes using spinning disc confocal microscopy and changes in BAX fluorescence at individual mitochondria were quantified using IMARIS 7.7. The curve fitting function of the SciPy library was used to fit the resulting quantitative data. Monitoring BAX non-oligomerizing mutants and cytochrome c release validated BAX oligomer formation in the system.

BAX oligomerization kinetics can be quantified at individual mitochondria. Oligomerization follows a sigmoidal growth function from which, we can calculate metrics for the initiation and rate of BAX oligomerization. Mitochondria in individual cells had nearly identical initiation times but exhibited varying rates of BAX oligomerization. The average rate of BAX oligomerization within a population of over 300 mitochondria from D407 cells is 0.38 ± 0.30 RFU/min and this oligomer formation, defined as the time of initiation to maximum saturation, occurs within 10-12 minutes. The distribution of BAX oligomerization rates between two divergent cell types, D407 and neuronally differentiated 661W cells, were not statistically different even when the average initiation time for each cell type varied by several hours. Finally, we observed that cytochrome c release occurred at the initiation time of oligomer formation. These preliminary results demonstrate that the study of BAX oligomerization kinetics can be a powerful tool for providing insight into the mechanism of BAX function in apoptosis.

P649**Board Number: B901****Nanoparticle-induced stress signaling and apoptosis in diverse cell lines.**A. Calixto¹, B.N. Manes¹, S.K. Alvarado¹, J.L. Brewster¹;¹Natural Science Division, Pepperdine Univ, Malibu, CA

Carbon black (CB) is a type of nanoparticle commonly found in air pollution generated through fossil fuel combustion. Exposure of cells to CB and other types of nanoparticles results in endocytosis and particle accumulation in the cytosol. In this work, we have begun to assess cellular toxicity and stress signaling pathways in cells exposed to CB. Doses of exposure ranged from 5-100 ug/ml. Size analysis of CB nanoparticles generated by sonication were shown to range upwards from 75 nm in diameter, with an average size of ~130 nm in diameter. Analysis of cell death activation was performed in several cell types, including adenocarcinomic human alveolar basal epithelial (A549), hamster fibroblasts (BHK21), and human bronchial epithelial cells (BHE16). Exposing cells over a time course of five days, CB exposure was shown to dramatically induce condensed nuclei in each cell type in a dose-dependent manner. Consistent with this finding, cell survival assays revealed CB exposure in doses of 40 ug/ml or higher to reduce cell survival in both BHK21 and BHE16 cells. Interestingly, the human A549 cells displayed only a mild sensitivity to CB exposure at high doses. Results of the cell death assay were confirmed to be apoptotic using standard nick end-labeling assay (TUNEL). CB-exposed cells displayed a transient elevation of reactive oxygen species (ROS) levels, consistent with other reports noting nanoparticle-induced stress signaling. Efforts are underway to evaluate which stress signaling pathways are responsible for triggering apoptotic death in these cells, with focused attention being applied to the endoplasmic reticulum.

Chaperones, Protein Folding, and Quality Control 1**P650****Board Number: B902****Quality control of GPI-anchored proteins in the secretory pathway.**P. Satpute-Krishnan¹, J. Lippincott-Schwartz^{2,3};¹Cell Biology and Metabolism Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD, ²Physiology Course at Marine Biological Laboratory, Woods Hole, MA, ³Cell Biology and Metabolism Program, NICHD, NIH, Bethesda, MD

Accumulation and aggregation of misfolded secretory and membrane proteins can lead to various degenerative diseases. To avoid this, cells employ quality control systems that route misfolded proteins for degradation, including the well studied ER associated degradation (ERAD) pathways. ERAD involves retrotranslocation of the protein from the ER to the cytosol for proteasomal degradation. However, not all misfolded secretory pathway proteins are efficient ERAD substrates, requiring alternate degradation

pathways. In particular, we found that misfolded GPI-anchored proteins (GPI-APs) are poorly recognized by ERAD systems. GPI-APs encompass a major class of proteins that play essential roles in critical life processes including embryogenesis, fertilization, neurogenesis, and immunity (1). The GPI-anchor is a post-translational modification conserved in all eukaryotes (1). Despite the prevalence and ubiquity of GPI-APs, little is known about how their quality control is regulated.

To elucidate how cells handle misfolded GPI-APs, we created a diverse panel of fluorescent protein-tagged misfolded variants of GPI-APs and monitored them by live cell microscopy combined with biochemical analysis. We identified a novel degradation pathway that operates constitutively but is markedly enhanced during ER stress (2). At the onset of stress, misfolded GPI-APs dissociate from ER chaperones and through requisite interactions with p24 ER-export factors leave the ER to the secretory pathway. Inhibiting this pathway through depletion of its key ER-export factor results in their aggregation in the ER. We named this stress-inducible mechanism RESET (for rapid ER stress-induced export) as it helps to reset ER homeostasis during the critical period before induction of the unfolded protein response.

Intriguingly, after release from the ER into the secretory pathway, misfolded GPI-APs transiently access the cell-surface before destruction in lysosomes, implicating plasma membrane-level quality control. Although misfolded transmembrane proteins have been shown to be downregulated from the plasma membrane after ubiquitination on their cytosolic regions, GPI-APs lack a cytosolic domain, implicating a distinct pathway for rapid downregulation of misfolded GPI-APs. We are now using the tractable experimental systems that we have developed to reveal novel mechanisms in plasma membrane quality control.

Lipid Disequilibrium Destabilized a Subset of Membrane Proteins.

B.S. Ng¹, S. Hofelzer², D.T. Ng^{2,3}, G. Thibault^{1,4};

¹School of Biological Sciences, Nanyang Technological University, Singapore, Singapore, ²Temasek Life Sciences Laboratory, Singapore, Singapore, ³Biological Sciences, National University of Singapore, Singapore, Singapore, ⁴Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore

Hundreds of distinct lipids, of varying concentrations, assemble to form biological membranes. The most abundant, phospholipids, varies according to head group structures, acyl chain length and double bounds. In eukaryotes, lipid compositions can differ widely among organelles. In most cases, the

biological significance of these differences remains unclear. However, links between disease states and lipid disequilibrium have been proposed. It was reported by several groups that change in the ratio of the most two abundant phospholipids, phosphatidylcholine / phosphatidylethanolamine (PC/PE), might cause non-alcoholic fatty liver disease (NAFLD). Recently, we reported on how budding yeast cells respond to and cope with PC/PE disequilibrium. Using lipidomic, genomic, and proteomic technologies, the data revealed that the adaptive cells responded by remodeling the protein homeostasis network without restoring lipid composition. We termed this process the membrane stress response (MSR). Interestingly, we observed that some transmembrane proteins (TP) were strongly up- and down-regulated at the genomic and proteomic levels, respectively. Diverse candidate proteins were analyzed from normal and mutant cells to characterize their stability. Results suggest the stability of certain mature TPs is affected from lipid imbalance. Furthermore, premature degradation of the candidates directly affects ER functions such as protein translocation and degradation if not for the intervention of the unfolded protein response (UPR). We are currently exploring how lipid imbalance affects the stability of such TPs.

Disulfide bond formation regulates PMEL amyloid potential.

T. Ho^{1,2}, B. Watt², M.S. Marks³;

¹Pathology and Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA, ²Cell and Molecular Biology, University of Pennsylvania School of Medicine, Philadelphia, PA, ³Pathology and Laboratory Medicine, University of Pennsylvania Children's Hospital of Philadelphia, Philadelphia, PA

The deposition and accumulation of amyloid protein is a common feature of many neurodegenerative diseases. However, not all amyloid proteins are associated with disease. For example, premelanosome protein (PMEL) is a functional amyloid protein that forms nontoxic amyloid fibrils that serve to template the polymerization of melanins within the melanosomes of pigment cells. PMEL is synthesized as a type I transmembrane protein and navigates the secretory pathway in a non-amyloid form; only within stage I melanosomes do proteolytically processed PMEL fragments form benign amyloid fibrils under normal physiological conditions. Here we provide evidence that disulfide bond formation with a partner protein might regulate the timing of PMEL amyloid formation, potentially preventing the formation of toxic amyloid isoforms. Results from non-reducing SDS-PAGE, size exclusion chromatography, and sedimentation velocity analyses support the existence of two covalent PMEL complexes of approximately 250kDa (complex 1) and 160kDa (complex 2). By metabolic pulse-chase and immunoprecipitation, complex 1 forms concomitant with or soon after ER exit, whereas complex 2 is generated in the late Golgi or a post-Golgi compartment. By 2-D non-reducing/reducing PAGE of metabolically labeled and immunoprecipitated material, these complexes consist of both full-length, Golgi-matured PMEL and post-Golgi cleaved PMEL fragments. No additional proteins were detected by 2-D PAGE or by mass spectrophotometric analysis of tryptic peptides from purified complex 2. Formation of both complexes is impaired by mutagenesis of cysteine 301 (C301S) within the

amyloidogenic M α domain, whereas formation of complex 2 is uniquely disrupted by mutagenesis of cysteine residues within a cysteine-rich Kringle-like domain that lies outside of the amyloidogenic region. Importantly, these mutations have very different effects on amyloid fibril formation upon transient overexpression in a non-pigment cell type, HeLa. Due to the absence of melanosomes in this system, amyloid fibrils composed of wild-type PMEL form in late endosomal multivesicular compartments. Compared to wild type PMEL, the C301S variant displays relatively normal levels of amyloid fibril formation in these compartments, whereas a C566S variant (lacking a Kringle-like domain cysteine residue) displays drastically reduced levels of amyloid fibril formation. Together, these results indicate that (1) disulfide bonds within the Kringle-like domain are necessary to chaperone the PMEL amyloidogenic domain for effective amyloid formation, and (2) complex 1 might serve to inhibit premature fibril formation, such that resolution of this species to complex 2 is necessary for normal fibril formation.

Conformationally promiscuous prion-like domains coordinate RNP granule condensation/dissolution dynamics during stress.

S. Kroschwald¹, S. Alberti¹;

¹MPI-CBG, Dresden, Germany

The formation of large supramolecular assemblies, such as stress-inducible RNP granules, is a poorly understood process. Here, we perform an extensive analysis of P bodies and stress granules in budding yeast and find that they have very distinct material properties: whereas P bodies behave as liquid droplets, stress granules adopt a solid material state, which originates from co-aggregation with misfolded proteins. Maintenance of the liquid P body state depends on the continuous action of protein disaggregases, and interference with this process results in the entrapment of P body components in stress granules. We further demonstrate that RNP assembly can be nucleated through multiple pathways and requires scaffolding factors such as misfolded proteins or RNAs. Low complexity domains can also drive RNP granule assembly, and we find that these domains do not undergo prion-like conformational conversions but function as versatile molecular adaptors that promiscuously interact with other low complexity domains or misfolded proteins. In summary, our findings reveal a high degree of adaptability and redundancy in RNP granule biogenesis, which is regulated and maintained by ATP-driven disaggregating machines.

P654**Board Number: B906****Intracellular Calcium Regulates Nonsense-Mediated mRNA Decay in Human Cells.**A. Nickless¹, E. Jackson², J. Marasa², P. Nugent¹, R.W. Mercer¹, D. Piwnica-Worms³, Z. M.D. Anderson Cancer Center, Houston, TX

The nonsense-mediated mRNA decay (NMD) pathway functions as an RNA surveillance system that selectively eliminates aberrant transcripts containing premature translation termination codons (PTCs). In addition, NMD acts as a gene expression regulatory mechanism that controls the levels of a number of physiological mRNAs. NMD modulates the clinical outcome of a variety of human diseases, including cancer and many genetic disorders, and may represent an important target for therapeutic intervention. To investigate the NMD pathway and to begin to develop NMD-targeting therapeutics, here we have developed a novel multicolored, bioluminescence-based reporter system that can specifically and effectively assay NMD in live human cells. Using this reporter system, we conducted a robust high-throughput small-molecule screen in human cells and, unexpectedly, identified a group of cardiac glycosides including ouabain, digoxin, digitoxin, proscillaridin and lanatoside C as potent inhibitors of NMD. Cardiac glycoside-mediated effects on NMD are dependent on binding and inhibiting the Na⁺/K⁺-ATPase on the plasma membrane and subsequent elevation of intracellular calcium levels. Induction of calcium release from endoplasmic reticulum also leads to inhibition of NMD. Thus, this study reveals intracellular calcium as a key regulator of NMD and has important implications for exploiting NMD in the treatment of disease.

P655**Board Number: B907****A mechanism of polarized inheritance of proteome damage during yeast asymmetric cell division.**C. Zhou¹, R. Li², B.D. Slaughter², J. Unruh²;¹Rong Li lab, Stowers Institute for Medical Research, Kansas City, MO, ²Stowers Institute for Medical

Research, Kansas City, MO

Formation and propagating of protein aggregates cause many aging-related and amyloid diseases. In yeast, the process of replicative aging is naturally associated with accumulation of damaged protein aggregates that are distributed asymmetrically during cell division. In a crowded cytosolic environment with many organelles, aggregate formation can be a consequence of non-native protein structures being introduced into these well-organized intracellular compartments. How do membrane-based organelles contribute to and coordinate the formation and distribution of protein aggregates is not well understood. In this study, we investigated the role of organelles in the formation, dissolution and

distribution of protein aggregates. We obtained evidence that cytosolic unfolded proteins do not aggregate spontaneously; instead, active translation and nascent polypeptides are required to initiate protein aggregation on the surface of ER, an organelle harboring a majority of translation sites. In addition to ER, mitochondria play important roles in the dynamics and asymmetric segregation of aggregates during mitosis.

General occurrence of pausing in translation of the *E. coli* proteome members as studied by direct detection of nascent polypeptides.

Y. Chadani¹, S. Chiba², K. Ito²;

¹Graduate School of Biosciences and Biotechnology, Tokyo Institute of Technology, Yokohama, Japan,

²Kyoto Sangyo University, Kyoto, Japan

Detailed knowledge only recently started to accumulate about the progression of translation elongation, which is not simply a latent step in the central dogma and takes tens of seconds in prokaryotes and a few minutes in eukaryotes. Some nascent polypeptides interact with the ribosomal exit tunnel to modulate elongation speed as a means of gene regulation (1). Translational modulation could also affect the fates of the polypeptide products including folding, modification and subcellular targeting. Although the methodology of ribosome profiling has recently been used to detect events of translation pausing, we still need more direct detection of translation intermediates. We use the chemical trait of having a covalently attached tRNA moiety to detect and profile the global complement of nascent polypeptide chains or "nascentomes" in the cell (2), as well as to collect elongation profiles of individual proteome members. Thus, we examined the generality of the occurrence of translational pausing by directly detecting nascent chain intermediates in the biosynthesis of *E. coli* proteins. Combined approaches of in vivo pulse-chase labeling and cell-free translation revealed that the majority of the ~1,000 proteins examined underwent one or multiple event(s) of pausing either in vitro, in vivo, or both. Classification of the pausing events showed that some interesting correlation exists between the modes of pausing and subcellular localizations of proteins. (1) Ito, K. and Chiba, S. P657**Board Number: B909****The ERAD lectin OS-9 facilitates turnover of non-native, hyper-glycosylated forms of the ER HSP90, GRP94.**D. Dersh^{1,2}, S.M. Jones³, D. Eletto², J.C. Christianson³, Y. Argon²;¹Biochemistry and Molecular Biophysics, University of Pennsylvania, Philadelphia, PA, ²The Children's Hospital of Philadelphia, Philadelphia, PA, ³Ludwig Institute for Cancer Research, University of Oxford, Oxford, United Kingdom

In order to produce properly folded secretory, transmembrane, and cellular proteins, quality control (QC) pathways in the endoplasmic reticulum (ER) rely on efficient synergy between protein folding and disposal mechanisms. Terminally misfolded or orphaned polypeptides can be cleared via ER-associated degradation (ERAD), a process that involves substrate recognition, retrotranslocation across the lipid bilayer to the cytosol, and proteasomal degradation. While some ERAD-initiating signals have been uncovered (for instance the rate limiting trimming of mannose residues on N-linked glycans), little is known about the coupling of pro-folding components with ERAD machinery during protein QC. We hypothesized that the ER-resident HSP90 family member GRP94 could play a role in this crosstalk because it is a well-documented molecular chaperone that also associates robustly with OS-9, a lectin involved in the substrate recognition phases of ERAD. Unexpectedly, we discovered that GRP94 does not participate with OS-9 in the degradation of misfolded substrates, nor does it interfere with OS-9's capacity to recognize and clear ERAD targets. Instead, the GRP94/OS-9 complex forms because OS-9 preferentially associates with a subpopulation of GRP94 marked by hyper-glycosylation. Molecules of GRP94 that are aberrantly modified on cryptic N-linked glycan acceptor sites have a non-native conformation and lower activity, rendering them biologically unstable. OS-9 sequesters these species and assists in their disposal via an ERAD-independent, lysosomal-like mechanism. Therefore, the GRP94/OS-9 complex is important not for coordination in ERAD but rather to trap and degrade a pool of malformed chaperone. This highlights a novel mode of protein regulation, whereby glycosylation of cryptic acceptor sites dictates the function and fate of a typically long-lived ER-resident chaperone.

This work was funded by NIH grants to Y.A. (AI-18001 and GM-77480) and D.D. (F31-NS084666-01 and T32-GM8275).

P658**Board Number: B910****PERK activation interferes with myelin formation and signals in a mouse model of CMT1B.**M. Sidoli^{1,2}, N. Musner³, D.R. Cavener⁴, M. Feltri⁵, L. Wrabetz⁵;¹Biochemistry, University at Buffalo, Buffalo, NY, ²Hunter James Kelly Research Institute, Buffalo, NY,³San Raffaele Scientific Institute, Milan, Italy, ⁴Pennsylvania State University, University Park, PA,⁵Biochemistry and Neurology, University at Buffalo, Buffalo, NY

Schwann cells (SCs) are the myelinating glial cells of the peripheral nervous system. To form functional myelin, SCs produce an enormous amount of proteins and lipids, and the quality control of the myelin proteins is highly regulated. Mutations in myelin genes result in a variety of inherited neuropathies and a wide range of phenotypes. Myelin Protein Zero (MPZ, P0), is a type I transmembrane protein abundantly produced by myelin-forming SCs. Deletion of serine 63 from P0 (POS63del) causes Charcot-Marie-Tooth type 1B (CMT1B) demyelinating neuropathy both in humans and mice. POS63del accumulates in the endoplasmic reticulum (ER) of SCs where it elicits an unfolded protein response (UPR). PERK, ATF6 and IRE1 UPR transduction pathways are active in nerves of POS63del mice. In particular, PERK phosphorylates the translation initiation factor eIF2 α , which attenuates global translation and reduces ER stress. In fact, *Perk* ablation specifically in POS63del Schwann cells (*S63del//Perk^{cko}*) decreased the level of phospho-eIF2 α compared to S63del nerves. Moreover, extensive accumulation of P0 misfolded protein remains in the ER of SCs. Nonetheless, conditional ablation of *Perk* paradoxically improves the demyelinating phenotype of POS63del mice in vivo and in myelinating explant cultures. We therefore investigated the hypothesis that *Perk* ablation may provoke a compensatory hyperactivation in the other two arms of the UPR, ATF6 or IRE1. However, in *S63del//Perk^{cko}* compared to S63del nerves neither cleaved ATF6 and its target chaperones, nor spliced Xbp1 mRNA levels were increased. These data suggest that PERK may interfere with signals outside of the UPR. We have preliminary data that PERK inhibits a target in a pro-myelinating pathway. This finding would be consistent with the notion that the UPR participates in physiological processes not related to unfolded or misfolded proteins.

P659**Board Number: B911****Identifying structural elements within the ENaC α subunit required for chaperone-dependent ER-associated degradation (ERAD).**T.M. Buck¹, A. Jordahl¹, E. Cook¹, J.L. Brodsky²;¹Biological Sciences, Univ Pittsburgh, Pittsburgh, PA, ²Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA

The epithelial sodium channel, ENaC, is responsible for the reabsorption of sodium in the kidney collecting duct. ENaC is a heterotrimer, composed of homologous α -, β - and γ -subunits. Each subunit contains two transmembrane segments, a large extracellular domain, and short cytosolic N- and C-termini. Gain-of-function mutations in ENaC lead to high blood pressure and Liddle's syndrome, whereas loss-of-function mutations lead to low blood pressure, salt-wasting, and Pseudohypoaldosteronism Type1. We and others have shown that unassembled ENaC subunits and even a significant fraction of the assembled channel are recognized by the quality control machinery in the endoplasmic reticulum (ER), and targeted for ER-associated degradation (ERAD). The ERAD machinery recognizes proteins that fail to properly fold or assemble and selects them for degradation by the cytosolic 26S proteasome. In order to characterize the ERAD requirements for ENaC, we have employed a yeast expression system. Using this system we recently determined that the ER molecular chaperone, Lhs1, which is a GRP170 homolog, is required for targeting α ENaC for ERAD, but is dispensable for degrading the β - or γ ENaC subunits (Buck et al., JBC, 2013).

To identify the structural elements that are unique to α ENaC and are required for Lhs1-dependent degradation, we constructed a series of chimeric ENaC subunits and tested their stabilities in wild type and mutant yeast strains. Because only the C-terminus of the α subunit harbors an ER exit site, we initially hypothesized that this and perhaps other elements within the C-terminus of α ENaC were necessary for Lhs1-dependent degradation. We determined that the C-terminal region of α ENaC is at least partially responsible for Lhs1-targeted ERAD. Replacing the C-terminus of α ENaC with the C-terminus of either β - or γ ENaC reduces Lhs1-dependent degradation, and replacing either the β - or γ ENaC C-terminus with that of α ENaC changes the Lhs1-dependent degradation profile. However, the glycosylation state and extracellular domains are also likely playing a role in Lhs1-dependent ERAD targeting. Ongoing studies are investigating the role of the large extracellular/ER lumenal loops in Lhs1-dependent degradation. This work is supported by National Institute of Health grants DK090195 to T.M.B., GM75061 to J.L.B., and DK79307 (University of Pittsburgh George O'Brien Kidney Research Center).

P660**Board Number: B912****The degradation requirements for topologically distinct quality control substrates in the yeast endoplasmic reticulum.**C.J. Guerriero¹, A.A. Augustine¹, J.L. Brodsky¹;¹Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA

In eukaryotic cells, nearly one third of all newly synthesized proteins are translocated into the endoplasmic reticulum (ER). Inside the ER, proteins are post-translationally modified and folded by molecular chaperones into their native states. Mutations, transcriptional or translational errors, or failure to obtain the proper post-translational modifications can result in protein misfolding. A quality control pathway, ER-associated degradation (ERAD), recognizes and degrades misfolded proteins to prevent toxic gain-of-function aggregates. Given the vast array of conformers that proteins may adopt, it is not surprising that many diseases result from protein misfolding or protein aggregation, which cannot be averted by ERAD.

The rate-limiting step during ERAD is substrate retrotranslocation from the ER lumen into the cytoplasm, which occurs prior to 26S proteasome-mediated degradation. Therefore, the retrotranslocation step can tune degradation efficiency to mitigate ERAD-related diseases. Retrotranslocation is energetically driven by Cdc48p, which extracts integral membrane proteins either directly from the ER membrane or through an as-yet-elusive retrotranslocation channel. Integral membrane proteins have diverse topologies with varying degrees of exposure to the cytoplasmic or luminal faces of the ER. However, little is known about how the topology of an ERAD substrate influences ERAD efficiency. We predict that extraction of a large ER luminal domain may slow retrotranslocation kinetics.

To test this hypothesis, a pair of model ERAD substrates were designed to contain the same truncated nucleotide-binding domain from a well-characterized ERAD substrate, Ste6p, *but on opposite sides of the ER membrane. We previously demonstrated that a soluble version of this domain, NBD2, when expressed as a cytoplasmic protein is degraded by the proteasome, and therefore can be used as a transposable degenon* (Guerriero *et al.*, *JBC*, 2013). *The first model substrate, Chimera A, is a dual pass membrane protein fused to NBD2 exposed to the cytoplasm. By contrast, Chimera γ , is a single pass membrane protein which deposits NBD2 in the ER lumen.* Initial characterization confirms the proper topology of these substrates and their proteasome-dependent degradation. Moreover, the substrates rely on ER resident E3 ligases, Hrd1p and Doa10p, for efficient degradation. We are currently determining the relative dependence on Cdc48p for both degradation and retrotranslocation in order to better understand the energetic barriers to ERAD (Supported by NIH grants DK101584 to C.J.G. and GM075061 to J.L.B.).

P661**Board Number: B913****Potentiated Hsp104 Variants Antagonize Diverse Proteotoxic Misfolding Events.**M.E. Jackrel¹, M.E. DeSantis¹, B.A. Martinez², L.M. Castellano¹, R.M. Stewart³, K.A. Caldwell², G.A. Caldwell², J. Shorter⁴;¹Biochemistry and Biophysics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²University of Alabama, Tuscaloosa, AL, ³Department of Cell Biology, Yale University, New Haven, CT, ⁴Department of Biochemistry and Biophysics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA

There are no therapies that reverse the proteotoxic misfolding events that underpin fatal neurodegenerative diseases, including amyotrophic lateral sclerosis (ALS) and Parkinson's disease (PD). Treatments for these disorders remain palliative, and no therapeutics exist that address their underlying cause. However, not all amyloidogenic events are associated with toxicity. In yeast, amyloids are utilized for beneficial purposes and thus tightly regulated. Hsp104, a conserved hexameric AAA+ protein from yeast, solubilizes disordered aggregates and amyloid but has no metazoan homolog and only limited activity against human neurodegenerative disease proteins. We have reengineered Hsp104 to rescue TDP-43, FUS, and α -synuclein proteotoxicity by mutating single residues in the middle domain or the small domain of nucleotide-binding domain 1. Potentiated Hsp104 variants enhance aggregate dissolution, restore proper protein localization, suppress proteotoxicity, and in a *C. elegans* PD model attenuate dopaminergic neurodegeneration. Potentiating mutations reconfigure how Hsp104 subunits collaborate, desensitize Hsp104 to inhibition, obviate any requirement for Hsp70, and enhance ATPase, translocation, and unfoldase activity. Furthermore, these variants suppress the toxicity of disease-associated missense mutant versions of TDP-43, FUS, and α -synuclein. Our work establishes that disease-associated aggregates and amyloid are tractable targets and that enhanced disaggregases can restore proteostasis and mitigate neurodegeneration.

P662**Board Number: B914****Subcellular Localization of Heat Shock Factor 1 Alpha and Beta Isoforms.**K. Hassman¹, J.R. Williams¹, N.J. Bachman¹;¹Biology Department, SUNY Oneonta, Oneonta, NY

Heat shock causes proteins to denature or unfold which alters their function in the cell. Heat shock transcription factor 1 (HSF1) is responsible for the transcriptional response to produce heat shock proteins to protect cells from induced stress. Research is being conducted on different isoforms of HSF1, predominantly alpha and beta isoforms. Isoforms are versions of the protein that are similar, but not identical, and they may serve distinct functions. The goal of this research is to discover the subcellular localization pattern of HSF1 alpha and beta isoforms in the presence or absence of heat shock. The experimental approach involved growing NIH 3T3 cells on fibronectin coverslips. Separate dishes were

transfected with expression plasmid DNA encoding the isoform. Coverslips were then incubated with primary (anti-HA-tag) and fluorescent secondary antibody (conjugated to green Alexa 488), and viewed using fluorescent microscopy to visualize localization of the isoforms in NIH 3T3 cells. We have observed a different pattern of localization for the alpha and beta isoforms. HSF1 beta seems to be mostly localized in the nucleus both before and after heat shock. HSF1 alpha is distributed in both the cytoplasm and the nucleus, although more nuclear than cytoplasmic staining is seen. Following heat shock; there is an even lower proportion of cytoplasmic staining for HSF1 alpha. To test the effects on isoform distribution after disrupting nuclear import, nuclear localization signal (NLS) mutants of the HSF1 alpha isoform tagged with HA were constructed by overlap extension PCR. Essentially all fluorescent staining of HA was found in the cytoplasm, consistent with previous studies. We are currently constructing putative NLS mutants of HSF1 beta to see if the beta isoform is imported by the same pathway. This work was supported by NIH NIGMS grant R15 GM096231 to N. J. B.

Board Number: B915

Adaptations in the proteostasis network of *Dictyostelium discoideum* cause an unusual resilience to protein aggregation.

L. Malinovska¹, S. Palm¹, K. Gibson¹, J. Verbavatz¹, S. Alberti¹;

¹MPI-CBG, Dresden, Germany

Many protein-misfolding diseases are caused or exacerbated by proteins carrying prion-like domains, which are sequences of low complexity enriched for polar amino acids, such as asparagine and glutamine. These sequences are called 'prion-like', because they show extensive sequence similarity to proteins that undergo structural conversions from an intrinsically disordered to an aggregated prion state, which often conveys self-propagating capabilities. Using a bioinformatic algorithm for the identification of prion-like sequences, we screened the proteome of the social amoebae *Dictyostelium discoideum*. We find that *D. discoideum* has the highest content of prion-like proteins of all organisms investigated to date, suggesting that its proteome has a high overall aggregation propensity. To study mechanisms involved in the regulation of these proteins, we analyzed the behavior of several well-characterized prion-like proteins from other organisms, such as an expanded version of the exon 1 of human huntingtin (Q103) and the prion domain of the yeast prion protein Sup35 (NM) in *D. discoideum*. We find that these proteins remain soluble in the cytosol and are innocuous to *D. discoideum*, in contrast to observations in other organisms, where the same proteins form cytotoxic cytosolic aggregates. However, when exposed to heat stress or drugs that inhibit molecular chaperones, these proteins aggregate and become cytotoxic, suggesting a major role for molecular chaperones in the regulation of prion-like proteins. We further show that the disaggregase Hsp101, a molecular chaperone of the Hsp100 family, dissolves heat-induced aggregates of prion-like proteins and promotes thermotolerance. Additional findings indicate that the nucleus serves as a compartment for protein quality control, where prion-like proteins are targeted for degradation by the ubiquitin-proteasome system. Taken together, our data suggest that the protein quality control system of *D. discoideum* has

undergone specific adaptations that increase the proteostatic capacity of this organism and allow for an efficient regulation of its aggregation-prone prion-like proteome.

Ameliorating potentiated Hsp104 variants.

K.L. Mack¹, M. Jackrel¹, J.E. DeNizio², J. Shorter³;

¹Biochemistry and Biophysics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²Department of Biochemistry and Biophysics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ³Department of Biochemistry and Biophysics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA

Hsp104 is a hexameric, AAA+ protein disaggregase with no metazoan homologue found in *S. cerevisiae*. Hsp104 refolds protein aggregates, resolubilizes prefibrillar oligomers and amyloid, and is an attractive agent for combatting protein misfolding underlying many neurodegenerative diseases. We previously engineered hyperactive Hsp104 variants that potently suppress toxicity from disease substrates TDP-43, FUS, and α -synuclein, and are not overly proteotoxic to yeast. This enhanced activity would be best honed against a specific disease substrate to avoid nonspecific unfolding of proteins. We hypothesized that by introducing subtle changes in conserved tyrosine residues in the substrate-binding pore loops of Hsp104, we could engineer potentiated variants to be selective for a single disease substrate. We used an overexpression system with a galactose-inducible promoter to explore a wide range of potentiated variants. In using several different backgrounds containing activating mutations as starting platforms to rationally introduce specific mutations, we found hyperactive variants capable of strongly suppressing toxicity from all three disease substrates. We additionally uncovered several variants that seem to selectively rescue α -synuclein toxicity, thus enhancing the substrate specificity of Hsp104.

Adenosine Receptors as Modulators of the Cellular Stress Response.

E.E. Wilkinson¹, A. Robinson²;

¹Tulane Univ Chemical Engineering, New Orleans, LA, ²Chemical and Biomolecular Engineering, Tulane University, New Orleans, LA

Both inhibitory and stimulatory adenosine receptors are aberrantly expressed in the tissue of patients with neurodegenerative diseases, but the exact role that these receptors play in the progression of disease is not clear. While previous data from our lab has indicated that expression of inhibitory receptor A1R plays a role in modulation of SIRT1 activity, other research implicates A1R in activation of the inflammatory pathways. We hypothesize that during oxidative stress, a common pathway in neurodegeneration, adenosine receptor expression modulates epigenetic factors, such as SIRT1, to

activate the cellular stress response pathways. Thus, these receptors may play a role in controlling the stress response and ultimately cell survival. Using immunoblot, ELISA and mitochondrial function assays, we will demonstrate the role that adenosine receptors play in controlling the stress response, particularly in the presence of reactive oxygen species. We will show a change in receptor localization following oxidative stress, as well as an increase in SIRT expression as a result of increased receptor expression.

Involvement of ER stress and Ca²⁺ signaling in colitis-associated damage in intestinal epithelial cells.

S. Chotikatum¹, N. El-Najjar¹, H.Y. Naim¹;

¹Department of Physiological Chemistry, University of Veterinary Medicine Hannover, Hannover, Germany

Ulcerative colitis (UC) can extend to the terminal ileum through the influx of colonic content via an inflamed ileocecal valve. Under these circumstances, gut mucosa integrity and functions are altered and may contribute to the pathogenesis of UC. The endoplasmic reticulum (ER) has a crucial role in the synthesis, correct folding and sorting of proteins, and is the main calcium (Ca²⁺) reservoir in the cell. A chronic decrease in ER Ca²⁺ concentrations can lead to misfolded proteins and eventually to ER stress. The aim of this work is to study the role of Ca²⁺ signaling in ER stress, a hallmark of UC, and how this is linked to the dysfunction of the intestinal epithelial cells. A mixture consisting of the cytokines IL-1 β -, MCP1, and TNF- α was used to induce ER stress in Caco-2 cells 0, 3 and 7 post- confluency. ER stress induction in Caco-2 cells was tested by measuring the levels of chaperone proteins. Interestingly, we found that the stress markers BiP and Chop were significantly increased 8 and 24 hours after the cytokine treatment. Moreover, the activity of sucrase-isomaltase, a major glycoprotein of the intestinal brush border membrane, significantly decreased after 8 and 24 hours of treatment of 3 and 7 days post-confluent cells. Furthermore, transepithelial resistance (TEER) was significantly decreased after treatment at 8, 24 and 48 hours. The results to date suggest that ER stress is indeed induced by the mixture of the cytokines utilized and that the epithelial barrier integrity is affected. Ongoing experiments will focus on studying the link between ER stress and Ca²⁺ signaling to gain insights into the mechanisms that affect the activity of intestinal brush border enzymes in UC.

P667**Board Number: B919****Increased Expression of the Large Conductance, Ca²⁺ Activated and Voltage-Dependent (BK) Channel Represents an Early Event During Neurodegeneration.**J. Braun¹, J. Donnelier¹, B. Kyle², C. Koutras¹, E. Ahrendt¹;¹Biochemistry and Molecular Biology, Univ Calgary/Hotchkis Brain Institute, Calgary, AB, ²Univ Calgary/Libin Brain Institute, Calgary, AB

We have previously shown that in the CSP α KO mouse model of neurodegeneration, there is a 2.5 fold increase in the expression of the large conductance, Ca²⁺ activated and voltage-dependent (BK) channel. Functionally, neuronal BK channels are activated by both membrane depolarization and elevated intracellular Ca²⁺ levels and are central to the regulation of action potential duration and neurotransmitter release. CSP α (cysteine string protein) null mice have age-dependent and activity-dependent synapse loss and neurodegeneration. CSP α is a synaptic vesicle-associated molecular chaperone. The cellular chaperone network maintains protein homeostasis and cellular function and imbalances in proteostasis may trigger pathogenic cascades that lead to neurodegeneration. CSP α is essential for synapse maintenance. Mutations in CSP α cause adult neuronal ceroid lipofuscinosis (ANCL) a rare neurodegenerative disease.

Here we evaluate the time course of expression changes in BK channel in the severe mouse model of Alzheimer's disease (5XFAD). 5XFAD transgenic mice overexpress mutant human amyloid precursor protein (APP(695)) with the Swedish (K670N, M671L), Florida (I716V), and London (V717I) mutations as well as human presenilin1 (PS1) harboring, M146L and L286V that cause familial Alzheimer's disease. Degeneration, neuron loss and amyloid deposits start at about 3 months, A β 42 accumulates and memory is impaired recapitulating pathologic and behavioral characteristics of Alzheimer's disease. Like the CSP α knock out mouse model, synapse loss is characteristic of 5XFAD mice. However, in contrast, the impairment of synaptic function in 5XFAD mice develops later (i.e. post natal 3 months (5XFAD) vs 3 weeks (CSP α KO)).

Our latest results suggest that elevation of BK channel levels represent an early event in the onset of neurodegeneration. Impairment of CSP α activity leads to dysregulation of BK channel levels in these neurodegenerative mouse models. Together these findings provide new insight into the possibility of re-purposing therapeutic agents that target ion channels for the treatment of neurodegenerative diseases. We conclude that CSP α -associated changes in BK channel levels may contribute to the pathogenic cascade of events leading to neurodegeneration.

P668**Board Number: B920****Ixeris dentata induces regulation of amylase secretion and inhibits Endoplasmic Reticulum stress in Streptozotocin induced diabetic rats.**K. Bhattarai¹, H. Kim², H. Chae^{3,4};

¹Department of Pharmacology, Chonbuk National University, Jeonju, Korea, ²Department of Dental Pharmacology, Wonkwang University, Iksan, Korea, ³Department of Pharmacology, Chonbuk National University medical school, Jeonju, Korea, ⁴Department of Pharmacology, Chonbuk National University medical school, Jeonju, Korea

Ixeris dentata, is an herbal plant which is generally used for the treatment of liver diseases, diabetes and to improve appetite in Korea and China. ER stress is activated in various tissues under conditions related to obesity and diabetes. Conditions such as hyposalivation and xerostomia also can alter the protein folding capacity and cause ER stress. The objectives of this study were to investigate the effects of IXD extract in streptozotocin induced diabetic rats and to improve the salivation rate on dry mouth condition induced by diabetes. Type 1 diabetes was induced by a single intraperitoneal injection of freshly prepared STZ (65mg/kg), and 5% IXD extract (100mg/kg) was administered orally for 10 days to observe the effect. Treatment with extracts of IXD resulted in a significant increase in salivary flow rate and also have increased the salivary gland weight in IXD treated diabetic rats. IXD also reduced the total protein concentration in saliva of diabetic rats. The amylase activity was also increased in IXD treated diabetic rats in both saliva as well as in gland lysates. Immunohistochemistry data proved this result and has shown more secretion of alpha amylase in IXD treated diabetic rats. IXD improved the morphology of sub mandibular serous acinar cells in treated rats. Moreover, we checked whether IXD extract inhibits ER stress, and found the increased ER stress response in diabetic control rats and was inhibited by the treatment of IXD extracts. The decreased expression of GRP78, and XBP-1 shows the inhibitory effect of IXD extracts. So, this study revealed the potential value of the IXD extract for the treatment of diabetes or its resultant condition such as xerostomia and ER stress. Key words: IXD, ER stress, Xerostomia,

Protein expression profile of human insulin secretory granules mapped by 2D-DIGE and 1D SDS-PAGE coupled with nanoLC-ESI-MS/MS bottom-up proteomics.

C.C. Clement¹, R. Kuliawat², L. Santambrogio¹;

¹Pathology, Albert Einstein College of Medicine, Bronx, NY, ²Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY

Insulin secretory granules (ISGs) are crucial organelles of pancreatic β -cells and represent a key participant to glucose homeostasis. Insulin is packed and processed within these vesicles before its release by exocytosis. It is therefore vital to acquire qualitative and quantitative data on the ISG proteome, in order to increase our knowledge on ISG biogenesis, maturation and exocytosis. Many efforts have been made in the past years to increase the coverage of the ISG proteome. However, much of the existing work on the composition of granules was done in immortalized cell lines or rodent tissues which may not faithfully reflect the composition of granules in human islets. The major goal of the current research was to characterize the proteome of an enriched fraction of ISGs from the human beta cells. Herein, we present the global proteomic profiling of human ISGs using two analytical methodologies coupled with nanoliquid chromatography-tandem mass spectrometry: one-dimensional gel electrophoresis (1DEF nanoLC Orbitrap-ESI-MS/MS), and two-dimensional fluorescence difference-in-gel electrophoresis (2D-DIGE nanoLC-ESI-MS/MS). The 253 significantly identified proteins (p

One Step Detection of Oxidative Stress-Induced Carbonylation in Live Mammalian Cells.

K. Mukherjee¹, T.I. Chio¹, A.M. Sorrentino¹, D.L. Sackett², S.L. Bane¹;

¹Chemistry, SUNY-Binghamton, Binghamton, NY, ²Program in Physical Biology, NIH/NICHD, Bethesda, MD

Carbonylation of proteins, lipids and DNA is a common manifestation of oxidative stress. Due to the involvement of oxidative stress in disease conditions, such as neurodegenerative diseases and diabetes, cellular carbonylation is considered a biomarker in understanding the etiology and progression of these diseases. Presently used methodologies for detecting intracellular carbonylated biomolecules require fixing or lysing the cells for lengthy downstream processing. Here, we present two hydrazine-functionalized synthetic fluorophores (coumarin hydrazine and benzocoumarin hydrazine) that permit a single step detection of biomolecule-carbonyls in live cells. When administered to the cells, these fluorophores readily react with biomolecule-carbonyls; the resultant hydrazone products exhibit a shift

in absorption and emission maxima, and an increase in quantum yield. These photochemical properties of the fluorophore allow the detection of the products in the presence of unreacted fluorophore, thereby obviating the necessity of removing excess detection reagent. Additionally, these fluorophores are non-toxic. Therefore we report that a one step detection method, involving a brief incubation of the cells with the hydrazine-fluorophore before microscopic analysis, enables visualization of carbonylated biomolecules in live cells. We demonstrated the applicability of these fluorophores in PC3 and A549 cell lines. Hydrogen peroxide- and serum starvation-induced biomolecule carbonylation were conveniently detected by these coumarin based fluorophores. This one step method for detecting oxidative stress induced carbonyls in live cells should be applicable for high content screening for inducers of intracellular carbonylation.

Aptamer-gated silica nanoparticles synthesized via click chemistry.

O. Dilek¹, V.C. Ozalp¹;

¹School of Medicine, Istanbul Kemerburgaz Univ, Istanbul, Turkey

Precise targeting of drug loaded nanocapsules to the diseased locations is a challenging task. Aptamer technology provides viable alternative to overcome the present limitations with specific cell targeting. Aptamer-gated nanocapsules have been developed as drug delivery system with dual function of biorecognition and molecular gating. In this study, mesoporous silica nanoparticles were grafted with amino-silane and used for immobilization of aptamers via click chemistry. Synthesized particles were characterized by DLS, Fourier transform infrared spectroscopy (FTIR), and transmission scanning electron microscopy (TEM). The aptamers were alkyne-functionalized for conjugation with azide-modified silica particles via click chemistry reaction. The kinetic constants (K_m and V_{max}) were determined by measuring initial reaction rates using the artificial chromogenic substrate. Fluorescence properties of synthesized aptamer-gated nanoparticles were also monitored before/after click reaction with the fluorophore. Kinetics of the release of loaded Cargo were determined and compared to aptamer-gated particles synthesized via traditional conjugation chemistry techniques.

P672**Board Number: B925****Efficient phosphate-catalyzed hydrazone reaction with improved biocompatibility for bioorthogonal conjugations.**O. Dilek¹, S.L. Bane², A.M. Sorrentino²;¹School of Medicine, Istanbul Kemerburgaz Univ, Istanbul, Turkey, ²Chemistry, SUNY-Binghamton, Binghamton, NY

Bioorthogonal site-specific chemical reaction to label biomolecules in vitro and in living cells is one of the most powerful tools in chemical biology. A reactive pair frequently used for chemical conjugation is aldehydes/ketones with hydrazines/hydrazides/oximes. Although the reaction is generally specific for the two components, even in a cellular environment, the reaction is very slow under physiological conditions. Additives such as 10 mM aniline are often used to increase the reaction rate, but these chemicals can be detrimental to the biological system under investigation. We have found that adding an ortho-phosphate group to an aromatic aldehyde increases the reaction rate with a hydrazine or hydrazide by an order of magnitude. An added benefit is that phosphate enhances the aqueous solubility of the reagent and its hydrazone product. We have synthesized phosphate-substituted aldehyde synthetic models to study kinetics of their reactions with hydrazines and hydrazides that contain a fluorophore. Fluorescence properties of hydrazone products are also investigated. This rapid bioorthogonal reaction should therefore be potentially a very useful strategy for routine site-specific chemical ligations to study and image complex cellular processes in biological systems.

P673**Board Number: B926****GSK-3 modulates cellular responses to a broad spectrum of kinase inhibitors.**C.A. Thorne¹, C. Wichaidit¹, A.D. Coster¹, B.A. Posner², L.F. Wu³, S.J. Altschuler³;¹Green Center for Systems Biology, University of Texas Southwestern Medical Center, Dallas, TX,²Department of Biochemistry, University of Texas Southwestern Medical Center, Dallas, TX, ³Department of Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA

A fundamental challenge in treating disease is identifying molecular states that affect cellular responses to drugs. Here, we focus on GSK-3, a key regulator for many of the hallmark behaviors of cancer cells. We alter GSK-3 activity in colon epithelial cells to test its role in modulating drug response. We find that GSK-3 activity broadly affects the cellular sensitivities to a panel of oncology drugs and kinase inhibitors. Specifically, inhibition of GSK-3 activity can strongly desensitize or sensitize cells to kinase inhibitors (e.g. mTOR or PLK1 inhibitors, respectively). Additionally, colorectal cancer cell lines, in which GSK-3 function is commonly suppressed, are resistant to mTOR inhibitors and yet highly sensitive to PLK1 inhibitors and this is further exacerbated by additional GSK-3 inhibition. Finally, by conducting a kinome-wide RNAi screen, we find that GSK-3 modulates the cell proliferative phenotype of a significant fraction (~35%) of the kinome, which includes ~50% of current, clinically relevant kinase-targeted drugs. Our results

highlight an under-appreciated interplay of GSK-3 with therapeutically important kinases and suggest strategies for identifying disease-specific molecular profiles that can guide optimal selection of drug treatment.

Endogenous reactive oxygen species in α -syntrophin knock-downed cells hindered myoblast differentiation.

A. Moon¹, S. Choi¹, H. Kim¹;

¹Biological science, Ajou University, Suwon, Korea

α -Syntrophin is a component of dystrophin-glycoprotein complex which interacts with various intracellular signaling proteins in muscle cells. To study on the function of α -syntrophin in muscle cell, α -syntrophin knock-downed C2 cell line was established by infecting lentivirus particles with α -syntrophin shRNA. Muscle differentiation is a multi-step process including the expression of muscle regulatory factors, cell cycle arrest and cell fusion into multinuclear myotubes. The α -syntrophin knock-downed cells (SNKD), however, were characterized by defect of terminal differentiation and reduction of cell fusion index. Myogenesis is also importantly accompanied by an intensive mitochondrial biogenesis. Since the amount of reactive oxygen species (ROS) correlates with mitochondrial content, the generation of intracellular ROS is also inescapably increased during myogenesis. To confirm an excessive accumulation of intracellular ROS during differentiation of SNKD cells, mitochondrial H₂O₂ imaging was performed using two-photon microscopy. The result shows that mitochondrial H₂O₂ in SNKD myotubes increased than that of control shRNA transfected cells. Epigallocatechin-3-gallate (EGCG) is a well-known ROS scavenger as well as an antioxidant chemical. By using differentiation media containing EGCG, a reduction of fusion index in SNKD cells was dramatically recovered. It demonstrates that intracellular ROS produced during myogenesis hinders terminal differentiation of SNKD cells. In addition, the activity of antioxidant enzymes is changed during myoblast differentiation, which enables myotubes to modulate the susceptibility to oxidative stress. We found that the expression of catalase was substantially decreased during differentiation of SNKD cells. These results suggest that α -syntrophin knock-downed cells have a low capacity for antagonizing oxidative stress endogenously generated during myogenic differentiation.

P675**Board Number: B928****The Protective Effects of J-10 in Preventing Cell Proliferation and Migration of Vascular Smooth Muscle Cells in Balloon Injury-Induced Neointimal Hyperplasia.**P. Li^{1,2}, C. Wu³;¹PHARMACY, China Medical University, Taichung, Taiwan, ²Pharmacy, University of Southern California, Los Angeles, CA, ³Pharmacy, Taipei Medical University, Taipei, Taiwan

Restenosis after balloon angioplasty procedures is a significant clinical problem. The major biological process of restenosis are proliferation and migration of vascular smooth muscle cells (VSMCs). The compound J-10, which is isolated from marine coral, has shown antioxidant activity, but has not been reported to have an anti-restenosis effect. The growth inhibitory effect of J-10 on VSMCs were determined by MTT assay. The mechanism analysis of migration were determined by using a wound healing assay, a transwell assay, gelatinase zymography, and western blotting. The effect of J-10 on restenosis were accessed by the ratio of the neointima-to-media area (N/M ratio). The results showed that J-10 reduced neointima formation in the artery of rats. J-10 significantly inhibited VSMCs proliferation and migration through FAK, PI3K, AKT, and ERK1/2 pathway, as shown by western blot. In addition, enzymatic action of matrix metalloproteinases 2 and 9 (MMP-2 and MMP-9) was carried out by gelatinase zymography. The compound J-10 decreased the expression levels of MMP-2 and MMP-9. This is the first study to show the compound J-10 prevented balloon angioplasty-induced neointimal hyperplasia as well as VSMCs proliferation and migration both *in vivo* and *in vitro*. Thus, J-10 may be a novel useful anti-restenosis agent.

P676**Board Number: B929****Structure-activity relationship study for integrin $\alpha 6\beta 1$ -binding peptide A2G10 derived from mouse laminin $\alpha 2$ chain sequence.**F. Katagiri¹, R. Yamanaka¹, R. Suyama¹, N. Nakajima¹, Y. Yamada¹, K. Hozumi¹, Y. Kikkawa¹, M. Nomizu¹;¹School of Pharmacy, Tokyo Univ Pharm/Life Sci, Hachioji, Japan

Laminins are major components of basement membrane, consists of three different subunits, α , β , and γ chains, and so far, five α , three β , and three γ chains have been identified. We have constructed the synthetic peptide library derived from the laminin sequences, and identified cell adhesive peptides. We have reported that A2G10 peptide (SYWYRIEASRTG, mouse laminin $\alpha 2$ chain, 2223-2234) interacts with integrin $\alpha 6\beta 1$, and promotes strong cell adhesion [1]. Recently, integrin $\alpha 6\beta 1$ is suggested to play an important role for stem cells to maintain their functions [2]. In this study, we investigated the structure-activity relationship of A2G10 to identify the specific motif for integrin $\alpha 6\beta 1$. The truncated peptides of A2G10 (A2G10Nd1--4, A2G10Cd1--4) were synthesized by Fmoc-solid phase methods, and evaluated their human dermal fibroblast (HDF) attachment activities. The A2G10-derived peptides which were

deleted Ser1 (A2G10Nd1) from N-terminal and Arg10-Thr11-Gly12 from C-terminal (A2G10Cd3) showed HDF attachment activity. From the result we designed A2G10min peptide (YWYRIEAS, mouse laminin α 2 chain, 2224-2231). A2G10min promoted HDF attachment, which was inhibited by EDTA, anti-integrin α 6, and β 1 antibodies. Next, the peptides substituted each amino acid residue for alanine (A2G10A1--A6, and A8) or glycine (A2G10minG1--G8) were prepared, and evaluated their HDF attachment activities (Ala and Gly scan). The peptides substituted Arg4 and Ser8 for Ala (A2G10minA4 and A8) maintained HDF attachment activities. The peptides substituted Ala7 and Ser8 for Gly (A2G10minG7 and G8) maintained HDF attachment activities. The result of Ala scan suggested that Arg4 and Ser8 residues of A2G10min were not important for integrin α 6 β 1 binding. From the result of Gly scan, we designed A2G10min-derived peptide A2G10minX (YWYRIEGG) and its C-terminus truncated peptides A2G10minY (YWYRIEG) and Z (YWYRIE). A2G10minX, Y, and Z promoted HDF attachment, which was inhibited by EDTA, anti-integrin α 6, and β 1 antibodies. We concluded that the core motif of A2G10 to interact with integrin α 6 β 1 was YWYRIE (mouse laminin α 2 chain, 2224-2229).

Assembling proteins with modular DNA scaffolds: a strategy for engineering antibodies and probing cellular signaling complexes.

S.I. Liang¹, J.M. McFarland², D. Rabuka², Z.J. Gartner^{3,4};

¹Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA, ²Redwood Bioscience Inc., Emeryville, CA, ³Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, ⁴Center for Systems and Synthetic Biology, University of California, San Francisco, San Francisco, CA

An antibody's class is determined by its constant region, or scaffold, which encodes the valency, effector functions, and higher-order architecture of the variable domains. *In vivo*, antibodies of different classes serve specialized roles during the immune response and have different biological activities. Expansion of scaffold diversity has the potential to generate enhanced therapeutics with properties that include increased avidity, increased specificity, and the ability to recognize specific combinations of receptors on cells or deliver protein-based effectors. However, systematic exploration of antibody scaffold geometry, valency, and combinatorial binding capacity is difficult with protein-based scaffolds due to the challenges associated with protein design. Instead, we are using DNA-based scaffolds, which are modular, programmable and can control the position and orientation of pendant proteins with nanometer resolution. This strategy requires a simple and modular technique for site-specific conjugation of synthetic oligonucleotides to proteins. Our approach uses the aldehyde tag, which can be genetically incorporated into proteins expressed in both bacterial and mammalian expression systems.

We designed and optimized four different reactions that generate DNA–protein conjugates to provide flexibility in linker chemistry. Using this strategy, we conjugated oligonucleotides to a suite of antibody fragments, including an N-terminal tagged Fab, a C-terminal tagged Fc, and an internally-tagged IgG. Using SDS-PAGE and transmission electron microscopy, we demonstrated that the protein-DNA conjugates can be efficiently assembled into dimeric and trimeric structures. Our DNA-scaffolded antibodies bind their targets on live cells and can be hierarchically assembled into structures of greater valency and complexity. We are applying these techniques to develop bispecific antibodies targeting cell surface proteins on a triple negative breast cancer cell line. Additionally, we are using these modular DNA scaffolds to investigate the effect of nanoscale organization on the signaling profiles of receptor tyrosine kinases by systematically guiding the assembly of signaling complexes on cells.

Treatment of Hydraulic Fracturing Contaminated Water using *Closterium moniliferum*: Growth rate, nuclear integrity, and Ba elemental analysis of algal biomass.

L. Jubic¹, K. Resendes¹, H. Boylan², L. Miller²;

¹Biology, Westminster College, New Wilmington, PA, ²Chemistry, Westminster College, New Wilmington, PA

The acquisition of metals is essential for a variety of protein and cellular functions, including sensing of environmental conditions. To sense gravitational force, some algae actively accumulate metal sulfates to cellular concentrations well above the surroundings' concentration. The single-celled green algae *Closterium moniliferum* selectively accumulates approximately 1 picogram of the toxic, heavy metal barium (Ba) per cell after a 24 hour period, which is then incorporated as barium sulfate crystals as statoliths in the terminal vacuoles. Thus, *C. moniliferum* may be used to contain accidental release of Ba into the environment from industrial activities, such as hydraulic fracturing. Hydraulic fracturing technology collects natural gas through the injection and subsequent collection of hydraulic fracturing fluid into and from shale rock. In addition to gas absorption, fracking fluid dissolves Ba containing minerals and upon recovery contains a Ba concentration of thousands of milligrams per liter. *C. moniliferum* is an attractive candidate for phycoremediation of Ba from mutagenic, biocidal fracking contaminated water because of its robust DNA repair system. To further assess its candidacy for remediation, this study sought to characterize the algae's growth, protein expression, and nuclear integrity in fracking fluid. The algal population growth was negatively correlated with the percentage of fracking fluid present in the media. However, the population was sustained in as much as 1% hydraulic fracking fluid. While growth was inhibited, no general changes in overall protein expression levels were observed when comparing Coomassie stained SDS-PAGE gels of samples from media containing up to 10% hydraulic fracking fluid. *C. moniliferum*'s population stability and unaltered protein expression further supports its candidacy in remediating of water contaminated by hydraulic fracturing. Additionally, the nucleus and mitotic division of *C. moniliferum* were observed by novel incubation in 1%

toluene before DAPI staining. Nuclear integrity and mitotic fidelity are expected to be minimally affected by the presence mutagenic fracking fluid. Furthermore, the cytosolic Ba accumulation rate will be determined by flame atomic absorption spectroscopy (FAAS), while Ba binding to surface proteins will be characterized by Fourier transformed infrared spectroscopy (FTIR). While known to be incorporated as vacuolar statoliths, Ba's interaction with surface proteins and entrance into the algae cell is poorly characterized. It is expected that FTIR will reveal Ba interactions with the algae's sulfur rich surface proteins. The current and expected results support the use of *C. moniliferum* in the phycoremediation of water contaminated by hydraulic fracturing.

Morphology, Institute of Biosciences, Univ. Estadual Paulista UNESP, Botucatu, Brazil, ⁴Faculty of

Medicine of Marília FAMEMA, Marília, SP, Brazil

Nandrolone decanoate (ND) is a well known anabolic androgenic steroid, and its indiscriminate use leads to subclinical alterations in the hypothalamic-pituitary-gonadal axis, which can impair the functioning of androgen-dependent organs. This study was proposed to evaluate the effects of ND, associated or not with physical resistance training, on the morphophysiology of ventral prostate in adult and aged rats. Sprague-Dawley rats were divided into eight experimental groups (n=7): sedentary or trained and supplemented or not with ND. The groups were treated during adulthood for eight weeks. During this period the experimental groups were allowed to physical training with jump sessions in water (the animals conducted four sets of 10 jumps each, three times per week) and/or received the ND twice a week (5 mg / kg). Animals were euthanized after 48 hours post-treatment cessation and blood and tissue samples were collected for further analysis. The aged rats were subjected to the same experimental protocol during the adulthood, remaining untreated until reaching 300 days of age, when they were euthanized. The ventral prostate was processed for molecular and morphometrical analyzes to the androgen (AR) and estrogens (ER α and ER β) receptors, 5-alpha reductase 2 (5 α -R2), aromatase (cytochrome P450), proliferative nuclear cell antigen (PCNA) and protein pro-apoptotic 4 (PAR4). Testosterone levels were reduced in both adult and aged animals regardless of treatments, and estradiol increased only in the ND-treated groups. The expression of 5 α -R2 and aromatase was increased in exercised adult animals. Conversely, in aged groups was observed a reduction of 5 α -R2 in those exercised without ND, whereas aromatase expression was decreased in all treatments. The ER α and β increased in prostate of adult animals that received ND, and only ER β was reduced with age and treatment. AR expression was decreased in aged trained groups. The height of the prostate epithelium was reduced in all experimental adult groups compared to control group, coinciding with the increase in

PAR4 levels. Therefore, not only the ND, but also the modality of physical activity alter the hormone levels and differentially modulate the expression of AR and ERs. Overall, ND associated or not to physical resistance training during post-puberty stage is able to interfere with the morphophysiology of the prostate in adulthood and throughout the ageing process. Financial Support: FAPESP 2013/00649-7, 2013/07203-4.

Copper Sulfide Nanoparticles: Potential Agents in Photothermal Therapy.

D. Gilbert¹, D.M. Peterson², S. Henderson-Jones³, A. Oki⁴, L.E. Carson⁵, E.C. Regisford¹;

¹Department of Biology, Prairie View AM University, Prairie View, TX, ²Biology, Prairie View AM University, Prairie View, TX, ³Prairie View AM University, Prairie View, TX, ⁴Chemistry Department, Prairie View AM University, Prairie View, TX, ⁵Cooperative Agricultural Research Center, Prairie View AM University, Prairie View, TX

The swiftly developing research field of nanomedicine has great potential in fighting against the complex disease of cancer. Photothermal therapy (PTT) is a minimally invasive therapy in which light energy is converted into heat to kill cancer cells. Nanoparticles, like gold, strongly absorb light and convert photon energy into heat quickly and efficiently, thereby making them superior agents for PTT. This gold nanoparticle-assisted PTT has shown great popularity and success in recent years. However, gold is expensive and the long term effects of this element in the body are not known. Copper Sulfide (CuS) is less expensive and its individual components are used by the body, even though in minute amounts. Therefore, the objective of this project was to determine if CuS can be used as a potential PTT agent in cancer cells. We hypothesized that CuS will be effective in killing cancer cells when used as a PTT agent. It has been reported that folate receptors are up-regulated in cancer cells. Therefore to test our hypothesis, we treated two cancer cell lines, A549 (lung cancer cell line, folate receptor negative) and HeLa (cervical cell line, folate receptor positive), with 0 or 100ng/mL of CuS, Folate and CuS + Folate for 24 hours. After 24 hours the cells were subjected to laser light at a wavelength of 900nm for 60 seconds. An MTT assay was then performed to determine the viability of cells. Preliminary results indicate that both cell lines treated with CuS and exposed to infrared light had decreased viability. However, HeLa cells that were treated with CuS + Folate had the greatest decrease in cell viability of all treatment groups. Therefore, CuS may be considered as a potential PTT agent.

P681**Board Number: B934****EU-OPENSREEN: Chemical tool compounds for cell biologists.**B. Stechmann¹, R. Frank¹;¹EU-OPENSREEN / FMP Leibniz-Institute for Molecular Pharmacology, Berlin, Germany

Small molecules that can be applied as chemical 'tool' compounds (or 'probes') have become indispensable in basic research for the elucidation of fundamental biological mechanisms. They act directly with the protein-of-interest and often allow for the interrogation of biological processes that cannot be properly studied with traditional genetic or RNA interference approaches.

EU-OPENSREEN (www.eu-openscreen.eu) is the largest emerging academic chemical biology research infrastructure initiative in Europe with the aim to collaboratively develop novel research tool compounds with independent cell biologists. As a joint effort of national networks in 16 European countries, EU-OPENSREEN offers access to high-throughput screening platforms, chemistry services and a large compound collection. It welcomes cell biologists who have a robust and suitable biological assay and are interested in collaboratively developing chemical tool compounds to validate their targets-of-interest. Selected assays are screened against a collection of 100,000-200,000 compounds, incl. confirmatory and counter screening, IC/EC50 determination, SAR (structure-activity relationships) and QC of confirmed hit compounds.

EU-OPENSREEN will start operations in late 2015, but it can already look back on a growing number of transnational activities: joint screening projects, exchange of local compound libraries, development of new design principles for its compound collection; exchange of experimental data through its pilot database etc.

Tissue Development and Morphogenesis 1**P682****Board Number: B936****Bone mineral and skeletal muscle formation induced by different gravitational exercise.**T. Sato¹, T. Watanabe², S. Igawa³;¹Department of Human Environmental Sciences, Jissen Women's University, Tokyo, Japan, ²Human Health Science, Hachinohe Gakuin University, Hachinohe, Japan, ³Dep. Health Science, Nippon Sport Science University, Yokohama, Japan

The constant influence of weightlessness during space flight leads to modifications of several physiological processes. Degradation of physical performance of astronauts after long-duration space missions is one of the topical but still unresolved problems of space medicine. The phenomenon is

commonly interpreted as a consequence of deconditioning of not only antigravity muscle but also bone structure because of long absence or reduction of mechanic and gravitational loads. It is well known that osteoporosis and muscle atrophy are affected by aging and insufficiency gravity stimulus as the human walking. The present study investigate the influence of such gravitational exercise as drop jump compare to swimming exercise in improving of bone minerals and muscle mass. The study was carried out with 21 Wister rats divided into three groups each 7 rats, i.e. gravitational exercise(drop jump), low gravitational exercise(swimming) and control. The experiments were performed after basically 5weeks breeding. During experiments periods for 8 weeks all animals were given standard laboratory diet and water available freely per day. It was increased gravitational effects on drop jump from 25cm(1 week), 30cm(2 week), 35cm(3 week) to 40cm(4-8 weeks) as gravitational training. In swimming group as low gravitational exercise were performed swimming 1 hour per day in 5 times per week by automatically pumping wave. The present study was carried out in accordance with the Japanese law, which allows experiments on laboratory animals in Nippon Sport Science University accordance to the Principles of laboratory animal care. After each one week exercise, hole femoris bone was isolated, bone density diagnosis both bone mineral content(BMC,g) and bone mineral density(BMD, g/cm^2). One-way ANOVA was used for statistical analysis of data between difference group, and P

Deconstruction of a bio-mechanical ratchet during tissue morphogenesis.

A. Munjal¹, T. Lecuit¹, J. Philippe¹;

¹Institut de Biologie du Développement de Marseille, CNRS UMR 7288, Marseille, France

Myosin II motors generate forces that power cell shape changes during tissue morphogenesis. Such actomyosin networks function like a mechanical ratchet where phases of pulsed contraction and cell deformation alternate with phases of stabilization. *Drosophila* ectoderm extension exemplifies this differential behavior whereby pulses of acto-myosin flow towards junctions aligned in dorso-ventral axis leading to their shrinkage in order to facilitate cell intercalation(1). A planar polarized pool of Myosin II enriched at these junctions stabilizes the deformation resulting in an irreversible process(2). The mechanisms for regulation of these networks remain unknown. We investigated the role of dynamic phosphorylation of Myosin II regulatory light chain (RLC) by the Rho1-ROCK pathway. We find that spatial control over RLC phospho-cycles by Rok and Myosin II phosphatase mediates planar-polarized accumulation of Myosin II through regulation of its recruitment and dissociation. Investigating Myosin II temporal dynamics, we report that Myosin II pulses involve *de novo* recruitment of mini-filaments concomitant with their contraction, followed by disassembly. Interestingly, Myosin II pulses with its regulators Rho1, ROCK and Myosin II phosphatase. We refute a model where Myosin II pulsatility is enslaved by the upstream biochemical pacemaker Rho1. Instead, we propose a bio-mechanical feedback model postulating emergence of pulses through self-organization of its components. We find that pulsatility is set by the balance of recruitment of Myosin II by advection- mediated concentration of upstream regulators, and a delayed phosphatase-dependent depletion of Myosin II.

PROBING COLLECTIVE MIGRATION OF A COMPLEX MULTI-CELLULAR EMBRYONIC TISSUE THROUGH NOVEL 3D BIOETCHING.

M. Hazar¹, Y. Kim², L.A. Davidson^{3,4}, P.R. LeDuc¹, W.C. Messner⁵;

¹Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA, ²Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, ³Bioengineering, University of Pittsburgh, Pittsburgh, PA,

⁴Developmental Biology, and Computational and Systems Biology, University of Pittsburgh, Pittsburgh, PA, ⁵Mechanical Engineering Department, Tufts University, Medford, MA

Embryonic development consists of a complex series of cell signaling, cell migration and cell differentiation processes that are coordinated during morphogenesis. Collective cell sheet migration is an important process that sculpts the shape of an organism and its internal tissues during early development. Studies of these collective cell movements have focused on the behavior of epithelial monolayers of cultured cells such as Madin Darby canine kidney MDCK cells. By contrast, most embryonic development and tissue self-assembly requires the integration of cell movements within multiple cell layers composed of different cell types. Although the role of cell mechanics in tissue self-assembly has been demonstrated, little is known about the mechanical response of the multi-layer tissues to environmental cues. One of the reasons for this knowledge gap is the lack of the technologies to analyze the individual responses of epithelial and mesenchymal cell sheets in a multi-cell layer tissues. To investigate the processes that guide collective movements of multiple cell layers our group has focused on developing a novel microfluidic technique capable of producing complex patterns of multicellular structures. We call this technique "3D tissue-etching" by analogy with silicon micromachining techniques used to fabricate 3D microelectromechanical structures (MEMS) by successive steps to remove material from a monolithic solid. We use tissue etching to shape a complex multi-layered embryonic tissue and explore the dynamic collective responses of epithelial and mesenchymal cells in a single tissue. We use a custom-designed microfluidic control system to deliver a range of tissue etching reagents (detergents, chelators, proteases, etc.) over tissues microsurgically isolated from embryos of the African Claw-toed frog, *Xenopus laevis*. Using etching we produce free-edges of epithelial cells over mesenchymal cells and free-edges of mesenchymal cells. This allows us to study multi-layer coordination of epithelial and mesenchymal cell layers, as well as acute mechanical and behavioral responses of intact epithelial and mesenchymal cell sheets to the removal of neighboring or overlying tissues. The ability to control the forms of multicellular tissues will have high impact in tissue engineering and regeneration applications in bioengineering and medicine as well as in the synthesis of highly complex 3D integrated multicellular biosystems.

P685**Board Number: B939****RNA polymerase I transcription and craniofacial dysmorphology.**

S.J. Baserga¹, C. Zhao^{2,3}, V. Andreeva², M. LaBonty², Y. Zhou⁴, L. Zon⁴, K.L. McCann⁵, P.C. Yelick², J.N. Griffin⁶, S.B. Sondalle⁵, F. del Viso⁶, M.K. Khokha^{5,6};

The transcription of rRNA by RNA polymerase I is the first step in making ribosomes in the nucleolus of eukaryotic cells. Transcription and the subsequent processing of the pre-rRNA requires hundreds of protein factors. Treacher-Collins Syndrome is an autosomal dominant craniofacial dysmorphology syndrome characterized by underdeveloped lower jaw and cheekbones, downward slanting eyes, conductive hearing loss, and malformed or absent ears. So far, mutation of 3 genes all involved in RNA polymerase I transcription have been found causative of Treacher-Collins Syndrome (TCOF1, POLR1C, or POLR1D). The latter 2 are also shared with RNA polymerase III. Thus, Treacher-Collins Syndrome is a ribosomopathy.

To further investigate a role for RNA polymerase I transcription factors in craniofacial dysmorphology, we have probed the role of two t-UTPs. t-UTPS, first characterized as essential proteins in the yeast, *S. cerevisiae*, are required for both RNA polymerase I transcription and pre-rRNA processing. We have explored whether intact UTP5 (WDR43) and NOL11 are required for normal development of the face in zebrafish and frog models, respectively. We have found that they are, and that disruption of their function leads to cranial neural crest apoptosis. The craniofacial defects can be rescued by inhibition of p53 function in both cases, demonstrating a conserved nucleolar stress response among vertebrates. Our results suggest the possibility of mutation of other nucleolar proteins in disorders of human craniofacial development.

P686**Board Number: B940****Small peptides induce selective ubiquitination to activate the transcription factor Shavenbaby by proteasome protein processing.**J. Zanet¹, E. Benrabah¹, T. Li², A. Pelissier-Monier¹, B. Ronsin¹, H. Bellen², F. Payre¹, S. Plaza¹;¹CNRS, Center of Developmental Biology, Toulouse, France, ²Neurological Research institute, Baylor College of Medicine, Houston, TX

Recent studies based on bio-informatics and ribosome profiling experiments revealed that a wide variety of RNAs contain small Open-Reading-Frames (smORFs) in yeast, invertebrates and mammals. However, the existence and the putative mode of action of smORF-encoded peptides remain elusive in the absence of direct evidence. The *Drosophila* *polished rice/tarsaleless* (*pri/tal*) gene encodes smORF peptides that control developmental processes. We previously showed that Pri peptides switch the transcriptional activity of Shavenbaby (Svb), a transcription factor required for epidermal differentiation. Here we demonstrate that Pri peptides induce a proteasome-mediated protein processing of Svb. Genome-wide RNAi screening identified the E3 ubiquitin ligase that targets, in a pri-dependent manner, Svb to the proteasome, which limited degradation ensures processing. As shown *in vitro* using synthetic peptides, we find that Pri peptides promote the binding of the E3 ligase to the Svb Nterminus. This in turn triggers ubiquitination of the Svb N-term degron and proteasome processing to release the activated form of the Svb transcription factor. Genetic ablation further demonstrates that this E3 ligase is essential for Svb processing *in vivo* and therefore for epidermal differentiation. These mechanistic insights into the action of Pri smORF peptides show how such small compounds can control proteasome action and, thereby, the execution of developmental programs.

P687**Board Number: B941****Annealing: the changing role of junctional actomyosin in epithelial cell packing during tissue development.**S. Curran¹, C. Strandkvist¹, B. Baum²;¹University College London, MRC Laboratory for Molecular Cell Biology, London, England, ²Laboratory for Molecular Cell Biology, University College London, London, United Kingdom

Epithelial morphogenesis is driven by actomyosin dependant changes in cell shape and neighbour exchange. Previous studies have focused on the polarised local movement of myosin during rapid morphogenetic processes, such as *Drosophila* germ band elongation. Less well understood is the role that the actomyosin cytoskeleton plays in regulating junctional rearrangements that occur in epithelia under conditions of homeostatic growth. As a model to investigate this process, we use the *Drosophila* *notum*. In this mono-layered epithelium, cell intercalation occurs without associated changes in tissue shape.

Here we show that actomyosin is not required to drive local cell rearrangements in this system. Conversely, when junctional levels of myo-II are increased through *sds22* RNAi, a negative regulator of myosin and moesin phosphorylation, junction length fluctuations and neighbour exchange events are inhibited. Interestingly, a similar change is observed during development as myosin progressively accumulates at junctions. Increased junctional myosin correlates with reduced junction length fluctuations and reduced neighbour exchange. This shift in actomyosin organisation appears to function like annealing to ensure that cell packing gradually orders over developmental time.

During rapid morphogenesis polarised junctional actomyosin provides the forces required for irreversible neighbour exchange and changes in global tissue shape. Based upon our data we propose that junctional sliding due to myosin-independent fluctuations contributes to cell packing and tissue refinement in epithelia under resting conditions.

Apical mitotic position in pseudostratified epithelia is independent of the centrosome but facilitates cell reintegration following division.

P.J. Strzyz¹, C. Norden¹, H.K. Lee¹, I.P. Weber¹, J. Sidhaye¹;

¹MPI-CBG, Dresden, Germany

Pseudostratified epithelia (PSE) are proliferating tissues prevalent during animal development. These tissues feature a single layer of elongated cells whose nuclei adopt various positions along the apico-basal axis. Strikingly, regardless of their interphase position, all nuclei migrate towards the apical surface before mitosis. These nuclear movements result in apical localization of all divisions that canonically ensue with perpendicular cleavage planes. Following division nuclei are displaced from the apical surface and acquire more basal positions. This bidirectional movement of nuclei has been known as interkinetic nuclear migration (IKNM). To date, substantial insights into mechanics of this phenomenon have been gathered. However, the purpose of this nuclear migration and the resulting apical divisions in PSE remain elusive.

Notably, in PSE centrosomes localize apically. This means that in the interphase the centrosome and the respective nucleus remain at a distance. As centrosomes serve as spindle organizing centers, the centrosome and the nucleus associate before mitosis. It has therefore been proposed that apical nuclear migration in PSE ensures that nuclei and centrosomes meet for mitosis. We aimed to test this hypothesis. Surprisingly, we uncovered that apical IKNM occurs independently of the centrosome. We show that apical migration of nuclei takes place in cases when the centrosome and the nucleus meet non-apically. In this scenario, cells can enter mitosis at non-apical position. However, despite non-apical mitotic entry, the actomyosin-based machinery driving apical migration is still activated, resulting in the movement of the cell soma towards the apical surface. We additionally demonstrate that apical nuclear migration takes place even in cases when the integrity of the apical centrosome is perturbed. Collectively, this implies that apical IKNM is a highly robust phenomenon.

Next, we aimed to shed light on the cause of this remarkable reproducibility of apical nuclear migration and apical divisions. To achieve this we introduced non-apical divisions within the intact PSE. We observe that such ectopic divisions impair reintegration of the daughter cells into the epithelial structure and lead to cell delamination from the tissue. These delaminated cells continue proliferating basally, forming clusters that interfere with tissue architecture and subsequent maturation. Interestingly, we also demonstrate that upon the perturbation of the perpendicular cleavage planes of apical divisions tissue integrity is not compromised. We therefore propose that positioning all dividing nuclei apically safeguards the integrity of the PSE by allowing the cells to reintegrate into the epithelium following division.

O- linked N-acetylglucosamine transferase accumulates at *Mgea5* , β -N-acetylglucosaminidase gene loci in mouse trophoblast stem cells.

K. Nishitani¹, K. Hayakawa¹, M. Hirose¹, S. Tanaka¹, K. Shiota¹;

¹Dep. of Anim. Res. Sci., The University of Tokyo, Tokyo, Japan

The placenta, which expresses numerous physiological factors such as hormones and enzymes, plays an important role during fetus development. The sensing of the maternal and fetal metabolism in the placenta is needed to achieve gene regulation. UDP-GlcNAc, a donor substrate for O-GlcNAcylation, exists abundantly in cells and is produced by the hexosamine synthetic pathway, which interacts with several other pathways such as amino acid and fatty acid metabolism. O-GlcNAcylation has recently emerged as an administrative system of epigenetic regulation via the modification of nuclear proteins, including histones. The enzyme O-GlcNAc transferase (OGT) catalyzes the O-GlcNAcylation of various proteins, and the enzyme β -N-acetylglucosaminidase (O-GlcNAcase) removes the O-GlcNAc from proteins. OGT gene is located in the X chromosome, and the gene encoding O-GlcNAcase has been mapped to chromosome 19, as *Mgea5* in the mouse genome. Trophoblast stem cells (TSCs) exhibit multipotency and differentiate into all of placental cells as spongiotrophoblasts and trophoblast giant cells. We noticed that *Ogt* expression is much higher in undifferentiated TSCs than in the differentiated ones. The protein expression level was confirmed with western blotting and immunostaining. To investigate the role of O-GlcNAcylation in the placenta, we determined the OGT target loci in undifferentiated and differentiated TSCs using chromatin immunoprecipitation sequencing (ChIP-seq) analysis. The genomic target loci were found to be much less abundant in undifferentiated TSCs than in the differentiated ones. More than 10,000 OGT target loci were identified in the differentiated TSCs, in contrast to less than 1,000 in the undifferentiated ones. This result suggests that OGT localizes to the nucleosome regions during differentiation. Alternatively, in the undifferentiated TSCs, almost all of the OGT may exist in the extra-nucleosome area. Both undifferentiated and differentiated TSCs showed accumulation of OGT around the transcription start sites and gene body. Intriguingly, the accumulation of OGT was detected by ChIP-PCR at the *Mgea5* locus in the differentiated TSCs, but not in the TSCs or in the mouse embryonic stem cells. Thus, *Mgea5* was one of the OGT targets that is present only in

differentiated TSCs. *Ogt* overexpression in differentiated TSCs led to increase in the *Mgea5* expression, which suggests that *Ogt* expression facilitates *Mgea5* expression. This phenomenon might be necessary for maintaining the O-GlcNAcylation levels in the trophoblast cells. In conclusion, OGT change the target loci dramatically before and after differentiation in TSCs. In addition, there is an intimate relationship between *Ogt* and *Mgea5* for genome-wide regulation of O-GlcNAcylation.

A critical role of an exon junction complex (EJC) factor, RBM8a, in regulation of embryonic cortical progenitors.

Y. Mao¹, D. Zou^{1,2}, C. McSweeney¹;

¹Biology, Pennsylvania State University, University Park, PA, ²The First Affiliated Hospital, Guangxi Medical University, Nanning, Guanxi, China

Nonsense-mediated mRNA decay (NMD) is a well-known RNA surveillance mechanism that ensures the speedy degradation of mRNAs carrying premature termination codons (PTCs). This mechanism relies on several key exon junction complex (EJC) factors to distinguish PTC from the normal stop codon. But how this mechanism modulates the embryonic brain development is largely unknown. Interestingly, mutation in *Magoh*, an important EJC factor, leads to defective neural stem cell division and microcephaly in mice. Human mutations in *Upf3b* have been reported to cause X-linked mental retardation and autism. This indicates that NMD may represent a novel pathway that regulates brain development and behaviors. Recently, we have identified that another key EJC factor, RBM8a, regulates anxiety behaviors in mice, further supporting the importance of EJC factors in brain functions. In this study, we demonstrated that RBM8a plays a key role in neural progenitor proliferation and differentiation. First, RBM8a is highly expressed in the subventricular zone of early embryonic cortex, suggesting that RBM8a may play a role in regulating neural progenitor cells (NPCs). To test this hypothesis, we used in utero electroporation to overexpress or knock down RBM8a in mouse brain at E14. RBM8a stimulates embryonic neural progenitor proliferation and suppresses neuronal differentiation, indicating that RBM8a positively regulates NPC proliferation. Conversely, knockdown of RBM8a in the neocortex reduces NPC proliferation and promote premature neuronal differentiation. Moreover, overexpression of RBM8a suppresses cell cycle exit and keeps cortical NPCs in proliferative state. Severe morphological defects were observed in immature neurons. Consistently, *Nes-cre*; RBM8a^{fl/+} mice show severe developmental defects including microcephaly and postnatal lethality. When RBM8a is overexpressed in the dentate gyrus of adult brain using stereotactic viral injection, mice showed altered anxiety and depressive-like behaviors. To uncover the underlying mechanisms, genome-wide RNA-immunoprecipitation-RNAseq identifies potential substrates of RBM8a in the brain, which have been implicated in neurogenesis and plasticity. Interestingly, autism- and schizophrenia-risk genes are highly representative in RBM8a-associate transcripts. Taken together, we identify a novel role of RBM8a in regulation of neurodevelopment and behaviors. Our studies provide a deeper insight on

causes of mental illnesses and will facilitate the development of new therapeutic strategies for neurodevelopmental illnesses.

the Endocytic Recycling Regulator EHD1 regulates Ciliary Morphogenesis and Signaling during Neural Tube Closure.

S. Bhattacharyya¹, M. Rainey², P. Arya³, M. Holzapfel⁴, T. Barger³, G. Todd³, J. Geineau van-Waes², V. Band^{3,5,6}, H. Band^{1,3,5,6};

¹Pathology/Microbiology, University of Nebraska Medical Center, Omaha, NE, ²College of Medicine, Creighton University, Omaha, NE, ³Genetics, Cell Biology and Anatomy, University of Nebraska Medical Center, Omaha, NE, ⁴Pathology, University of Nebraska Medical Center, Omaha, NE, ⁵Eppley Institute for Research in Cancer and Allied Diseases, University of Nebraska Medical Center, Omaha, NE, ⁶Fred and Pamela Buffett Cancer Center, University of Nebraska Medical Center, Omaha, NE

EHD1 is a member of the highly conserved dynamin-like C-terminal Eps15 homology domain-containing (EHD) protein family that function as essential components of endocytic recycling in cell systems. To define its biological functions in mammals, we have engineered *Ehd1* deletion in mice. In a predominantly B6 background, *Ehd1* deletion resulted in mid-gestation embryonic lethality. We show that EHD1 is expressed early during embryonic development, and that *Ehd1*-null embryos exhibit defective neural tube closure, axial turning and patterning of the neural tube. Importantly, *Ehd1*-null embryos exhibit stubby primary cilia architecture in the developing neural tube and this phenotype is recapitulated in *Ehd1*-null mouse embryonic fibroblasts together with a decrease in the number of primary cilia. As primary cilia are hubs for Hedgehog (Hh) signaling in vertebrates, we analyzed downstream effectors of Hh signaling and found that *Ehd1*-null embryos exhibit features of increased Sonic Hh (Shh) signaling with a severe down-regulation in Gli3 repressor expression. The *Ehd1*-null embryonic neural tubes showed reduced expression of markers for dorsal cell identities (Pax6 & Pax7) and severely restricted dorsal domains, with a moderate expansion of markers for ventral identities (Foxa2 and Nkx6.1). Based on our observations, we suggest that EHD1-regulated membrane traffic is a critical determinant of primary cilia morphogenesis and Shh signaling. Further studies of the model we have developed should enhance our understanding of primary cilia morphogenesis and may provide avenues to better understand the pathogenesis of neural tube defects, one of the most common birth defects occurring in approximately one in 1,000 live births in the United States.

P692**Board Number: B946****Investigation of Caprin2 function in lens fiber cell homeostasis.**S. Dash¹, C.A. Dang², D.C. Beebe³, S.A. Lachke^{2,4};¹UDel, Newark, DE, ²Biological Sciences, University of Delaware, Newark, DE, ³Department of Ophthalmology and Visual Sciences, Washington University School of Medicine, St. Louis, MO, ⁴Center for Bioinformatics and Computational Biology, University of Delaware, Newark, DE

The eye disease cataract is the leading cause of blindness worldwide and is caused by the loss of lens transparency. In order to prevent or delay cataract, it is essential to understand the molecular mechanisms that contribute to the formation and maintenance of lens transparency. We recently developed a bioinformatics tool iSyTE (integrated Systems Tool for Eye gene discovery) that identifies genes highly enriched in mouse lens development and uses this information to effectively predict candidates whose deficiency associates with mammalian cataracts. Using iSyTE we recently identified two post-transcriptional regulatory proteins (Tdrd7 and Celf1) that are components of cytoplasmic RNA granules, and are essential for vertebrate lens development. This is demonstrated by the severe lens defects including cataracts that are caused by their deficiency in multiple animal models, in turn suggesting a conserved function for RNA granule component proteins in lens development across diverse species. Here we investigate the function of a third conserved RNA granule component protein Caprin2 that is newly identified by iSyTE to be associated with lens biology. Caprin2 protein has multiple conserved domains including the coiled-coil and RGG domains as well as the C1q domain, which is found in TNF super-family of proteins to facilitate protein-protein interactions. Interestingly, Caprin2 expression has been recently shown to be responsive to induction by FGF8 in chicken lens fiber cells, supporting a potential role in the lens. As predicted by iSyTE, we confirmed by performing qRT-PCR, in situ hybridization, western blotting and immunostaining that Caprin2 mRNA and protein exhibits highly lens-enriched expression in mouse embryonic and postnatal lens. To functionally characterize this protein, we crossed mice obtained from EUCOMM that carried Caprin2 conditional mutant alleles (Caprin2^{tm2a(EUCOMM)}Wtsi) with an established lens Cre deleter line Pax6GFPCre to generate lens-specific Caprin2 conditional knockout (cKO) mutants. Phenotypic characterization has revealed that Caprin2 cKO mutants exhibit, albeit with incomplete penetrance, lens and eye defects, including a developmental defect called Peter's Anomaly. Scanning electron microscopy demonstrates that Caprin2 cKO mutants have a mild but consistent abnormality in lens fiber cells that contribute to the bulk of the lens tissue. Interestingly, Caprin2 has been associated with terminal differentiation of erythroblasts from a highly proliferative state into cells devoid of nuclei, similar to the transition of lens epithelial cells into terminally differentiated fiber cells that undergo nuclear degradation for lens transparency. In sum, our data has revealed a new function for Caprin2 in mammalian lens fiber cell.

P693**Board Number: B947****The role of N-cadherin in lens fiber cell elongation and lens morphogenesis during development.**S. Rajakaruna¹, C.M. Logan², G.L. Radice³, S. Menko⁴;¹Thomas Jefferson University, Philadelphia, PA, ²Anatomy, Thomas Jefferson University, Philadelphia, PA, ³Thomas Jefferson Univ, Philadelphia, PA, ⁴Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA

The process of lens fiber cell elongation is a central feature of lens morphogenesis. We investigate the role of N-cadherin junctions in this process in vivo. Here, we show how molecular interactions between N-cadherin and cytoskeleton regulate lens morphogenesis. Our study focus on investigating how N-cadherin function is integrated with microfilaments (MFs) and microtubules (MTs) to promote fiber cell elongation, and to examine the molecular regulators of N-cadherin/cytoskeletal interactions in fiber cell elongation and morphogenesis. To evaluate the impact of N-cadherin we generated a lens fiber cell specific NcadcKO with MLR10 Cre mice. In MLR10 NcadcKO lens at early E13.5 showed a change in directionality in MFs and MTs, while at E18.5 there was a dramatic change in MFs/MTs directionality and deregulation, and subsequent epithelial-fiber interface (EFI) separation in the lens. Proteins that link N-cadherin complexes to cytoskeleton such as β -catenin, and acetylated-tubulin identifying the stable microtubule populations were also suppressed in MLR10 NcadcKO lenses. Myosin II activation required for MF based cell motility was also deregulated as there was an increased expression of phospho Myosin (p-Myosin) in MLR10 NcadcKO lenses. Our preliminary data strongly implicates the importance of N-cadherin as the key focal point for lens fiber cell elongation and morphogenesis in lens cell development, and may serve as crucial knowledge required for designing effective strategies in regenerative medicine.

P694**Board Number: B948****A conserved RNA binding protein Celf1 is essential for vertebrate lens development and fiber cell differentiation.**A. Siddam¹, C. Gautier-Courteille², V. Legagneux², A. Kakrana³, A. Méreau², C.A. Dang¹, J. Viet², D. Scheiblin¹, L. Perez-Campos⁴, D.C. Beebe⁵, J. Gross⁴, L. Paillard², S.A. Lachke^{1,3};¹Biological Sciences, University of Delaware, Newark, DE, ²Institut de Génétique et Développement de Rennes, Université de Rennes, Rennes, France, ³Center for Bioinformatics and Computational Biology, University of Delaware, Newark, DE, ⁴Department of Molecular Biosciences, University of Texas, Austin, TX, ⁵Department of Ophthalmology and Visual Sciences, Washington University School of Medicine, St. Louis, MO

The ocular lens is a transparent tissue made of epithelial and fiber cells that focuses light on the retina to enable high-resolution vision. Loss of lens transparency results in cataract - the leading cause of blindness affecting 40 million worldwide. While the significance of signaling molecules and transcription factors in lens development, homeostasis, and cataractogenesis is well characterized, that of post-transcriptional regulators is unclear. Post-transcriptional regulation - controlled by RNA binding proteins (RBPs) among other molecules and defined as regulation of RNA transcript processing, localization, stability, degradation, and translation - is essential for cell function. Yet, while the human genome encodes 1500 RBPs, less than 20 are associated with development or disease. To identify new regulators associated with lens differentiation and cataract, we developed a novel systems tool iSyTE (integrated Systems Tool for Eye gene discovery) and reported that deficiency of an RNA granule (RG) protein Tdrd7 results in juvenile cataracts in human and mouse (Lachke 2011 Science 331:1571). Here, we report a new iSyTE-identified RG-RBP Celf1 (Cugbp1) that functions in the post-transcriptional control of gene expression in vertebrate lens fiber cell differentiation. Celf1 has three RNA Recognition Motifs that bind to target RNAs to control mRNA decay, pre-mRNA alternative splicing or translation. We find that Celf1 exhibits a highly fiber cell-enriched expression pattern that is conserved in fish, frog and mouse. To investigate its function in fiber cells, we generated and characterized both germline and lens-specific Celf1 deletion mouse mutants. We find that Celf1^{-/-} mice develop fiber cell defects during embryogenesis that result in severe cataracts at birth. Significantly, Celf1 knockdown in Zebrafish and Xenopus also causes lens defects. Moreover, Celf1 deficient Zebrafish and mouse mutants exhibit fiber cell nuclear degradation defects emphasizing its functional conservation across diverse vertebrate species. Interestingly, microarray-based expression profiling of Celf1^{-/-} mouse lens reveals down-regulation of Dnase2b, an enzyme necessary for nuclear degradation in fiber cell differentiation. Furthermore, Celf1 deficiency results in mis-regulation of the cyclin-dependent kinase inhibitors p21 and p27 and of the F-Actin cross-linking protein Actn2. Finally, we find that Celf1 directly binds to Dnase2b and p27 transcripts and regulates their stability or translation into protein, respectively. In sum, we describe a new function for Celf1-mediated control mechanisms that critically function in vertebrate lens development by regulating diverse cellular properties such as fiber cell differentiation, cell cycle control and cell cytoskeleton.

Role of Dnmt1 in photoreceptor differentiation.

I.O. Nasonkin¹, R.K. Mallela¹, J. Roger², P.K. Cornuet¹;

¹Ophthalmology, University of Pittsburgh, Pittsburgh, PA, ²SCaNR / CERTO UPR 3294 Bâtiment 445, Université Paris-Sud, Paris, France

DNA methylation is a major epigenetic mechanism that participates in retinogenesis during eye development, and is facilitated by DNA methyltransferases, which catalyze the transfer of a methyl group to cytosine during DNA replication. This process leads to gene silencing in the genome. Objective: This study focuses on the role of DNA methyltransferase-1 (Dnmt1) in photoreceptor differentiation

during retinogenesis. DNMT1 (maintenance DNA methyltransferase), plays a significant role in replicating the parental DNA methylation patterns in the daughter DNA strands. Reducing Dnmt1 expression or/and introducing deletions into functionally important parts of the protein leads to reduction of DNA methylation. Mammalian retina is an excellent and simple model to study the impact of epigenetics (DNA methylation) on cell fate determination during Central Nervous System (CNS) development. Only six different neuronal cell types, one glial cell type and one pigmented cell type are produced during retinogenesis. Rod and cone photoreceptors play a major role in phototransduction and originate from bipotential Crx[+] rod-cone progenitors. Methods: We chose the Nrl knockout (Nrl -/-) mouse model where the loss of neural retina leucine zipper transcription factor leads to conversion of all rods into cones. This model of cone-only retina is a valuable model of human macula. This model, in combination with the conditional Dnmt1 knockout model, generated in our previous studies, is used here to delineate the impact of DNA demethylation on the conversion of rods into cones. We knocked out Dnmt1 in mouse retina using Rx-cre transgene in an Nrl -/- background and determined the impact of partial DNA demethylation on the conversion of rod photoreceptors into cones. We evaluated changes in gene expression, histology and started comparing changes in retinal function (electroretinogram) in Dnmt1 flox/flox, Rx-Cre, Nrl -/- “mutant” mice and “control” Nrl -/- animals. Results: First, we validated this model at the mRNA level and found no expression of Nrl and Rhodopsin in both “control” and “mutant” retinas. Next, we found the upregulation of genes such as Chx-10 and Otx2 (expressed at earlier stages of photoreceptor development) in mutants, while the S-opsin and M-opsin genes were downregulated in mutants. Further, we found some changes in retinal histology in mutant mice such as decreased number of rosettes, typical for Nrl -/- retina. Conclusions: Reduction of DNA demethylation in developing retina may impact cone photoreceptor development in this cone-only model. These data highlight the need to further investigate the role of Dnmt1 in photoreceptor development.

TRPV4 channel is necessary for appropriated establishment of the tight junctions in corneal epithelium and regulates its barrier function in combination with EGF.

J. Martinez-Rendon¹, E. Sanchez², A. Rueda³, F. Castro-Munozledo², R. Garcia-Villegas¹;

¹Department of Physiology, Biophysics and Neuroscience, CINVESTAV, México D.F, Mexico, ²Department of Cell Biology, CINVESTAV, Mexico D.F., Mexico, ³Department of Biochemistry, CINVESTAV, Mexico D.F., Mexico

We are interested in identifying ionic channels that regulate the proliferation and/or differentiation of epithelial cells. We study the spontaneously immortalized cell line RCE1-5T5, from rabbit corneal epithelium, which reproduces in vitro early stages of differentiation of this tissue. After screening for ionic channels differentially expressed between proliferative and differentiated RCE1-5T5 cultures, we observed that TRPV4 channel in differentiated culture is localized in the apical membrane of the more external cells layer in the stratified epithelium while in proliferative, cells it is expressed homogeneously in the cell. In spite of this, its mRNA levels remains constant and protein channel decreases 3.5 folds

when cells differentiate. TRPV4 is a cationic channel, activated by hypotonic cell swelling, heat, endogenous agonist like arachidonic acid and endocannabinoids and synthetic specific agonists 4 α -PDD and GSK1016790A (GSK101). It has been reported that TRPV4 mediates the regulatory volume decrease behavior in human corneal epithelial cells. TRPV4 also regulates the epithelial barrier function of tight junctions (TJ) in skin keratinocytes, mammalian gland cells and lung endothelium. With these antecedents we first demonstrate by calcium imaging that TRPV4 is functional in RCE1-5T5 cells and induces an increment of intracellular calcium in the presence of its specific activator GSK101 (100 nM) which is avoided by treatment with RN1734 (30 μ M), an specific blocker of TRPV4 or EGTA (2mM). We then analyzed the role of TRPV4 on TJ recording the Transepithelial Resistance (TER) of RCE1-5T5 cultures grown in presence of GSK101 or RN1734. We found that TRPV4 is necessary for the establishment of TJ. Additionally in mature epithelia, activation of TRPV4 increases the TER value. This effect seems to be mediated by augmentation of claudin 1 and 4 in the cell-cell contact of the most apical cell layer. It has been reported that TRPV4 as heteromer with TRPP2 forms an EGF activated channel at the apical membrane of renal collecting duct cells. On the other hand, EGF modulates TER in RCE1-5T5 cells. Therefore we evaluated the possible participation of TRPV4 in the regulation of TER in RCE1-5T5 by EGF. We found that activation of TRPV4 can enhance the values of TER in absence of EGF while the blockade of TRPV4 avoids the normal increase of TER even in presence of EGF. In conclusion our results suggest that TRPV4 is necessary for the correct establishment of the barrier function of TJ in corneal epithelia. Additionally in the differentiated epithelium, activation of TRPV4 regulates the barrier function of TJ increasing the values of TER and it is also involved in the regulation of TJ by EGF.

Gene expression and the differentiation of gastric epithelial cells: can early weaning disturb the developmental program?.

D. Ogias¹, L.C. Nogueira¹, L.Y. Hosoya¹, J.G. Zulian¹, P. Gama¹;

¹Cell and Developmental Biology, Institute of Biomedical Sciences University of Sao Paulo, Sao Paulo, Brazil

Background: Rat gastric epithelial cells differentiate during the third postnatal week and complete functional maturation is detected on suckling-weaning transition. From the five main cell populations, mucous and zymogenic cells depend on the expression of genes that regulate the activity of secretory apparatus. It is known that early weaning (EW) disrupts the gradual nutritional and behavioral transitions, but it also disturbs the differentiation program. Objective: In order to test how EW alters gastric epithelial cell differentiation and to check whether changes persist in young adults, we evaluated the expression of genes involved in the maturation of secretory apparatus in mucous (MC) and zymogenic cells (ZC), and studied the distribution of mucous neck cells. Methods and Results: Wistar rats were submitted to EW at 15d (protocol approved by Ethical Committee on Animal Use, ICBUSP) and gastric samples were collected at 18, 30 and 60d for qRT-PCR. Mist1 acts in the terminal differentiation of mucous neck cells (MNC) into ZC, and we found that EW immediately decreased mist1 expression (p

P698**Board Number: B1002****MODIFYING PROSTATE GLAND EPITHELIAL PHENOTYPES WITH FATTY ACIDS.**D.L. Ferrucci¹, H.F. Carvalho²;¹Structural and Functional Biology, State University of Campinas, Campinas/SP, Brazil, ²Structural and Functional Biology Department, State University of Campinas, Campinas SP, Brazil

Prostate cancer (PCa) is the second most common malignancy among men and benign prostate hyperplasia (BPH) is the fourth prevalent disease in men over the age of 50 years. Prostate growth (either PCa or BPH) is multifactorial and may be influenced by genetic, age, ethnicity, hormonal, exercise engagement and nutritional factors. Experimental data indicate that the amount of fatty acid in the diet is positively correlated with prostate gland disorders, and hence diets rich in fatty acids cause prostate enlargement. As a matter of fact fatty acid quality interferes with prostate growth, but this is poorly studied. We showed before that fatty acid quality affects cell proliferation with lard promoting and linseed oil having opposite effects. The objective of this study was to investigate the effects of fatty acid quality in normolipidic diets on the growth and gland architecture of the ventral prostate in C57/BL6 mice. Animals were divided into three groups fed with isocaloric normolipidic diets (7% fat) containing soybean oil, linseed oil and rendered pork fat (lard) for 10 and 32 weeks starting immediately after weaning. The results demonstrate that diets resulted in similar weight gain until the tenth week, but linseed oil resulted in leaner bodies, as measured as total body density. After puberty, the soybean oil diet resulted in higher body weight and ectopic fat pad, animals treated with lard and linseed oil presented similar weights gains and body composition. Lard and soybean oil based diets promoted increased prostate weight, while the linseed oil resulted in smaller prostates with an atrophic epithelium. Stereology demonstrated that lard and soybean oil based diets promoted prostate enlargement and altered tissue architecture, with increased epithelium and smooth muscle cell volumes. Interestingly, the group fed with saturated fatty acid content contributed to a decrease in lumen compartment. Increased androgen receptor content was determined by Western blots in the group fed with lard, with the opposite effect seen with linseed-based diets, which caused reduced androgen receptor content. The present results showed that lard results in a hyperplastic epithelium, while the linseed oil resulted in epithelial atrophy. It was remarkable that soybean oil caused animal and prostate growth. Continuing analysis will focus on the mechanism contributing to the prostate phenotype.

P699**Board Number: B1003*****MacF1* is Essential for Visceral Endoderm Development in Mouse Embryos.**K.M. Gonzalez¹, J. Rivera-Perez²;¹University of Massachusetts Medical School, Holden, MA, ²Cell and Developmental Biology, University of Massachusetts Medical School, Worcester, MA

Microtubule Actin Crosslinking Factor 1 (MacF1) a member of the spectraplakins family of proteins, binds actin filaments and microtubules in the cytoskeleton. *MacF1* is a positive regulator in the *Wnt* signaling pathway and its deficiency is lethal at early post-implantation stages in mouse embryos. In zebrafish, *MacF1* is essential for axial specification and its maternal deficit leads to the failure to establish the molecular asymmetry responsible for the formation of the anteroposterior axis. To understand the role of *MacF1* in murine axial specification and development we generated maternal and tissue specific mutations in mice. Our results show that *MacF1* acts downstream of *Wnt3* during gastrulation and that it is essential for the development of the visceral endoderm (VE). *MacF1*-VE mutant embryos show abnormal posterior VE cell structure and abnormal gastrulation compared to wild type littermates. Lack of maternal *MacF1*, however, does not affect embryonic development. These results suggest that *MacF1* has a fundamental role in post-implantation mouse embryos but unlike zebrafish, maternal *MacF1* does not appear to play a role in axial development in mouse embryos.

P700**Board Number: B1004****The role of iASPP in epithelial cell motility.**Z. Dedic¹, X. Lu^{1,2};¹Nuffield Department of Medicine, The University of Oxford, Oxford, United Kingdom, ²Nuffield Department of Clinical Medicine/ Ludwig Cancer Research, The University of Oxford, Oxford, United Kingdom

The majority of cancer-related mortality is due to cancer metastasis, a biological process that involves cell migration, proliferation and resistance to apoptosis. These processes also occur during morphological and physiological events including embryonic eyelid closure and wound healing. In addition, signalling pathways implicated in eyelid closure and wound healing are involved in metastasis. Examination of the regulation of molecular pathways involved in embryonic eyelid closure and wound healing could give us insight into the molecular mechanisms of metastasis. One of the main eyelid closure signalling pathways—the EGFR pathway—is deregulated in many cancers. The deregulation of EGFR has been associated with resistance to cancer therapies and worse prognosis for cancer patients. This led to generation of anti-EGFR cancer therapies, which yielded only moderate efficiency due to acquired cancer resistance to EGFR inhibiting treatments. p53 regulates EGFR. Loss of p53 and p53-induced cell cycle arrest and apoptosis is thought to contribute to acquired cancer resistance to EGFR treatments. iASPP binds and regulates p53-induced pro-apoptotic transcriptional activity. Lack of iASPP

in mouse models results in the eyelid-open at birth (EOB) phenotype, wavy hair and heart defects. These phenotypes are also observed in mice with deregulated EGFR signalling suggesting a potential role of iASPP in the regulation of EGFR signalling, which could be p53 dependent. Here we studied a potential link between iASPP and EGFR signalling by examining histological and molecular mechanisms by which loss of iASPP induces EOB phenotype. We show EOB phenotype in iASPP mutant mice is due to impaired epithelial sheet progression, which is not due to altered proliferation. Increased apoptosis is one of the contributing factors for this trait. In vitro analysis of migratory behaviour of keratinocytes showed faster and disorganized motility in iASPP deficient cells, implicating migration defect in impaired embryonic eyelid closure. Consistent with this, iASPP is highly expressed in the migratory cells of eyelid epithelia and wound closure, which depends on keratinocyte migration, is delayed in absence of iASPP in vivo. Increased expression of phosphorylated ERK, a downstream component of EGFR signalling, observed in iASPP deficient keratinocytes suggests that iASPP could regulate EGFR signalling. Future studies will aim to elucidate the mode of action of iASPP in EGFR pathway, and what effects this has on motility. Moreover, the mechanistic regulation of iASPP in the mediation of motility will be examined. It is hoped that this study, will extend our understanding of some of the mechanisms that influence cancer progression, and facilitate the development of new therapeutic strategies.

New mammary epithelial ducts form through coordinated polarization of the initiation of subcellular protrusions.

N.M. Neumann¹, R.J. Huebner¹, A.J. Ewald¹;

¹Department of Cell Biology and Oncology, Johns Hopkins University School of Medicine, Baltimore, MD

Morphogenesis in the mammary gland occurs iteratively during embryonic, fetal, and postnatal development. During each stage of morphogenesis, the mammary epithelium undergoes characteristic changes in architecture, including stratification and loss of apico-basal polarity. Cells within elongating epithelial buds migrate collectively, which raises the question of how these adherent cells can accomplish directional migration. Single cell migration can be guided through control over the polarization of protrusive activity. We sought to understand whether a similar mechanism could explain the initiation and elongation of mammary epithelial ducts.

The mammary stroma is composed of numerous adipocytes that scatter light and make direct observation *in vivo* highly challenging. To overcome this barrier, we developed 3D organotypic culture techniques to study morphogenesis in real-time. Briefly, the mammary gland is isolated, enzymatically digested, and the resulting epithelial organoids are explanted into 3D extracellular matrix gels. Next, we image the cellular dynamics through mosaic fluorescent labeling of single-cells within these organoids during branching morphogenesis.

We are able to image the initiation of new epithelial buds, ductal elongation, and polarization to a mature simple epithelium. We observe active cell migration during each of these processes and

cytoplasmic labeling revealed extensive protrusive activity within the epithelial group. Cells initiating new buds move in concert and initiate protrusions preferentially in the direction of tissue growth. We observe a diversity of protrusive shapes and individual cells can exhibit one dominant protrusion or many fine protrusions. Cells distant from the elongating duct initiate protrusions in an undirected manner and their migration is uncoordinated with their neighbors. Cells contributing to elongating ducts initiate more protrusions, display a greater polarization of protrusive activity in the direction of elongation, have higher velocities, and migrate over longer distances, when compared to cells in the body of the organoid.

Taken together, our data suggest a model in which epithelial ducts initiate through the coordinated polarization of protrusive activity. We are now focused on understanding how external cues are mediated through receptor tyrosine kinase signaling to control the orientation of protrusive activity and the coordination of migratory behavior.

Polycystin-1 binds Par3/aPKC and controls Convergent Extension during Renal Tubular Morphogenesis.

M. Castelli¹, M. Boca¹, M. Chiaravalli¹, H. Ramalingam^{2,3}, I. Rowe¹, G. Distefano¹, T. Carroll^{2,3}, A. Boletta¹; ¹Genetics and Cell Biology, San Raffaele Hospital, Milan, Italy, ²Department of Internal Medicine - Division of Nephrology, University of Texas Southwestern Medical Center, Dallas, TX, ³Department of Molecular Biology, University of Texas Southwestern Medical Center, Dallas, TX

Several organs, including lungs and kidneys, are formed by epithelial tubes whose proper morphogenesis ensures correct function. This is best exemplified by the kidney, where defective establishment or maintenance of tubular diameter results in polycystic kidney disease (PKD), a common genetic disorder. Most PKD cases result from loss-of-function mutations in the PKD1 gene, encoding Polycystin-1 (PC-1), a large receptor of unknown function. Here we demonstrate that PC-1 plays an essential role in establishment of correct tubular diameter during nephron development. Counting the number of cells in the cross-section of DBA-positive tubules in wild-type or Pkd1 mutant kidneys at different developmental stages (from E13.5 to E16.5) revealed that, while the tubules in wild-types become progressively narrow, in Pkd1 mutants this property is impaired. No significant differences in proliferation or apoptosis were detected to explain this defect. Conversely, morphometrical analysis of the epithelium lining the tubules of Pkd1 mutants revealed a failure to achieve mediolateral cell orientation, essential for a convergent-extension(CE)-like process occurring during renal tubular morphogenesis. In line with this, cells lacking PC-1 fail to properly orient during cell migration. Using cells and tissues derived from a mouse line expressing HA-tagged endogenous PC-1, we found that PC-1 associates with Par3 favoring the assembly of a pro-polarizing Par3/aPKC complex. Furthermore, PC-1 and Par3 undergo a similar regulation of expression during renal development. GST pull-down assays revealed that the C-terminal tail of PC-1 directly associates with the first two PDZ domains of Par3. Finally, we found that PC-1 regulates a Par3/aPKC complex important for oriented cell migration and for

CE during tubular morphogenesis. Consistently, Par3 inactivation in the developing renal tubules results in defective number of cells per tubular cross-section, defective mediolateral cell orientation and renal cystogenesis. Our data define PC-1 as central to cell polarization and to epithelial tube morphogenesis and homeostasis.

Tuning Myosin Activity to Investigate How Myosin Drives Cell Shape Change.

T.D. Cupp¹, C.D. Higgins¹, B. Goldstein²;

¹University of North Carolina, Chapel Hill, NC, ²Department of Biology, University of North Carolina, Chapel Hill, NC

Cytoskeletal dynamics govern changes in cell shape that form the basis of tissue morphogenesis. Gastrulation is a critical developmental process in which a single sheet of cells folds inward. In many organisms, apical constriction drives cell shape change to produce tissue folding. This can occur through contraction of the actomyosin network at the apical surface of constricting cells. We would like to understand how apical junctions become coupled to the contracting actomyosin networks, eliciting constriction of the apical cortex of cells. Here, we asked whether coupling is promoted by myosin-generated tension in the apical cortex. Phosphorylation of myosin's regulatory light chains (rMLC) at conserved sites leads to heavy chain assembly, permitting actomyosin network contraction. In *C. elegans* embryos, the endodermal precursor cells Ea and Ep are the first cells to undergo internalization, at the 26-cell stage of development. Prior to the onset of gastrulation, myosin accumulates apically and becomes activated in these cells. To investigate whether coupling is promoted by myosin-generated tension in the apical cortex, we attempted to tune myosin activity up or down and determine if this can lead to earlier or later cell internalization. Overexpressing a nonphosphorylatable form of myosin regulatory light chain in E cells delayed cell internalization, consistent with multiple models in which myosin activity is required for cell internalization. We tried increasing myosin activity by expressing a phosphomimetic rMLC construct in E cells or by overexpressing a kinase required for apical myosin activation. Interestingly, both methods led to delays in E cell internalization. Taken together, these results suggest that increasing myosin activity may not be sufficient to cause premature coupling and E cell internalization. We are currently examining whether the phosphomimetic rMLC and kinase overexpression increase myosin activity and tension in the cell cortex as predicted.

P704**Board Number: B1008****A critical and previously unsuspected role for Doublecortin at the neuromuscular junction in mouse and human.**

F. Bourgeois¹, J. Messéant¹, E. Kordeli¹, J.M. Petit², P. Delers¹, N. Bahi-Buisson³, V. Bernard⁴, S. Sigoillot¹, C. Gitiaux³, F. Francis⁵, C. Legay¹;

¹CNRS UMR 8119, Sorbonne Paris Cité, Université Paris Descartes, Paris, France, ²Service commun de Microscopie, Sorbonne Paris Cité, Université Paris Descartes, Paris, France, ³INSERM U1016, Hôpital Necker Enfants Malades, Université Paris Descartes, Paris, France, ⁴UM CR18, Neurosciences Paris Seine, Université Pierre et Marie Curie, Paris, France, ⁵INSERM UMRS 839, Institut du Fer à Moulin, Université Pierre et Marie Curie, Paris, France

The microtubule-associated protein doublecortin (DCX) is primarily expressed in post-mitotic neurons during embryonic development of the nervous system. Human mutations cause type I (X-linked or XLIS) lissencephaly in hemizygous males and subcortical band heterotopia in females (SBH), developmental disorders associated with brain malformations and characterized at the cellular level by defects in neuronal migration which affect cortical lamination.

We found that, besides the well-established expression in migrating neurons in brain, doublecortin is also expressed in embryonic motor neurons and skeletal muscle in mice, raising the possibility of a role in synaptogenesis. Studies with whole-mount preparations of embryonic mouse diaphragm revealed that lack of doublecortin leads to abnormal presynaptic arborization and significantly increased incidence of axonal extensions beyond innervated acetylcholine receptor clusters in the developing neuromuscular junction (NMJ). Our data suggest the contribution of doublecortin to a stop/stabilizing signal at the synapse which would normally limit further axonal growth following establishment of synaptic contact with the postsynaptic element. Importantly, we also identified abnormal and denervated NMJs in a muscle biopsy from a 16-year old female patient with SBH, showing both profound presynaptic and postsynaptic morphological defects.

Overall, these results point to a critical role of doublecortin in the normal establishment of the presynaptic element and suggest a possible involvement of this protein in the maintenance of NMJs in humans.

P705**Board Number: B1009****An essential morphogenetic role for Integrins in regulating tissue level tensile force by modulation of cell mobility.**E. Lostchuck¹, S. Ellis¹, K.E. Goodwin¹, D. Gunne¹, T. Zulueta Coarasa², S. Wistorf¹, J.J. Feng³, R. Fernandez-Gonzalez^{4,5,6}, G. Tanentzapf¹;¹University of British Columbia, Vancouver, BC, ²Univ Toronto, Toronto, ON, ³Department of Mathematics, University of British Columbia, Vancouver, BC, ⁴Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, ⁵Department of Cell and Systems Biology, University of Toronto, Toronto, ON, ⁶Developmental and Stem Cell Biology Program, The Hospital for Sick Children, Toronto, ON

Integrin-mediated Cell-ECM adhesion is essential for tissue morphogenesis. Integrins facilitate morphogenetic processes by supporting cell migration, stabilizing cellular architecture, and by regulating cell behavior. Here, we describe an additional way that integrins contribute to morphogenesis: they ensure that the biomechanical parameters that exist within a tissue promote the desired morphogenetic outcomes. Our work focuses on Dorsal closure (DC), an integrin-dependent morphogenetic process that occurs during fly embryogenesis. We have identified novel integrin-containing adhesive structures on the basal surface of the amnioserosa, an extra-embryonic epithelium that is essential for DC. Since these in vivo structures share many features with focal adhesions we termed them Focal Adhesion-Like Structures (FALS).

Using mutations that either increase or decrease integrin-based Cell-ECM adhesion, we show that integrins regulate the mobility of amnioserosa cells within the two-dimensional epithelial sheet. Furthermore, using mathematical modeling, quantitative image analysis, and in vivo laser ablation experiments we find a direct correlation between cell mobility and the amount of tension in the tissue. Specifically, mutations that exhibit increased cell mobility within the tissue result in less tension, while mutations that decrease cell mobility result in more tension within the tissue. Finally, we show that mutations that alter cell mobility and tension within the amnioserosa result in defective DC. We are able to corroborate this data using a mathematical model of DC, in which modulation of the friction factor recapitulates the phenotypes that we observe in our mutants. Overall, our data demonstrates that integrin-mediated cell-ECM adhesion determines cell mobility, and consequently, tension within a tissue and that this regulation has profound effects on tissue morphogenesis. We propose a model whereby integrin-mediated Cell-ECM adhesion is required to maintain tissue-level tension and other biomechanical parameters within an ideal range that promotes morphogenesis. Our results therefore uncover a fundamental and likely conserved mechanism for developmental regulation that links integrin-based adhesion, tissue biomechanics, and morphogenesis.

P706**Board Number: B1010****The role of Tcf4 and connective tissue fibroblasts in myogenesis.**S.J. Mathew¹, G. Kardon²;¹Regional Centre for Biotechnology, Gurgaon, India, ²Department of Human Genetics, University of Utah, Salt Lake City, UT

The vertebrate musculoskeletal system comprises the muscle, muscle connective tissue, tendon and bone. The muscle connective tissue includes the extracellular matrix and the connective tissue fibroblasts, which secrete the extracellular matrix. We discovered that the Wnt/beta-Catenin pathway transcription factor Tcf4 is strongly expressed in the connective tissue fibroblasts, and weakly by myofiber nuclei. We also generated the Tcf4GFP-Cre mice where Cre mediated reporter activity was detected in the connective tissue fibroblasts, allowing genetic manipulation of these fibroblasts. Our results indicate that Tcf4 plays dual roles in myogenesis: first, an intrinsic role wherein Tcf4 expressed by myogenic cells regulates both slow and fast muscle fiber type development, and second, an extrinsic role whereby Tcf4 dependent signals from the connective tissue fibroblasts promote slow myogenesis and repress developmental embryonic myosin heavy chain expression. Thus, using mouse genetic experiments and in vitro co-cultures we show that Tcf4 and the MCT fibroblasts are crucial for proper muscle maturation, differentiation and function. From these results, we conclude that the connective tissue is not only important for adult muscle structure and function, but is a vital component of the niche within which muscle progenitors reside and is a critical regulator of myogenesis.

P707**Board Number: B1011****The Role of Nonmuscle Myosin II-A and II-B in Coronary Vessel Development in Mice.**X. Ma¹, Y. Uchida², C. Bowen¹, Y. Mukoyama², R.S. Adelstein³;¹Laboratory of Molecular Cardiology, Genetics and Developmental Biology Center, NIH/NHLBI, Bethesda, MD, ²Laboratory of Stem Cell and Neuro-Vascular Biology, Genetics and Developmental Biology Center, NIH/NHLBI, Bethesda, MD, ³Laboratory of Molecular Cardiology, Genetics and Developmental Biology Center, NHLBI/NIH, Bethesda, MD

To understand the functions of the different nonmuscle myosin II isoforms (NM IIs) during mouse heart development we crossed mice expressing cre-recombinase controlled by various promoters with floxed NMHC II-A and II-B mice. Nkx2.5-Cre mediated ablation of NM II-B (B^{Nkx}/B^{Nkx}) in cardiomyocytes caused cytokinesis defects similar to those seen in NM II-B ablated mouse hearts. A^{Nkx}/A^{Nkx} cardiomyocytes on the other hand showed no defects in heart development. Mice ablated for NM II-B by SM22a-Cre in epicardial and myocardial cells (B^{SM22}/B^{SM22}) survived to adulthood. B^{SM22}/B^{SM22} hearts showed marked abnormalities in coronary vessel remodeling. These mice developed arrhythmogenic right ventricular cardiomyopathy (ARVC) and died suddenly at the age of 6 months. B^{SM22}/B^{SM22} mice resemble humans

with ARVC with the exception that they lack fat cell deposition in the myocardium. Defects in coronary vessels were confirmed in mice ablated for NM II-B specifically in epicardial cells by crossing to WT-1-Cre mice however B^{WT}/B^{WT} mice died during embryonic development for unknown reasons. Consistent with abnormal coronary vessel formation, epicardial explants showed that genetic ablation of NM II-B or inhibition of all NM II activity by blebbistatin impaired epicardial EMT. Surprisingly, despite significant expression of NM II-A in epicardial cells, A^{SM22}/A^{SM22} mice showed no obvious heart defects and survived to adulthood. We next ablated NM II in endocardial cells using Tie2-Cre mice. Except for a minor delay in coronary plexus coverage in embryonic hearts, B^{Tie2}/B^{Tie2} mice survived to adulthood with no obvious defects. In contrast A^{Tie2}/A^{Tie2} mice showed defects in coronary vessel formation in embryonic hearts and died during embryonic development. Of note A^{Tie2}/A^{Tie2} embryonic mouse hearts at E14.5 showed marked impairment in coronary coverage over the heart surface indicting a sprouting defect during coronary vessel formation. Furthermore compound Tie2-Cre mice ablated for one allele of NM II-A and both alleles of NM II-B ($A^{+}/A^{Tie2}; B^{Tie2}/B^{Tie2}$) developed a severe defect in coronary coverage suggesting that NM II-B functions when NM II-A expression is limited. These results reveal that NM II-A and II-B function in two different developmental processes during coronary vessel formation in the mouse heart. NM II-A regulates coronary plexus expansion over the heart surface through the endocardial/endothelial cell lineage. NM II-B regulates coronary vessel remodeling through the epicardial derived cell lineage.

VEGF immunoexpression related to the ectomesenchymal cells differentiation into osteoblasts during early development of alveolar process in rat molars.

G.R. Sasso¹, R.F. Silva¹, E. Sasso-Cerri², M.J. Simões¹, P.S. Cerri²;

¹Morphology and Genetics, Federal University of São Paulo (UNIFESP), São Paulo, Brazil, ²Morphology, Univ Estadual Paulista - UNESP, Araraquara, Brazil

The alveolar process is produced by osteoblasts derived from ectomesenchymal (ECM) cells during tooth germ development. As soon as root tooth formation begins, osteoblasts derived from ECM of dental follicle secrete alveolar bone on the inner surface of the alveolar process; this bone layer plays an important role for the maintenance of tooth in the alveolar process. It has been suggested that vascular endothelial growth factor (VEGF) can stimulate osteoblast proliferation and differentiation. Runx2 is a transcriptional factor required for cells differentiate into osteoblasts. Alkaline phosphatase (APh), osterix and osteocalcin (OCN) are considered osteoblast markers. In the present study, we evaluated the immunoexpression pattern of VEGF, Runx2, APh, osterix and OCN by ECM cells in the developing alveolar process. The heads of 16-, 18- and 20-day-old embryos (EM) and 5-, 10- and 15-day-old male rats were fixed and embedded in paraffin. Sections exhibiting ECM surrounding the first upper molar tooth germs were subjected to immunohistochemistry for VEGF, Runx2, APh, osterix and OCN detection; numerical density of immunolabeled-ECM cells was computed. Data were statistically evaluated by Tukey's test ($p \leq 0.05$). Sections of 16- and 20-day-old EM were submitted to von Kossa for detection of calcified bone matrix. In 16-day-old EM, clusters of VEGF-positive ECM cells were observed near to

blood vessels; immunoexpression of Runx2, osterix and APh was also observed in the ECM. von Kossa bone trabeculae surrounding the first molars were observed in the 16- and 18-day-old EM, characterizing the beginning of the development of alveolar process. Osteoblasts adjacent to the bone surface exhibited strong osterix, APh and OCN immunolabeling. However, a significant reduction in the number of osteoblast markers immunopositive ECM cells was verified in the dental follicle from 18-day-old EM to 5-day-old rats in comparison to 16-day-old EM. However, the early formation of tooth root (10-day-old rats) was coupled with a significant increase in the VEGF, Runx-2, osterix and OCN immunolabeled ECM cells in the dental follicle. Thus, the high number of VEGF-immunolabeled ECM cells in the beginning of the formation of alveolar process (16-day-old EM) and alveolar bone (10-day-old rats) suggests a participation of this vascular factor in the process of osteoblast differentiation.

Rab8a vesicular traffic maintains Wnt activity in intestinal stem cell niche.

S. Das¹, S. YU¹, R. Sakamori¹, Q. Feng¹, A. Hoffman², J. Fu³, P. Vedula¹, A.J. Rodriguez⁴, R. Dobrowolski¹, A. Harada⁵, W. Hsu³, E.M. Bonder¹, M.P. Verzi^{2,6}, N. Gao^{1,6};

¹Rutgers University, Newark, NJ, ²Genetics, Rutgers University, Piscataway, NJ, ³University of Rochester Medical Center, Rochester, NY, ⁴Federated Department of Biology, Rutgers University, Newark, NJ, ⁵Cell Biology, Graduate school of Medicine, Osaka University, Osaka, Japan, ⁶Rutgers Cancer Institute of New Jersey, New Brunswick, NJ

Wnt proteins are a critical group of ligands that drive embryogenesis and maintain adult tissue homeostasis in all animals. Extensive studies using the mammalian intestinal crypt as a model have been conducted to elucidate the role of Wnt signaling in adult stem cell niche maintenance and colorectal tumorigenesis. However, in contrast, little is known about the molecular mechanisms regulating Wnt ligand secretion from the signal-providing cells. We demonstrate that a Ras-like small GTPase, Rab8a directly controls Wnt secretion and signaling in vitro and in mouse intestinal epithelium, contributing to the intestinal stem cell homeostasis. Rab8a knockout intestinal crypts demonstrate significant reduction in canonical Wnt activity that could be partially restored by exogenous ligands or by activating downstream signaling pathway. Despite a significant reduction of the Wnt-producing Paneth cells, an expansion of proliferative transit amplifying cells was detected. Mechanistically, we observed that Rab8a vesicles intersect the traffic of G-protein coupled receptor 177 (Gpr177/Wls), the Wnt-specific transporter. Our study suggested the role of Rab8a in sorting Gpr177-Wnt complexes for exocytosis.

P710**Board Number: B1014****Development and Characterization of an *in vitro* Co-culture Angiogenesis Model Using hTERT Immortalized Cells.**C. Zou¹, C. Zhang¹, I. Oliva¹, M.S. Enuameh¹;¹ACS, ATCC, Gaithersburg, MD

Angiogenesis is the key multi-step physiological process during normal tissue development and is involved in a large number of disease states; an *in vitro* angiogenesis model provides a very useful tool to study this important physiological process. Additionally this model can be used in drug screening applications. Currently, several *in vitro* co-culture models have been developed using primary cells, however, donor variability, low cell quantity per lot and short lifespan of primary cells used for these co-culture models limit their usefulness and consistency.

In this study, we established an *in vitro* co-culture model system using TeloHAEC(an aortic endothelial cell line), and hTERT-MSC cells(adipose derived mesenchymal stem cells); both cell lines were immortalized by hTERT alone and have been well characterized showing the cells retain the most important characteristic of their parental counterparts; when TeloHAEC was co-cultured with BJ primary fibroblast for 14 days in optimized ATCC angiogenesis medium, fine tubular structures were formed as shown by staining with CD31 endothelial cell marker. The tubular length elongated with increasing doses of VEGF stimulation, and the tubular formation can be completely blocked by Suramin or VEGF antibody in a dose dependent manner. Next, we introduced GFP into the TeloHAEC cell line(TeloHAEC-GFP), allowing for real time visualization of angiogenesis when co-cultured with BJ fibroblasts; then another hTERT immortalized cell line, hTERT-MSC, is used to replace the BJ-primary fibroblast in the co-culturing system; results showed that the new model not only can form the tubular structures in less than 7 days instead of 14 days, but also responds effectively to VEGF stimulation and compounds treatments such as suramin, and furthermore, the hTERT-MSC cells which surround the tubular structures have undergone transformation indicated by positive α SMA staining which is a marker of smooth muscle cells, this indicates the system has physiological relevance; most importantly, the tubular structures in this system can be blocked completely with the increasing doses of clinical cancer drugs- such as sunitib, indicating the system is reliable for drug screening purpose. In a word, the co-culture models developed by using hTERT immortalized cell lines described in this report provide a much more consistent and robust *in vitro* co-culture system for studying vascular biology, drug screening and tissue engineering.

P711**Board Number: B1015****Characterization of a Three-Dimensional (3D) Organotypic Skin Model using Keratinocytes and Mesenchymal Stem Cells Immortalized by hTERT.**A. Briley¹, C. Zhang¹;¹ATCC, Manassas, VA

Primary and hTERT immortalized keratinocyte cultures are important cell models for the study of normal and pathological biology of the cutaneous epithelia. Primary keratinocytes can form skin equivalents that mimic the architectural features and behavior of normal skin in a three-dimensional (3D) organotypic culture model in an air-liquid interface (ALI). However, primary keratinocytes have finite lifespan in culture, which greatly restricts their use as in vitro cellular model.

In this study, we compared primary keratinocytes to hTERT immortalized keratinocytes, co-cultured with either fibroblasts or hTERT immortalized mesenchymal stem cells (MSCs). We confirmed that both primary keratinocytes and a hTERT immortalized keratinocyte cell line, Ker-CT are able to fully differentiate into skin equivalents in an ALI 3D culture model, when co-cultured with primary fibroblast or hTERT immortalized mesenchymal stem cells (MSCs). To confirm the functionality of the co-culture models, both primary keratinocytes and Ker-CT ALI co-cultures were subjected to a scratch assay. Re-epithelialization occurred in both cell lines and several markers show increased expression corresponding to crosstalk between keratinocytes and MSC/Fibroblast. The immortality of Ker-CT cell line makes it an invaluable model for the research of keratinocyte biology, as it eliminates the issue of short life span and donor variation seen with primary cells.

P712**Board Number: B1016****Proteomics of mammary epithelial morphogenesis. The role of primary cilia and annexin family proteins.**S. Rossetti¹, W. Bshara¹, J. Reiners¹, F. Corlazzoli¹, A. Miller¹, N. Sacchi¹;¹Roswell Park Cancer Institute, Buffalo, NY

Three dimensional (3D) organotypic models are extensively used to identify the mechanisms of mammary epithelial morphogenesis. The disruption of these mechanisms by different oncogenic insults leads to an atypical mammary epithelial acinar architecture, which is a characterizing phenotype of early breast cancer lesions, such as ductal carcinoma in situ (DCIS). Proteomics analysis of a panel of isogenic clones derived from human mammary epithelial cells let us identify within a common protein signature of aberrant 3D acinar morphology members of two groups of proteins: proteins associated with primary cilia structure and function, and members of the Annexin superfamily. By analyzing different morphogenetic stages of normal 3D mammary development, we found that primary cilia arise in mature 3D acini, where they protrude into the lumen. In contrast, in morphologically aberrant 3D acini, primary

cilia are shorter and show no polarization. Moreover, we mechanistically show that deregulation of two annexin proteins, ANXA2 downregulation or ANXA8 upregulation, is sufficient to disrupt 3D acinar architecture of human mammary epithelial cells. The latter is particularly significant because ANXA8 is far more expressed in DCIS samples relative to normal tissue, and correlates with tumor grade and stage and might qualify as a biomarker of breast cancer tumorigenesis.

This study was funded by the NCI R01 CA127614 grant, the Susan Komen Foundation, the Breast Cancer Coalition of Rochester, the Friends for an Earlier Breast Cancer Test, the Terri Brodeur Breast Cancer Foundation.

Disruption of periosteal osteochondroprogenitor primary cilia stunts postnatal bone growth.

E.R. Moore¹, J.C. Chen¹, C.R. Jacobs¹;

¹Biomedical Engineering, Columbia University, New York, NY

Periosteal primary cilia are crucial for proper differentiation and migration of bone and cartilage cells in the embryonic appendicular skeleton, but their influence on these cell populations is surprisingly unexplored in postnatal bone. Primary cilia are non-motile organelles that extend from the apical surface of the cell membrane and are involved in mechano- and chemosensing. Previous studies indicate periosteal primary cilia are responsible for the osteochondroprogenitor nature of periosteal cells and are involved in the migration of osteochondroprogenitors to form the embryonic skeleton. However, these findings are limited to prenatal development due to the embryonic lethality of current mouse models. Because periosteal primary cilia are critical in embryogenesis, we hypothesized that their influence extends into postnatal bone development. Our goal in this study was to evaluate *in vivo* the effects of disrupted primary cilia on the differentiation and migration of periosteal osteochondroprogenitors and resulting endochondral ossification of the postnatal appendicular skeleton. We developed a novel mouse model that allows us to track periosteal progenitor daughter cells and disrupt their primary cilia at developmental time points of our choosing. This model utilizes a periosteal progenitor specific promoter (Prx1) that drives expression of a tamoxifen-inducible conditional Cre recombinase (CreER) and a GFP tag. Recombination at Kif3a, a gene that encodes for a subunit of a ciliary motor protein, is known to disrupt primary cilia. Prx1CreER-GFP; Kif3a^{fl/fl} experimental and Kif3a^{fl/fl} control littermates were injected daily with tamoxifen from postnatal day 5 (P5) until P15. Upon sacrifice, the ulna and radius were dissected and prepared for histochemistry. In mice with disrupted periosteal primary cilia, the proliferation zone contains fewer chondrocytes and the chondrocytes that are present are less densely packed and vertically aligned than those observed in control mice. The hypertrophic zone is a clear boundary between the proliferation and ossification zones in controls, but is less distinct in mice with disrupted cilia. The growth plates are properly formed but the proliferation zones are disorganized and smaller in experimental mice, indicating endochondral ossification is present but stunted when periosteal primary cilia are disrupted. Our data suggest

disrupting postnatal periosteal primary cilia results in a failure to adequately access osteochondroprogenitor stores, resulting in fewer chondrocytes and osteoblasts participating in endochondral ossification. Because primary cilia are sensory organelles involved in Hedgehog and Wnt signaling, it is likely that they facilitate the differentiation of periosteal osteochondroprogenitors. Given the novelty of these findings it is unclear whether periosteal primary cilia are also involved in the migration and proliferation of osteochondroprogenitors, as seen in embryonic studies. Future studies should focus on elucidating the role of periosteal primary cilia in order to manipulate cell stores as a regenerative tool.

Evolutionary, Environmental, and Behavioral, Analyses of Disrupted-in-Schizophrenia-1 (DISC1) in a Conditional Knock-in Mouse.

C.A. Howard¹, B.S. McAdory²;

¹Biological Sciences, Tennessee State University, Nashville, TN, ²Tennessee State Univ, Nashville, TN

Cytogenetics, along with linkage and association studies, implicated Disrupted-in-Schizophrenia-1 (DISC1) as a predisposing risk factor for neuropsychiatric illnesses (Chubb et al, 2008). Additionally, a number of social factors have also been shown to increase the risk of schizophrenia (Thomson et al, 2013). Thus, we hypothesized that aberrant DISC1 function, combined with external environmental stimuli, will affect behavior and protein expression within the hippocampus and prefrontal cortex over a period of time. A three-pronged approach was undertaken. First, the evolutionary relationship of DISC1 across different species was explored. In order to explore DISC1's conservation across species, bioinformatics tools were used to compare nineteen named DISC1 protein sequences chosen from national databases and from nineteen different organisms. The N- and C-terminal regions were shown to be conserved in primates, rodents, and omnivores (with few exceptions). Phylogenetic tree analysis further illustrated the evolutionary relationship of DISC1 in these organisms. Second, we wanted to know if changes in environment could affect protein expression in mutant versus wild type (WT) mice. Following exposure to different environments, animals were sacrificed at ages determined to be important for continued CNS cognitive abilities (Chubb et al, 2008) and analyzed for changes in protein expression. Analysis of protein bands by silver staining disclosed differences in intensity of several gel bands from both the cortex and hippocampus. The proteins in these bands were identified using Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS). Proteins identified in the cortex, which is involved in cognitive abilities, were alpha-enolase (Eno1) and β -Tubulin (TUBB) while fructose-bisphosphate aldolase C (Aldoc) was identified in bands from hippocampus, an area associated with memory formation. Finally, we wanted to know if different environments adversely affected the behavior of mutant versus WT mice. Data analyses of a forced swim test (FST) showed a statistically significant difference (p

P715**Board Number: B1019****Effects of prolactin, EGF and dexamethasone on mechanism for regulating β -casein expression and secretion.**S. Oyama¹, C. Kuki², H. Kumura², K. Kobayashi²;¹Research Faculty of Agriculture, Hokkaido university, Sapporo, Japan, ²Research Faculty of Agriculture, Hokkaido University, Sapporo, Japan

Mammary alveolar epithelial cells (MECs) synthesize and secrete milk constituents including lactose, milk fat and milk protein during lactation. The milk production ability of MECs is induced by a variety of lactogenic hormones and growth factors. In particular, prolactin, glucocorticoid and EGF have been reported to stimulate milk production in MECs around parturition. However, the regulatory mechanisms of milk production in MECs are still incompletely understood. Therefore, in this study, we focused on regulatory mechanism of β -casein synthesis and secretion by prolactin, EGF and dexamethasone using in vitro milk-secreting model. MECs were isolated from the mammary gland of 8-13-week-old virgin ICR mice and cultured in growth medium without prolactin and dexamethasone. After 6-7 days of culture (approximately 3 days after reaching confluence), MECs were transferred into differentiation medium containing prolactin, EGF and dexamethasone and cultured for 5 days to examine the temporal change of β -casein synthesis and secretory ability. Next, we prepared the incomplete medium, which lacked one of three factors and cultured MECs in each medium for 5 days to evaluate effects of three factors on β -casein expression and secretion in vitro. MEC expressed and secreted β -casein into the medium in the presence of prolactin, EGF and dexamethasone. The immunostaining images showed the subcellular localization of β -casein in endoplasmic reticulum (ER), Golgi apparatus and secretory vesicles in MECs. On the other hand, MECs, which were cultured in the incomplete medium, showed different influences of prolactin, EGF and dexamethasone on β -casein expression and secretion. Beta-casein expression was not detected in the absence of prolactin. Prolactin induced dose- and time-dependent increases in β -casein expression. EGF induced a dose-dependent increase in β -casein expression in the range between 0 and 10 ng/ml although high concentration of EGF (50 ng/ml) inhibited β -casein expression. Dexamethasone also stimulates β -casein expression but didn't show dose-dependent increase of β -casein expression in the range between 1 and 1000 nM. In addition, dexamethasone facilitated β -casein secretion in the presence of prolactin and EGF. These results suggest that prolactin, EGF and dexamethasone stimulate β -casein expression and have differential roles for appropriate β -casein production such as initiation of β -casein expression by prolactin and stimulation of beta-casein secretion by dexamethasone.

P716**Board Number: B1020****Differential roles of prolactin and glucocorticoid in mammary alveolar tight junction formation during lactation in mice.**K. Kobayashi¹, S. Oyama¹, C. Kuki¹, H. Kumura¹;¹Research Faculty of Agriculture, Hokkaido University, Sapporo, Japan

In lactating mammary glands, alveolar tight junctions (TJs) are impermeable and thus allow milk to be secreted from the apical membrane without the leakage of milk components from the lumen into paracellular pathways. The full functional integrity of alveolar TJs is established shortly after parturition and they remain closed throughout lactation. We have previously reported that claudin-3 is one of the major components of mammary alveolar TJs during lactation whereas claudin-4 is down-regulated after parturition until weaning. Thus, it is suggested that claudin-3 and -4 are differentially regulated after parturition to form impermeable alveolar TJs. However, it remains unclear what regulates the expression of claudin-3 and -4 during lactation. In this study, we focused on prolactin/STAT5 and glucocorticoid/glucocorticoid receptor (GR) pathways, which are activated in mammary alveolar epithelial cells (MECs) after parturition and during lactation. Activation of prolactin/STAT5 pathway decreased expressions of claudin-3 and -4 in time- and dose-dependent manners in MECs *in vitro*. In contrast, activation of glucocorticoid/GR pathway increased claudin-3 and -4 in time- and dose-dependent manners. Immunostaining images of claudin-3 and -4 showed that glucocorticoid induced continuous TJs between MECs although prolactin causes discontinuous TJs. Interestingly, co-application of prolactin and dexamethasone specifically decreased the expression of claudin-4. The continuous and clear staining pattern of claudin-3 was observed between MECs with weak staining for claudin-4. We also measured transepithelial resistance (TER) and fluorescein flux across MEC monolayers in the presence of prolactin and/or glucocorticoid. Prolactin induced a decrease in the TER of MECs and an increase in fluorescein flux. In contrast, glucocorticoid induced an increase in the TER of MECs and a decrease in fluorescein flux in the presence or absence of prolactin. These results indicate differential roles of prolactin and glucocorticoid in mammary alveolar TJ formation through regulating claudin-3 and -4 expressions.

P717**Board Number: B1021****Endothelial cell dynamics in Angiogenesis *in vitro*—Anastomosis and Pattern Formation.**M. Shan¹, W.R. Bedell¹, A. Diaz-Santana¹, A.D. Stroock¹;¹Chemical and Biomolecular Engineering, Cornell University, Ithaca, NY

This study dissects *in vitro* the cellular dynamics underlying two stages of angiogenesis: pattern formation during the initiation of sprouting, and vascular anastomosis in the final stages of sprouting.

The heterogeneous differentiation or patterning of neighboring endothelial cells enables the formation of a multicellular sprout; the anastomosis of two vascular lumens enables blood circulation and perfusion to the tissue. These two processes govern the beginning and the end of angiogenesis and are critical targets for the controlling the formation of new vascular networks.

To begin our exploration of endothelial patterning, we analyzed four hypothetical gene regulatory networks (GRNs) suggested by previous experimental studies of endothelial differentiation. We determined the qualitative and quantitative tissue-scale patterning features each GRN would produce should it be the primary mechanism for initial self-assembly in the endothelium. Our analysis suggests that current models endothelial gene regulation can produce multicellular patterns from uniform initial conditions, though the spatial patterns formed are limited to close-packed 'checkerboards' of heterogeneous differentiation that may or may not reflect the earliest patterns of endothelial cell gene expression in response to angiogenic stimuli. We propose additional mathematical and experimental work to clarify the multi-scale gene regulation underlying the initiation of sprouting angiogenesis.

In the study of vascular anastomosis, we exploited a three-dimensional (3D) culture platform *in vitro* to examine the endothelial cell (EC) dynamics during vascular anastomosis and the post events by mimicking angiogenesis and vasculogenesis in parallel. We showed that the cell interactions are present during anastomosis between sprouts formed by angiogenesis from an endothelium and tubes formed by vasculogenesis in the bulk of a 3D matrix. We observed that pericytes were co-localized with the lumen structures, which suggests an important role of pericytes in vessel maturation. We conclude that the occurrence of anastomosis between ECs undergoing sprouting angiogenesis and vasculogenesis can be achieved in this 3D homotypic co-culture platform. We hypothesize that vascular structures act as cellular tracks to promote endothelial cell migration in the process of anastomosis.

Cation/proton exchanger 1 protein (Cax1), a maternal-effect regulator of zebrafish cytoplasmic segregation and mRNA localization.

R. Fuentes¹, M. Escobar-Aguirre¹, A. Kugath¹, F. Montecinos-Franjola², P. López³, J. Fernández³, M.C. Mullins¹;

¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA,

²Laboratory of Integrative and Medical Biophysics (LIMB), National Institutes of Health (NIH), Bethesda, MD, ³Department of Biology, University of Chile, Santiago, Chile

Early developmental processes are regulated by maternally-provided gene products accumulated in the egg during oogenesis. In the zebrafish, egg activation is followed by cytoplasmic movements toward the animal pole along specific pathways or streamers to form a prominent cytoplasmic domain or blastodisc. This process is called cytoplasmic segregation. The nature and function of maternal factors controlling

cytoplasmic movements, as well as other cellular processes remain largely unexplored in vertebrates. To this end, we are using large-scale forward and reverse genetic screens to identify maternal regulators required to ensure normal zebrafish embryogenesis. We have identified two recessive maternal-effect mutants, *emulsion* (*emn*) and *cax1*, which exhibit defective cytoplasmic segregation. Molecular and cellular approaches reveal that mutant embryos display reduced animal-ward transport of cytoplasm and maternal mRNAs, abnormal streamers and blastodisc formation, altered cleavage pattern and axis determination. Also, the calcium-dependent assembly of parallel arrays of microtubules involved in the transport of maternal determinants appears affected in the mutants. Positional cloning and whole exome sequencing strategies indicate that the *emn* and *cax1* genes encode a Cation/proton exchanger 1 protein (Cax1). Predicted transmembrane segments of Emn/Cax1 suggest that the mutant transcripts would produce a structurally incomplete protein lacking the C-terminal portion. Phylogenetic analysis of protein sequences displays a high level of similarity among unicellular and multicellular organisms, specifically concerning with this part of the protein. Interestingly, homology modeling performed on the C-terminal portion of zebrafish Emn/Cax1 shows a higher sequence similarity to the overall protein structure of bacterial and fungal variants. Thus, our results strongly suggest: 1) a strictly maternal role of Emn/Cax1 controlling early developmental processes, 2) an interdependence between calcium and protons to control cytoplasmic movements, 3) that the gradient of protons across the endomembrane compartments could be utilized to re-uptake calcium after a signaling event and 4) a bifunctional topology of zebrafish Emn/Cax1, with the ion exchanger activity mapped to the C-terminal portion of the protein and the N-terminal portion with a specific function that has not yet been described. Functional studies will allow us: a) to decipher how the *emn/cax1* gene regulates cytoplasmic segregation and mRNA localization, b) Emn/Cax1 kinetics in transport of ions and maintenance of calcium homeostasis, and c) to generate a high-quality structural model to understand the biophysical and molecular basis of Emn/Cax1 function during early vertebrate development.

Dynamics and Shaping of the BMP Signaling Gradient by the BMP Antagonists during DV axial Patterning.

J.M. Zinski¹, W. Dou², Y. Huang², D. Umulis², M.C. Mullins¹;

¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA,

²Agricultural and Biological Engineering, Purdue University, West Lafayette, IN

A gradient of Bone Morphogenetic Protein (BMP) signaling patterns the Dorsal-Ventral (DV) axis of the vertebrate embryo. However, its shape and dynamics during zebrafish DV patterning have not been quantified. Furthermore, how the known extracellular BMP regulators shape the gradient in time and space is not known. To measure the BMP signaling gradient, we quantified the nuclear intensities of fluorescently stained Phosphorylated-Smad5 (P-Smad) in every cell of the embryo at 30-minute intervals from blastula through early gastrula stages. We used automated algorithms to identify the thousands of individual nuclei present at each embryonic time-point, and to measure their corresponding P-Smad

intensities. In WT embryos, we show that the P-Smad gradient intensifies and steepens in the late blastula before stabilizing in the early gastrula. We compared the BMP signaling gradients in WT and BMP antagonist loss-of-function embryos of Chordin (Chd), Noggin (Nog), and Follistatin (Flst) to determine their spatiotemporal functions. Though Chd primarily inhibits BMP signaling, its homologue Sog has been shown to enhance BMP signaling by transporting BMP ligand in *Drosophila* DV patterning and crossvein formation. However, we find that Chd only inhibits BMP signaling laterally in DV patterning in the gastrula. This region-specific inhibition allows Chd to steepen the BMP gradient. In contrast, loss of Nog and Flst have no effect on the gradient. However, the loss of all three antagonists causes a massive embryo-wide increase in BMP signal, far exceeding the lateral-only increase seen when Chd alone is absent. To elucidate mechanisms explaining these results, we generated a mathematical model of the system and screened thousands networks consisting of different rates of production, diffusion, degradation, and binding between the BMP ligand, Chd, Nog, Flst, and Tolloid/Bmp1a. Our results suggest that: 1) in a WT system, Chd functions as the primary sink for BMP ligand. 2) When Chd is absent, Nog and Flst take over as the primary sink for the BMP ligand. 3) When all three antagonists are absent, no extracellular sink exists, and BMP signaling increases embryo-wide.

Split top: A Maternal Regulator of Dorsal-Ventral Patterning and Cell Migration in Zebrafish.

Y.G. Langdon¹, T. Gupta², F.L. Marlow^{3,4}, E.W. Abrams¹, M.C. Mullins¹;

¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA,

²Organismic and Evolutionary Biology, Harvard University, Cambridge, MA, ³Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY, ⁴Dominick P. Purpura Dept of Neuroscience, Albert Einstein College of Medicine, Bronx, NY

Little is known about the maternal factors that function in body axis formation during vertebrate embryonic development. To identify these factors, our lab has performed a recessive maternal-effect mutagenesis screen in the zebrafish and found a number of mutants with defects in early developmental processes, including early morphogenesis and body axis formation. One such mutant, *split top* exhibits a dorsalization of the embryonic axis. Clutches of embryos from *split top* mutant mothers are characterized by the five classic dorsalized phenotypic classes, as well as some additional defects. The mutant embryos show an expansion of dorsal markers and a corresponding reduction in ventral markers during gastrulation indicative of dorsalization. The dorsalization defects can be rescued by misexpression of either BMP2 or BMP7 ligands, or by derepression of BMP signaling by knockdown of BMP antagonists. The additional defects appear to be the result of altered morphogenesis, including defects in epiboly progression, the process by which the blastoderm cells migrate over and surround the yolk. Mutant embryos display altered microtubule and actin cytoskeletal networks in the yolk cell, which can account for the epiboly defects observed. *split top* mutant embryos also appear to be defective in the cell movement process of convergence and extension. We mapped the *split top* mutation to

chromosome 17, and have identified a candidate gene through RNA-Seq and traditional positional cloning methods.

Identification and characterization of paternal-effect lethal mutants in *C. elegans*.

A. Jaramillo-Lambert¹, A. Golden¹;

¹NIDDK/NIH, Bethesda, MD

Infertility affects ~15% US couples and ~25% of couples in developing countries. In many cases the underlying cause of infertility is unknown. While the field of reproductive medicine is rapidly growing, in the cases where the cause of infertility is unknown the needs of these couples are not being addressed. Therefore, understanding the genetic and molecular basis of fertilization and early embryogenesis is important. At fertilization the oocyte and the sperm fuse, restoring the somatic chromosome number and initiating zygotic development. Despite both deriving from meiosis, the morphologies of oocytes and sperm are distinct. Oocytes are large, sedentary cells that provide a haploid genome and large stockpiles of maternal RNA and proteins necessary for early embryogenesis. Sperm are small, motile cells streamlined for fertilization but also play essential roles in early development. The sperm provides a haploid genome, centrosomes, and initiates the embryonic program. There is evidence that sperm contain other factors required for embryogenesis. Absence of these paternally provided components results in paternal-effect embryonic lethality (PEL). In *C. elegans*, *spe-11* is the only strictly PEL gene. SPE-11 is a novel protein supplied by the sperm. The absence of functional SPE-11 results in embryonic failure at early stages. I am interested in the further characterization of SPE-11 through structure function analysis. I have recently demonstrated that the extreme C-terminus of SPE-11 is important for the production of viable embryos.

In addition to *spe-11*, I have identified another novel PEL mutant. This mutant was previously identified in a screen for maternal-effect embryonic lethal mutants. However, embryonic lethality of this mutant can be rescued by mating to wild-type males indicating a potential sperm defect. Analysis of this mutant showed that it has >95% rescue of the embryonic lethality phenotype upon mating to wild-type males. Initial analysis of this mutant, *mel-15*, confirms that sperm from *mel-15* mutant males produce dead embryos, even when fertilizing wild-type oocytes. In addition, characterization of early embryonic events indicates fertilization is successful and that sperm components (e.g. centrosomes) are transmitted to the embryo, but that *mel-15* sperm lack DNA. I am currently in the process of determining the molecular identity of *mel-15* and where in the meiotic cell cycle sperm DNA is being mis-segregated.

P722**Board Number: B1026****Studying The Regulation of Temporal Patterning of String Transcription in Early *Drosophila* Cell Cycles.**A. Momen Roknabadi¹, S. Di Talia², E. Wieschaus¹;¹Department of Molecular Biology, Princeton University/HHMI, Princeton, NJ, ²Department of Cell Biology, Duke University Medical Center, Durham, NC

An embryo develops in a highly intricate spatiotemporal pattern. Although there is much understood about the mechanisms underlying spatial patterning throughout the life of an organism, we still do not know whether there are additional regulators that modulate the temporal patterning in various key biological processes, including but not limited to cell cycle or cell differentiation. In this study, we aim to understand, at a molecular level, how a temporal pattern can be achieved. Here, we have chosen as a model the spatiotemporally patterned 14th mitosis in the early *Drosophila* embryo. This pattern is regulated by the transcription of the *cdc25* homolog, *string* (*stg*), which drives the mitosis in 25 distinct and highly reproducible mitotic domains (MD). We hypothesize that the temporal patterning is controlled by how fast the rate-limiting regulators accumulate to the level required for triggering *stg* transcription globally or in each specific MD. Therefore we predict that by changing the dosage of *stg* regulators, we can change the observed temporal pattern. Using a whole-genome screen we have identified several rate-limiting effectors that encode the underlying molecular clock for specific domains.

In this study, we use heterozygous deficiency lines to identify dosage dependent effectors that regulate the temporal expression of *stg* in MD 1 and 2. Heterozygote embryos develop with normal spatial pattern, thereby allowing us to study the effect of the candidate regulators. In this screen, we count the number of cells undergoing mitosis in MD 1 and 2 in the wild type (WT) and the heterozygote deficiency lines. Using this measurement, we compute the relative timing of the onset of mitosis in MD 1 and 2. In theory, a rate-limiting factor may either act as a general factor that sets up the timing globally throughout the embryo, or acts more locally in a domain-specific manner. Here, we have observed hardly any evidence for the global regulators, yet we have identified several factors that regulate timing of specific domains. For example the relative time difference of mitosis between the MD1 and 2 from 3 minutes in WT is changed to a simultaneous division by halving the dosage of *buttonhead*. The results of this screen suggest that every domain has its own clock. The majority of the identified domain-specific regulators are known patterning genes that also regulate the spatial patterning in the corresponding mitotic domain. Therefore, we conclude that the transcriptional factors that confer the spatial pattern are also the rate-limiting factors that set the temporal pattern in development. The rate at which these spatial regulators accumulate through time comprises the molecular clock that we observe at different stages of develop

P723**Board Number: B1027****Investigating the importance of size scaling relationships in *Xenopus* development.**R. Gibeaux¹, R. Heald²;¹University of California, Berkeley, Berkeley, CA, ²Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Determining how size is controlled is a fundamental question in biology that is poorly understood at the organism, cellular and subcellular levels. The two frog species *Xenopus tropicalis* and *Xenopus laevis* differ in size at all three of these levels. Diploid wild-type (WT) *X. tropicalis* has 20 chromosomes and is smaller (~4 cm adults), whereas diploid WT *X. laevis* has 36 chromosomes and is bigger (~10 cm adults). Scaling at the organismal and genome levels is accompanied by differences in the size of the egg as well as nuclei and mitotic spindles formed in egg extracts. Despite these size differences, the close phylogenetic relationship between these two species allows the production of hybrid embryos by cross-fertilization. Taking advantage of the viable hybrid produced when *X. laevis* eggs are fertilized by *X. tropicalis* sperm (*lexts*), we are investigating how an embryo that is initially identical in size and developmental rate to that of *X. laevis* generates a hybrid frog closer in size to *X. tropicalis*. Using live embryo imaging to monitor early cleavage phases, and immunofluorescence to determine nucleocytoplasmic and genome-spindle size ratios, and by comparing *lexts* hybrids to diploid and haploid *X. laevis*, we are assessing the importance of scaling relationships in embryo development. In parallel, we are investigating the reverse hybrid generated by the fertilization of *X. tropicalis* eggs with *X. laevis* sperm (*texls*), which is not viable and dies at the late blastula stage. We observed gross mitotic defects prior to embryo death and are testing the hypothesis that *texls* hybrid death is caused by scaling defects that lead to chromosome segregation errors, resulting in large-scale apoptosis.

P724**Board Number: B1028****Centrin-2 mediated regulation of FGF/FGFR gene expression in *Xenopus*.**M. Winey*¹, J. Shi¹, Y. Zhao¹, T. Vonderfecht¹, M. Klymkowsky*¹;¹MCDB, University of Colorado-Boulder, Boulder, CO

Centrins (CETNs) are highly conserved, widely expressed and multifunctional Ca²⁺-binding eukaryotic signature proteins best known for their roles in ciliogenesis and to a lesser extent as critical components of the UV DNA damage repair system. The clawed frog *Xenopus laevis* contains three *Cetn* genes, *Cetn2*, *Cetn3*, and *Cetn4* whose RNAs are provided maternally and throughout embryogenesis. Using ectodermal and ectodermal/mesodermal explants and a range of analytical methods, we have characterized the phenotypes associated with morpholino-based loss of *Cetn* function. In addition to defects in the formation of epidermal multiciliated cells, we have identified a previously unreported *Cetn2*-specific function, namely in the regulation of FGF signaling, specifically through the regulation of

FGF and FGF receptor RNA levels. Cctn2 was found associated with RNA polymerase II binding sites of the CETN2-regulated FGF8 and FGFR1a genes, but not at the promoters of genes whose expression was not altered by down-regulation of CETN2. We are in the process of defining the universe of genomic targets associated with Cctn2 and its associated proteins. These observations point to a previously unexpected role of CETN2 in the regulation of gene expression and embryonic development that could have implications in a range of cellular systems.

Regulation of BMP signaling by Pitx1 during the formation of Xenopus cement gland.

Y. Jin¹, D. Weinstein¹;

¹Biology, Queens College, FLUSHING, NY

The cement gland is one of the first fully functional tissues to differentiate during the development of the frog *Xenopus laevis*. It secretes mucus to help the developing tadpole attach to solid supports and live in relative safety. The gland develops from the outer layer of anterior ectoderm between the neural plate and non-neural ventral ectoderm. As a marker of anterior ectodermal fate, the cement gland is a useful model to study how different signaling pathways are regionally integrated in the embryo. It has previously been proposed that an intermediate level of Bone Morphogenetic Protein (BMP) signaling promotes cement gland formation. Additionally, several transcription factors have been related to cement gland differentiation. One of them is Pitx1, a homeobox gene which is both sufficient and necessary to induce ectopic cement gland formation. However, the mechanisms by which Pitx1 function in this context remains obscure. We hypothesized that the appropriate level of BMP signaling within cement gland primordium is regulated by Pitx1. Our lab found that injection of synthetic Pitx1 messenger RNA into the animal pole of early *Xenopus* embryos not only leads to the induction of cement gland markers, consistent with previous studies, but also suppresses BMP-responsive target genes in a dose dependent manner. A chimeric protein, consisting of the full length Pitx1 fused to a VP16 activation domain, also inhibits BMP targets, while introduction of a Pitx1-Engrailed repressor domain fusion protein does not significantly affect expression of these genes. These results suggest that Pitx1 activates downstream targets to partially suppress BMP signaling, leading to cement gland formation. Taken together, this study links Pitx1 to regulation of BMP signaling during the formation of this anterior-most ectodermal organ.

P726**Board Number: B1030****microRNA-31 Regulates Skeletogenesis of the Sea Urchin Embryo.**N. Stepicheva¹, J.L. Song¹;¹Biological Sciences, University of Delaware, Newark, DE

The microRNAs (miRNAs) are small non-coding RNAs that regulate the translation and stability of target mRNAs. Recently miR-31 has been found to modulate bone formation. It regulates osteoblast differentiation by targeting Osterix and Satb2 and osteoclast activity by inhibiting RhoA. The sea urchin miR-31 has the same sequence as in human, and our work indicates that miR-31 plays a conserved regulatory role in skeletogenesis of the sea urchin. Upon miR-31 knockdown (KD), sea urchin embryos have a significant decrease in primary skeletogenic mesenchyme cells (PMCs), leading us to hypothesize that miR-31 regulates the movement and specification of PMCs. miR-31 KD embryos have abnormal localization of PMCs, as well as highly irregular and extensive connections among the PMCs. Using luciferase reporter constructs and site-directed mutagenesis, we identified Pmar1, Alx1 and Cyp1 within the skeletogenic gene regulatory network to be directly post-transcriptionally regulated by miR-31. Pmar1 indirectly activates Alx1, a key skeletogenic transcription factor that activates PMC-specific genes such as Cyp1. To test the effect of miR-31 regulation on Alx1, we used miRNA target protector morpholinos to mask the two miR-31 regulatory sites within the Alx1 3'UTR and observed PMC mislocalization. Based on our work in the sea urchin, we predict that the vertebrate Alx1 may be regulated by miR-31. Alx1 mediates the fusion of frontonasal, nasomedial, nasolateral, and maxillary processes during early embryogenesis. Alx1 autosomal recessive mutations in vertebrates have frontonasal dysplasia. Bioinformatic analysis identified two miR-31 binding sites within the mouse Alx1 3'UTR, suggesting that miR-31 has an evolutionarily conserved role in regulating the Alx gene family. Our study contributes to the understanding of miR-31 function during early embryogenesis and suggests that the sea urchin animal model can be used to discover conserved miR-31 functions that may be shared by vertebrates.

P727**Board Number: B1031****Role of Cdc42 in the morphogenetic events of the sea urchin embryo.**S.P. Sepulveda¹, J. Hernandez¹, A. Ellis¹, A. Meyer-Miner¹, R. De La Rosa¹, C.B. Shuster¹;¹Biology Department, New Mexico State University, Las Cruces, NM

During gastrulation, changes in cell shape, adhesion and motility drive the formation of the primary germ layers. In the sea urchin, a complex gene regulatory network has been described that drives the specification of the mesoderm and endoderm. However, far less is known about how these specification events contribute to the actual morphogenetic rearrangements during gastrulation. The Rho-family GTPases Rac, Rho and Cdc42 have been shown to be fundamental for these processes in a number of model systems, and indeed, work in other labs has implicated RhoA in the formation of the primary

invagination during sea urchin gastrulation. Given the many advantages of the sea urchin as a model organism for developmental biology, we aim to better characterize the role of Cdc42 in the sea urchin embryo. Using a combination of live cell probes and immunofluorescence, we have identified Cdc42 as a potential regulator of Primary Mesenchymal Cell (PMC) motility and skeletogenesis. PMCs form the spicules of the larvae that give rise to the larval skeleton, and Cdc42 was enriched in PMCs following ingress. Further, inhibition of Cdc42 using small molecule inhibitors had no effect on the PMC epithelial to mesenchymal transition, PMC ingress and fusion. However, Cdc42 inhibition blocked filopodial extension, PMC alignment and spicule deposition. Similarly, inhibition of Cdc42 expression using anti-sense morpholinos showed a delay in PMC ingress. Additionally, PMCs did not exhibit their stereotypical alignment in morphant embryos and failed to form spicules. Lastly, the archenteron failed to extend in Cdc42 morphants, suggesting a possible role for Cdc42 in convergent extension and gut formation. Together, these results suggest that while Cdc42 may be dispensable for establishment of epithelial polarity and PMC ingress in the early embryo, Cdc42 plays a specific role in skeletogenesis, and may also be instrumental in formation of the primordial gut.

Visualization of an Adenosine 5'-triphosphate levels in mouse embryo.

M. Yamamoto¹;

¹ASRLD Unit, Gunma University, Maebashi, Japan

Adenosine 5'-triphosphate (ATP) is produced in energy metabolism, is the major energy currency in animal and plays an important role in many biological processes. Recent research provides real-time monitoring system of ATP levels inside individual living cells. To monitor the ATP levels in mouse, I generated the transgenic mouse using this system. I examine the ATP levels in developmental stage of mouse embryo. In cleavage stage, ATP levels around nuclear are lower than that in marginal zone until 2 cell stage. In gastrulation stage, ATP levels are high in specific region, organizer and primary heart field. To understand the role of high ATP, I examined the inhibition of glycolysis and/or oxidative phosphorylation by chemical inhibitor. In the result, oxidative phosphorylation would regulate the axis formation and heart formation. I would like to discuss about recent data.

P729**Board Number: B1033****Effects of dynamic myosin phosphorylation on tissue mechanics and integrity during apical constriction.**C.G. Vasquez¹, A.C. Martin¹;¹Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA

Embryonic development requires coordinated cell shape changes to induce global tissue shape change. In the *Drosophila* embryo, apical constriction of a strip of ~1,000 cells along the ventral midline results in higher tension oriented along the long axis of the embryo, relative to the short axis, and higher constriction directed along the short axis, compared to the long axis. This force asymmetry is associated with the formation of a long narrow furrow (ventral furrow) along the length of the epithelium. Apical constriction in ventral furrow cells is driven by cycles of assembly and disassembly of the contractile motor non-muscle myosin II (Myo-II); these cycles (pulses) result in step-wise constriction of the cells, which is staggered between neighboring cells. A still unanswered question is why cells undergo step-wise rather than continuous contraction during tissue morphogenesis. We have found that Myo-II pulses are spatially and temporally associated with pulses of apical Rok suggesting that Myo-II phosphorylation organizes contractile pulses. Mutants that mimic Myo-II light chain phosphorylation or depletion of myosin phosphatase inhibit Myo-II contractile pulses, disrupting both actomyosin coalescence into apical foci and cycles of Myo-II assembly/disassembly. Coupling dynamic Myo-II phosphorylation to upstream signals organizes contractile Myo-II pulses in both space and time. Mutants that lock Myo-II in a specific phosphorylation state undergo a more continuous, rather than incremental, apical constriction. A tissue-scale consequence of continuous constriction is that these mutants fail to maintain intercellular actomyosin network connections during tissue invagination, suggesting that Myo-II pulses are required for tissue integrity during morphogenesis. In addition, we find that cells expressing phosphomimetic Myo-II constrict isotropically, without directionality. Thus, it is possible that Myo-II dynamics are required to generate or respond to patterns of epithelial tension during tissue invagination, ensuring effective cell invagination without compromising tissue integrity. These results provide a mechanism and a function for contractile pulses, suggesting that proper Myo-II regulation is required to ensure appropriate tissue movements during morphogenesis. To further investigate how Myo-II regulation affects the mechanical properties of the ventral furrow tissue, we are performing laser ablation experiments to compare the response of wild-type and Myo-II phospho-mutant embryos.

P730**Board Number: B1034****Functional Epigenomics and Evolutionary Diversification of Mammalian Pre-implantation Blastocysts and Male Fertility.**S. Kwok¹, R. Oliveira², A. Moura², A. Kaya³, A. Perkins⁴, R. Wills⁵, E. Memili⁶;

¹Molecular and Cellular Biology, University of Maine, Orono, ME, ²Department of Animal Sciences, Federal University of Ceara, Sobral, Brazil, ³Alta Genetics, Inc., Watertown, WI, ⁴Computer Science and Engineering, Mississippi State University, MS State, MS, ⁵CVM Pathobiology/Population Med Dept, Mississippi State University, MS State, MS, ⁶Animal and Dairy Science, Mississippi State University, Mississippi State, MS

Oocyte fertilization by fusion with a spermatozoon initiates embryogenesis and further development. Although both maternal and paternal epigenetic factors have been found to play a role in gamete fertility, embryo viability, and embryo survival, the exact mechanisms regulating maternal:embryonic interaction and embryo development are unclear. This gap in the knowledge base is impeding advances in the science of early mammalian developmental, including fertility prediction and improvement. The objectives of this study were to ascertain cellular characteristics of individual bull sperm samples of distinctly different fertility levels, and to investigate functional epigenomic networks of pre-implantation blastocysts in mice, humans, and cattle. To achieve these objectives we used a combination of scanning electron microscopy (SEM) and ImageJ, and computer-assisted sperm analysis (CASA) for the bull sperm investigation. In order to investigate the blastocyst epigenomic regulation, the networking tools MetaCore and AmiGO were used to examine the expressed epigenome, focusing on DNMT3L, BMI1, and L-selectin to further explore blastocyst epigenetic regulation by DNA methylation and chromatin remodeling, and embryonic adhesion to the mother, respectively. Current findings indicate that there are differences between the individual bull sperm samples in both morphology and function, and in sperm velocity. Furthermore, DNMT3L, BMI1, and L-selectin are interconnected and highly conserved between mice, humans, and cattle. Individual sperm samples from two bulls with high and low fertility scores (5.6 and -14.7) show significant differences in sperm head length (0.8845 μ M) and width (-0.1366 μ M), and tail length (1.6427 μ M). CASA results of sperm from 10 bulls indicate a positive correlation between fertility score and straight line velocity ($p=0.0442$, $r=0.64$). Sequences for DNMT3L, BMI1, and L-selectin show sequence overlaps 51.145%, 95.706%, and 65.065% between all three species, respectively. The findings are significant because they illuminate cellular mechanisms regulating sperm fertility and epigenetic mechanisms regulating implantation of conceptus to endometrium. The knowledge can be used to improve assisted reproductive technologies.

P731**Board Number: B1035****Dunk stabilizes the tensile actomyosin network at the leading edge of the cleavage furrows during *Drosophila* cellularization.**B. He¹, A.C. Martin², E. Wieschaus³;¹Department of Molecular Biology, Princeton University, Princeton, NJ, ²Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, ³Department of Molecular Biology, Princeton University/HHMI, Princeton, NJ

In *Drosophila*, the formation of the cellular blastoderm is achieved by cellularization, during which plasma membrane invaginates from the surface of the embryo and partitions the syncytial nuclei into individual cells. During cellularization, a dynamic network of actin-myosin localizes at the basal leading edge of the cleavage furrows (“furrow canals”) and subsequently reorganizes into individual contractile rings that pinch off the cell basally at late cellularization. Here we describe the characterization of novel gene *dunk*, mutation in which disrupts the proper organization of the actin-myosin network at the furrow canals. Using laser ablation, we find that basal myosin is already under tension while it organizes into an interconnected network. Mutation in *dunk* leads to disruption of the network and causes myosin to deplete from the edges and accumulate at the vertices. This in turn leads to a delay in the subsequent formation of myosin rings and causes defect in their morphology. The expression of *dunk* is restricted at the blastoderm stage, and its protein product co-localizes with myosin at the furrow canals. The localization pattern and the mutant phenotype suggest that *dunk* directly involves in stabilization of the actomyosin network at the basal cortex during early cellularization. Computer simulation demonstrates that vertex-accumulation of myosin in *dunk* mutant embryos can be recapitulated by a uniform myosin loss coupled with a positive feedback mechanism that prevents myosin loss upon myosin contraction. We propose that Dunk promotes homogeneous myosin distribution by preventing myosin loss, therefore help to maintain basal contractility symmetry at the invagination front.

P732**Board Number: B1036****A Rho-GAP regulates two key processes during *C. elegans* embryonic morphogenesis.**A.G. Wallace¹, M.C. Soto¹;¹Rutgers - Robert Wood Johnson Medical School, Piscataway, NJ

Rearrangement of the actin cytoskeleton is important during embryonic morphogenesis. In the *C. elegans* embryo, cell migrations that occur during morphogenesis are coordinated by tight regulation of actin dynamics controlled by axonal guidance signals. Previous work in our lab have shown that axonal guidance signals UNC-40/DCC, SAX-3/Robo, and VAB-1/Eph regulate the actin cytoskeleton through a pathway controlled by the WAVE/SCAR complex which is modulated by the CED-10/Rac1 GTPase.

Subsequently, we performed an RNAi screen for regulators of WAVE by screening for enhancers of *unc-40* embryonic lethality. Our screen identified HUM-7, which is the *C. elegans* homolog of the vertebrate Myosin IX gene. Loss of HUM-7 alone results in a small percentage of dead embryos, most of which have morphogenesis defects similar to what is seen in WAVE mutants. Like its vertebrate homolog, Myo9, HUM-7 has a myosin domain in its head and a RhoGAP domain in its C-terminus. The presence of the RhoGAP domain combined with *wve*-like morphogenesis phenotypes, led us to predict that HUM-7 is functioning as a GAP for CED-10 during embryogenesis. To test this hypothesis, we analyzed genetic and RNAi doubles of *hum-7* and hypomorphic alleles of three *C. elegans* GTPases, RHO-1, CDC-42 and CED-10 or their regulators. The results did not support our predictions since HUM-7 genetically behaved like a GAP for RHO-1 and CDC-42 but not for Rac1. These results were further supported by protein-protein interaction assays that showed binding between the GAP domain of HUM-7 and the GTP-loaded forms of RHO-1 and CDC-42 but no binding to Rac-1. Similar to other known RHO-1 pathway genes, loss of HUM-7 causes defects in seam cell constriction, which is a crucial process in the formation of the worm from the embryo. Live imaging of actin dynamics in the *C. elegans* embryo shows that loss of HUM-7 results in increased levels of actin and increased actin dynamics at the leading edge of migrating cells. This suggests that HUM-7 is needed to properly organize actin events that occur during embryonic morphogenesis. In addition, these results suggest a role for RHO-1 in the regulation of actin-based cell migrations that occur during embryonic morphogenesis. Overall, these results suggest that HUM-7 has a role in two key events that occur during morphogenesis, the induction of cell migrations and elongation.

Physical Properties of P-granule Components.

L. Jawerth¹, S. Saha², F. Jülicher¹, A. Hyman³;

¹Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, ² Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ³Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

We study the proteins that comprise the major constituents of liquid droplets called “p-granules”. During the one-cell stage of *Caenorhabditis elegans* development, these p-granules preferentially form on the posterior side of the cell and remain there preferentially as the cell divides leading to the majority of droplets remaining in one of the daughter cells. This process repeats during subsequent cell divisions with, again, the majority of droplets residing in one cell. When this process concludes and the worm continues to develop, the cell containing the p-granule droplets will eventually become the gonad of the adult worm. Previous work has suggested that the spatial segregation of p-granules that occurs at each stage is the result of a phase separation analogous to classic liquid-liquid demixing. We study this process under various buffer conditions *in vitro* by using a model system consisting of purified p-granule components. We find that these components can form liquid droplets under physiological conditions which resemble p-granules. We further report on the physical properties of these liquids and how they

compare to their in vivo counterparts. In particular, we measure their surface tension and viscosity. We find surface tensions around 10^{-7} Nm and viscosities much higher than that of water.

A model-systems approach to coral cell biology.

M. Bucher¹, I. Wolfowicz^{1,2}, A. Guse¹;

¹Center for Organismal Studies, Heidelberg University, Heidelberg, Germany, ²Instituto de Ciências Biomédicas de Abel Salazar, Universidade do Porto, Porto, Portugal

Coral reefs are the most biodiverse marine ecosystems and of high ecological as well economic importance. Corals (phylum Cnidaria) thrive in very nutrient-poor waters and their immense productivity strictly depends on a functional symbiosis between corals and dinoflagellates (genus *Symbiodinium*). The photosynthetic symbionts reside within the gastrodermal host cells and transfer energy to the host. Despite the importance of coral reefs we only have limited knowledge about the cellular basis of symbiosis establishment, maintenance and breakdown (also known as “coral bleaching”). The lack of cellular information about the ecologically critically symbiosis is mainly due to the fact that corals are not very suited as laboratory model organisms allowing cellular and molecular analysis. Here we introduce *Aiptasia*, a marine sea anemone, as an emerging laboratory model organism to analyze cnidarian-endosymbiosis. *Aiptasia*, just as many reef-building corals acquires symbionts during planula larval stages from the environment anew each generation. To develop *Aiptasia* into a model system allowing analysis at the cellular and molecular level, a detailed description of the cellular processes involved in symbiosis establishment and maintenance is required as well the development of functional tools. To date, we have generated a detailed description of *Aiptasia* embryonic development and different planula larval stages. Moreover, we have analyzed when and where symbionts are intracellularized and find that *Aiptasia* larvae take up symbionts at a constant rate as early as two days 2 post fertilization (pf) until ten days pf, but uptake efficiency increases thereafter. Accordingly, the region of efficient symbiont uptake changes over time. Initially (day 2 - day 8 pf), symbionts are predominantly taken up in the aboral region of the gastric cavity, while later the uptake region expands to the more oral areas of the cavity. Moreover, we have developed in situ hybridization protocols to analyze gene expression in *Aiptasia* planula larvae and are currently developing further techniques to extend the tool-kit for cellular and molecular analysis.

Pathogen Entry and Intracellular Trafficking

Junin virus DC-SIGN- mediated entry.

M.B. Forlenza¹, J.S. Roldan², M.G. Martinez³, S. Cordo¹, N. Candurra¹;

¹Biological Chemistry, IQUIBICEN, FCEyN, UBA, Buenos Aires, Argentina, ²Quimica Biologica, IQUIBICEN, FCEyN, UBA, Buenos Aires, Argentina, ³Department of Cell Biology, Albert Einstein College of Medicine, Bronx, NY

Virus entry and dissemination can be mediated by calcium dependant c-type lectines as DC-Specific ICAM-3 grabbing non-integrin (DC-SIGN), which is a member of a family of receptor that recognizes carbohydrates structures. In previous studies we provided evidence that hDC-SIGN recognizes and internalizes the New World arenavirus Junin (JUNV), etiologic agent of hemorrhagic argentinian fever, which presents highly glycosylated proteins in its envelope. In the present study we provide evidence of the interaction between hDC-SIGN and JUNV, and characterize the early stages of hDC-SIGN-mediated entry. NHI3T3 and NIH3T3-hDC-SIGN cell were infected in presence or absence of EGTA or the carbohydrate bynding agent Griffithsin (GRFT). Both compounds inhibited infection in cultures that express the human lectin. To better understand how the lectins are involved in virus internalization, NIH3T3 cells were transfected with expression plasmids encoding hDS-SIGN wild type or mutants of the conserved cytoplasmatic motifs: dileucine (LL), and triacid cluster (EEE) which are believed to be involved in the regulation of ligands uptake, and trafficking respectively. Our results show that mutations in the cytosolic domain of DC-SIGN impair its ability to enhance JUNV infection. We used compounds that specifically blocked different entry pathways to determine if the virus endocytic route is affected when lectins are expressed in the cell surface. Our results show that virus infection is inhibited with dynasore (DYN), which inhibits the dynamin II-dependent endocytosis, Chlorpromazine (CZ), that inhibit the clathrin- dependent endocytosis and methyl-B-cyclodextrin (MBCD) which inhibit the cholesterol-dependent endocytosis. Using plasmids codifying proteins involved in the endocytic pathway, or its dominant negative forms, we determine cellular proteins and compartments involved in virus entry in the presence of hDC-SIGN. Our studies show that JUNV infection depends on EPS15 and Dynamin-2, both involved in clatrhin-mediated endocytosis. As many entry pathways are dependant of cell cytoskeleton, we studied the rol of microfilaments and microtubules during early virus infection. Inhibition of infection was observed when cells were treated with LatrunculinA which disrupts cortical and cytoplasmic microfilament whereas cytochalasin D, that affects cytoplasmic microfilaments did not inhibit JUNV multiplication. In contrast, drugs that depolymerize microtubules did not show to affect JUNV multiplication. Taken togheter our results demonstrate that JUNV interacts with hDC-SIGN and that JUNV internalization is dependent on clathrin-mediated endocytosis. In addition JUNV infection in the presence of the human lectin depends on cholesterol and intact cortical actin filaments.

P736**Board Number: B1041****HIV-1 antagonism of Tetherin-mediated restriction of macrophage-T cell virus transmission.**S. Giese¹, M. Nijmeijer¹, M. Mazzon¹, M. Marsh¹;¹MRC/UCL Laboratory for Molecular Cell Biology, London, United Kingdom

Bst-2/Tetherin is a cellular protein that inhibits the release of enveloped viruses by physically tethering them to their host cells. A growing body of evidence suggests that the efficient counteraction of Tetherin was a crucial factor for the pandemic spread of the main (M) group human immunodeficiency viruses type 1 (HIV-1). Here we show that in primary macrophages, Tetherin localises to the plasma membrane, the trans-Golgi network, as well as intracellular plasma membrane-connected compartments (IPMCs), which serve as the preferred sites for HIV assembly and budding. Upon infection, Tetherin retains nascent HIV particles in IPMCs, which may cause their passive expansion, but the restriction factor is not required for the formation of the membrane compartments *per se*. In addition to diminishing virus release, we demonstrate that Tetherin inhibits the direct cell-cell transmission of HIV from macrophages to T cells, apparently by promoting the transfer of infectious virus clusters to a limited number of target cells. The viral accessory protein Vpu efficiently counteracts Tetherin in macrophages and thereby overcomes the restriction on cell-free and cell-cell HIV spread.

During SIV/HIV evolution, different viral proteins have adapted to antagonise the Tetherin proteins of their respective hosts, but all M group HIV-1 strains are thought to exclusively rely on Vpu to overcome human Tetherin and ensure their efficient replication. We show that at least one M group HIV-1 uses a viral protein other than Vpu to reduce the levels of Tetherin at the cell surface.

Overall, we show that Tetherin, one of the most potent restriction factors identified to date, inhibits HIV spread from macrophages regardless of the mode of transmission, and that HIV-1 proteins other than Vpu may have anti-Tetherin activity.

P737**Board Number: B1042****Calcium signaling mediated influenza virus entry into host cells.**Y. Fujioka¹, M. Tsuda², A. Nanbo¹, T. Hattori³, J. Sasaki⁴, T. Sasaki⁵, T. Miyazaki^{3,6}, Y. Ohba¹;¹Dep Cell Physiol, Hokkaido Univ Grad Sch Med, Sapporo-shi, Japan, ²Dep Cancer Pathol, Hokkaido Univ Grad Sch Med, Sapporo-shi, Japan, ³Res Ctr Zoonosis Cntl, Hokkaido University, Sapporo-shi, Japan, ⁴Akita Univ Grad Sch Med, Akita, Japan, ⁵Akita Univ Grad Sch Med, Akita-shi, Japan, ⁶Hokkaido Univ Inst Genet Med, Sapporo-shi, Japan

We have reported that Ras-PI3K signaling mediates endocytosis, and influenza viruses exploit this pathway to expedite their efficient incorporation into cells. In this study, we explored in detail the

mechanism by which Ras is activated upon infection with influenza. Because it is well established that Ca^{2+} signaling converge to activate Ras, Ca^{2+} concentration before and after viral infection was analyzed; Cameleon, a FRET based Ca^{2+} sensor showed that robust oscillations in the intracellular calcium concentration were induced by viral infection. Given that buffering Ca^{2+} abolished the virus-dependent Ras activation, Ca^{2+} transmits signals to activate Ras upon infection. We also revealed that RhoA and Ca^{2+} constitute a positive feedback loop, with RhoA not only being activated by Ca^{2+} , but also inducing subsequent $[\text{Ca}^{2+}]_i$ elevation during virus infection, which thereby activates endocytosis. Taken together, signaling mediated by RhoA and Ca^{2+} is demonstrated as a key host-oriented mechanism for viral entry. We further performed high-speed imaging experiments with fluorescently labeled virus particles in order to gain further insight into the spatiotemporal dynamics of Ca^{2+} responses upon virus entry. Immediately after infection, localized and modest Ca^{2+} elevations, prior to the aforementioned robust Ca^{2+} release from ER, were detected in the regions where labeled particles were adsorbed. Moreover, sialidase treatment suppressed virus-dependent such Ca^{2+} increases. Collectively, our data indicate that the localized Ca^{2+} elevation is accounted for by sialylated cell surface protein(s), which may in turn evoke subsequent robust Ca^{2+} signaling during virus infection.

Adaptor protein Sorting Nexin 17 is involved at different stages of the human papillomavirus trafficking.

M. Bergant^{1,2}, M.A. Ozbun³, S.K. Campos⁴, L.M. Banks²;

¹Center for Biomedical Sciences and Engineering, Univ Nova Gorica, Nova Gorica, Slovenia, ²Tumour Virology, ICGEB, Trieste, Italy, ³University of New Mexico, Albuquerque, NM, ⁴Department of Immunobiology and the BIO5 Institute, University of Arizona, Tuscon, AZ

The Human Papillomavirus (HPV) L2 capsid protein plays an essential role during the early stages of viral infection, but the molecular mechanisms underlying its mode of action remain obscure. We have identified the adaptor protein, Sorting Nexin 17 (SNX17) as a strong interacting partner of HPV-16 L2. This interaction occurs through NPxF/Y phosphotyrosine-binding domain, which is present in all papillomavirus (PV) types analysed. Using mutants of HPV-16 L2 defective for SNX17 interaction, or siRNA ablation of SNX17 expression we demonstrate that the interaction between L2 and SNX17 is crucial for viral infection with multiple PV types, indicating an evolutionary highly conserved viral entry mechanism. Loss of the L2-SNX17 interaction dramatically decreases the efficiency with which viral genomes transit to the nucleus. We also show that capsids defective in their capacity to bind SNX17 transit much more rapidly to the lysosomal compartment, suggesting that L2-SNX17 interaction is delaying or redirecting HPV capsids from the major lysosomal pathway. We observed that HPV capsids have a peak of colocalisation with SNX17-positive vesicles 2 hours post-infection, which was confirmed also by viral DNA staining. While vesicular fractioning shows some unspecific relocalisation of SNX17-positive vesicles during an early stage of HPV infection, the duration of stay is strongly HPV L2-dependent. Moreover, partial peri-nuclear localisation of SNX17 later during an HPV-16 infection

suggests that SNX17 is involved also in the transport of the L2-DNA complex to the nucleus. These studies reveal a novel role for SNX17 in aiding viral infection processes, and raise the possibility that normal cellular recycling pathways are perturbed as a result of HPV infection.

Imaging the Alphavirus Exit Pathway.

M.G. Martinez¹, E.L. Snapp^{2,3}, G.S. Perumal⁴, F.P. Macaluso⁴, M.C. Kielian¹;

¹Department of Cell Biology, Albert Einstein College of Medicine, Bronx, NY, ²Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ³Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, ⁴Analytical Imaging Facility, Albert Einstein College of Medicine, Bronx, NY

Alphaviruses such as Chikungunya virus are important and widely distributed human pathogens, and there are no effective vaccines or antiviral therapies available. Alphaviruses are small, highly organized RNA viruses with a membrane envelope derived by budding through the host cell plasma membrane (PM), excluding host membrane proteins. Viral particles contain an internal nucleocapsid and an external lattice of the viral E2 and E1 transmembrane proteins. While alphavirus entry has been widely studied, the process and dynamics of assembly and budding remain poorly understood. Here, we generated Sindbis viruses (SINV) with fluorescent protein labels on the E2 envelope protein and exploited them to characterize virus assembly and budding in living cells. Using confocal and total internal reflection fluorescence microscopy we observed that during virus infection E2 became enriched in localized patches on the PM and in short filopodia-like extensions. These E2-labeled patches and extensions contained all of the viral structural proteins and the non-structural protein nsP1. Correlative light and electron microscopy studies established that the patches and extensions co-localize with virus budding structures, while light microscopy showed that they exclude a freely diffusing PM marker protein. Protein exclusion required the interaction of the E2 protein with the capsid protein, a critical step in virus budding, and was associated with the immobilization of the envelope proteins on the cell surface. Virus infection induced at least two different types of extensions: the shorter extensions describe above ($3.19 \mu\text{m} \pm 0.94$; $n=30$) that exclude the PM marker, actin and tubulin, and longer extensions ($12.09 \mu\text{m} \pm 0.4$; $n=30$) that contain all of these marker proteins and appear to mediate virus particle transfer. Together our data support a model in which alphavirus budding occurs at specialized sites of virus-induced reorganization of the PM.

P740**Board Number: B1045****Deficient protein palmitoylation in the deadly fungus *Cryptococcus neoformans* affects pathogenesis by altering fungal interactions with host cells.**F.H. Santiago-Tirado¹, M. Yang¹, T.L. Doering¹;¹Molecular Microbiology, Washington University School of Medicine, Saint Louis, MO

Cryptococcus neoformans is the most common fungal cause of meningitis, responsible for over 625,000 deaths every year. Most of these deaths are in immunocompromised patients, historically in the setting of AIDS, but currently also affecting patients with other underlying conditions such as cancer or organ transplant. *C. neoformans* is a facultative intracellular pathogen, and adherence to and uptake by host phagocytes during infection are key events that are central in its pathogenesis. Fungal engulfment by host cells and subsequent intracellular proliferation has been implicated in latency, dissemination, and virulence, but the full complement of *C. neoformans* gene products that participate in these processes has not been defined. To address this question, we used an automated high content imaging method to quantify the interactions between a human macrophage-like cell line and mutant fungi from a partial deletion collection. We identified multiple genes whose deletion led to alterations in the adherence and/or phagocytic indexes. One of the genes identified encode a protein S-acyl transferase, one of a family of DHHC domain-containing proteins that catalyzes lipid modification of proteins. Deletion of this gene, termed *PFA4*, results in enhanced adherence to and phagocytosis by human macrophages. Mutant cells lacking *PFA4* exhibit morphological defects that are exacerbated under host-like conditions, and are sensitive to a variety of cell wall stress conditions *in vitro*. Consistent with these observations, they have a profound defect in intracellular growth and are avirulent in a mouse model of cryptococcal infection. These results suggest a surface defect but, interestingly, the mutant cells show no obvious defect in the polysaccharide capsule that surrounds their cell walls, which is a major virulence factor. They do, however, display altered cell wall structure and increased exposure of surface glycans compared to wild type. Defects in lipid modification may cause mislocalization or degradation of the substrate proteins, leading to their dysfunction. We hypothesize that *C. neoformans* uses palmitoylation to regulate its surface composition and thereby modulate its interactions with the host. Our current efforts are directed at identifying the specific protein substrate(s) responsible for the changes we observe in the *pfa4* mutant. Little is known about the role palmitoylation plays in virulence of this or other pathogenic fungi, hence these findings open a new area of investigation and promises novel avenues for therapeutics based on the role of palmitoylation in fungal pathogenesis.

P741**Board Number: B1046****Comparison of the Role of Human PI 3-kinase Pathway in Internalization of the Bacterial Pathogens *Yersinia enterocolitica* and *Listeria monocytogenes*.**K. Ireton¹, G.C. Dowd¹, R. Thomas¹;¹Microbiology and Immunology, University of Otago, Dunedin, New Zealand

Human type IA Phosphoinositide (PI) 3-kinase plays a critical role in infection by many microbial pathogens, including enteric bacteria (*Listeria monocytogenes*, *Yersinia enterocolitica*, *Campylobacter jejuni*), parasites (*Trypanosoma cruzi* and *Toxoplasma gondii*), and viruses (Ebola, Influenza A virus). PI 3-kinase regulates a multitude of cellular processes by controlling the localization and/or activity of at least 50 downstream proteins. A key unresolved question is how host PI 3-kinase promotes internalization ('entry') of various microbes into human cells. Do different microbes utilize similar or distinct PI 3-kinase-mediated signaling pathways? A previous study employed an RNA interference (RNAi)-based screen to identify nine host downstream effectors of PI 3-kinase needed for entry of the food-borne bacterium *Listeria monocytogenes* (Jiwani et al., 2012. *Infect. Immun.* 3: 1252). The objective of this work was to perform a similar RNAi screen to identify human PI 3-kinase pathway components involved in internalization of *Yersinia enterocolitica*, allowing a comparison of the entry pathways employed by *Listeria* and *Yersinia*. HeLa cells were transfected with an siRNA library targeting ~70 human proteins comprising the type IA PI 3-kinase signaling pathway. Many of the human proteins targeted are known to bind directly to the lipid product of PI 3-kinase, phosphatidylinositol 3,4,5-tris phosphate. The effects of the siRNAs on target gene expression were assessed by real time PCR. siRNAs that inhibited human gene expression were examined for effects on *Yersinia enterocolitica* entry, using a commonly employed antibiotic protection assay. From these studies, we identified eight human proteins in the type IA PI 3-kinase pathway that are needed for internalization of *Yersinia enterocolitica*. These proteins include the GTPase Rab5c, regulators of host Rho or Arf GTPases (Centaurin-alpha1, Dock180, PSCD3), the focal adhesion component FAK, Phospholipase D 2 (PLD2), the scaffolding protein LL5-alpha, and the serine/threonine kinase mTor. At least four of the eight host proteins involved in *Yersinia* entry (Rab5c, Centaurin-alpha1, PSCD3, and mTor) are also needed for *Listeria* uptake. FAK and PLD2 are dispensable for *Listeria* entry. Of the nine PI 3-kinase pathway components involved in *Listeria* uptake, four have no detectable role in *Yersinia* internalization. We conclude that host PI 3-kinase controls entry of *Yersinia* and *Listeria* through both shared and distinct downstream effectors. Future work will focus on the molecular mechanisms by which these downstream effectors promote bacterial infection.

P742**Board Number: B1047****Deciphering the molecular mechanisms of *Listeria* transcytosis across the intestinal epithelium in intestinal organoids.**C. Fevre^{1,2}, N. Barilone^{1,2}, M. Lecuit^{1,2};¹Institut Pasteur, Paris, France, ²Inserm, Paris, France

The human intestinal mucosa is a physical barrier that delineates the frontier between the external environment and the host. It can be crossed by luminal antigens and enteroinvasive microbes. *Listeria monocytogenes* (*Lm*), a Gram-positive foodborne bacterial pathogen responsible for human listeriosis, crosses the intestinal barrier across goblet cells to access the lamina propria and disseminate systemically. This translocation requires the interaction between *Lm* surface protein InlA and its species-specific epithelial receptor E-cadherin, but is independent of LLO (involved in *Lm* escape from the vacuole) and ActA (involved in *Lm* intracellular motility), suggesting that *Lm* is transferred across goblet cells by transcytosis. Beside E-cadherin and microtubules, the host factors involved in *Lm* transcytosis across goblet cells are unknown. *Lm* transcytosis is not observed in *in vitro* cultured epithelial cells, which are either too polarized to express apically accessible E-cadherin, or unpolarized and devoid of *bona fide* apical basal vesicular trafficking. To identify the host factors involved in *Lm* transcytosis across goblet cells, we have used intestinal organoids (miniguts), which recapitulate faithfully *ex vivo* intestinal epithelium differentiation into intestinal epithelial cell subtypes, including goblet cells, and which are genetically amenable. Using high-resolution confocal microscopy to follow the fate of microinjected *Lm* inside minigut lumen, we have shown that, similar to what is observed *in vivo*, *Lm* is translocated through goblet cells, in a microtubule- and InlA-dependent manner but InlB- LLO- and ActA-independent manner, validating the intestinal organoid as a suitable model to identify the host factors involved in this process. Our working hypothesis is that *Lm* takes advantage of E-cadherin recycling from the apical to basolateral pole of enterocytes. In such a scenario, inhibition of E-cadherin recycling would interfere with *Lm* transcytosis. To test this hypothesis, inducible organoid mutants expressing inactive forms of a series of proteins involved in E-cadherin recycling, such as Rab GTPases and exocyst components have been generated. Our preliminary results show that their inhibition prevents *Lm* transcytosis, and experiments are now under way to fully decipher the molecular mechanisms of *Lm* transcytosis across the intestinal epithelium. Intestinal organoids stand as a very promising model for the spatial and temporal studies of the cell biology of host-pathogen interactions, as it preserves cell differentiation, polarization and tissue architecture, which are exploited by pathogens to invade the host.

P743**Board Number: B1048*****Neisseria gonorrhoeae* breaches the epithelial barrier by inducing Ca²⁺ flux and Ca²⁺-dependent activation of non-muscle myosin II for tissue invasion.**L. Wang¹, W. Song², Q. Yu¹, B. Lin¹;¹CBMG, University of Maryland, College Park, MD, ²Department of Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

Neisseria gonorrhoeae (GC) infects epithelial cells lining the female reproductive tract, which can lead to pelvic inflammatory and disseminated diseases. We have previously shown that GC interactions with epithelial cells induce the transactivation of epidermal growth factor receptor (EGFR); however, how EGFR activation contributes to GC infection is unknown. This study demonstrates that the interactions of GC with the apical surface of polarized epithelial cells induce Ca²⁺ flux and the accumulation of active non-muscle myosin II (NMII) at the apical junction and the apical surface of epithelial cells. GC-induced activation of Ca²⁺ is dependent on EGFR activation, while the activation and redistribution of NMII require Ca²⁺ flux and myosin light chain kinase that is activated by Ca²⁺-bound calmodulin. Inhibition of either GC-induced Ca²⁺ flux or NMII activation blocks GC-induced disruption of the apical junction and reduces GC transmigration, while having no significant effect on GC adherence and invasion into polarized epithelial cells. Compared to wild type GC, a mutated GC strain where all 11 genes of GC surface protein Opa are deleted induces the disassembly of the apical junction and the activation and redistribution of NMII to significantly greater magnitude, consequently transmigrating at a much higher efficacy. Electron microscopic analysis showed that unlike wild type GC, the Opa deletion mutant alters the apical morphology and forms extensive interaction with the apical membrane of polarized epithelial cells. Taken together, our results reveal that GC disrupts the apical junction of the epithelial barrier by inducing EGFR-dependent Ca²⁺ flux and Ca²⁺-dependent activation and reorganization of junction-associated actomyosin, which facilitates GC invasion into the mucosal tissue. These results reveal a new mechanism by which GC establishes infection using signaling and cytoskeletal apparatus of epithelial cells.

P744**Board Number: B1049****Chlamydia psittaci encodes a functional BAR domain Inc protein that targets inverted and everted inclusion membrane extensions and associates with gap junction proteins.**D.A. Phillips¹, R. Hsia², S. Mojica¹, J. Ravel³, P. Bavoil⁴;¹Department of Microbial Pathogenesis, University of Maryland, Baltimore, Baltimore, MD, ²Core Imaging Facility, University of Maryland, Baltimore, Baltimore, MD, ³Institute for Genome Sciences, University of Maryland, Baltimore, Baltimore, MD, ⁴Department of Microbial Pathogenesis, University of Maryland School of Dentistry, Baltimore, MD

Bacteria of the genus *Chlamydia* are ubiquitous pathogens that grow strictly within an intracellular plasma membrane-derived vacuole, termed the chlamydial inclusion. *Chlamydia trachomatis* (Ctr), a prevalent sexually transmitted pathogen, causes infection that is usually limited to the human genital or ocular mucosal epithelia. In contrast, *Chlamydia psittaci* (Cps), a prevalent avian pathogen, is an aggressive, tissue-invasive pathogen that can cause life-threatening zoonotic infection in humans and animals. We have proposed that chlamydiae of all species replicate while in contact with the chlamydial inclusion membrane (CIM). Chlamydiae secrete type III secretion (T3S) effector proteins into and across the CIM, whose roles are to subvert host activities to benefit chlamydial growth. Among these are proteins of the Inc family characterized by a bilobar hydrophobic sequence serving to anchor Incs into the CIM. The IncA ortholog of Cps differs from IncAs in other *Chlamydia* spp. owing to the presence of a predicted BAR domain within its C-terminus closely related to BAR domains found in eukaryotic sorting nexins. Purified recombinant IncA (IncA/Cps) was able to reconfigure liposomes into tubules *in vitro*, a canonical test for BAR domain functionality. In contrast, neither IncA/Ctr nor IncA/Cps with a BAR R188G mutation produced tubules. Transfected HEK293T cells expressing GFP-IncA/Cps displayed fluorescent tubular/fibrous structures in the cell cytosol. Cps-infected HeLa cells stained with anti-IncA/Cps antibodies revealed similar inverted structures within the lumen of the inclusion that did not co-localize with replicating chlamydiae, as well as everted CIM extensions into the cytosol. The former but not the latter were ablated when infected cells were exposed to the sphingolipid biosynthesis inhibitor myriocin, suggesting that the IncA-positive inclusion lumen structures are continuous with the inclusion membrane. Further, transfected IncA/Cps fused to the promiscuous biotin ligase BirA resulted in the specific biotinylation (Bio-ID) of several proteins of tight junctions and vesicular trafficking. In summary, our study demonstrates that *C. psittaci* expresses and secretes an Inc protein with a functional BAR domain that is absent in orthologs of other *Chlamydia* spp. While this the first characterized prokaryotic BAR domain, it is consistent with the need of intracellular chlamydiae to acquire eukaryotic-like functions to subvert host cell function. IncA-positive inverted extensions are consistent with the need of Cps to replicate in contact with the CIM. Everted extensions and the identification of tight junctions and vesicular trafficking proteins as targets of IncA suggest a possible role in intercellular trafficking.

P745**Board Number: B1050****Analysis of the interaction and internalization of *Bacillus thuringiensis* Cry toxins in different human cell lines.**R.G. Silva-Delgado¹, K. Leyva², B.E. Garcia-Perez², J.M. Favela-Hernandez³, G. Guerrero⁴;¹Facultad de Quimica-UJED, Gomez Palacio, Dgo, Mexico, ²Immunologia, Escuela Nacional de Ciencias Biologicas IPN, Mexico City, Mexico, ³Facultad de Quimica-UJED, Gomez Palacio, Mexico, ⁴Unidad Academicas de Ciencias Biologicas-UAZ, Zacatecas, Mexico

Bacterial toxins have the ability to mount significant immune responses at the systemic and mucosal sites. *Bacillus thuringiensis* Cry toxins has been used for decades in the biological control of insects (López et al., 2013 Review). However, several studies *in vivo* and *in vitro* support its role as strong immunogens (Vazquez-Padrón et al., 1999; 2000; Moreno-Fierros et al., 2000; Guerrero et al., 2004), adjuvants (against *Naegleria fowleri* ameba) (Rojas-Hernández et al., 2004:2010) and carriers of clinically important antigens (Moreno-Fierros et al., 2003; Guerrero et al., 2007ab ; Esquivel R and Moreno-Fierros L., 2005). Furthermore, it has been showed that they induce the expression of the pIgR(Reséndiz-Albor et al., 2010) as well as the FcRn(Verdín-Terán et al., 2009) in the small intestine. Despite of these wealth of data, remains to be defined and clarified the effects of the interaction and internalization of the Cry toxins with epithelial cells from the gut and lung of mammals. The aim of the present work is to analyze the interaction and internalization of the Cry toxins using different human cell lines. A kinetic of internalization using immunofluorescence analysis was followed. At very early times, particles labelled+ Cry toxin-10 µg/ml started the interaction with proteins-like-receptors in the surface of the A549 cell lines, and THP-1 respectively (macrophages derived with PHA) and at later times, particles labelled + Cry toxin internalized by process called macropinocytosis. These data would implicate that once ingested (by oral route) or inhaled by intranasal route), *Bt* Cry toxins are internalized by the different cell in the gut or lung of the mammals and trigger responses that are key for the observed immunogenic and adjuvant properties in mice.

P746**Board Number: B1051****pH Alkalinization by Chloroquine Suppresses *Burkholderia* T6SS-1 Gene Expression, Phagosomal Escape and Multi-Nucleated Giant Cell Formation.**J. Chua¹, J. Senft¹, S. Lockett², P. Brett³, M. Burtnick³, D. Deshazer¹, A. Friedlander¹;¹Bacteriology, USAMRIID, Fort Detrick, MD, ²Optical Microscopy and Analysis Laboratory, Frederick National Laboratory for Cancer Research, Frederick, MD, ³Microbiology and Immunology, University of South Alabama, Mobile, AL

Burkholderia mallei and *B. pseudomallei*, Gram negative facultative intracellular pathogens, cause the often fatal diseases glanders and melioidosis, respectively, in humans and animals. A morphological

hallmark of pathogenesis is formation of granulomas containing multi-nucleated giant cells (MNGCs) and necrosis in different organs. These processes are dependent on the Type VI secretion system-1 (T6SS-1), which is required for virulence in animals and regulated by the two component regulatory system VirAG. To understand the disease mechanisms and develop treatments, we examined the cell biology of MNGC formation and cell death. Chloroquine (CLQ) inhibits these processes by retarding intracellular growth and preventing phagosomal escape of the pathogens. This depends on the ability of CLQ to neutralize acid pH intracellularly because other alkalinizing compounds also inhibit phagosomal escape and MNGC formation. By alkalinizing the endocytic pathway, CLQ hampers bacterial virulence protein expression because T3SS and T6SS/ VirAG regulated protein expression is induced at acid pH. Specifically, acid pH upregulates the expression of a Type VI secretory apparatus protein Hcp1 and the deubiquitinase TssM. CLQ treatment of *Burkholderia* infected Madagascar Hissing Cockroaches increases survival. This study highlights multiple mechanisms by which CLQ, through alkalinization of phagosomal pH, inhibits growth and virulence and argues for CLQ's inclusion in treatment for *Burkholderia* diseases.

Junin virus infection triggers the autophagy pathway in a human cell line.

J.S. Roldan¹, L. Delgui², N.A. Candurra¹;

¹Química Biológica, IQUIBICEN, FCEyN, UBA, Buenos Aires, Argentina, ²IHEM, UNCuyo-CONICET, Mendoza, Argentina

Autophagy is a conserved degradative pathway that plays a key role in maintaining cellular homeostasis through eliminating unwanted proteins and damaged organelles by cellular self-digestion in the lysosome to fulfil the demand for aminoacids required for cell survival. The first step of this process is the formation of double membrane vesicles, denominated autophagosomes, around portions of cytoplasm which then fuse with lysosomes where enzymatic degradation occurs. This process has a crucial role in protecting cells from viral invasion. However, viruses have been able to subvert this pathway in their own benefit. Junin virus (JUNV) belongs to the phylogenetic clade B of the Arenaviridae family. It is the aetiological agent of Argentine haemorrhagic fever, an endemo-epidemic disease affecting the population of the most fertile farming land of Argentina. We analysed the role of autophagy in the course of JUNV infection employing human cell line A549. We used LC3 as a protein marker of autophagy pathway modulation after viral infection. Mammalian LC3 is a cytoplasmic protein (LC3-I) that becomes lipidated and membrane associated (LC3-II) upon induction of autophagy. When detected by confocal laser scanning microscopy, vesicles associated LC3-II appears as discrete green dots. We have observed that cells overexpressing EGFP-LC3 and infected with JUNV showed an increased number of LC3 dots similar to what we have shown after starvation- or BafilomycinA1-treatment, which leads to autophagosome formation induction or accumulation, respectively. We have monitored the conversion of LC3-I (cytosolic) to LC3-II (associated to autophagosomes) by Western blot technique observing that levels of LC3-II in JUNV-infected cells were similar to that observed in starved cells. Moreover, cells pre-treated with rapamycin, a pharmacological autophagy inductor, enhanced

virus yield with respect to the control situation. In addition, we have assayed the replication capacity of JUNV in Atg5 knock-out cells (a key molecular component of the autophagic pathway), but no differences were found when compared to the wild type Atg5 cells. At last, we have kinetically studied the number of LC3 dots after JUNV infection over a period of 24 h post infection (p.i.) and found that the pathway was activated by the presence of the virus since 2 h p.i. and remained activated until the end of the mentioned lapse of timer monitored. All together, these results allowed us to conclude that JUNV infection leads to an autophagic response in the infected cells. However, a functional autophagy pathway does not seem to be required for efficient virus replication.

Characterization of the vesicular donor compartments to Yersinia-containing vacuoles positive for LC3 and with a single limiting membrane.

L. Ligeon¹, N. Barois², F. Lafont¹;

¹CNRS UMR 8204-CMIP, Institut Pasteur de Lille, Lille, France, ²BioImaging Center Lille, Institut Pasteur de Lille, Lille, France

Yersinia pseudotuberculosis is an enteropathogenic bacterium which is able to replicate within both macrophages and epithelial cells by subverting the autophagy pathway. The autophagy is characterized in its classical form by the formation of vacuoles with double membrane and displaying LC3 proteins giving rise to a specific internal vesicles so-called: autophagosomes. We showed that in function of cells types *Y. pseudotuberculosis* is contained in two different LC3 positive vacuoles. In fact, in macrophages the bacteria could block the autophagosome maturation, to create a replicative niche with double limiting membranes (Moreau et al. 2010). While, in the epithelial cells, *Y. pseudotuberculosis* can replicate inside non-acidic vacuoles displaying the autophagic marker, LC3, but with only one limiting membrane (Ligeon et al. 2014). The autophagosome formation during bacteria invasion is characterized by the dynamic rearrangement of cell membrane structures via multiple membrane fusion events (Ligeon et al., 2011). Membranes forming the autophagosome can result from fusion of different vesicular donor compartments (ER, mitochondria, endosomes,...). Here, we investigated which donor compartment plays a role during the formation of the Yersinia-containing vacuoles (YCVs). In epithelial cells, we observed fusion of YCVs with different types of endosomes vesicles and LC3-positive small vesicles. We propose that both the autophagy and the endocytic pathway participate as membrane sources for the growing YCV during bacteria entry and replication.

Moreau et al. Cellular Microbiology (2010) 12:1108-1123 Ligeon et al. Cellular Microbiology (2011) 13:1303-1311 Ligeon et al. Autophagy (2014) in press

P749**Board Number: B1054****Activation of Focal Adhesion Kinase by Salmonella Suppresses Autophagy via an Akt/mTOR Signaling Pathway and Promotes Bacterial Survival in Macrophages.**K.A. Owen¹, C.B. Meyer¹, A.H. Bouton², J. Casanova¹;¹Cell Biology, University of Virginia, Charlottesville, VA, ²Microbiology, University of Virginia, Charlottesville, VA

Autophagy has emerged as an important antimicrobial host defense mechanism that not only orchestrates the systemic immune response, but also functions in a cell autonomous manner to directly eliminate invading pathogens. Pathogenic bacteria such as *Salmonella* have evolved adaptations to protect themselves from autophagic elimination. Here we show that signaling through the non-receptor tyrosine kinase focal adhesion kinase (FAK) is actively manipulated by the *Salmonella* SPI-2 system in macrophages to promote intracellular survival. In wild-type macrophages, FAK is recruited to the surface of the Salmonella-containing vacuole (SCV), leading to amplified signaling through the Akt-mTOR axis and inhibition of the autophagic response. In FAK-deficient macrophages, Akt/mTOR signaling is attenuated and autophagic capture of intracellular bacteria is enhanced, resulting in reduced bacterial survival. We further demonstrate that enhanced autophagy in FAK^{-/-} macrophages requires the activity of Atg5 and ULK1 in a process that is distinct from LC3-assisted phagocytosis (LAP). *In vivo*, selective knockout of FAK in macrophages resulted in more rapid clearance of bacteria from tissues after oral infection with *S. typhimurium*. Clearance was correlated with reduced infiltration of inflammatory cell types into infected tissues and reduced tissue damage. Together, these data demonstrate that FAK is specifically targeted by *S. typhimurium* as a novel means of suppressing autophagy in macrophages, thereby enhancing their intracellular survival.

Immune System**P751****Board Number: B1057****TNC Induced Regulation of IL-12 Promoted Apoptosis among DP Thymocytes.**S. Miller¹, S. Henley¹, F.R. Davis¹, L. Johnson², M. Martinez³;¹Integrative Biosciences, Tuskegee University, Tuskegee, AL, ²Biology, Morgan State University, Baltimore, MD, ³Biology, Tuskegee University, Tuskegee, AL

Central tolerance of thymocytes is a dynamic process involving complex interactions between cytokines, developing thymocytes and the cells of the thymic stroma. Among the cells of the thymic stroma are thymic nurse cells (TNCs). TNCs are cortical epithelial cells of the thymus that appear to play a significant role in central tolerance of T-cells. TNCs specifically interact with and internalize CD4⁺CD8⁺TCR^{lo} double positive (DP) thymocytes. Thymocytes at this developmental stage are

undergoing MHC restriction, a process where the cells learn to recognize self MHCs. DP thymocytes are reported to be non-responsive to a variety of cytokines, yet responsive to IL-12. IL-12 is a Th1 type cytokine whose secretion is upregulated following interactions between CD40 on APCs and CD40 ligand (CD154) on T-cells. Although IL-12 promotes pro-inflammatory responses in the periphery, it influences the deletion of the DP thymocytes in the thymus. Prior work in this lab has demonstrated that IL-12 secretion is significantly increased in co-cultures containing TNCs where negative selection is high. However, it could not be determined whether the TNCs themselves were the source of the increased IL-12 concentrations. Therefore, we hypothesize that TNCs can secrete IL-12 via CD40/CD40L interaction, and that IL-12 plays a role in the interaction between TNCs and DP thymocytes. Using in vitro experimental systems composed primarily of TNC cultures or TNC/thymocyte co-cultures, we investigated the potential for TNCs to secrete IL-12 in co-cultures and the effects of IL-12 on thymocytes in TNC/thymocyte co-cultures. Lipopolysaccharide stimulated TNCs demonstrated time dependent increases IL-12 secretion and correlative increases in CD40 expression. Furthermore, thymocytes cultured with TNCs also demonstrated a time dependent increase in CD154, regardless of negative selection conditions.

However, thymocyte apoptosis was found to be severely reduced among DP thymocytes in all co-cultures containing TNCs. And thymocyte rescue from apoptosis observed in cultures that included recombinant IL-12 was found to be greater than observed in cultures which did not include the cytokine. Reductions in apoptosis correlated with increases in thymocyte maturation and significant reduction of the IL-12 receptor on DP thymocytes in these co-cultures. These results lead us to conclude that TNCs can regulate DP thymocyte numbers by both increasing apoptosis through IL-12 secretion and decreasing apoptosis by downregulating the IL-12 receptor.

The role of interleukin-27 receptor signaling in the development of abdominal aortic aneurysm.

I. Peshkova¹, P. Makhov², V. Hou¹, D. Posocco¹, E. Koltsova¹;

¹Immune Cell Development and Host Defense Program, Fox Chase Cancer Center, Philadelphia, PA,

²Cancer Biology Program, Fox Chase Cancer Center, Philadelphia, PA

Rationale: Abdominal aortic aneurysm (AAA) is a cardiovascular disease, which is characterized by aortic wall dilation with subsequent rupture and internal bleeding. Inflammation in the vessel wall is a key component of atherosclerosis development and could also contribute to AAA formation. Various pro-inflammatory cytokines were investigated in atherosclerosis and AAA, while little is known about the contribution of anti-inflammatory cytokines with regard to their ability to control vascular inflammation. Interleukin (IL)-27 is a recently discovered member of the IL-6/IL-12 family. The IL-27 receptor is composed of IL-27 receptor A (WSX-1) and gp130 and is required for all established IL-27 signaling pathways. The functions of IL-27 and its receptor signaling in AAA remain unknown. Objective: The aim of this study was to test whether IL-27R signaling is required to suppress abdominal aortic aneurysm

formation in Angiotensin II mouse model. Methods and Results: Angiotensin II containing pumps were surgically implanted into Il27ra^{-/-} x Ldlr^{-/-} and Il27ra^{+/-} x Ldlr^{-/-} control mice with already developed atherosclerosis. The progression of AAA was analyzed 4 weeks later. We found that Il27ra^{-/-} x Ldlr^{-/-} mice developed large AAA with visual hemorrhage into artery wall compared to Il27ra^{+/-} x Ldlr^{-/-} counterparts. Augmented disease correlated with increased accumulation of myeloid cells and T cells in the area of AAA formation. Preliminary analysis of gene expression profile revealed upregulation of IFN γ , TNF, CCL5, S100A9, MMP9 - possible players in pathogenesis of AAA. Conclusions: Altogether our data suggest that IL-27R signaling may play an important role in suppression of inflammation in aortic wall during AAA development.

CELL-SPECIFIC APPROACHES TO DISSECTING PUTATIVELY FUNCTIONAL GENETIC ASSOCIATIONS IN PEDIATRIC AUTOIMMUNE DISEASES.

Y.R. Li^{1,2}, J. Li², R.N. Baldassano³, E.T. Prak⁴, H. Li⁵, B.J. Keating^{2,6,7}, H. Hakonarson^{2,7,8};

¹Medical Scientist Training Program, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, ²Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, ³Division of Gastroenterology, Children's Hospital of Philadelphia, Philadelphia, PA, ⁴Department of Pathology and Lab Medicine, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, ⁵Department of Biostatistics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, ⁶Department of Surgery, Division of Transplantation, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, ⁷Department of Pediatrics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, ⁸Division of Pulmonary Medicine, Children's Hospital of Philadelphia, Philadelphia, PA

Autoimmune (AI) disorders affect 1 in 12 people living in the Western Hemisphere, representing a significant cause of chronic morbidity and disability. As demonstrated by the identification of hundreds of susceptibility genes by genome wide association studies (**GWAS**), genetic risk factors play an important role. These results show that many loci are shared across clinically-distinct disease groups, consistent with AI diseases having common etiologies.

To investigate the genetic architecture of pediatric autoimmune diseases (**pAIDs**), we performed a heterogeneity-sensitive GWAS (**hsGWAS**) across 10 pAIDs in a nested case-control study including over **6,000** cases and nearly **11,000** controls. We identified **137** independent loci nominally associated with one or more pAIDs, **31** of which show evidence of being pan-pAID significant ($P_{PPS} < 5 \times 10^{-8}$), when adjusted for the use of a common control. A number of the top SNPs map to or near candidate genes with established or compelling immunoregulatory functions (e.g., **CD40LG**: $P_{PPS} < 5.37 \times 10^{-9}$ and **TNFSF11B**: $P_{PPS} < 8.43 \times 10^{-10}$). All **31 PPS** lead SNPs, or their nearby proxies ($r^2 > 0.8$ within 1MB), are known coding ($n=4$), regulatory ($n=22$), conserved ($n=19$) or literature-supported ($n=27$) SNPs. The lead loci are specifically enriched for DNase hypersensitivity sites ($p < 0.01$), eQTLs, and coding variants ($p < 0.001$, respectively). To examine if there is evidence for cell-type specific functional

enrichment, we annotated pAID-associated variants using Encode transcription factor binding (TFBS), histone modification (HM), digital genomic footprinting (DGF), and DNase hypersensitivity (DH) datasets across available cell types. Compared to the genomic background, the 137 lead associated SNPs ($P_{\text{nominal}} < 1 \times 10^{-6}$) are consistently enriched for regulatory functions across Monocytes, Th1, Th2, Treg, and lymphoblastoid B-cells (Bonferroni-adjusted $P_{\text{adj}} <$ from 3×10^{-7} to $P_{\text{adj}} < 0.047$). We further characterized the expression profiles of candidate genes across over three hundred unique human and murine tissues and immune-specific cell types. We show the expression of candidate pAID-associated gene transcripts are enriched across immune cells and we have identified sets of genes shared by two or more related diseases with closely correlated expression profiles, for example Type-1-Diabetes and Thyroiditis. Integration of multiple *in silico* analytical approaches has identified highly-shared autoimmune signals (e.g., ***IL2RA*: $P_{\text{PPS}} < 2.41 \times 10^{-10}$**) associated with 6 different pAIDs and demonstrating converging roles for the JAK-STAT, innate, and TH₁-TH₂/TH₁₇ mediated T-cell signaling molecular pathways, which are attractive pharmacological targets for future functional studies.

Since clinical application of MSCs requires long-term ex vivo culture inducing senescence in MSCs and reducing the therapeutic activity of transplanted MSCs, numerous efforts have been attempted to sustain the active state of MSCs. Substance P (SP) is a neuropeptide that functions to activate the cellular physiological responses of MSCs, including proliferation, migration, and secretion of specific cytokines. In this study, we explored the potential of SP to restore the weakened immune modulating activity of MSCs resulting from long-term culture by measuring T cell activity and interleukin-2 (IL-2) secretion of CD4+ Jurkat leukemic T cells. As the number of cell passages increased, the immunosuppressive function of MSCs based on T cell activity decreased. This weakened activity of MSCs could be restored by SP treatment and nullified by co-treatment of an NK1 receptor blocker. Higher levels of transforming growth factor beta 1 (TGF-beta1) secretion were noted in the medium of SP-treated late passage MSC cultures, but IL-10 levels did not change. SP-treated MSC-conditioned medium decreased T cell activity and IL-2 secretion in CD4+ Jurkat leukemic T cells even in the presence of lipopolysaccharide (LPS), both of which were successfully blocked by inhibiting the TGF beta signaling pathway. This stimulatory effect of SP on late passage MSCs was also confirmed in direct cell-cell contact co-culture of MSCs and T cells. Collectively, our study suggests that SP pretreatment to MSCs may recover the immunosuppressive function of late passage MSCs by potentiating their ability to secrete TGF-beta1, which can enhance the therapeutic activity of ex vivo expanded MSCs in long-term culture. Keywords: Substance P, mesenchymal stem cells, T cells, TGF-beta1, IL-2, immune modulation.

P755**Board Number: B1061****Substance P ameliorates collagen II-induced arthritis in mice via suppression of the inflammatory response.**P. Ju Hyung¹, H. Hong², Y. Son^{3,4};¹Graduate School of Biotechnology, Kyung Hee University, Yong-In, Korea, ²College of Medicine, Kyung Hee University, Seoul, Korea, ³Graduate School of Biotechnology, Kyung Hee University, Yongin, Korea, ⁴Department of Genetic Engineering, Kyung Hee University, Yongin, Korea

Rheumatoid Arthritis (RA) is a chronic autoimmune disease with systemic inflammatory disorder that may mainly attack synovial joints. Main therapy for RA has been focused in the suppression of inflammation to alleviate symptoms. Recently, substance-P (SP) was found to have functions as an injury-inducible endogenous factor to mobilize bone marrow stem cell to wound site and anti-inflammatory agent. Considering the function of SP, it was expected that SP may exerted the therapeutic effect on RA. In this study, SP effect was explored using collagen type 2-induced arthritis (CIA) animal model that was induced by injecting emulsion containing 100µg of collagen II (CII) into subcutaneous tissue of the tails and 3 weeks later, boosting with 100 µg CII emulsified with an equal volume of incomplete Freund's adjuvant. At 4 weeks post immunization, the mouse showed CIA phenotype and SP was injected twice a week to observe phenomenon of RA. In result, compared to vehicle-treated group, SP reduced local inflammatory signs such as swelling and erythema of the paw and inhibited joint cartilage degradation. Moreover, SP treatment reduced the size of spleens which became enlarged due to excessive inflammation, increased IL-10, anti-inflammatory cytokine and decreased TNF-alpha and IL-17, pro-inflammatory cytokines in the serum, indicating that SP inhibited systemic inflammation. Our study revealed that SP might have a beneficial effect for RA, which may be occurred by inhibition of the inflammatory responses. Furthermore, SP is anticipated to be utilized to treat diverse autoimmune diseases as well as RA.

P756**Board Number: B1062****IMMUNE RESPONSE TO BACTERIAL LYSATES MIXTURE INJECTION IN A RAT MODEL.**D. Cid¹, I. Vargas¹, S. Sanchez², R.M. Ramirez³, M.A. Lopez¹, D.A. Garcia^{1,2}, E.E. Lopez¹;¹Lab. Biología Celular y Neurobiología, Univ Autónoma De Zacatecas, Zacatecas, Mexico, ²Univ Autónoma De Zacate, Guadalupe, Mexico, ³Lab. de Enfermedades Infecciosas, Universidad Autónoma de Zacatecas, Zacatecas, Mexico

BACKGROUND: The bacterial lysates mixtures are widely used in patients with repeated respiratory infections. **METHODS:** We took three study groups, each with three rats. The Group 1, Study Group,

received the injection of a Bacterial Lysate Mixture (Staphylococcus aureus 300mmol/ml, Staphylococcus albus 300mmol/ml, non-hemolytic Streptococcus 100mmol/ml, Neisseria catarrhalis 100mmol/ml and Candida albicans 100mmol/ml). Group 2, positive control, received Lipopolysaccharide (LPS) (e. coli strain O111:B4). To group 3, negative control, was administered Evans solution. The way of application was subcutaneous injection in the spine of the rat. All groups were injected with increased doses at day 0, and day 8, with taking samples of blood at time zero, 24 hours, day 8, and day 15. Blood from the eye corner was obtained for measurement of cytokines IL-1b, IL-4, IL-10 and IFN-g by ELISA assay, and complement C3 and IgG antibody by radial immunodiffusion assay. RESULTS: In the case of Group 1 with bacterial lysates mixture (BLM), there is an initial response to 24 hrs with a decrease cytokines with respect to its basal level and a final increase at fifteenth day. In the statistical analysis there is a difference of concentrations of IL-10 in the 24hrs sample in group of bacterial lysates mixture (24.7pg/ml) compared to LPS group (117.9pg/ml) with a p value = 0.049. The levels of IL-1b shows a significant difference at 24 hours between the groups BLM and LPS (63.1 pg/ml vs 92.6pg/ml, respectively); p value = 0.047; and a significant difference in IL-4 between BLM and LPS, in this case at 8 days (52.9 pg/ml vs 0.00 pg/ml) p value = 0.024. The difference of groups in INF-g was significant in the measurement at 15 days, in this case BLM vs LPS (24.2. pg/ml vs 52.4 pg/ml, respectively, p value = 0.030) and LPS vs Evans solution (52.4 pg/ml vs 23.9 pg/ml, respectively, p value = 0.028). In the case of complement C3 fraction, there was a difference between BLM and LPS at 24hrs (2000.33 mg/dl vs 2422.33 mg/dl, respectively, p value = 0.045). IgG antibody measure there was no difference in the three groups. CONCLUSIONS: Our results show a change in immune response to stimulus with Bacterial Lysates Mixture in this rat model, identifying an effect at 24hrs for IL-10, IL-1b and C3 complement, and at 8th day for IL-4, between BLM and LPS groups, suggesting the greater effect of Bacterial Lysates is short term.

Substance P enhances M2 phenotype of resting microglia and induces skewing from interferon- γ and tumor necrosis factor- α -stimulated M1 toward M2 microglia.

S. Kim¹;

¹Tissue engineering, Kyung Hee University, Yongin-si, Gyeonggi-do, Korea

Microglia are resident immune cells of central nervous system (CNS). In healthy brain, microglia are resting status and regulate brain homeostasis. Microglia become activated after brain injury either classically activated or alternatively activated referred as M1 and M2 type, respectively. It has been known that pro-inflammatory M1 type shows detrimental roles in injured environment, whereas anti-inflammatory M2 type has neuroprotective properties actively involved in tissue repair. We firstly identified protective roles of substance P (SP) in tissue repair from CNS injury by induction of M2 macrophages and microglia. In this study, we aimed to determine the effects of SP in primary cultured microglia. To obtain microglia, mixed glial cell culture was prepared from brain of postnatal day 1-3 inbred Lewis rat. Microglia were isolated by magnetic-activated cell sorting using CD11b antibody.

Primary cultured microglia showed mixed phenotypes of amoeboid, intermediate, and ramified morphology and considered as resting microglia. Characterization of microglia was confirmed by immunofluorescence staining using microglia specific antibodies against CD11b, ionized calcium-binding adapter molecule 1 (Iba-1), and CD68. Resting microglia showed anti-inflammatory M2 phenotype determined by high expression of CD206, CD163, and CX3CR1 with phagocytic activity of *E.coli* particles. Administration of SP significantly increased CD163 and CX3CR1 expression, suggesting enhanced M2 phenotype of resting microglia. To further analyze SP-induced M2 polarization from M1 type, we stimulated resting microglia by tumor necrosis factor- α (TNF α) and interferon- γ (IFN γ), mimicking injury-induced inflammation, with or without SP. In TNF α and IFN γ -stimulated microglia, CX3CR1 was significantly reduced, suggesting M1 microglia. However, administration of TNF α and IFN γ with SP completely nullified reduction of CX3CR1, moreover, increased expression of CX3CR1 was detected. Taken together, SP contributes to polarization of M2 microglia from resting and M1-activated phenotype.

PPAR γ activation following apoptotic cell instillation promotes resolution of lung inflammation and fibrosis.

J.L. Kang¹, Y. Yoon¹, S. Kim¹, M. Kim¹;

¹Physiology, Ewha Womans Univ Sch Med, Seoul, Korea

Changes in macrophage phenotype have been implicated in apoptotic cell-mediated immune modulation via induction of peroxisome proliferator-activated receptor gamma (PPAR γ). In this study, we characterized PPAR γ induction by apoptotic cell instillation over the course of bleomycin-induced lung injury mice. Next, the role of PPAR γ activation in resolving lung inflammation and fibrosis was investigated. Our data demonstrate that apoptotic cell instillation after bleomycin results in immediate and prolonged enhancement of PPAR γ mRNA and protein in alveolar macrophages and lung. Moreover, PPAR γ activity and expression of its target molecules, including CD36, macrophage mannose receptor, and arginase 1, were persistently enhanced following apoptotic cell instillation. Co-administration of the PPAR γ antagonist, GW9662, reversed the enhanced efferocytosis, and the reduced pro-inflammatory cytokine expression, neutrophil recruitment, myeloperoxidase (MPO) activity, and hydroxyproline contents in the lung by apoptotic cell instillation. In addition, inhibition of PPAR γ activity reversed the expression of transforming growth factor beta (TGF- β), interleukin (IL)-10, and hepatocyte growth factor (HGF). These findings indicate that one-time apoptotic cell instillation contributes to anti-inflammatory and anti-fibrotic responses via upregulation of PPAR γ expression and subsequent activation, leading to regulation of efferocytosis and production of pro-resolving cytokines.

P759**Board Number: B1065****Itch Agonists as a Novel Approach to Regulate Immune Responses in Asthma.**S. Agarwal¹, M. Eddins¹, M. Kodrasov¹, J.G. Marblestone¹, J. Wu¹, J. LaRocque¹, M.R. Mattern¹, P. Oliver², S. Kumar¹;¹RandD, Progenra Inc., Malvern, PA, ²Children's Hospital of Philadelphia, Philadelphia, PA

Asthma is a chronic disease with considerable morbidity and no cures. Current treatments are symptomatic and although efficacious, can produce significant adverse effects. Thus, improved, targeted therapies for asthma are needed. The immune response leading to the development of asthma involves differentiation of T cells (CD4+) to effector T cells, which secrete cytokines that assist in the recruitment and proliferation of various innate immune cells. TH2 and TH17 cells contribute to pathogenesis by secreting inflammatory cytokines that induce the influx of neutrophils and eosinophils, leading to airway inflammation. Targeted suppression of pro-inflammatory cytokines and chemokines is thus an attractive strategy to dampen allergic responses in diseases such as asthma. Our approach exploits the ubiquitin proteasome pathway to identify a novel therapeutic. Protein ubiquitylation is a key regulatory mechanism of innate and adaptive immune systems. The E3 ligase Itch plays a significant role, negatively regulating the allergic immune response in asthma. Notably, genetic disruption of Itch in mice or humans has been shown to cause multi-system immune disorders and lung inflammation. Itch belongs to a family of E3 ligases that exist in an auto-inhibited state; it is kept inactive by the N-terminal auto-inhibitory domain and is activated by an adapter protein, Ndfip1, which relieves the auto-inhibition. Ndfip1 promotes Itch activity and, in doing so, limits TH2 differentiation and cytokine production in T cells, as well as the pathogenicity of TH17 cells. Significantly, Ndfip1^{-/-} mice develop inflammation in the lungs characteristic of that induced by TH2 cytokine producing T cells. Thus, Ndfip1 is a key negative modulator of T cell regulation and allergic inflammatory responses. A therapeutic mimetic of Ndfip1 should diminish allergic inflammation by selectively activating Itch mediated ubiquitylation, thereby limiting TH2 and TH17 cytokine production. Here we report that Progenra has developed and adapted their proprietary E3 ligase assay technology to identify activators of Itch to promote ubiquitylation. The most promising compounds are being analyzed in TH2 cells for proof of concept in assays measuring relevant allergy responses. Data will be presented summarizing our progress to date in targeting Itch for regulating the immune response in asthma.

P760**Board Number: B1066****Intrathymic Transplants of Thymic Nurse Cells Reduced Onset of Lupus-Like Symptoms in NZBWF1 mice.**S. Henley¹, S. Miller¹, F.R. Davis¹, M. Martinez², T. Graham³;¹Integrative Biosciences, Tuskegee University, Tuskegee, AL, ²Biology, Tuskegee University, Tuskegee, AL,³School of Veterinary Medicine, Tuskegee University, Tuskegee, AL

Thymic nurse cells (TNCs) are cortical epithelial cells which interact only with TCR^{lo}CD4⁺CD8⁺ (triple positive or TP) thymocytes. TNCs, which express class I and class II major histocompatibility (MHC) proteins, autoimmune regulator (AIRE) and T restrictive antigens (TRA), play a significant role in MHC restriction. TNCs are significantly reduced in all mouse models of systemic lupus erythematosus (SLE) with disease onset and progression. We hypothesized that defective TNC function in SLE mice contributes to reduced thymocyte apoptosis and in turn the release of potentially autoreactive T cells from the thymus. To investigate this normal TNC lines were created from BALB/cJ mice and transferred into the thymi of haplotype-matched 12 week old lupus prone NZBWF1 female mice. Serum, collected biweekly from recipient mice, was monitored by ELISA for anti-dsDNA antibodies and pro-inflammatory cytokines. Recipient NZBWF1 mice were humanely sacrificed 20 weeks post transplantation and kidneys were harvested for histological analyses. Urine collected at time of sacrifice was analyzed for total protein content. We observed that circulating levels of anti-DNA IgGs were consistently lower in animals treated with TNCs than in SHAM-treated control animals. Proteinuria was also significantly less in TNC-treated animals than in SHAM treated animals and immune complex glomerulonephritis was not observed in the kidneys of TNC-treated animals. These results suggest that intrathymic transplants of normal TNCs reduced SLE disease onset in NZBWF1 mice.

P761**Board Number: B1067****The study of ER stress regulator, Bi-1 protection against by Acetaminophen.**G. Lee¹, H. Kim², H. Chae^{1,3};¹Department of Pharmacology , Chonbuk National University medical school, Jeonju, Korea,²Department of Dental Pharmacology, Wonkwang University, Iksan, Korea, ³Department of Pharmacology , Chonbuk National University medical school, Jeonju, Korea

The liver is a major site of drug metabolism and elimination and as such is susceptible to drug toxicity. Drug induced liver injury is a leading cause of acute liver injury, of which acetaminophen (APAP) is the most frequent causative agent. APAP toxicity is initiated by its toxic metabolite NAPQI. However, downstream mechanisms underlying APAP induced cell death are still unclear. Endoplasmic reticulum (ER) stress and the unfolded protein response (UPR) have recently emerged as major regulators of metabolic homeostasis. The results show that intraluminal redox imbalance of the ER and consequential activation of signaling processes and proapoptotic events are involved in hepatocellular damage caused

by AAP overdose. Our data demonstrate tight connections between ER and cytosol to guarantee redox exchange across compartments: a reducing cytosol is important to ensure disulfide isomerization in secretory proteins. BI-1 were identified that Nrf-2 dependent regeneration of glutathione by GSR, GCL and GS plays a critical role in protection against APAP induced oxidative stress. ER stress regulator, BI-1 knock-out condition promotes cell death. We analyzed the role of UPR and BI-1 in mediating APAP hepatotoxicity. A toxic dose of APAP was orally administered to wild type (wt) and BI-1 knockout (KO) mice and damage mechanisms were assessed. BI-1 KO mice were damaged from APAP and exhibited increased liver necrosis and. APAP metabolism in BI-1 KO mice was disturbed and glutathione was more depleted compared with wt. In BI-1 knock-out mice, ER stress and UPR activation were more susceptible following APAP administration. We suggest that the arguments for and against a role for glutathione in facilitating disulphide-bond formation and consider its role in protecting the cell from endoplasmic-reticulum-generated oxidative stress. Thus, BI-1 plays a anti-damage role in response to APAP intoxication

The Involvement of Mesotocin in Incubation Behavior in the Female Native Thai Chicken.

Y. Chaiseha¹, P. Sinpru¹, N. Sartsoongnoen², M. El Halawani³;

¹School of Biology, Suranaree University of Technology, Nakhon Ratchasima, Thailand, ²Program of Biology, Nakhon Ratchasima Rajabhat University, Nakhon Ratchasima, Thailand, ³Department of Animal Science, University of Minnesota, St. Paul, MN

Oxytocin (OT) is well known to induce and regulate maternal behaviors in mammals via the supraoptic nucleus and paraventricular nucleus (PVN). In the native Thai chicken, mesotocin (MT; the avian homolog of OT) is associated with the reproductive cycle and rearing behavior in the nucleus preopticus medialis (POM) and PVN, whereas the function(s) of MT in incubation behavior is poorly understood. Therefore, the aim of this study was to investigate the role of MTergic system on incubation behavior in the native Thai chicken. Changes in the number of MT-immunoreactive (-ir) neurons that determined by immunohistochemistry in the nucleus supraopticus, pars ventralis (SOv), POM, and PVN of incubating hens (INC) were compared with those of nest-deprived hens (ND) on days 6, 10, 18, 21 (n=5). The results revealed that the number of MT-ir neurons in the PVN was high during incubation and decreased when hens were deprived of their nests for 6, 18, and 21 days ($P < 0.05$), but the difference was not observed within the SOv and POM between INC and ND groups. This study demonstrated, for the first time, the association between the MTergic system and incubation behavior in the SOv, POM and PVN, suggesting that the induction and maintenance of incubation behavior might be, in part, regulated by the MTergic input from the PVN.

P763**Board Number: B1069****Catecholaminergic Receptors in Peripheral Blood Mononuclear Cells: Opening the Pandora Box of Inflammatory Obesity?.**F. Leite^{1,2,3}, A.H. Santos^{1,2,3}, M. Lima^{2,3}, M. Legnaro⁴, F. Marino⁴, M. Cosentino⁴, L. Ribeiro^{1,5};¹Department of Biochemistry, Univ Porto (FMUP), Porto, Portugal, ²Clinical Haematology, Centro Hospitalar do Porto, Porto, Portugal, ³UMIB/ICBAS - Unit for Multidisciplinary Investigation in Biomedicine, Instituto de Ciências Biomédicas Abel Salazar, Porto, Portugal, ⁴Center of Research in Medical Pharmacology, University of Insubria, Varese, Italy, ⁵Medical Education and Simulation, Faculty of Medicine of the University of Porto,, Porto, Portugal

It is not clear at present which neuroendocrine regulators or metabolic factors affect the immune system in inflammatory obesity. Catecholamines (CA) regulate both metabolism and immune response. CA are synthesized by immune cells and modulate their function through adrenergic receptors (AR) and/or dopaminergic receptors (DRD1-5). The expression of both AR and DRD in immune cells under an obesogenic state is unknown. We hypothesize that the adrenergic and dopaminergic systems present in peripheral blood mononuclear cells (PBMCs) are important neuroendocrine regulators in inflammatory obesity.

We studied 63 blood donors considering waist circumference (WC), lipid profile, plasmatic CA and leptin. Monocyte subpopulations were investigated by flow cytometry using CD14, CD16, CD11b and CD36 markers. β 2-AR (n=60), DRD1-5 and tyrosine hydroxylase (TH) (n=30) expression was evaluated in PBMCs by real-time PCR. Ratio (R) between DRD and TH mRNA expression between individuals with and without central obesity (CO) was calculated. R <0.5 was considered under and >2.0 over expression. CO was defined according to the International Diabetes Federation criteria by using WC (\geq 80 cm for women and \geq 94 cm for men).

CO individuals showed higher plasmatic levels of total cholesterol (p=0.031), VLDL-cholesterol (p=0.023), triacylglycerol (p=0.034) and leptin (p<0.001) compared with non-centrally obese. CD16+ monocytes counting was similar in both groups, but showed lower cellular complexity (p=0.014) and lower CD14 expression (p=0.025) in CO. CO group showed lower β 2 AR expression comparatively to non CO group (p=0.002). While DRD1 was undetected in PBMCs, no differences were found in DRD3 and DRD4 expression between groups. DRD2 (R=0.25; p=0.001), DRD5 (R=0.13; p=0.001) and TH (R=0.43; p=0.004) were under expressed in CO in comparison with non-CO. DRD2 expression was positively correlated with both TH (r=0.771; p<0.001) and CD11b (r=0.927; p<0.001). VLDL, triacylglycerol and leptin plasmatic levels correlated negatively with the expression of DRD2 in PBMCs. In CO, DRD2, DRD5 and TH expression positively correlated with the plasmatic levels of HDL-cholesterol [r=0.605; p=0.013), (r=0.689; p=0.003), (r=0.500; p=0.049), respectively].

Taken together, these results suggest that β 2 AR, DRD2 and DRD5 under expression on PBMCs are associated with a higher inflammatory phenotype of peripheral immune cells and with a more atherogenic lipid profile in inflammatory obesity. Characterizing the involvement of CA in the cross-talk

between adipose tissue and immune cells will likely provide novel clues to the understanding of the mechanisms leading to obesity-associated chronic inflammation.

Hyperhomocysteinemia promotes CD40-CD40L mediated inflammatory monocyte induction in cardiovascular disease via DNA hypomethylation.

J. Yang^{1,2}, E.T. Choi^{1,3}, X. Yang^{1,2,4,5}, H. Wang^{1,2,4,5},

¹Centers for Metabolic Disease Research, Temple University School of Medicine, Philadelphia, PA,

²Department of Pharmacology, Temple University School of Medicine, Philadelphia, PA, ³Surgery, Temple University School of Medicine, Philadelphia, PA, ⁴Cardiovascular Research, Temple University School of Medicine, Philadelphia, PA, ⁵Thrombosis Research, Temple University School of Medicine, Philadelphia, PA

Hyperhomocysteinemia (HHcy), which is indicated by elevated plasma concentration of Hcy (homocysteine), a common risk factor for atherosclerosis, similar to smoking and hyperlipidemia. Previously we reported that Hcy elevates inflammatory monocyte (MC), promotes recruitment of inflammatory MC into atherosclerotic lesion, and contributes to vascular inflammation in animal model of HHcy. The mechanisms mediating the induction of inflammatory MC in human blood are not clear. Blood cell from cardiovascular disease (CVD) patients (n=28) and healthy donor (n=14) were assessed for phenotype characterization by flow cytometry. We found that Hcy, inflammatory MC are increased, positively correlated with CD40+ MC, negatively correlates with Hcy metabolites; S-adenosylmethionine/S-adenosylhomocysteine (SAM/SAH ratio), an indicator of methylation. Hcy produced inflammatory cytokines; IL-6, and TNF α , and synergistically upregulated CD40, reduced CD40 transcription and DNA methyltransferase 1 activity in cultured human MC. We identified two IFN γ /TNF α -responsible DNA hypomethylation CpG dinucleotides at p65 and PU.1 transcription factor consensus sequences on CD40 promoter in white blood cells isolated from CVD patients by Bisulfite pyrosequencing. Triggering CD40 by CD40 ligand (CD40L) induced while blocking CD40L ligation suppressed inflammatory MC development in cultured peripheral blood mononuclear cells. These findings suggest that Hcy potentiates inflammatory cytokine mediated-CD40 induction via CD40 DNA hypomethylation and inflammatory MC induction after binding of CD40 by CD40L.

A phloroglucinol and 3,4-(dihydroxyphenyl) acetic acid fraction with Vitamin C mediates the killing of *Trypanosoma brucei brucei* in vivo and ameliorates the parasite-associated pathological changes.

M. Ibrahim¹, A.M. Musa¹, H.T. Taye¹, M. Kassim¹, A.B. Aliyu¹, N. Habila¹;

¹Ahmadu Bello University, Zaria, Nigeria

The effects of a combined administration of a low dose phloroglucinol and 3,4-(dihydroxyphenyl) acetic acid-rich fraction of *Khaya senegalensis* (pfks) and vitamin C on the severity of *Trypanosoma brucei brucei* infection was investigated. Rats were intraperitoneally infected with *T. brucei brucei* and orally treated with a combination of pfks (100 mg/kg BW) and vitamin C (100 mg/kg BW). At the end of the experiment, the combined treatment demonstrated potent antitrypanosomal effects because it almost eliminated the parasites from the bloodstream (0.87 ± 0.09 (x10⁸) trypanosomes/mL) of the infected animals compared to infected untreated control (38.76 ± 4.21 (x10⁸) trypanosomes/mL). Furthermore, the trypanosome-induced pathological alterations such as anemia, hepatic and renal damages were reversed to near-normal by the combined treatment. Data from the study suggest that the combined treatment of a low dose of pfks and vitamin C is therapeutically potent as antitrypanosomal regimen and could effectively ameliorate the trypanosome-induced anemia and organ damage.

Sox9 positive cells contribute renal epithelial cell regeneration and kidney fibrosis development.

H. KANG¹, K. SUSZTAK¹;

¹University of Pennsylvania, Philadelphia, PA

Sox9 is one of the important transcription factors controlling cell proliferation, fate and differentiation in the development of many tissues and organs. Here we examined the role of Sox9 in renal epithelial cells.

To test the role of Sox9 in renal epithelial cell, we generated mice with tubule epithelial specific Sox9 deletion, by intercrossing the PAX8 rtTA-TetO cre and Sox9 floxed animals. In addition, we also isolated Sox9 positive cells from the mouse kidney to examine the proliferation and differentiation capacities in vitro.

To define the transcription factor related to progenitors in the kidney, we isolated tubule epithelial cells which showed proliferation and differentiation capacity in vitro. We performed genome wide gene expression analysis using microarrays and found cells that show high proliferation and differentiation

capacity had high Sox9, Lgr4, Foxd1 and Pax8 expression. In control mouse and human kidneys, Sox9 is rarely detected in the tubules but in injury models its expression is highly increased most tubules, especially dilated proximal tubules. To test whether Sox9 contributes to kidney regeneration we generated mice with tubule specific deletion of Sox9. These animals developed more severe injury after folic acid injection than wild type animals. Fibronectin, collagen1a and 4a were significantly increased and proliferation markers, cyclin A, B, D and E were remarkably decreased in Sox9 deleted kidney. Similar results were observed in different time courses, 4 weeks and 16 weeks after folic acid injection. In particular, we isolated Sox9 positive cells from mouse kidney and they showed the ability to self-renew and expressed progenitor cell markers. They also showed multi lineage differentiation potential especially renal tubule cells under the specific condition in vitro.

In summary, we demonstrated that Sox9 plays an important role in proliferating and regenerating the renal tubule epithelial cells. Deletion of Sox9 leads decreases proliferation and induce fibrosis development. Sox9 positive cells may represent progenitor cells in the regenerating kidney.

Single-pedicled fasciocutaneous flap survival in ageing rat model of voluntary cardiovascular exercise.

E. Aksamitiene^{1,2}, A.L. Baker¹, S. Roy¹, S. Hota¹, L. Zhang¹, K. Hobelmann¹, J. Rodin¹, R.N. Heffelfinger¹, J.B. Hoek², E.A. Pribitkin¹;

¹Department of Otolaryngology - Head and Neck Surgery, Thomas Jefferson University, Philadelphia, PA,

²Department of Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA

Impact of cardiovascular voluntary exercise on signaling events underlying composite flap survival was examined in twelve young adult (2 month old) and twelve older adult (6 month old) Sprague-Dawley rats that either had access to running wheel (exercising group, n=6) or not (resting group, n=6) prior to surgery, where a 3:8 width to length ratio pedicled fasciocutaneous flap based on the inferior epigastric artery was raised in each rat and rotated into a defect created in the ventral surface. Histological Hematoxylin and Eosin staining was performed on the flap segments of the biopsies taken on 7th post-operative day (POD). Tissue from the contralateral recipient site was snap frozen and used as baseline (day 0) for Western Blotting data comparison with the biopsies taken on 2nd, 5th and 9th POD. Endogenous VEGF-A, and FGF-2 protein expression, PARP cleavage and activating phosphorylation of Akt, STAT3, p38 MAPK and ERK1/2 were measured in proximal, middle and distal segments of the harvested flaps to reflect the pro-angiogenic, inflammatory, anti-apoptotic, stress, motogenic and mitogenic cellular responses. β -Actin, α -Tubulin, Grb2 and/or GAPDH levels were detected in the same loading of protein-adjusted lysates and used for signal normalization. Young and older exercising rats had significantly higher flap survival rates than their resting counterparts, which coincided with overall elevated VEGF-A levels, stronger PI3-kinase/Akt and MAPK activation and decreased apoptotic PARP cleavage, suggesting that exercise shortens inflammatory phase of wound healing and stimulates flap cell proliferation and motility. Moreover, young resting rats had higher basal VEGF-A levels than resting

old rats. Compared to the resting group, FGF-2 expression and tyrosine phosphorylation of STAT3 was augmented in all flap segments of exercising young adult rats, but there was no significant difference between resting and exercising older adult rats. Given multiple reports on the positive feedback of STAT3 to wound healing response, as well as the potential of FGF-2 to synergize with VEGF-A in promoting neo-angiogenesis and thus better nutrient/oxygen supply, our results may explain why the flaps of younger rats integrate better within the surrounding tissue than those of old rats.

neuroprotective and vasculoprotective microRNA-195 in stroke treatment.

S.H. Juo¹, h. cheng¹, Y. Wang²;

¹Genome Medicine, Kaohsiung Med Univ, Kaohsiung, Taiwan, ²National Taiwan University, Taipei, Taiwan

Acute ischemic stroke has been a major cause of death and the most important factor for disability worldwide. To protect ischemic but still viable neurons from apoptosis may reduce the impact from stroke. Currently, tissue plasminogen activator (tPA) is the only FDA approved drug to treat acute stroke. However, tPA does not have neuroprotective effect and tPA may also cause brain hemorrhage, which restrict its clinical use. We identified a neuroprotective and vascular protective microRNA called microRNA-195 (miR-195).

Two miR-195 binding sites were predicted in the 3'UTR of mRNA of the sema3A gene. Using the reporter assay, we experimentally confirmed these two binding sites. In vivo studies demonstrate that sema3A can influence several down-stream genes including up-regulation of CCND1, Cdc42, FasL, caspase-3, and down-regulation of Bcl-2. Our cellular studies show that sema3A levels are increased and miR-195 levels are decreased when the neuron cell line (SH-SY5Y) is damaged by oxygen-glucose deprivation (OGD). Furthermore, neuron cell viability was reduced by 35% after 3-h OGD and by 55% after 6-h of OGD. If miR-195 was transfected into the cell at 3h and 6h of OGD, a dose-dependent effect on rescuing the OGD-damaged cells was observed.

Previously we have reported that miR-195 has vascular protective effects by reducing inflammation. Now we further identify that miR-195 can suppress an NFkB upstream membrane receptor, which leads to inhibit NFkB pathway. In addition, miR-195 also directly target a component of NFkB complex. Interestingly, an NFkB binding site has been discovered in the promoter of miR-195 gene, and NFkB acts as a negative transcription factor for miR-195. Therefore, NFkB and miR-195 have reciprocal regulation.

To further test the clinical application of miR-195, ischemic stroke is induced in male SD rats by middle cerebral artery occlusion (MCAO) for 24 hours. Formulated miR-195 is injected to the tail vein after the onset of stroke. The animals are killed at 24h and brain infarct sizes were measured. The infarct size can be reduced by 30-40% when miR-195 is injected by 4.5h after stroke. Even though the treatment is at 6h

after stroke, infarct size can be still reduced by 20%. Noticeably, the major limitation of tPA in treating ischemic stroke is the concern of brain hemorrhage, but miR-195 has no such a side effect.

In conclusion, our cellular and animal data suggest miR-195 can be used a therapeutic agent to treat acute ischemic stroke. The lack of hemorrhage side effect and the longer therapeutic window between onset of stroke and miR-195 treatment make this molecule as a promising new drug.

Expression of semaphoring 3F in rat retinal ganglion cells after optic nerve crush.

J. Ko¹, C. Ohki², Y. Sugimoto², J. Hirata², Y. Kiuchi²;

¹Hiroshima Univ Grad Sch Biomedical Sciences, Hiroshima Hiroshima, Japan, ²Hiroshima Univ Grad Sch Biomedical Sciences, Hiroshima, Japan

Damage to the optic nerve in mammals induces degeneration and apoptosis of the retinal ganglion cell (RGC). Although many factors have been recognized to mediate RGC degeneration in glaucoma, but, the mechanism and process are largely unknown. Semaphorin are a family of glycoproteins that play an important role in repulsive axon guidance during embryogenesis, also, it has been reported to the functional involvement in neuronal apoptosis. We have now investigated that the expression of class 3 semaphorins, and the role of semaphorin in rat RGC after optic nerve crush.

Optic nerve crush injury was induced in Long avans rats. Eyes and retinas were collected at intervals of 3, 7 and 14 days after procedure. Aa a results, we found a decrease in semaphorin 3F levels in the retina at 7 and 14 days after optic nerve crush, but no change in others semaphorin 3 class (sema 3A, 3B or 3C). Particularly, these decreasing expression was seen in the retinal ganglion cell layers of retina. These events were also shown in retinal organ culture using retinas after optic nerve crush and control. These results suggest that neural guidance gene semaphorin 3F may play an important role in the regulation of retinal ganglion cells functions and provide more information about RGC survival.

Ubiquitin-Proteasome Pathway Activity in Cultured Oral Mucosal Epithelial Cell Sheet Grafts Used for Treatment of Experimental Limbal Stem Cell Deficiency in Rabbits.

F. Bardag-Gorce¹, I. Meepe¹, A.K. Wood¹, J. Garcia¹, D. Pan¹, J. Oliva¹, R.H. Hoft¹, Y. Niihara¹;

¹LA BioMed At Harbor UCLA, Torrance, CA

Cultured oral mucosal epithelial cell sheets (COMECS) have been proven successful in reconstructing the ocular surface. Harvested from a temperature responsive culture ware, COMECS quickly adhere and reepithelialize the cornea surface, thus speeding up wound healing process. The mechanism of action of

COMECS is complex. Our present study focused on characterizing COMECS ubiquitin-proteasome pathway to determine its role in the therapeutic effects of COMECS. Corneal epithelial cells scraped off the ocular surface of rabbits with limbal stem cell deficiency (LSCD, 3 months post limbectomy) showed a significant decrease in the proteasomal chymotrypsin-like, trypsin-like and caspase-like activities, while COMECS and normal corneal epithelial cells without experimentally-induced LSCD showed significant higher activities. The histological analysis also showed that COMECS stained positive for proteasome subunits beta5, beta1 and Rpt4, an ATPase subunit involved in the ubiquitin proteasome pathway responsible for clearance of damaged and aggregated proteins. Western blot analysis quantified the amount of proteasome subunits and our results showed that COMECS has higher levels of proteasome beta5, as well as higher levels of alpha subunits of the 20S proteasome, when compared to LSCD corneal epithelial cells. The ubiquitin-proteasome pathway was also histologically examined in cornea tissue sections of rabbits grafted with autologous COMECS. Results showed that grafted cornea stained positive for beta5 as well as for Rpt4. Similar to normal healthy corneas, grafted corneas showed that beta5 staining was localized in the cytoplasm and to a lower extent in the nucleus of basal cells. In contrast, corneas with induced LSCD that did not receive COMECS grafts markedly stained in the nucleus, suggesting a nuclear translocation of proteasome in the diseased cornea. In conclusion, our results showed that COMECS include higher levels of proteasome activities compared to LSCD cornea epithelial cells, indicating that COMECS grafting improves or restores the function of the ubiquitin proteasome pathway that is lacking in diseased cornea epithelium with LSCD. Mesenchymal stem cells (MSC) are adherent cells which come from several tissues. These cells have the capability of differentiation to chondrocytes, adipocytes, myoblasts and osteoblasts (plasticity). In vitro expansion in large scale with high viability, make of them suitable candidates in clinical application in the field of regenerative medicine and cell therapy for improve structural and functional tissues. In Mexico diabetes is one of the more important health problem with economic loss due incapacity of worker people and treatment for this has poor successful and finally the patient has loss of limb. In another hand in accordance with the criteria of ISCT (international society for cellular therapy), autologous MSC could be a suitable alternative for tissue regeneration and healing the damage produced in diabetic foot. In this work we showed two cases where autologous MSCs under criteria of ISCT were applied. MSCs

were cultured under quality conditions avoiding the use of SFB. Cells were applied in third passage and it was carry of wound healing during seven months. Evident regeneration and a partial functionality recover were showed in the patients treated with MSCs indicating that this procedure could be implemented as a treatment in lesions with severe damage and not only in diabetic foot. Mechanisms involved in the regeneration by the MSCs are now studied by our group of work.

Effect of dehydroepiandrosterone and (-)-epicatechin in the expression of BMP2, SPARC and RUNX2 in Mesenchymal Stem Cell from human Bone Marrow.

H. Diaz¹, L.F. Acevedo¹, A. Parra¹, J.L. Salas¹, J.E. Rios¹, X. Castro¹, J.M. Araujo¹, G.M. Ceballos¹, E. Mera¹, G. Gutierrez¹;

¹Escuela Superior de Medicina, Instituto Politécnico Nacional, Mexico City, Mexico

Introduction: Osteoporosis is a disease which is characterized by loss of bone and susceptibility to fractures¹. Although it has been applied different treatments most of them have important side effects and little benefits². On the other hand, has been demonstrated that antioxidants like dehydroepiandrosterone (DHEA) and (-)-epicatechin (EC) of green tea can improve bone density of menopausal women³. For this reason, in this work we studied the effect of DHEA and EC over expression of osteogenic genes (SPARC, RUNX2 and BMP2) in human Bone Marrow Mesenchymal Stem Cells (hBM-MSC). Methodology: hBM-MSCs were isolated from healthy people and characterized according the International Society for Cell Therapy standards, after that the cells were treated with different combinations of DHEA and EC for seven days and total RNA were obtained and used for final point PCR. Results: Ours endogenous gene (GAPDH) were expressed in all samples, in the same way SPARC and RUNX2 were present in all conditions. BMP2 was absent in the negative control (DMEM-F12 medium) and present in the positive control (osteogenic medium), while the cells with DHEA 1, 10 and 100uM express BMP2. When DHEA was mixed with 100uM of EC the expression was less, but DHEA 1, 10 and 100uM with 1uM of EC, BMP2 was inhibited. But when we mix DHEA 10 and 100 with 10uM of EC the expression of BMP2 were increased and it was absolutely inhibited with DHEA 1uM and EC 10uM. EC at 1 and 100uM induced BMP2 expression but not at 10uM. Conclusions: EC and DHEA in low concentrations induce expression of osteogenic gene (BMP2), which could result in improvement of bone density; this could be useful in the treatment of different bone diseases not only in osteoporosis. P773**Board Number: B1079****Fluorescence lifetime FRET measures transferrin tumor uptake using in vivo small animal imaging: Implications in the development of targeted drug therapy for estrogen receptor positive breast cancer.**A. Rudkouskaya¹, S. Rajoria¹, L. Zhao², X. Intes², M.M. Barroso¹;¹Cardiovascular Sciences, Albany Med Coll, Albany, NY, ²Biomedical Engineering, Rensselaer Polytechnic Institute, Troy, NY

Traditional cancer therapy generally leads to harmful side effects, thus warranting development of targeted therapies, which are better tolerated by cancer patients. Our goal is to develop *in vivo* non-invasive optical imaging assays for optimization of anti-cancer drug targeted therapy. We have established a fluorescence lifetime Förster Resonance Energy Transfer (FL-FRET) non-invasive whole-body *in vivo* imaging technique that can discriminate bound and internalized near-infrared (NIR)-labeled transferrin (Tfn) from free, soluble NIR-Tfn. The FRET-based assay exploits the homodimeric nature of transferrin receptor (TFR) that binds two molecules of Tfn in close proximity to determine dimerization and internalization of TFR-Tfn complexes into cancer cells. The Tfn FRET assay has been validated *in vitro* by visible intensity-based confocal microscopy and visible and NIR fluorescence lifetime microscopy (FLIM). Our approach provides a new method to optimize targeted drug therapy by accurately quantitating *in vivo* the tumor uptake of NIR-Tfn-drug conjugates, since the expression of TFR is upregulated in a wide variety of human tumors. T47D human breast cancer cells, a model of estrogen receptor positive (ER+) human breast cancer, show the highest TFR expression and Tfn uptake in comparison to those of normal human mammary epithelial cells (HMEC), suggesting that Tfn can be used as specific targeting ligand to ER+ breast cancer cells. FL-FRET tomographic imaging *in vivo* has been used to measure the internalization of tail-vein injected NIR-Tfn into human breast T47D tumor xenografts in live nude mice. Immunohistochemistry of tumor sections suggests that the injected NIR-Tfn is translocated to the tumor site. Quantification of FRET donor % (FD%) in T47D tumor xenografts *in vivo*, indicates a higher proportion of FD% with increasing acceptor:donor ratio, demonstrating tumor uptake of NIR-Tfn. Tfn uptake concentration curve shows high sensitivity of FL-FRET imaging using NIR-Tfn as low as 10µg/ml of blood. Furthermore, relative high FD% for holo-Tfn (iron-loaded) compared to that of apo-Tfn (iron-depleted) demonstrates specific TFR-mediated uptake of holo-Tfn by T47D tumor xenografts, as expected since iron-depleted apo-Tfn shows reduced binding affinity towards TFR. Recently, NIR-Tfn-oxalate, an iron release chemical mutant, has been tested in our tumor imaging assay. Elevated FD% levels of NIR-Tfn-oxalate are detected in T47D tumor xenografts in comparison to those of holo-Tfn, indicating increased NIR-Tfn-oxalate tumor cellular accumulation. In conclusion, our novel NIR FL-FRET assay successfully demonstrates the quantitative receptor-mediated uptake of Tfn into human breast tumors *in vivo* using a novel non-invasive NIR FL-FRET imaging assay.

P774**Board Number: B1080****Substance P modulates essential properties of murine bone marrow-derived stromal cells.**M.J. Dubon¹, N. Jung², J. Um¹, Y. Son^{3,4}, K. Park⁵;

¹Graduate School of Biotechnology, Kyung Hee University, Yong-In, Korea, ²Graduate school of Biotechnology, Kyung Hee University, Yongin, Korea, ³Graduate School of Biotechnology, Kyung Hee University, Yongin, Korea, ⁴Department of Genetic Engineering, Kyung Hee University, Yongin, Korea, ⁵East-West Medical Research Institute, Kyung Hee University, Seoul, Korea

Bone marrow-derived stromal cells (MSCs) have self-renewal characteristics, multilineage differentiation potential and are able to mobilize from the bone marrow (BM) into peripheral tissues where they promote wound healing and tissue repair. Previous studies demonstrate that substance P (SP) induces the proliferation of MSCs *in vitro* and promotes the migration of MSCs from the BM to injury sites. The aims of this study were to evaluate 1) the effects of SP on the homeostasis of MSCs within the BM, 2) whether SP can affect the differentiation potential of MSCs, 3) the effects of SP on factors that could be involved in the regulation of cell trafficking between the BM and the periphery, and 4) the mechanism involved in the mobilization of MSCs. Furthermore, we investigated the effects of SP on the proliferation and migration potential of MSCs *in vitro* using two mouse-derived MSCs like cell lines (OP9 and ST2) and searched for the mechanisms involved in the SP-mediated proliferation and mobilization of these cells. We found an increase in the CFU-F forming population of total bone marrow cells 2 days after SP injection. The mRNA levels of osteogenic markers (osteopontin and type 1 collagen) increased 1 day after SP injection, suggesting that SP induces the differentiation of MSCs towards this lineage. We also found an increase in the mRNA levels both of N-cadherin and SDF-1 at 1 day after SP injection which suggests their involvement in the mobilization of MSCs mediated by SP and in the regulation of stem cell trafficking between the BM and the periphery, respectively. Substance P induced the migration potential of ST2 cells and increased the proliferation of OP9 cells. Overall, these data suggests that SP has the ability to modulate certain properties of MSCs linked to their therapeutic potential and trafficking. Yet, the mechanisms involved in the SP-mediated proliferation and mobilization of MSCs remain to be explored in further experiments. (Supported by NRF-2012M3A9C6050499 and NRF-2012R1A1A2042265)

P775**Board Number: B1081****The effect of Mild Electrical Stimulation with Heat Shock on kidney dysfunction in type 2 diabetic KKAY mice.**Y. Kai¹, R. Fukuda¹, K. Omachi¹, Y. Okamoto¹, M. Suico¹, T. Shuto¹, H. Kai¹;¹Molecular Medicine, Kumamoto Univ Sch Pharm, Kumamoto, Japan

Diabetic Nephropathy (DN) is the most common cause of end-stage renal disease, but the treatment to decelerate the progression of DN is still inadequate. We previously showed that mild electrical stimulation (MES) with heat shock (HS) treatment ameliorated insulin resistance and suppressed some inflammatory cytokines in diabetes mouse models by enhancing insulin-stimulated Akt-phosphorylation. Furthermore, we showed MES+HS restrained the progression of albuminuria/proteinuria and nephritis in Col4a5 mutant mouse, which is a mouse model for hereditary glomerulopathy. However, it is uncertain whether MES+HS ameliorates kidney dysfunction in diabetes. In this study, we evaluated the effect of MES+HS on kidney dysfunction in type 2 diabetes model KKAY mice. Although, MES+HS did not affect the progression of albuminuria/proteinuria and renal injury in KKAY mice, MES+HS tended to suppress pro-inflammatory cytokines (IL-6, IL-1 β), and kidney injury marker (Lcn-2) in kidney. Furthermore, the kidney weight tended to be suppressed in MES+HS-treated mice. These results suggest that MES+HS improves renal hypertrophy in DN. Additionally, MES+HS improved insulin sensitivity assessed by intraperitoneal insulin tolerance test. In MPC-5, MES+HS suppressed high glucose-induced apoptosis via p38 pathway. Collectively, MES+HS improved not only diabetic phenotype but also kidney dysfunction in KKAY mice. Our data suggested that MES+HS has beneficial effect on kidney and MES+HS could be a novel therapeutic strategy for the amelioration of DN pathologies.

P776**Board Number: B1082****Substance P delays onset of type 1 diabetes.**J. Um¹, N. Jung², S. Choi³, Y. Son^{1,3}, K. Park⁴;¹Graduate School of Biotechnology, Kyung Hee University, Yongin, Korea, ²Graduate school of Biotechnology, Kyung Hee University, Yongin, Korea, ³Department of Genetic Engineering, Kyung Hee University, Yongin, Korea, ⁴East-West Medical Research Institute, Kyung Hee University, Seoul, Korea

Pancreatic islet in type 1 diabetes is characterized with the decrease in β -cell mass following autoimmune destruction. In this study, we investigated whether substance P (SP) can delay the onset of diabetes in non-obese diabetic (NOD) mice as SP plays key roles to modulate immune response. When SP (5 nmoles/kg) had been intravenously administered into NOD mice for 14 weeks or 21 weeks, hyperglycemia was delayed. Consistent with this result, SP preserved β -cells at the time points. Moreover, we found that SP increased β -cell proliferation in vitro. SP group also decreased significantly in infiltration degree of immune cells such as CD3 positive cells in comparison to the control mice. Furthermore, as we assumed that SP could systemically affect immune modulation, we analyzed

immune infiltration into salivary glands of NOD mice. SP treatment reduced immune infiltration into salivary glands. Collectively, it is likely that SP might play inhibitory roles in the progress of type 1 diabetes through the maintenance of β -cells homeostasis and the systemic immune modulation. (Supported by NRF-2012M3A9C6050499, NRF-2012R1A1A2042265, and HI13C1479)

Substance P preserves pancreatic endocrine β -cells in type 2 diabetes.

N. Jung¹, D. Kim², J. Um¹, M.J. Dubon¹, Y. Byeon¹, S. Lee², J. Moon², Y. Son^{1,3}, K. Park⁴;

¹Graduate School of Biotechnology, Kyung Hee University, Yongin, Korea, ²Gangdong Kyung Hee University Hospital, Seoul, Korea, ³Department of Genetic Engineering, Kyung Hee University, Yongin, Korea, ⁴East-West Medical Research Institute, Kyung Hee University, Seoul, Korea

A decrease in pancreatic β -cell population may contribute to the progress of type 2 diabetes. It has been reported that substance P (SP) can regenerate damaged tissues. Therefore, we investigated the effects of SP on the regeneration of β -cell population in db/db type 2 diabetic mice. For this purpose, mice were injected with SP (5 or 50 nmoles/kg) twice a week for 12 weeks. SP treatment reversed hyperglycemia in db/db mice. Interestingly, SP preserved population of β -cells in pancreas of db/db mice. It is also well known that pancreatic satellite cells (PSCs) are activated in response to pancreatic injury and the activated PSCs express α -smooth muscle actin (α -SMA). Significantly, the activated PSCs decrease mass of β -cells. We found SP reduced the frequency of intra-islet α -SMA positive cells in db/db mice. In our previous works, SP increases the cellular proliferation of β -cell in response to pancreas injury. Based on these results, we hypothesized whether SP can increase the cellular proliferation of β -cells for maintenance of β -cell homeostasis in db/db mice. To examine this hypothesis, we carried out BrdU incorporation assay by use of MIN6 cell line under high glucose condition. Importantly, SP increased the cellular proliferation of MIN6 cells. Taken together, it is very likely that SP might maintain β -cell homeostasis in type 2 diabetes through the increased proliferation of β -cells. (Supported by NRF-2012M3A9C6050499, NRF-2012R1A1A2042265, and HI13C1479)

IDOL Inhibitors for the Treatment of Hypercholesterolemia.

J.G. Marblestone¹, M. Eddins¹, J. Wu¹, J. LaRocque¹, S. Agarwal², M.R. Mattern¹, S. Kumar¹;

¹RandD, Progenra Inc., Malvern, PA, ²Progenra Inc., Malvern, PA

Despite the widespread use of statins and other approved therapeutics, hypercholesterolemia represents a significant medical issue for a large group of patients unable to effectively regulate their cholesterol levels, contributing to significant morbidity and mortality. Cholesterol uptake is primarily mediated by the hepatic low density lipoprotein receptor (LDLR) which binds and internalizes plasma

LDL. Elevated levels of LDLR are associated with reduced LDL levels and vice versa. Recently, the E3 ligase IDOL (Inducible Degradator of LDLR) was shown to be a key regulator of LDLR protein levels. IDOL is a unique E3 ligase that utilizes its FERM domain to specifically target LDLR for polyubiquitylation and subsequent lysosomal degradation. Genetic ablation of IDOL results in elevated levels of LDLR protein. Thus, inhibition of IDOL may be a beneficial approach for the treatment of hypercholesterolemia.

The ubiquitin-proteasome system provides a rich landscape for drug discovery. E3 ligases in particular are considered attractive therapeutic targets in a wide variety of disorders including metabolic disorders. The recent discovery that the IMiD class of drugs targets Cereblon E3 ligase provides the therapeutic validation of the E3 ligases. However, discovery and development of E3 ligase inhibitors as first in class clinical candidates remain challenging.

Here we report that using our UbiPro™ drug discovery platform we have discovered novel IDOL inhibitors that modulate cellular cholesterol homeostasis. Specifically these compounds increased LDLR levels and increased LDL association in various cellular models. Biophysical characterization revealed direct binding of the compounds to IDOL and perturbation of IDOL:LDLR interactions. The most promising compounds were used as starting point to develop novel drug like molecules and the efficacy of the lead compounds is being evaluated in translational models of hypercholesterolemia. Data will be presented summarizing our progress to date targeting IDOL for the treatment of hypercholesterolemia.

Apomine, an inhibitor of cholesterol synthesis, increases secretion of apolipoprotein E from human astrocytoma and liver hepatocyte cells.

C.M. Ott¹, J.T. Schott¹, P. De Lijser², N.V. Patel¹;

¹Biological Science, California State University, Fullerton, Fullerton, CA, ²Chemistry and Biochemistry, California State University, Fullerton, Fullerton, CA

Apolipoprotein E (apoE) genotype is the biggest known risk factor for Alzheimer's disease (AD). ApoE is an important protein involved with cholesterol homeostasis and other AD-associated processes. Apomine is a potent cholesterol-reducing compound that possibly mediates its actions through proteolytic degradation of HMGCoA-reductase (the rate-limiting enzyme in cholesterol synthesis) and may affect apoE levels. We hypothesize that cells treated with Apomine are programmed to increase apoE secretion to capture and internalize more cholesterol through lipid membrane receptors from external sources to compensate for the loss of HMGCoA-reductase activity.

Treatment of human CCF-STTG1 astrocytoma with Apomine in serum-free medium leads to a significant increase in secreted apoE (1.5-fold; determined by ELISA). Despite the increase in apoE secretion, there was not a significant increase in apoE mRNA expression (as determined by qPCR) in CCF-STTG1 cells. Consistent with our hypothesis, we found that Apomine increases expression of mRNA for several surface apoE receptors. This may be in-part due to Apomine-mediated decrease in inducible-degrader of

low-density lipoprotein receptor (LDLR) mRNA levels. This suggests that CCF-STTG1 cells will have increased levels of cell surface lipid receptor proteins, in preparation to uptake cholesterol-bound apoE.

Apomine-treated HepG2 liver hepatocyte cells also yielded increased levels of secreted apoE in serum-free medium (1.75-fold). Apomine treatment also increased mRNA levels for low-density lipoprotein receptor (LDLR) and very-low density lipoprotein receptor (VLDLR), but not other apoE receptors. However, in contrast to CCF-STTG1 cells, apoE mRNA was increased two-fold. This suggests that HepG2 cells will have increased apoE protein production and cell surface lipid receptor proteins to facilitate import of apoE-bound cholesterol.

This increase in secreted apoE was completely blocked if the HepG2 cells were treated with Apomine in bovine growth serum-containing medium. These results indicate that the presence of cholesterol in the growth medium suppresses the cell's drive to search for cholesterol through increased apoE secretion. These data suggest that Apomine regulates apoE expression at both the transcriptional and post-translational levels. This novel regulation of apoE expression by Apomine is relevant to the fields of AD and other cholesterol homeostasis related processes.

Defining genetic pathways of disease through genetic suppression screens in *Caenorhabditis elegans*.

A.S. Fabritius¹, A. Golden¹;

¹NIDDK/NIH, Bethesda, MD

There are approximately 7,000 rare diseases known in humans, many of which are monogenic (caused by a mutation in a single gene). *C. elegans* has orthologs of approximately 50 percent of the genes responsible for human diseases. We are using mutants in these orthologous genes in *C. elegans* to perform EMS mutagenesis suppressor screens to find genes that are involved in various disease pathways. This will provide insight into the genetic and molecular mechanisms of these diseases, offering possible therapeutic targets. We are using mutants in the *C. elegans* type IV collagens and the ubiquitin-activating enzyme in suppressor screens to identify potential novel therapeutic targets.

The ubiquitin-activating enzyme in human (UBA1 or UBE1) and in *C. elegans* (*uba-1*) is required for activation of ubiquitin for downstream ligation of ubiquitin by the ubiquitin ligases and subsequent substrate degradation by the proteasome. Mutations in human UBA1 cause early-onset spinal muscular atrophy and are involved in some cancers. UBA-1 is the only known ubiquitin-activating enzyme in *C. elegans* and the temperature sensitive (*ts*) *uba-1(it129)* allele causes embryonic lethality, larval lethality and sperm-specific sterility at restrictive temperatures.

We have obtained suppressors of the larval arrest and embryonic lethality phenotypes in *ts* alleles at restrictive temperatures of *emb-9*, *let-2* and *uba-1*, and we are currently in the process of doing whole genome sequencing to identify the genes responsible for suppression. One promising candidate for

suppression of the emb-9(hc70ts) allele is dig-1, a giant member of the immunoglobulin superfamily. We are currently testing this and other candidates to confirm their identities as suppressors.

We plan to continue to characterize the suppressor mutations as well as the genetic and molecular nature of the suppressor activity that allows the animals with the mutation to survive. We are also continuing mutagenesis screens to find suppressors of additional disease genes. These results will help further define genetic pathways and potentially identify genes that could serve as therapeutic targets to suppress disease symptoms.

Expanding the therapeutic possibilities of NOTCH3 Cysteine Quantity Correction in CADASIL.

A.M. Goldfarb¹, J.W. Rutten¹, J.G. Dauwese¹, D.J. Peters¹, G.J. van Ommen¹, A.M. Aartsma-Rus¹, S.A. Lesnik Oberstein²;

¹Human Genetics, Leiden University Medical Center, Leiden, Netherlands, ²Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands

Cerebral autosomal dominant arteriopathy with subcortical infarctions and leukoencephalopathy (CADASIL) is the most common monogenetic cause of vascular dementia and stroke. CADASIL is caused by highly stereotyped missense mutations in *NOTCH3*, which invariably alter the number of cysteine residues in one of the 34 epidermal growth factor-like repeat (EGFr) domains of the NOTCH3 protein. This results in an EGFr domain with an uneven number of cysteines, which disrupts normal disulphide bridge formation and leads to toxic NOTCH3 accumulation in the vasculature. We hypothesize that re-establishing the correct number of 6 cysteines in an EGFr domain (Cysteine Quantity Correction) leads to restored disulphide bridge formation, thereby counteracting NOTCH3 accumulation. To achieve this Cysteine Quantity Correction, exon skipping is used. In this technique, antisense oligonucleotides (AONs) are used to skip targeted *NOTCH3* exons from pre-mRNA. Previous work has focused on jointly skipping *NOTCH3* exons 4 and 5, which harbour the majority of CADASIL causing mutations. However, at least 12 *NOTCH3* exons are eligible for this exon skipping approach. The current study aims to expand the exon skip approach to other eligible *NOTCH3* exons. AONs targeting these additional exons were transfected into fibroblasts and CADASIL patient derived vascular smooth muscle cells. Isolated and joint exon skipping were successfully observed in *in vitro* experiments. Transient transfection of cDNA deletion constructs lacking the targeted exons showed that modified NOTCH3 proteins are formed. The exon skip approach to re-establish six cysteines now includes strategies to target five of the twelve eligible *NOTCH3* exons, which collectively harbour 57% of the distinct CADASIL-causing mutations. This work is supported by grants from the Brain Foundation of the Netherlands, grant no. F2009(1)-25, The Leiden University Research Institute (LURIS) exemplification grant, and by ZonMw, The Netherlands Organization for Health Research and Development, grant no. 40-41900-98-018.

P782**Board Number: B1088****Effect of 3,4',5-Trismethoxybenzophenone on Hepatitis C-Virus Expressing Hepatoma cells.**C.J. Patton¹, H.R. Kotturi²;¹Department of Biology, University of Central Oklahoma, Edmond, OK, ²Department of Biology, University of Central Oklahoma, Edmond, OK

Hepatitis C virus (HCV) is a positive strand RNA virus. HCV infection is a leading cause of chronic hepatitis (>80%). Chronic HCV infection is considered to be a prominent risk factor for the development of hepatocellular carcinoma (HCC). Currently, FDA-approved triple therapy for treating HCV infections consists of a protease inhibitor, ribavirin, and pegylated interferon (IFN) which is only partially effective and the success of treatment depends on the host's genetic make-up, ethnicity, viral variants, quasispecies, drug-resistance of HCV strains and tolerability. Hence, there is a growing need for developing safer and inexpensive drugs for treating HCV infections and HCC. Human hepatoma cell line (FCA4 cells) that harbors a subgenomic selectable HCV replicon was used to study the effect of 3,4',5-Trismethoxybenzophenone (TMBP). The Huh7 cell line lacking the replicon served as the corresponding control. Western blot was conducted to analyze the viral NS5B polymerase level in FCA4 cells treated with varying concentrations of the drug. The effect of TMBP on cell proliferation/viability was assayed using MTT method. TMBP was found to be highly effective in reducing NS5B polymerase level at 2.5 μ M, which was found to be below its IC₅₀ as determined by the MTT assay. Dimethylsulfoxide (DMSO) used as solvent showed no inhibitory effect on the NS5B abundance. TMBP also exhibited disruptive effects on the normal architecture of the HCV replicon-expressing cells. Only TMBP, but not DMSO inhibited the growth of 3D spheroids in cell culture. Our results indicate that TMBP is effective in inhibiting HCV replication in liver cells at lower concentration. It also possess anti-tumor properties against liver cancer and has a potential to be used as a therapeutic agent.

P783**Board Number: B1089****Screening of small compounds to develop endoplasmic reticulum-oriented drug for familial amyloid polyneuropathy.**K. Chosa¹, S. Takaki¹, R. Yamakawa¹, Y. Wakita¹, Y. Teranishi¹, T. Sato^{1,2}, T. Yokoyama³, M. Mizuguchi³, M. Suico¹, T. Shuto¹, H. Kai¹;¹Molecular Medicine, Kumamoto Univ Sch Pharm, Kumamoto, Japan, ²Cell Fate Control, Kumamoto Univ Institute of Molecular Embryology and Genetics, Kumamoto, Japan, ³Pharmaceutical Sciences, Toyama Univ, Toyama, Japan

Familial amyloid polyneuropathy (FAP) is one of the hereditary amyloidoses caused by point mutation in the human plasma protein, transthyretin (TTR). Amyloid fibrils derived from TTR variants accumulate in peripheral nerves and visceral organs. TTR variants are easily dissociated from tetramer to monomer because of having low energetic stability of their tetrameric structure in comparison with wild-type (WT) TTR. The only treatment currently available for FAP is liver transplantation. Therapeutic agents that are being developed aim at stabilizing extracellular TTR tetramer. Previously, we demonstrated that endoplasmic reticulum (ER) quality control system and ER-associated degradation (ERAD) of TTR are pathological determinants of FAP. The monomeric mutation introduced in the vast majority of TTR mutants that are normally secreted resulted in the ER retention and efficient degradation of these monomeric mutants by ERAD. Therefore, inhibition of TTR tetramerization in ER lumen and suppression of TTR variants secretion could be a promising therapeutic strategy for FAP. Here we employed two approaches to find tetramerization inhibitor, namely structure-based virtual screening (SVS) and high-throughput screening (HTS). In SVS, we identified some candidate compounds with a potential as destabilizer of intracellular TTR tetramer. The selected compounds were assayed using HEK293 cells stably expressing the most common variant, V30M TTR. Our data indicated that some of these compounds inhibited V30M TTR tetramerization and extracellular secretion of V30M TTR, suggesting a possible use for preventing TTR amyloid formation. In HTS, we checked the compounds that have the ability to dissociate or destabilize TTR tetramer by using ANS assay, which is a cell-free, in vitro method. We utilized the chemical library - the Core Library 9600 preserved at Open Innovation Center for Drug Discovery (OCDD) in Tokyo. The number of compounds showing >30% inhibition was 168 compounds ($S/B = 47.1 \pm 2.2$, $Z' \text{ factor} = 0.92 \pm 0.01$). We also screened the validated compound library in the LOPAC1280 for tetramerization-inhibitory activity. There were 20 compounds with >30% inhibition of TTR tetramerization ($S/B = 14.5 \pm 1.3$, $Z' \text{ factor} = 0.89 \pm 0.01$). The selected compounds will be further evaluated for their effects.

P784**Board Number: B1090****Analysis of miRNA target genes; a new approach to understand the cause of obesity.**M.J. Khan¹, W. Khan¹, A.A. Raja¹, A. Naeem¹;¹Department of Biosciences, COMSATS Institute of Information Technology Islamabad, Islamabad, Pakistan

Obesity is a health risk that leads to numerous metabolic complications. It has been known to cause serious diseases such as Type 2 Diabetes, atherosclerosis, degenerative disorders including dementia, and some types of cancer. Obesity related metabolic syndromes are now prevalent in children as well. Several genetic factors have been reported to cause obesity that is regulated at molecular level. Among the other regulatory factors, MicroRNAs (miRNAs) are partially or completely complementary to the messenger (mRNA) and their main function is to down regulate the gene expression. We carried out a study to explore the effects of miRNAs on differentially expressed genes (DEGs), taken from an experiment on child obesity. miRNA target genes were obtained using FINDTAR3 and the functional analysis was done using Database for Annotation, Visualization, and Integrated Discovery (DAVID). Role of all the miRNAs were observed in biological processes, cellular compartments, molecular functions, protein interaction and binding. Our preliminary results have identified the role of miR-143 in all biological processes including energy metabolism, homeostasis, and cell growth. The recently discovered miR-519d controlled the regulation of metal ion transport and positive regulation of RNA polymerase II promoter. In the category of cellular compartment of DAVID, miR-138 was the major regulator of gene expression in mitochondria. With this analysis, we identified genes and biological processes regulated by particular miRNAs that play crucial role in metabolic dysfunctions leading to obesity; this opens a new dimension for future studies to a better understanding of the cause of obesity.

Key words: obesity, miRNA, gene expression**P785****Board Number: B1091****Implication of TRPM4 channel in ischemia-reperfusion injury.**K. Takahashi¹, K. Naruse¹;¹Cardiovascular Physiology, Okayama Univ. Grad. Sch. Med. Dent. Pharmaceut. Sci., Okayama, Japan

Ischemic heart disease often causes heart failure. During ischemia-reperfusion (I/R), excessive reactive oxygen species (ROS), including hydrogen peroxide (H₂O₂), are produced in cardiac tissue, where they induce cell death. We previously reported that a TRPM4 channel inhibitor 9-Phenanthrol protects cardiac I/R injury in the excised rat heart. Based on this finding, we hypothesized that TRPM4 channels are involved in the pathophysiology of the cardiac I/R injury. We confirmed that intravenous application of 9-Phenanthrol mitigated the development of myocardial infarction caused by the occlusion of the left

anterior descending artery in rats. Positive expression of TRPM4 channels in the ventricular cardiomyocytes was confirmed by immunohistochemistry. To evaluate the toxic effect of ROS on cardiac cells, we measured cellular viability of H9c2 cardiomyocytes underwent H₂O₂ challenge. Pretreatment of 9-Phenanthrol preserved cellular viability. Furthermore, knockdown of TRPM4 channels preserved the viability of H9c2 cardiomyocytes exposed to H₂O₂. These results suggest that TRPM4 channels are involved in development of cardiac ischemia-reperfusion injury.

A novel small molecule antagonist of Id1 inhibits breast cancer metastasis to the lungs.

P.M. Wojnarowicz¹, R. Shah¹, R. Benezra^{1,2};

¹Memorial Sloan Kettering Cancer Center, New York City, NY, ²AngioGenex Inc., New York, NY

Breast cancer metastasis is one of the greatest therapeutic challenges to prolonging patient survival. Thus the identification of genes involved in metastasis is important for a greater understanding of the metastatic process, as well as for identifying clinically relevant targets for which novel therapeutics could be developed. The inhibitor of DNA-binding (Id) proteins have been implicated in breast cancer metastasis, with high Id1 expression being observed at metastatic sites. Furthermore, Id1 has been shown to play a role in mesenchymal-to-epithelial transition (MET), which allows for circulating cancer cells to seed distant metastatic sites, such as the lung. It was previously shown that knockdown of Id1 prevented MET of tumors cells in the lung, and the development of lung metastases in mouse models of breast cancer. Thus targeting Id proteins may be an effective and novel approach for treating and/or preventing metastases in breast cancer patients. Here we present data investigating the biology of a recently developed small molecule antagonist of Id proteins. An *in silico* small molecule screen of 2 x 10⁶ compounds was carried out to identify compounds that would bind a hydrophobic pocket adjacent to the dimerization domain of Id1, which would disrupt dimerization of Id1 with its binding partners, such as E47, and hence its downstream signaling. Of the 15 positive hits, one compound, named AGX-51 (supplied by Angiogenex Inc.) was able to enhance E47 binding to DNA, in a dose-dependent manner, suggesting that AGX-51 antagonizes Id1-E47 dimerization. Treating the murine breast cancer cell line 4T1 with AGX-51 resulted in decreased Id1 protein expression, suggestive of protein degradation. In cell culture assays, AGX-51 resulted in decreased cell viability, as measured by alamar blue assays, and inhibited the formation of mammospheres, consistent with previous Id1 knockdown experiments. To assess the effect of AGX-51 on metastasis, AGX-51 was administered at 50mg/kg via intraperitoneal injection, 24-hours after tail vein injection of 4T1 cells. Development of metastases was monitored using bioluminescent imaging. At two weeks we observed that AGX-51 dramatically inhibited the development of lung metastases. Furthermore, significantly greater inhibition of lung metastases was observed when AGX-51 administration was increased from once to twice daily. We are currently investigating the specific mechanisms of AGX-51's anti-metastatic activity, by investigating the effects of AGX-51 on the 4T1 transcriptome and the EMT/MET pathway. In summary, AGX-51 showed potent anti-

metastatic activity, and is a promising novel therapeutic for metastatic breast cancer, warranting further investigation for translation into the clinic.

An interdisciplinary project-based approach using *Drosophila* genetics and cell biology to improve reasoning, problem solving and foundational knowledge in high school students.

S.M. Hall¹, C. Hanzlick-Burton²;

¹Molecular Biosciences, University of Kansas, Lawrence, KS, ²Olathe Northwest High School, Olathe, KS

Mastery of foundational scientific concepts, problem solving, and reasoning skills are three areas that have been recognized as needing improvement in both undergraduate and high school students. Here we describe an educational initiative that uses an interdisciplinary approach between a science educator and research scientist to improve student performance in these three areas using project-based instruction. We have used *Drosophila melanogaster* to teach basic biological concepts related to genetics and cell biology to five classes of high school students in the Olathe school district of Kansas. The project was structured around the integration of the new Next Generation Science Standards and includes 7 core concepts: basic biochemistry, cell structure, cell division, molecular genetics, Mendelian genetics, biotechnology, and informatics. In addition to these core concepts, the project aims to improve student performance in the eight practices recognized as being essential for science and engineering students in K-12 in the Next Generation Science Standards including: asking questions, using models, planning and carrying out investigations, analyzing and interpreting data, using mathematics and computational thinking, constructing explanations, using evidence to argue, and obtaining, evaluating, and communicating information. To examine the success of our approach in increasing the students mastery of foundational scientific concepts, we used a pre-test and post-test from the AAAS Science Assessment Project that evaluates the students general knowledge of concepts covered within the scope of our project and many that also lie outside. Our results indicate that the students in our project-based classes scored higher than the national average on questions related both to and outside of the project.

P788**Board Number: B101****Biological Research Through Independent Investigations in a High School Setting.**A. Hoover¹, N. Kumar¹, J. Gleklen¹, M. Fields¹;¹Sidwell Friends School, Washington, DC

Students at Sidwell Friends School in Washington, D.C. are given the opportunity to conduct original research both inside and outside of the classroom. In Biology 1A, an accelerated biology course, ninth grade students conduct an Independent Research Project of their choosing. Later in their high school careers, students who wish to refine their research skills and to learn more advanced concepts in neuroscience may opt to take Sidwell's Neuroscience Research course. Additionally, students wanting to conduct research outside of class may join the Biological Research and Investigations in Neuroscience (BRAIN) Club. Experienced members of the BRAIN club act as mentors for the more junior members while also conducting their own research. The BRAIN Club also created a program referred to as Sci-Fins in which Sidwell students use an inquiry-based approach to tutor students from DC's Cesar Chavez Public Charter School in basic biology. Sidwell students are also provided the opportunity to further branch out in the scientific community by partnering with institutions such as the National Institutes of Health, the Georgetown University Medical Center, and the MAYO clinic. Most students decide to use zebrafish, *Danio rerio*, as a model organism for their projects in order to take advantage of its translucent embryos, rapid development, easy care, and completely mapped genome. Ongoing experiments involving *Danio rerio* include observing the effect of nicotine on the mesolimbic pathway, distinguishing shoaling preferences, evaluating the effect of pregnenolone on cell movement, and determining how ethanol affects a cell-signaling pathway known as the sonic hedgehog pathway, at different stages in zebrafish development.

P789**Board Number: B102****Identification of molecular targets of nutritional supplements in *Drosophila* oogenesis by Immersion Science High School Program Students.**D.M. Ruiz-Whalen¹, A. Bolotsky¹, L. Leonard², C. McAuliffe³, J. Raj⁴, Y. Miglo⁵, N. Archer⁶, C. Pritchard⁷, P. Zaveri², T. Singh¹, E. Boamah¹, T. Strohlic¹, M. Radu¹, R. Henry⁸, A.M. O'Reilly¹;¹Cancer Biology, Fox Chase Cancer Center, Philadelphia, PA, ²North Penn High School, Lansdale, PA,³Council Rock High School, Newtown, PA, ⁴Merion Mercy Academy, Merion Station, PA, ⁵Neshaminy High School, Langhorne, PA, ⁶Garnet Valley High School, Glen Mills, PA, ⁷Souderton Area High School, Souderton, PA, ⁸Cancer Epigenetics, Fox Chase Cancer Center, Philadelphia, PA

Reports on the positive and negative effects of nutritional supplements on health abound in the public media, but little scientific evidence exists to support most claims. Recently, we identified a single

nutrient, dietary cholesterol, that regulates proliferation rates of epithelial Follicle Stem Cells in the *Drosophila* ovary by controlling the levels of the growth factor Hedgehog available to the stem cell niche. This work defines a novel signal transduction pathway that controls FSC function in response to global changes in the external environment of the organism and suggests that a single nutrient can have dramatic effects on an individual cell population. To address the effects of individual nutrients on Follicle Stem Cells and other cellular events during oogenesis, 32 high school students in our newly developed Immersion Science laboratory research training program screened 48 nutritional supplements for effects on egg production in *Drosophila*. Compounds that directly targeted the EGFR resulted in phenotypes indistinguishable from those observed in EGFR mutant flies, demonstrating the efficacy of the assay. Nine additional nutritional supplements scored in the screen, including three that impaired signaling through Extracellular-Signal-Regulated-Kinase (ERK) and Hedgehog signaling pathways in the ovary. Here, we report the effects of two of these supplements on the development of proliferative masses of cells that exhibit extremely elevated levels of ERK signaling and resemble epithelial tumors.

Cultivating ensembles across biology education and research.

J.J. Alonzo¹, S. Walsh², V.A. Segarra², S. Pulford³, B. Natalizio⁴, S. Borinskaya⁵, R.M. Holmes^{6,7};

¹Communication and Theater Arts, ODU, Norfolk, VA, ²Biology, Rollins College, Winter Park, FL,

³University of Washington, Seattle, WA, ⁴Cell and Developmental Biology, Vanderbilt Univ, Nashville, TN,

⁵Center for Cell Analysis and Modeling, University of Connecticut Health Center, Farmington, CT,

⁶Improvscience, Boston, MA, ⁷Center for Computational Science, Boston University, Boston, MA

A diverse group of cell biology educators and researchers in collaboration with professionals in theater, leadership and human development are cultivating a STEM culture that is highly inclusive, collaborative and innovative. A growing population of Science Technology Engineering and Mathematics students and professionals are increasingly involved in this movement. These professionals have created non-major classes that integrate biology and theater, professional groups that use improvisation to advance their communication skills, and performance based workshops to support professional skill development for women and people from traditionally underrepresented groups. A common root in these efforts is their activity to cultivate ensembles- groups whose work is qualitatively different than the sum of its parts.

In 2012, the NSF funded two efforts: (1) Improvisational Theater for Computing Scientists (Holmes, 2011) and (2) RCN interdisciplinary Communication Lab for Undergraduate Education (Alonzo, Gaff, Watson, 2011). PIs and Co-PIs from these efforts organized a professional meeting: Cultivating Ensembles in STEM Education and Research (CESTEMER).

This meeting explored the relationship between performance, science and science education across a broad range of STEM disciplines. Of the 43 participants, members of ASCB presented posters, talks, and workshops on innovations in classroom curricula and dynamics (Wick and Matthes, 2011; Grabel et. al.

2013), building community and inclusion, facilitating improved mentor-mentee communication and basic biological research.

The interdisciplinary gathering inspired new work and collaborations within and beyond the life sciences that have led to publications, conference presentations, and performance based workshops to advance communication and collaboration skills. These performance-based approaches to STEM education are being integrated into undergraduate, graduate and professional curricula and courses at Boston University, Harvard Medical School, University of Washington and Rollins College. The goals include increased engagement with, understanding of and ability to communicate science among all audiences.

In this work, we present 1) how performance is used across these institutions to foster inclusion, collaboration and improved communication skills among scientists, faculty and students, and 2) how these scientists are continuing to organize opportunities to cultivate ensembles in STEM education and research.

Biomedical Science Ph.D. Career Development and Interest Patterns by Race/Ethnicity and Gender.

K. Gibbs¹, K. Griffin²;

¹NCI, Bethesda, MD, ²Counseling, Higher Education, Special Education, University of Maryland, College Park, MD

Recent biomedical workforce policy efforts have centered on the twin challenges of enhancing career preparation for graduate students and postdocs, and increasing diversity in the research workforce & professoriate. We report results from a survey of 1500 recent, American biomedical sciences Ph.D. graduates (including 276 from underrepresented minority (URM) backgrounds) that examined career preference changes over time, graduate training experiences, and determinants of career interest. At Ph.D. entry, 57% of respondents indicated their intentions to pursue a faculty career (a number that dropped to 42% by Ph.D. completion), yet fewer 25% indicated they entered graduate training knowledgeable about of the potential career options available to a Ph.D. biomedical scientist. Additionally, only 26% of respondents indicated they received structured career development during their graduate training. Scientists from all social backgrounds reported significantly decreased interest in faculty careers at research universities, and significantly increased interest in non-research careers (e.g. policy, law, consulting, etc.) at Ph.D. completion relative to entry. However, group differences by race/ethnicity and gender emerged in overall levels of interest (at Ph.D. entry and completion), and magnitude of the change in interest in these careers. Multiple logistic regression showed that when controlling for career pathway interest at Ph.D. entry, first-author publication rate, research self-efficacy, faculty support, and graduate training experiences, differences in career pathway interest between social identity groups persisted. All groups were less likely than men from well-represented (WR) racial/ethnic backgrounds to report high interest in faculty careers at research-intensive

universities (URM men: OR 0.60, 95% CI: 0.36-0.98, $p=0.04$; WR women: OR: 0.64, 95% CI: 0.47-0.89, $p=0.008$; URM women: OR: 0.46, 0.30-0.71, p

Impacts of a supplemental course that emphasizes study skills for an introductory biology course: An analysis of exam performance and student perceptions.

J.J. Fernandes¹, J. Sanjeevi¹, P. Callahan¹;

¹Miami Univ, Oxford, OH

Objective: A supplemental course was designed to emphasize learning strategies to benefit students in an introductory biology course. *Methods:* Impacts of this course on exam performance were assessed by comparing the grades with students who did not take the class. This analysis was conducted over 4 consecutive semesters (178 students), examining C/D/F grades between the control and experimental groups. Additionally, students in the supplemental course were interviewed to identify common themes in regard to challenges perceived in the introductory biology class, attributes of the supplemental course that were useful to overcome the challenges, and to determine if there were any changes in study habits. *Results:* In regard to exam performance over the 4 semesters, the mean grades (C/D/F) differed significantly for the first exam (Control: 64.5; Exp: 61.5; p

Modifying multi-section introductory labs to include student-designed experiments.

L.J. Robinson¹, K.R. Hogan¹;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA

Lab courses provide an opportunity to learn key scientific skills such as developing hypotheses, designing experiments with appropriate controls, analysis of results, and communication of findings. In order to introduce these skills into two sequential multi-section introductory biology lab courses, the “cookbook” versions of these courses were modified to include less breadth and more experimental design, as we have migrated structured lab protocols into student-designed experiments. One challenge with this approach is the inability to cover all topics within a semester. However, by constraining ourselves to a limited number of topics, we were able to emphasize elements of the scientific method in greater depth. Over the past several semesters, we have learned through trial and error which strategies are most successful. Student assessment from the first semester indicated that students were given only limited guidance and insufficient incentive for selection of research questions, proper experimental design, or even what should be included in their lab reports. We also found that consideration of

logistical constraints of these large multi-section lab courses is a major concern. For example, each section is taught by a different graduate teaching assistant (TA), some of whom are new to teaching, which can lead to major discrepancies between sections. Another concern is how to constrain student-designed experiments to the equipment, materials, and budget for these large multi-section courses. To address these concerns we have made a number of modifications that we are implementing this semester. Effective assignments for generating interesting research questions, increased student mentoring for experimental design, and clearer expectations for communicating experimental results have been developed. New TAs now attend a departmental workshop and weekly meetings aimed at giving them the skills necessary to help guide students through the process of experimental design. Student assessment of the lab courses will be presented, along with our syllabi, sample lab chapters and assignments from units emphasizing student-designed experiments, and our TA training agenda.

Board Number: B107

Introducing computational scientific thinking materials into freshman biology curriculum.

S. Borinskaya¹, J.A. Roecklein-Canfield², R.M. Holmes³;

¹Center for Cell Analysis and Modeling, University of Connecticut Health Center, Farmington, CT,

²Department of Chemistry, Simmons College, Boston, MA, ³Center for Computational Science, Boston University, Boston, MA

We present here a model for the incorporation of computational scientific thinking methods into undergraduate biology education. We evaluate if students develop an understanding and appreciation of the role of mathematical modeling and computation in scientific inquiry. In collaboration with Chemistry and Mathematics professors at Simmons undergraduate college, we pilot two computational science modules to first-year undergraduates. The modules provide practical computation approaches integrated into the scientific problem-solving paradigm. The materials will be introduced in October 2014 as part of the freshman learning community, *Your Microbes and You*. This course is an interdisciplinary problem-based class that uses bioinformatics to analyze the Human Microbiome.

Students learn to create models and perform simulations using Excel and Python programming language, which is used in other aspects of the course also. Our modules start with a scientific problem and then lead the students through its solution via building a computational model. We focus on exponential and logistic models of biological population growth. The *Exponential* and *Logistic Growth* modules are part of a larger set of curricular resources for teaching computational methods in scientific inquiry. These modules were developed for the NSF DUE project INSTANCES (Landau et al 2013, www.physics.orst.edu/~rubin/INSTANCES). Each module includes: learning objectives/skills/activities, a scientific problem, concept maps and system statements, the computational model, background information on the computational model, simulations of the model, and assessment in the form of formative assignments and a small project. Upon completion of the modules, we expect that students will gain a basic understanding and appreciation of the role of computation in biology.

We present the results of a survey evaluating the following outcomes:

- students' understanding of importance of computational methods in solving biological problems
- students' preference for a simulation tool: Excel or Python
- students' understanding of a process of creating computational model of biological phenomenon
- how students learn content introduced in combination with computational approach – if modeling enhanced understanding of biological question.

A Biotechnology Techniques Course Investigating Genetic Modification of Local Foods Using Protein and DNA Analyses.

J. Hurst-Kennedy¹, R. Haining¹, C. Achat-Mendes¹;

¹Georgia Gwinnett College, Lawrenceville, GA

Biotechnology Laboratory (BIOL4300) is an upper level course that focuses on biochemical and molecular biological laboratory techniques used in the field of Biotechnology. As part of the Georgia Gwinnett College 4-year Undergraduate Research Experience program, an initiative to give STEM students the opportunity to conduct course-embedded research at every stage in their undergraduate careers, the BIOL4300 curriculum has been redesigned to include an inquiry-based, semester-long project investigating genetically-modified (GM) foods. During the first phase of the project, students acquired skills needed to analyze foods at both the DNA level (DNA gel electrophoresis, traditional PCR, and Real Time PCR) and the protein level (ELISA, SDS PAGE, and immunoblotting). During the second phase, student groups were responsible for designing and conducting experiments to test food products from their local environments for the presence of GM food markers, including genes coding for *B. thuringiensis* crystal proteins and the glyphosate (“Round Up”)-resistant EPSP enzyme. Test foods included produce from local farmers’ markets, items from campus vending machines, and baby food sold at nearby grocery stores. Pre- and post-content assessment quizzes indicated that participation in the GM foods project increased student knowledge of biotechnological laboratory techniques and understanding of gene expression. Additionally, attitudinal surveys demonstrated that the new curriculum increased student interest in attending graduate school and pursuing careers in biotechnological research as well as student confidence in their ability to conduct independent research. Here, we present our curricular design and assessment as a model for incorporating the use of DNA and protein analytical techniques into a course-embedded, authentic biotechnological research experience.

P796**Board Number: B109****Data Analysis in the Biological Sciences: A 10-week hands-on course to equip students with tools for quantitative cell biology.**J.S. Bois¹;¹Division of Biology and Biological Engineering, California Institute of Technology, Pasadena, CA

The big questions in cell biology increasingly require quantitative approaches to get answers. A typical graduate student spends nearly as much time analyzing her data as she does acquiring them. Most graduate students, and indeed even senior researchers, learn analysis techniques as they need them. This often results in choosing the most familiar or commonly used analysis tool, as opposed to the optimal one.

To meet the growing needs of students as they begin their careers in quantitative biology, I developed a hands-on course covering basic data analysis techniques useful in cell and developmental biology. The goal is build a repertoire of *functional* skills with a basic understanding of the underlying mathematics. The target audience is senior undergraduates and beginning graduate students of biology and bioengineering. Each of the ten weeks of the course consists of a one hour lecture covering the theoretical background for the topic of the week, and a three hour "lab" session in which the TAs and I work with the students to analyze real biological data sets, including published results from literature and unpublished results from labs on campus. Each week's homework also features analysis of real data. Topics include regression, parameter estimation, outlier detection and correction, error estimation, denoising, hypothesis testing, image processing and quantification, and data display and presentation. (Absent is analysis of sequence data, for which Caltech offers a separate bioinformatics course.) We approach statistics from a Bayesian perspective and use Python as the instructional programming language.

I will present some of the examples of data sets we analyzed in the course, discuss the effectiveness of the course structure, and provide student feedback.

P797**Board Number: B110****3D printing in the biology classroom and laboratory: making the virtual tangible.**J.E. Honts¹;¹Biology, Drake University, Des Moines, IA

3D printing has existed for several decades, but the expiration of several key patents has promoted the rapid growth of the desktop 3D printing industry. A large array of affordable desktop 3D printers have become available in the last few years, ranging from DIY kits to ready-to-use pre-assembled printers. As a result, these printers had found increasing use in classroom, especially as a means of facilitating STEM

education. This technology provides faculty and students with the ability to turn virtual models of biological objects, whether organs, cells, or molecules, into tangible representations. A third generation MakerBot 3D printer has been used to explore how this technology can be used in the classroom and in the research laboratory. A diverse set of 3D printed objects have been fabricated for use in the lecture and laboratory class activities, for use as physical illustrations in research presentations, and for use as hands-on materials in outreach activities. This printer has also been used in research to build 3D representations of the distribution of GFP-tagged proteins in cells, using research data derived by means of confocal laser scanning microscopy. Computer-aided design and 3D modeling software packages have been used to precisely fabricate tools for use in teaching and research laboratories. A key accessory for a 3D printer is a 3D scanner, and we have adapted an Xbox console to capture 3D data from physical objects, which can be subsequently edited and printed. There are relatively few resources describing how to convert 3D data into appropriate data formats for 3D printing. Several protocols have been developed to prepare raw data and 3D models for 3D printing, starting with data file formats familiar to biologists. An unheralded aspect of 3D printing at present is the high frequency of print failures, which can occur for a variety of reasons, ranging from failure of printer hardware components to design flaws in the model to be printed. Tools and strategies have been identified to either prevent or correct many common problems. Desktop 3D printing is still in its infancy, it is not always user-friendly, and printers require continual maintenance. Yet it is clear that 3D printers will become a ubiquitous technology within the next decade. It is important that students begin to gain familiarity with this technology and its limitations. As has been the case with personal computers and mobile communications devices, 3D scanning and printing technologies have the potential to transform biological education, as well as basic and applied life sciences.

Board Number: B111

Student development of cell culture laboratory modules for new curricular offerings in biology and bioengineering at Rowan University.

D. Carrier¹, A. Toomer¹, I. Bakanas¹, T. Fortino¹, M. Everwine¹, A. Krufka¹, C. Iftode²;

¹Rowan Univ, Glassboro, NJ, ²Biological Sciences, Rowan University, Glassboro, NJ

Students designed and tested laboratory modules for a new upper level curricular offering “Fundamentals in Cell Culture Methods” as part of an NSF-TUES grant to integrate biomaterial science in the engineering and biology curricula. Two student-led teams, consisting of biology and bioinformatics students with varying levels of experience with cell culture, designed experiments to optimize human embryonic kidney (HEK)-293 cell proliferation through manipulation of culture media and substrate material. Cell proliferation was tested in different growth media at varying concentrations of fetal bovine, calf and horse serum with 10% fetal bovine serum determined to be the best medium for optimal HEK-293 cell growth. Cell proliferation in different substrates including bovine fibronectin, collagen I, gelatin, poly-L-lysine, bovine serum albumin were compared, with gelatin supporting the highest overall cell densities. In addition to designing experiments, students developed teaching

materials for cell culture modules, including lab protocols, instructions for the use of laboratory equipment, and course tutorials emphasizing data analysis and experimental design. The five undergraduate biology and bioinformatics students were specifically selected to represent the skill and experience levels expected for students that will ultimately enroll in the newly developed course. They ranged in academic standing from rising sophomores to seniors, cell culture experience from none to extensive, and prior research experience from none to one year. The students incorporated their prior laboratory and course-work experience in the overall conduct of the experiments and the subsequent writing of teaching materials for the curriculum. Throughout the project, the students developed specific laboratory skills such as aseptic liquid transfer, medium and substrate preparation, counting cells with a hemacytometer, passaging and freezing cells, microscopy, and use of ImageJ. In addition, students developed problem solving strategies, analytical skills, and curriculum development abilities. Students will continue module development and turn their focus to cell viability assays and cellular differentiation of mesenchymal stem cells, to further integrate bioengineering and cell culture concepts and skills in an upper level undergraduate lab-intensive course.

Board Number: B112

Flipped Fridays in Cell Biology.

K.B. Shannon¹;

¹Biological Sciences, Missouri ST, Rolla, MO

In the Fall of 2013, I flipped one day a week of my Cellular Biology course. For the flip, students were required to watch 2-3 short video lectures and complete an online quiz on the content before class. Class time was used for students to work in groups on a problem set. The purpose of doing the flip was to give the students practice with challenging questions that asked them to apply what they had learned and interpret representations of experimental data. Comparison of the flipped Friday class with the previous semester, which was traditional lecture three days a week, showed no difference in exam averages between semesters. Analysis of student video viewing patterns using Kaltura metrics showed that videos needed to be fifteen minutes or shorter, and that most students were watching the videos only once on Thursday nights. A few students did not watch any videos and many students viewed some but not all, or started watching the video but did not finish. Student comments on evaluations indicate that most students liked the flipped Friday approach, but there is also student resistance to the method. Benefits of the flipped Friday were increased student-student interaction, increased faculty-student interaction, and introduction of more challenging problems. Ideas to improve student engagement further will be discussed.

P800**Board Number: B113****Introducing CourseSource: a peer-reviewed, open-access journal of evidence-based resources for teaching biology.**R.L. Wright¹, J. Blum¹;¹Biology Teaching and Learning, University of Minnesota, Saint Paul, MN

Over the past 20 years, many national reports have called for transformation of undergraduate science education. For example, in 2012, the President's Council of Advisors on Science and Technology issued the Engaged to Excel report, advocating implementation of evidence-based pedagogy to enable the United States to produce an additional 1,000,000 STEM graduates over the next decade. In response to such calls to action, colleges and universities nationwide are approaching their undergraduate STEM courses in new ways, but this change has been slow and fragmented. One of the greatest challenges to STEM education transformation is the time, energy, and vision that instructors need to create evidence-based lessons, courses, and curricula. Addressing this need was highlighted in the 2009 report, Vision and Change in Undergraduate Biology Education, which recommended creation of a repository of "student-centered, outcomes-oriented" resources. This poster will describe creation of a repository in the form of a peer-reviewed, open-access journal called *CourseSource*.

CourseSource publishes activities, lessons, labs, and other teaching resources that: (1) incorporate student-centered, evidence based pedagogy; (2) focus on professional society-developed learning goals and objectives; (3) can be quickly retrieval by instructors; and (4) are organized to enable easy implementation by other instructors. Publication in *CourseSource* provides authors with a high-quality vehicle for documenting their scholarly teaching efforts, accomplishments, and innovations.

To date, *CourseSource* includes learning objective frameworks for cell biology from ASCB, genetics from GSA, plant biology from ASPB and BSA, and microbiology from ASM. We expect that the appropriate societies will shortly approve frameworks for developmental biology, ecology, evolution, bioinformatics, biochemistry, and molecular biology. The site will go live to the public by the end of 2014.

Funded by a grant from the Howard Hughes Medical Institute

P801**Board Number: B114****RolePlaying: An Effective Pedagogical Tool.**L. Jayant¹, C. Priano¹;¹Science, Borough of Manhattan Community College, New York, NY

Engaging the interests of students in introductory science courses is a common challenge shared by educators all around the world. Our studies indicate that roleplaying can be used as an effective pedagogical technique to teach difficult concepts in undergraduate introductory majors Biology. Simple

roleplaying lesson plans can be designed to be quick while engaging a large number of students and without major effort or dramatic training. After explaining a cellular concept such as chemiosmosis during a regular lecture class, students are asked to act out the process. Students assume the roles of different molecules or structures. They then orchestrate a visual demonstration of the biological activity. The remaining students in the class participate as they critique, correct, and comment on their peers' acting roles. After the exercise, students are assessed on their knowledge and application of these concepts through quizzes or written assignments. We have successfully used roleplaying to reinforce concepts of chemiosmosis, mitosis, DNA replication, and protein synthesis. Our assessment results suggest that employing this technique as a supplement to conventional teaching methods greatly improves classroom involvement and retention of subject matter. Results of students' performance and retention rates will be discussed.

Effects of in-class group problem solving sessions on group studying outside of class.

K.E. Tiff¹, M. Reese², E. Fisher¹;

¹Department of Biology, Johns Hopkins University, Baltimore, MD, ²Center for Educational Resources, Johns Hopkins University, Baltimore, MD

Due to the demonstrated benefits of collaborative learning, we encourage students in our large biochemistry lecture course to study in groups. However, our anecdotal observations indicated that students use traditional study methods instead of more active methods, including group studying. We hypothesized that in-class group problem solving would increase the use of and/or improve attitudes about group studying. In 2013 we implemented two in-class problem sessions with 265 students randomly assigned to groups of 5. We evaluated studying behavior and attitudes using a study skills survey given to students at the beginning (pre) and end of the semester (post) and to alumni (2012) with no in-class problem sessions. Although student response to the in-class problem sessions was positive, the sessions did not significantly affect short-term behavior or attitudes on group studying. Interestingly, a number of students report feeling that group studying is effective, but do not use it regularly. We plan to investigate the reasons these students do not study in groups. In Fall 2014, the study skills surveys will be repeated and the problem sets will be implemented earlier in the semester. Our results will inform efforts to revise this course to encourage collaborative learning inside and outside of class.

P803**Board Number: B116****Does a first-year mentoring and research experience impact STEM retention?.**L. Caslake¹, C. Liew², R.A. Kurt¹;¹Biology, Lafayette College, Easton, PA, ²Computer Science, Lafayette College, Easton, PA

The Science Horizons program at Lafayette College involves 20 incoming first-year students in five mentoring sessions each semester, a three-week research project, and participation at a regional science conference. The mentoring sessions provide guidance concerning the many possibilities available to students on and off campus during their college years as well as career opportunities and graduate education directly or indirectly involving the life sciences. All 20 students participate in a three-week research project with faculty over our January interim session, a time when they can focus on research without commitments to classes. We anticipate that the mentoring sessions and early research experience will increase retention in the sciences and spark the interest of students in conducting more research. Over the past five years, 58% of students completing General Biology declared a STEM major, while over 90% of our first cohort declared a STEM major. Following their first year, five of these students are selected to receive support for three summers of research. Research projects in the first summer span multiple disciplines and require two research mentors. Following their second year, students conduct research on campus and following their third year, off campus. In addition to the regional conference, funding is available to send these five students to a national scientific conference of their choice. We hope to learn from students participating in these additional research experiences whether longevity in research impacts student retention and pursuit of advanced degrees. Early results show that the mentoring and early research experiences improve students understanding of the nature of science and research and provides a foundation for future studies for students interested in majoring in any STEM field. Students are asked to rate their skills in numerous areas in the fall of their first semester and are provided the same survey in the spring. The mentoring and early research experience allows student to recalibrate their self-assessment in numerous areas relating to general research skills and career options in the sciences. For example, in the fall students rated their general research skills as 'moderate to high' (4.3 on a 6 point scale), while after the interim research experience their retrospective analysis of their skills on entry dropped to 'very low to low' (2.5 on a 6 point scale; p

P804**Board Number: B117****Undergraduate research in the life sciences: Influence of the mentor.**M. Aikens¹, E.L. Dolan¹;¹Univ Texas-Austin, Austin, TX

Many undergraduate researchers in the life sciences are mentored by graduate or postdoctoral researchers (i.e., postgraduates) who themselves are mentored by faculty members, creating a

mentoring “triad” configuration. This unique mentoring configuration has not been the focus of empirical research even though faculty and postgraduate mentors are likely to have unique and important effects on undergraduate protégés. The goal of this study is to understand how undergraduate researchers in the life sciences are affected by being mentored by a postgraduate and a faculty member. Specifically, we are (1) empirically characterizing the range of mentoring triad structures at research universities, (2) determining how different mentoring triad structures relate to outcomes experienced by undergraduate researchers, and (3) determining whether female or underrepresented students experience different mentoring configurations and outcomes.

To accomplish this, we are collecting data from a national sample of matched triads: undergraduates and their postgraduate and faculty mentors. Using online surveys comprised of established, valid, and reliable measures, we are determining the types of triads found in undergraduate research mentoring, measuring the strength and functions of these mentoring relationships, and measuring the outcomes undergraduates realize from participating in research.

In the data collected to date, we have observed variance in mentoring triad structures, the functions of mentoring relationships, and the outcomes by triad type, demonstrating that students experience a range of mentoring. We have found that two triads are common in undergraduate research settings at research universities: a closed triad in which all members are connected, and a triad in which the undergraduate interacts with the postgraduate and the postgraduate interacts with the faculty member. Our preliminary analysis indicates that undergraduates in closed triads reported greater outcomes related to learning, confidence in their scientific abilities, and scientific identity than undergraduates in triads with only undergraduate-postgraduate and postgraduate-faculty ties. Therefore, mentoring structures in which the undergraduate directly interacts with both the faculty member and the postgraduate appear to be more beneficial than those in which the undergraduate is only interacting with the postgraduate. This is supported by the additional finding that postgraduates and faculty differ in the support they give; postgraduates provide more instrumental support (i.e., “how-to” help) whereas faculty provide more networking support.

For undergraduate research programs to be effective, we need to understand the ways in which mentoring affects undergraduate outcomes. The results of this work will yield unprecedented insights into the latitude we have for designing undergraduate research experiences.

P805**Board Number: B118****Spreading Vision and Change Through Long-Term Mentorship Opportunities: the ASCB Mentorship in Active Learning and Teaching (MALT) program.**M.J. Wolyniak¹, D.E. Allen², J.K. Hood-DeGrenier³, G.E. Plopper⁴, A.J. Prunuske⁵, S.M. Wick⁶, A.N. Becalska⁷, J. Dyer⁸, L.A. Gurski⁹, M. Kokes¹⁰, S. Murugesan¹¹, W. Xie¹²;¹Biology Department, Hampden-Sydney College, Hampden-Sydney, VA, ²University of Delaware, Newark, DE, ³Worcester State University, Wellesley, MA, ⁴Rensselaer Polytech Inst, Troy, NY, ⁵Medicine, University of Minnesota-Duluth, Duluth, MN, ⁶University of Minnesota, Saint Paul, MN, ⁷Biology, Brandeis University, Waltham, MA, ⁸MIT, Cambridge, MA, ⁹Urology, Univ Pittsburgh Med School, Pittsburgh, PA, ¹⁰Biology, Duke University, Durham, NC, ¹¹NIH\NHLBI, Bethesda, MD, ¹²Institute of Medical Biology, Singapore, Singapore

Extensive pedagogical research recognizes active learning strategies as the most effective way to teach STEM disciplines, yet a disparity exists between these ideas and their widespread and effective practice. To promote reform in undergraduate STEM education, the 2013 *Vision and Change* in Biology Undergraduate Education working group challenged professional scientific societies to take action to help their members implement lasting changes in their approaches to teaching. In response to this call to action, the ASCB has created the Mentoring in Active Learning and Teaching (MALT) program, which is designed to give society members access to a long-term hands-on experience implementing active learning in their classrooms. This small grant program allows individuals at any point in their career path to work with faculty who are experienced in employing active learning practices in their classrooms, providing mentees with hands-on experience and long-term mentorship in active learning best practices. A pilot version of MALT began in late 2013, matching 6 experienced active learning-based teachers with enthusiastic mentees responding to a call put out in ASCB communications. The mentees have thus far engaged in a range of activities with their mentors: giving department seminars; collaborating on course development; and developing multi-session active-learning modules. Preliminary assessment through interviews with mentees suggests a rise in their confidence in developing and implementing active learning strategies in their classes. As the program grows, we intend to assess the degree of use of active learning materials with a newly developed, validated tool called the Classroom Observation Protocol for Undergraduate STEM (COPUS) (Smith *et al.*, 2013). COPUS utilizes a coding system to observe and record the actions of instructors and students at given points of time in a class period. The ASCB intends to partner with the Genetics Society of America (GSA) and the American Society of Plant Biologists (ASPB) to create an expanded version of MALT that will best serve the increased need for active learning mentorship.

P806**Board Number: B119****Genome Solver: Training Faculty to Deliver Bioinformatics Content to Life Science Students.**A.G. Rosenwald¹, G. Arora¹, R. Madupu², J.A. Roecklein-Canfield³, J. Russell⁴;¹Department of Biology, Georgetown University, Washington, DC, ²J. Craig Venter Institute, Rockville, MD, ³Department of Chemistry, Simmons College, Boston, MA, ⁴Center for New Designs in Learning and Scholarship, Georgetown University, Washington, DC

Bioinformatics is becoming a routine part of biological research, yet students entering the workforce may not have had much training in this relatively new discipline. This stems in part from the fact that many life science faculty have little training and so are reluctant to teach this material. To address this deficit, we have developed the Genome Solver Project. Over the past 3 years, we have trained more than 120 faculty members at a variety of different institutions, including community colleges and minority serving institutions, to use basic, open-source bioinformatics tools, within a context involving good pedagogical practices. In addition, we are now in the process of developing a community science project using the rich DNA sequence data sources available in public databases to examine horizontal gene transfer between bacteriophages and bacteria to demonstrate how to use bioinformatics for original undergraduate research experiences.

P807**Board Number: B120****Biology of Global Health: Preparing Students for Multi-disciplinary Group Work.**H.G. Elmendorf¹, A.G. Rosenwald²;¹Georgetown University, Washington, DC, ²Department of Biology, Georgetown University, Washington, DC

Training undergraduate students to tackle complex multi-dimensional issues is a challenge for educators. Problems that will have relevance into the future include ones in global health – chronic and infectious disease, clean water and food for 7 billion people, pollution, climate change, etc. Issues like these require multidisciplinary teams with expertise in different realms, and the experts need to be able to communicate with one another to bring about effective interventions. In order to address this challenge, we have developed a novel major, called Biology of Global Health (BGH). This major emphasizes science (students take at least 10 courses in biology and at least 6 additional courses in chemistry, math, and statistics), but also emphasizes the interplay between science and society (students are also required to take at least 2 courses in ethics, policy, economics, international health, history, etc. beyond the required college core requirements).

Much of class time in the sophomore level Introduction to BGH course, the gateway to the major, is devoted to discussing information from a wide variety of sources, including the scientific literature.

However, much of the work occurs outside of class, where students in teams of 3-5 tackle projects in which they must communicate a scientific topic to a particular audience using a specific type of media. Recent projects have included a website describing a health disparity in the District of Columbia to members of the community, a policy briefing to a member of the Institute of Medicine on tobacco use, a 1 minute video public service announcement for use by a local food bank, and the specific aims page for an NIH grant, among others. Reflections from the students after each project uniformly mention that given the short turn-around time for each project (usually 2 – 2 ½ weeks), teamwork was crucial for creation of an effective final product. Survey results from graduates of the major show that learning how to work in groups is an important skill they carried forward. Therefore the Introduction to BGH course gives students a chance to practice teamwork skills that will be useful in their post-graduate careers, skills that are often absent in many lecture-based science classes.

Incorporation of linked research experiences into biology and chemistry courses promotes student confidence and interdisciplinarity.

P.K. Hanson¹, L.K. Stultz²;

¹Biology, Birmingham-Southern College, Birmingham, AL, ²Chemistry, Birmingham-Southern College, Birmingham, AL

Pedagogical studies suggest that course-based undergraduate research experiences (CUREs) can increase student knowledge of and interest in related subject matter, improve student retention, and influence student choice of academic and career paths. Explicitly interdisciplinary curricula also positively impact students by increasing awareness of the connections between scientific disciplines and improving articulation of cross-disciplinary concepts. Here we describe the development of cross-disciplinary CUREs that are integrated into upper and lower-level biology and chemistry courses. Students in impacted labs develop their own hypotheses and apply a variety of biological and chemical approaches to make novel discoveries about the anticancer ruthenium complex indazolium *trans*-[tetrachlorobis(1*H*-indazole)ruthenate (III)], also known as KP1019. To promote cross-disciplinary thinking and collaboration, students upload their findings to a CURE-associated wiki and consult the wiki during experimental design and data analysis. On anonymous end-of-semester surveys, students self-reported that these CUREs significantly increased their degree of experience with integrating disciplines. Since students constructed large portions of the wiki, its structure was analyzed as a possible measure of students' cross-disciplinary thinking. The large proportion of links between data generated in chemistry and biology courses supports the conclusion that these KP1019-focused CUREs promote student appreciation of interdisciplinarity. These results are consistent with the findings from focus groups conducted by an external evaluator. This consultant also noted that students who participated in more than one KP1019-focused CURE reported greater learning gains. In addition to the unique benefits associated with these cross-disciplinary CUREs, formative assessment data suggest that the gains associated with more traditional CUREs were still attained. For example, students self-reported

significant increases in their degree of experience with working on problems with no known outcome. With respect to their ability to interpret results, to analyze data, and to write scientifically, students reported gains comparable to those obtained during intensive summer research programs. In addition to validating the pedagogical value of integrating research and teaching, this work suggests that cross-disciplinary CUREs provide a robust mechanism for helping students integrate their knowledge of different disciplines. Moreover, virtual collaboration tools, such as wikis, can be used to illustrate the interdisciplinary nature of modern research.

Board Number: B122

Research Experience for Peruvian Undergraduates (REPU): A sustainable student-run scientific training program for STEM undergraduates in developing countries.

D. Tafur-Cotrino¹, P. Moreno-Roman², K. Saito-Diaz³, S. Espinoza⁴;

¹Department of Cell Biology, University of Connecticut, Farmington, CT, ²Department of Biology, Stanford University, Stanford, CA, ³Department of Cell and Developmental Biology, Vanderbilt University, Nashville, TN, ⁴Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

The Research Experience for Peruvian Undergraduates (REPU) program is a science outreach effort that aims to build scientific capacity in Peru. The program complements Peruvian undergraduate scientific education by setting up 10-week research-intensive internships in laboratories in the United States and Europe in the biomedical sciences, chemistry, and engineering. Peruvian graduate students and post-docs all over the world have run the program since 2007. So far, 25 outstanding Peruvian undergraduates have participated in the three branches of the program: REPU-Biology, REPU-Chemistry and nanoREPU.

Over the years, the program structure has evolved empirically: the program has implemented several educational techniques to enhance the scientific experience of the undergraduate participants. The program relies on a multi-step and rigorous selection process, and a one-on-one mentor-mentee strategy. Our selection process ensures an outstanding student performance in their host laboratory; for instance, 6 students have stayed as post-bac associates, and 2 publications have REPU alumni as authors for their contributions during the internship. In our mentor-mentee strategy, Peruvian graduate students mentor REPU students and help them shape and pursue their academic goals. Our methodology have allowed REPU alumni that applied to graduate school to have a 100% acceptance rate at competitive graduate programs at Yale University, Harvard University, Stanford University, etc. Finally, after being part of the experience, around 80% of our alumni have taken leadership roles in at least one of the organizational committees of the program, and two have become directors of the program, making the program sustainable. We believe the REPU model can be reproduced to be successful in other developing countries sharing Peru's scientific situation.

The educational model that REPU currently uses is dynamic, sustainable, and successful. In the next few years, REPU plans to expand to new branches of science like physics, and to new locations like Canada. Thus, REPU will continue pursuing its main goal: to help building scientific capacity in Peru by creating a long-lasting network of young, well-connected scientists who are committed to helping Peruvian science.

Board Number: B123

Creating an authentic research experience in an undergraduate advanced cell biology laboratory.

M.L. Styers¹;

¹Biology, Birmingham-Southern College, Birmingham, AL

Research and research-like course activities have been shown to enhance the educational experience of undergraduate students. The goal of this project was to incorporate bona-fide research into a course-associated, undergraduate advanced cell biology laboratory. Advanced Cell Biology is a 400-level course with lecture and laboratory components that enrolls 12-16 students. The goals of the laboratory were to engage students in an authentic research project, yielding novel data, and to facilitate implementation of the scientific method. Each student pair was assigned a strain of fission yeast that contained a deletion in a gene of interest. Genes were selected based on the following criteria: 1) the gene had never been characterized in fission yeast, and 2) analysis of homologs revealed a potential function in membrane transport. During the first week of lab, students used freely available bioinformatic tools (<http://workbench.sdsc.edu/>) to analyze their genes and identify homologs in other species as a basis for literature searches. Over the next 7-8 weeks, students performed instructor-designed assays to compare cell growth and division, drug sensitivity, and membrane trafficking between the wildtype and mutant strains. Based on findings from this structured portion of the laboratory and the literature, students then developed a hypothesis regarding the function of their gene and designed an experimental procedure to test their hypothesis that was carried out in the final 2-3 weeks of the laboratory. The most surprising barrier to implementing the laboratory was student expectations. Students were initially uncomfortable with not knowing what “should” happen. Encouraging discussion and data comparisons between different groups seemed to alleviate student anxiety. Students were evaluated based on laboratory participation, a laboratory report, and a final presentation describing the hypothesis and data from their individual projects. Evaluations showed that 87.5% of students rated the laboratory as excellent with respect to “overall evaluation of this laboratory experience in teaching the discipline and its techniques.” Comments revealed that “the labs never seemed like a waste of time because every experiment had a new goal and new results.” Students found that the lab “[got] students excited/involved in research” and “challenged students to interpret results.” The class also promoted further interest and engagement in scientific research for juniors. The lab was beneficial for the instructor’s research laboratory, as preliminary findings led to further studies that resulted in a

publication. This type of research-like experience is being implemented in an increasing number of laboratories at BSC, and we hope to engage more and younger students.

Board Number: B124

The effects of herbal remedies in reversing chemically induced cell death: an undergraduate project encompassing cell biology, molecular genetics, and neuroscience.

A.J. Ettinger¹, K.J. Karnas¹;

¹Biological Sciences, Cedar Crest College, Allentown, PA

Cell biology is at the nexus of many biological subdisciplines, including molecular genetics, developmental biology, and neuroscience. The project described here brings together these areas of research as undergraduate biology, neuroscience, and genetic engineering majors investigate the effects of teratogens, apoptosis-inducing chemicals, and herbal supplements on cell growth, ion channel physiology, and gene expression. The faculty partnership has spanned five years, beginning as a project that bridged upper-division courses with the objectives of increasing content knowledge across subdisciplines and providing research experiences in teaching laboratories. This project has since been expanded to include students working towards their undergraduate theses as well as summer interns, and portions are supported by an NSF-TUES grant. The initial project investigated gross morphology of treated chicken embryos or isolated chick neurons in combination with a microarray analysis of gene expression across several thousand genes. To better examine cellular apoptosis, the project has shifted to cell culture models, mainly focusing on DT40 chicken lymphoblast cells and using HeLa cultures for comparisons. Genetic analysis has progressed to the use of pathway specific PCR arrays and real time PCR analysis. Furthermore, electrophysiology has been incorporated through the use of an automated patch clamp system that is pedagogically amenable to undergraduate use. Challenges encountered in this project have ranged from ones typically noted in undergraduate laboratories, such as bacterial contamination of cells, to much more sophisticated research dilemmas. An example of the latter was the decision to choose a non-neural, immortal cell line to replace primary neuron culturing, to allow for a project focused on a single cell type rather than a mixed culture of neurons, glial cells, and fibroblasts. An additional challenge is that this cell line has been described in the literature as lacking p53, leading to questions about the activation of apoptosis pathways in these cells; measuring apoptosis using fluorescent markers has been difficult to replicate and quantitate. Future experiments will focus on treatment and assessment of additional cell lines, such as the human neuroblastoma SH-SY5Y, and on purified chicken neurons. One outcome of this project has been student-developed and student-revised protocols that are written explicitly for use by undergraduates. Student learning gains and shifts in attitudes toward scientific research were assessed before and after participation. In addition, student researchers have collected cell images, quantified cell survival, and assayed gene expression successfully and will describe this work in student poster presentations.

P812**Board Number: B125****Caenorhabditis elegans as a Potential Model for Manganese Nanoparticle Toxicity.**T. Smith¹, F. Norflus¹, J. Jordan¹;¹Department of Natural Sciences, Clayton State University, Morrow, GA

As part of the Careers in Science Initiative at CSU to evolve freshman and sophomore students in undergraduate research, one of the authors spent the summer researching the dangers of exposure to metal oxide nanoparticles (less than 100 nm size), like manganese nanoparticles. The study involved using the nematode worm *Caenorhabditis elegans* (*C. elegans*) as the model organism. Our interest lies in the indication that nanoparticles such as Mn₂O₃ have been involved in the Parkinson's disease-like symptoms that are irreversible (manganism). To study the neurotoxicity of nanoparticles, we exposed *C. elegans* to increasing concentration of Mn nanoparticles. These worms are routinely used in the neurotoxicity of drugs and pesticides. In this study, we observed the morphology of the worms following a 1 and 5 day exposure to increasing concentration nanoparticles (up to 1000 µg) using light and fluorescence microscopy. Oxidative stress was monitored in the control and treated worms using a fluorescent dye marker. The results suggest an increase in the generation of free radicals following an increase in nanoparticle concentration. Preliminary studies also suggest a change in the gene expression of CED-9 gene in *C. elegans* and indicator of some protection of the worm from programmed cell death. In summary, *C. elegans* may serve as an important model in evaluating the toxicity of Mn nanoparticles.

P813**Board Number: B126****Careers in Science College Initiative: Undergraduate Research Experience for Freshman and Sophomore Biology and Chemistry students.**J. Jordan¹, F. Norflus¹, R. McFarlane¹, D. Day¹;¹Natural Sciences, Clayton State University, Morrow, GA

On numerous occasions, students enter college unprepared for the rigor of pursuing a degree in a science-related field. Studies show student involvement in undergraduate research early in their careers has a dramatic impact on academic success as well as providing personal and professional benefits for the student. The overall goal of this initiative was to stimulate student interest in careers in science by involving them in an undergraduate research experience with faculty. The close interaction with faculty would help the student develop important academic, research, and communication skills. These skills are carried over into the classroom setting and assist in building student self-esteem and confidence. Workshops were held where faculty gave short presentations of their research. The faculty also talked with the students about different opportunities for undergraduate research and what opportunities this

would afford them in the future. At a different informational meeting, the faculty gave presentations on maintaining a laboratory notebook, laboratory safety, and on how to do perform literature detailed literature searches. The students were recruited to the program by the faculty advertising this initiative in posting flyers around campus and announcements in introductory biology classes. In order to assess the effectiveness of this project, the students were given a pre-test prior to their involvement in the project and a post-test at the end. On these tests, the students were asked demographical data relating to their backgrounds, their knowledge of careers in science, and necessary skills in laboratory science. The end of the test then asked the students specific questions relating to the research of the faculty with whom they decided to work. Several students have participated in this project. To date, the data has been positive and supportive of the importance of involving students early in their scientific career in undergraduate research.

Board Number: B127

Implementing a Classroom Undergraduate Research Experience (CURE) in a Bioinformatics and Genomics Class.

C.E. Howell¹;

¹Department of Biological Sciences, Lock Haven University, Lock Haven, PA

Delivering upper-level undergraduate courses in bioinformatics and genomics at a Primarily Undergraduate Institution (PUI) presents unique challenges. A special difficulty is that course assignments and hands-on activities often become obsolete or outdated from one year to the next as online tools change so rapidly. BIOL323 "Bioinformatics and Genomics," an upper-level major elective at Lock Haven University, can only be offered every other year, compounding the difficulty. As a number of educators in the field have confronted these issues, we have sought to formalize our collaboration in order to develop and implement a Classroom Undergraduate Research Experience in Bioinformatics (CURE). To this end, in the summer of 2012 Lock Haven University joined the Genomics Education Partnership (GEP), a consortium of PUI faculty working in partnership with the Department of Biology and the Genome Institute at Washington University in St. Louis. The goal of the Partnership is to provide professional development, software tools, and an overarching project framework that allow faculty to provide publishable research projects in the context of undergraduate courses in bioinformatics and genomics. By distributing the work of annotation of genes and other genome features among a large number of undergraduates enrolled in courses at many institutions, the Partnership maximizes both research productivity and opportunities for up-to-date, hands-on, real-world experiences for participants, directly analyzing fundamental questions in the field. Classroom activities and their pedagogical and research outcomes will be presented.

P815**Board Number: B128****Identification and annotation of gene features in *Drosophila biarmipes* contig59 using a computational-genomics approach.**J. Nelson¹, T. Sadikot¹;¹Biology, Washburn University, Topeka, KS

The genome of *D. melanogaster* was completed in 2000 and it has since become a model organism. This fly is one of the most studied species in biology and serves as a model organism for studying many developmental and cellular processes common to higher eukaryotes. In this study, the well-annotated *D. melanogaster* was used as a reference for conservation-based analysis to annotate and identify all the genes present within the contig59 sequence of *Drosophila biarmipes*. Using a number of open-source computational genomic tools for sequence alignment, gene-prediction and *Drosophila* genome browsing, the *Drosophila biarmipes* contig59 was examined for relevant genomic elements such as genes, pseudogenes and repetitive elements. Contig59 corresponds to the dot chromosome of *D. biarmipes* and was observed to contain three putative genes, all in the order and minus orientation, consistent with that found in *D. melanogaster*. Our analysis revealed that of the three genes predicted within this contig, CaMKI erroneously appears in this region only due to shared-conserved domains with CamKII. Thus, in our final conclusion, we state that the *Drosophila biarmipes* contig59 only contains two genes, CamKII and Zyx which are both well conserved between *D. melanogaster* and *D. biarmipes*.

P816**Board Number: B129****The Genomics Education Partnership (GEP): An undergraduate bioinformatics research network providing transformative course-based research experiences.**M. Laakso¹, C. Arrigo², J. DiAngelo³, D. Dunbar⁴, C. Howell⁵, A. Kleinschmit⁶, L. Paliulis⁷, J. Porter-Kelley⁸, J.A. Roecklein-Canfield⁹, A.G. Rosenwald¹⁰, M.J. Wolyniak¹¹, L. Zhou¹², W. Leung¹³, C. Shaffer¹³, S. Elgin¹³;

¹Department of Biology, Eastern University, St. Davids, PA, ²Department of Biology, New Jersey City University, Jersey City, NJ, ³Department of Biology, Hofstra University, Hempstead, NY, ⁴Department of Science, Cabrini College, Radnor, PA, ⁵Department of Biological Sciences, Lock Haven University, Lock Haven, PA, ⁶Biology Program, Adams State University, Alamosa, CO, ⁷Biology Department, Bucknell University, Lewisburg, PA, ⁸Department of Life Sciences, Winston-Salem State University, Winston Salem, NC, ⁹Department of Chemistry, Simmons College, Boston, MA, ¹⁰Department of Biology, Georgetown University, Washington, DC, ¹¹Biology Department, Hampden-Sydney College, Hampden-Sydney, VA, ¹²Department of Health Information Management, University of Pittsburgh, Pittsburgh, PA, ¹³Biology Department, Washington University School of Medicine, St. Louis, MO

The *Vision and Change* and PCAST reports call for an increased use of collaboration and research-based educational practices as vital to engaging students in modern science and preparing them to be both

potential participants in the STEM workforce and informed citizens in a complex society. The use of bioinformatics in a multi-institutional community of practice provides an outstanding way for students at all types of institutions to engage in research resulting in real and publishable scientific data in an accessible and inexpensive manner. The Genomics Education Partnership (GEP) is a network of more than 100 colleges and universities serving over 1000 undergraduates annually that uses a central platform at Washington University in St. Louis to provide course-based research experiences that can be adapted to the specific needs of each class and institution type, including large universities, small undergraduate institutions, and community colleges. GEP research projects are used in short introductions (~10 hr), deeper class investigations (~ 44 hr), and independent study. GEP curriculum, which utilizes the power of comparative genomics, focuses on research questions considering the evolution of the Muller F element, a domain with unique hetero- and euchromatic properties, in multiple species of *Drosophila*. GEP undergraduates work to improve the draft genomic sequences and/or annotate these improved sequences. Their findings contribute to student co-authored publications, provide data for elucidating the regulation of chromatin structure and its impact on gene expression, and benefit the scientific community through data submission to public databases. We find that students who engage with GEP materials, regardless of institution type, show noteworthy learning gains as well as the ability to prosper in a research-intensive curriculum. Current work in the GEP is focusing on how to best adapt bioinformatics curricula for use in an introductory-level biology course, and how to synergize with wet-lab components. Overall, national projects like the GEP take advantage of modern technologies to build cost-effective collaborations that engage undergraduate classrooms; these strategies are having a widespread impact on life-science teaching.

Maximizing Undergraduate Research Opportunities By Combining Independent Senior Projects With Lower-Level Classroom Labs.

J.P. Brandt¹, C.M. Ferrante², M.J. Wolyniak²;

¹Biology Department, Hampden-Sydney College, Hampden Sydney, VA, ²Biology Department, Hampden-Sydney College, Hampden-Sydney, VA

In recent years, a wide variety of institutions have implemented course-based research experiences (CUREs) as an integral part of a complete education in the life sciences. An inhibiting factor for many faculty interested in developing CUREs is the development of research questions that can be adequately expanded and adapted for a large number of students in a classroom setting and that also provides students with a feeling of project ownership. At Hampden-Sydney College, a small liberal arts college in central Virginia, we are taking advantage of senior honors projects to develop CUREs that can be employed in introductory or intermediate-level biology classes. We believe that this system of CURE development can provide a variety of authentic research experiences to the majority of Hampden-Sydney biology majors while also allowing an exciting level of undergraduate engagement in the process as upperclassmen play a significant role in the planning and execution of research that will be performed

by themselves as well as their fellow students. As a pilot for this CURE development model, we are using a project based on antibiotic design to combat bacterial infection. The project builds on the work of Wenzel *et al.* (2014) that tested the effectiveness of a peptide consisting of arginine and tryptophan repeats (RWRWRW-NH₂) as an antibiotic. This work found that the peptide could embed itself in the cell wall of a bacterium but left many questions unanswered as to the efficacy of derivatives of this peptide against common bacteria of genus *Bacillus* and *Staphylococcus*. A research project of this nature requires the synthesis of several polypeptide derivatives and the testing of these polypeptides against several bacterial species; thus, we believe it is a strong candidate to serve as both a senior honors project and a CURE that can be taught by a faculty instructor with the assistance of senior honors researchers.

We are using this antibiotics project during the 2014-15 academic year in Hampden-Sydney's Genetics and Cell Biology course, which is traditionally taken in the first two years of a student's undergraduate education. Students are taking polypeptides designed by the senior thesis researchers and using them to design and execute experiments on their ability to influence the ability of *Bacillus* and *Staphylococcus* growth. Assessment of the CURE is focused on student confidence in their ability to perform authentic scientific research, attitudes on project ownership, and communication of results in paper and poster forms. Thus, this CURE represents the development of an exciting pedagogical model in which upperclassman research projects provide research participation opportunities that can reach the majority of biology students.

Board Number: B131

Amplification and RFLP analysis of the "caffeine gene" in the genetics classroom.

Y. Zephyr¹, S. Walsh¹;

¹Biology, Rollins College, Winter Park, FL

Caffeine is the most popular stimulant in the world. However, the effect of caffeine on an individual varies widely. Along with environmental factors, this is due, in part, to the genetic differences in how caffeine is metabolized by liver enzyme cytochrome P450 1A2 (CYP1A2). Those who metabolize caffeine quickly will be less affected, whereas slow metabolizers will feel the effects long after consumption. A single nucleotide polymorphism (SNP rs762551) within an intron of CYP1A2 exists as either an A or a C. Fast metabolizers are homozygous A, while those who are homozygous C or heterozygous are slow metabolizers. The goal of this project was to generate a series of classroom laboratories analyzing this SNP from the students' own DNA. DNA was isolated from cheek cells, and a specific region of CYP1A2 was amplified via PCR. The PCR product then underwent RFLP analysis using the enzyme *Apal* to detect the SNP, and *SacI* served as a control. Using agarose gel electrophoresis, each genotype was distinguished by the size of the RFLPs. As additional controls, unknown data were compared against individuals reported to be homozygous A, homozygous C, or heterozygous by the DTC genetic testing company 23andme. Using RFLP is a more cost-effective analysis than other sequencing-based

laboratories. Importantly, this exercise can be scaled up or down to meet the needs of majors and non-majors alike. Overall, this series of laboratories exposes students to a variety of basic genetics techniques, correlates to an observable phenotype without causing serious health concerns, and caters to students' innate desire for self-discovery.

Board Number: B132

pClone: A New Synthetic Biology Laboratory Module that Improves Student Learning.

M. Campbell¹, T. Eckdahl², B. Cronk³, L. Heyer⁴, J. Poet⁵, C. Andresen², P. Frederick², S. Huckuntod², C. Shinneman², A. Wacker¹, J. Yuan²;

¹Biology, Davidson College, Davidson, NC, ²Biology Department, Missouri Western State University, St. Joseph, MO, ³Psychology Department, Missouri Western State University, St. Joseph, MO, ⁴Mathematics and Computer Science, Davidson College, Davidson, NC, ⁵Computer Science, Math and Physics Department, Missouri Western State University, St. Joseph, MO

The Vision and Change report recommended genuine research experiences for undergraduate biology students. Authentic research improves science education, increases the number of scientifically literate citizens, and encourages students to pursue research. Synthetic Biology is a new, interdisciplinary field that blends chemistry, engineering, mathematical modeling, computer science, molecular biology and systems biology. Synthetic biology is well suited for undergraduate research, is practiced by a growing community of undergraduate educators, is attracting federal and corporate funding, and provides promising job opportunities for future scientists. After years of training undergraduates to conduct synthetic biology research, we are familiar with the best methods to use with inexperienced students. Our pedagogical goal was to develop an inexpensive and simple laboratory module that AP Biology and college faculty could adopt easily to their local conditions while accomplishing specific learning objectives. We developed a laboratory module called pClone that empowers students to use advances in molecular cloning methods to discover a new transcriptional promoter or mutate a canonical promoter and measure promoter activity in *E. coli*. pClone uses typical laboratory equipment, requires minimal preparation time and meets the increased demands placed on faculty and departments. pClone leverages the modern method of Golden Gate Assembly as a cutting-edge molecular cloning tool that can be used by students with little or no experience in molecular biology. We also developed the Registry of Functional Promoters, an open access database of student promoter research results. This poster describes our "action research" that documents learning gains by students using pClone and details the simple procedures by which pClone can be adopted by others. Action research is defined as faculty-led research and dissemination of an innovation that enhances student learning. Our educational goals are consistent with Vision and Change and emphasize core concepts and competencies. Using pre- and post-tests, we measured significant learning gains among students using pClone in Introductory Biology and Genetics classes. Student post-test scores were significantly better than scores by students who did not use pClone. pClone is an easy and affordable mechanism for large

enrollment labs to meet the high standards of Vision and Change. The pClone module provides an inexpensive entry point to synthetic biology and promoter analysis for faculty to offer authentic research experiences for their students within the context of laboratory classes.

Board Number: B133

The “WHY, HOW, WHERE, WHAT, SO WHAT?” strategy for teaching scientific Results writing in undergraduate courses: what is it, and does it work?.

J.K. Hood-DeGrenier¹, D. Barnard¹;

¹Worcester State University, Wellesley, MA

Learning to write about data in the style of a scientific research paper is a valuable experience for undergraduate students regardless of whether they may ever be in the position of actually preparing a manuscript for publication. Asking students to write a standard Results section in particular provides a measure of a student’s understanding of experimental questions and procedures, as well as their ability to analyze data and draw logical conclusions. Furthermore, learning to craft a well-written Results section develops general organizational and communication skills that students can apply to other forms of writing and to oral presentations. Thus, there is clear value in pairing research paper-style writing assignments with course-associated laboratory investigations. However, students often find such assignments daunting, and instructors are often dissatisfied with the outcomes, especially given the effort required to evaluate and provide feedback on this type of student work. To address these problems, we have developed, implemented, and assessed the efficacy of a “formula” to assist students with writing a Results section: the “WHY, HOW, WHERE, WHAT, SO WHAT?” strategy. We will detail this teaching strategy, provide examples of assignment descriptions and grading rubrics that employ it, and present data from two types of assessment: student surveys and rubric-directed evaluation of student writing from introductory, intermediate, and upper level courses in cell and molecular biology and genetics.

P821

Board Number: B134

Using HeLa cell stress response to introduce first year students to the scientific method, laboratory techniques, primary literature, and scientific writing.

K. Resendes¹;

¹Biology, Westminster College, New Wilmington, PA

Incorporating scientific literacy into inquiry driven research is one of the most effective mechanisms for developing an undergraduate student’s strength in writing. Additionally, discovery-based laboratories help develop students to approach science as critical thinkers. Thus, a three-week laboratory module for an introductory cell and molecular biology course that couples inquiry based experimental design with

extensive scientific writing was designed at Westminster College to expose first year students to these concepts early in their undergraduate career. In the module students used scientific literature to design and then implement an experiment on the effect of cellular stress on protein expression in HeLa cells. In parallel the students developed a research paper in the style of the undergraduate journal BIOS to report their results. HeLa cells were used to integrate the research experience with the Westminster College "Next Chapter" first year program, in which the students explored the historical relevance of HeLa cells from a sociological perspective through reading *The Immortal Life of Henrietta Lacks* by Rebecca Skloot. This work describes the design, delivery, student learning outcomes, and assessment of this module and while this exercise was designed for an introductory course at a small primarily undergraduate institution, suggestions for modifications at larger universities or for upper division courses are included. Finally, based on student outcomes suggestions are provided for improving the module to enhance the link between teaching students skills experimental design and execution with developing student skills in information literacy and writing.

Board Number: B135

Crowd-funding for Undergraduate Research.

L.C. Keller¹;

¹Biological Sciences, Quinnipiac University, Hamden, CT

Being an educator and conducting mentored research with students at a primarily undergraduate institution is both incredibly rewarding and challenging. The two main factors that play into a faculty's productivity are time and resources. It is difficult to maintain an active research program while teaching three or four classes every semester and trends in higher education have institutions and departments strained for resources. The increasing cost of education in our country, ever-changing labor markets, and the introduction of new technology have many universities facing serious financial struggles. As educators and undergraduate mentors we need to start getting creative about our time and funding capabilities. For many of us summer is the time when we can really focus on our research, but funding opportunities for summer projects are scarce and applying to larger governmental grants is time-consuming and very competitive. I turned my sights to crowd-funding. The two science-specific crowd-funding websites that I researched are Start Up Scholar and Experiment.com. These crowd-funding websites have a platform for you to design a website with images, videos, scientific explanations, a defined budget, and endorsements from the scientific community. It is then the responsibility of the researcher to advocate and spread the word about the campaign. The project is only funded if the monetary goal is reached within a defined time period. These professional websites then take a small percentage (5-7%) of your funds and provide you with a check for the remaining amount. My crowd-funding campaign on Experiment.com entitled "Flies on the Brain: Can Fruit Flies Aid in Curing Neurodegeneration?" was kicked off in April 2004 and 30 days later was successfully funded for \$4125. This funding covered housing and summer salary for a summer undergraduate research student conducting biomedically relevant research in my laboratory.

P823**Board Number: B136****Tactile Literacy: Customizing STEM Education.**A.N. Gonzales¹, L. Van Tuyl¹, B. Martinez¹, E. Hasper², T. Hedgpeth³, R.A. Windhorst², D.P. Baluch¹;¹School of Life Sciences, Arizona State Univ, Tempe, AZ, ²School of Space and Earth Exploration, Arizona State Univ, Tempe, AZ, ³Disability Resource Center, Arizona State Univ, Tempe, AZ

Achieving a successful career in STEM (science, technology, engineering and mathematics) requires not only a great education but extensive training and preparation. This high level of training is especially important with the predicted shortage of qualified professionals where it is estimated that by 2018 the nation is expected to have 8.6 million STEM jobs available where 60% will require skills possessed by only 20% of the workforce. Over the last decade, the U.S. government has invested \$3 billion dollars a year in 220 programs across 13 different agencies to improve the STEM education system in order to create a sustainable pipeline of trained professionals. Although many programs have been created to provide additional training to graduate and post-doctoral students to prepare their transition into a professional appointment, the focus is beginning to shift to the K-12 and post-secondary level education to ensure that students not only receive adequate training but are encouraged to pursue a STEM career. In a recent study, researchers developed customized tactile teaching tools, such as images converted into 3D tactile boards, to test if these could increase the performance and participation of visually impaired students. Results from this study found that both sighted and blind/visually impaired (BVI) students, who were taught using the hands-on tactile laboratory setting, enjoyed their lessons much more than their peers who only participated in the text based format. When compared on retention and understanding, the tactile learners received an average increase of 15% in their test scores as compared to their peers who used the text based format. These assessments demonstrated that in order to improve student performance, some concepts, especially in lab based disciplines, are best taught using a tactile learning style that moves beyond what standard Braille and raised line diagrams, graphs and outline drawings are able to provide. An additional benefit of this study was that the tactile teaching elements, which are customizable to the subject area, enable instructors to reach a greater diversity of multidisciplinary students. Results from this study suggest that tactile literacy may become viewed as a necessary component to help sighted and BVI students pursue higher levels of post-secondary education and ultimately increase the prospect of obtaining professional employment in a STEM field. In addition, these findings highlight the importance of developing and testing new customizable tactile technologies in order to make STEM education accessible and enjoyable for future students.

P824**Board Number: B137****Development and Assessment of an Undergraduate Teaching Assistantship (UTA) Program in Biology Laboratories at American University.**N. Zeller¹, M. Bentley²;¹Biology, American University, Washington, DC, ²American University, Washington, DC

Recent reports and pedagogical research has suggested that an open-ended research experience can help science undergraduates develop problem-solving skills, work within a team, communicate science, and develop their own scientific interests. Unfortunately, many institutions are unable to sustain access for multiple undergraduates in faculty-led research programs for many reasons – including lack of resources and significant teaching loads for faculty. An alternative to students doing individual research projects is the creation of course-based research experiences (i.e., CUREs), which are proven methods to provide students with significant research experiences leading to the development of the skills and attitudes described above. Here, we propose a third alternative, the creation of the undergraduate teaching assistants, or UTAs. American University is a mid-size liberal arts university with a growing research faculty and student body interested in medicine, basic research and public health. In the department of Biology, Master's Students serve as teaching assistants for the laboratory portion of the introductory and non-major courses. Two years ago, we added UTAs to laboratories that were particularly technique heavy or where students struggled with fundamental concepts. Currently, UTAs participate in five of the 12 laboratories each semester and in TA training prior to each lab. Since the beginning of the UTA program, we have surveyed the UTAs pre- and post-semester as well as asked students taking the course to comment on the value of their UTA. We have found that UTAs report increased interest in science, increased confidence in trouble-shooting and understanding of fundamental concepts in biology. Students enrolled in laboratories served by UTAs report an average of 6 contact points with their UTA per semester. We have also found that the ease with which UTAs are recruited and trained has provided a mechanism for the more frequent involvement of women and under-represented minorities in the biology labs. We propose that the UTA position is an efficient, effective strategy to 1) teach undergraduates the skills often learned in a traditional research lab, 2) augment the pedagogical quality of laboratories and 3) increase the participation of underrepresented populations, including transfer and first-generation college students, in the sciences.

P825**Board Number: B138****Mouse Color Genetics as an Undergraduate Laboratory Exercise.**L.P. Lyman-Henley¹, L.E. Bailey¹;¹Biological Environmental Sciences, Texas AM University-Commerce, Commerce, TX

Finding laboratory exercises that engage undergraduate students in introductory biology and zoology courses can be challenging, especially when attempting to incorporate hands-on training in basic

research that stimulates critical thinking. I have developed a basic genetics exercise which beginning undergraduate students can perform in a 6 to 8 week period that allows them to learn basic inheritance patterns, collect data to test a hypothesis, and write a complete research-style laboratory report, which students find both educational and engaging.

“Mousy Match-Maker” allows students working in groups to choose from available live lab mice demonstrating a variety of coat colors and types. Students learn about phenotype and genotype in describing their chosen mice and referring to published information about mouse color genetics to attempt to identify the alleles represented by their subjects. Students then form hypotheses regarding the alleles that should be exhibited by the offspring of their mouse pair, following at least 2 distinct genes. Mice have a 21 day gestation period, so young are generally born within a month of pairs being introduced, and students can determine the coat color of offspring in another 2 to 3 weeks. Students can then record the actual coats of their young mice, and compare that to their predictions using Punnett squares. Chi-square tests are easily utilized to compare observed to expected results, and students can use “surprise” results to revise their original hypotheses.

One full lab period is devoted to the project at start up and at end. In the intervening weeks other lab exercises are scheduled, with brief weekly “installments” where students work on specific aspects of the project and check up on the progress of their mice. All of this makes an excellent project to describe in a scientific paper format while illustrating basic inheritance patterns, and generates far more interest and effort than any other “pre-packaged” genetics laboratory exercises used.

Board Number: B139

A new course and textbook on Physical Models of Living Systems, for science and engineering undergraduates.

P. Nelson¹;

¹Physics/Astronomy, University of Pennsylvania, Philadelphia, PA

I'll describe an intermediate-level course on "Physical Models of Living Systems." The only prerequisite is first-year university physics and calculus. The course is a response to rapidly growing interest among undergraduates in a broad range of science and engineering majors.

Students acquire several research skills that are often not addressed in traditional courses:

- Basic modeling skills
- Probabilistic modeling skills
- Data analysis methods
- Computer programming using a general-purpose platform like MATLAB or Python
- Dynamical systems, particularly feedback control

These basic skills, which are relevant to nearly any field of science or engineering, are presented in the context of case studies from living systems, including:

- Virus dynamics
- Bacterial genetics and evolution of drug resistance
- Statistical inference
- Superresolution microscopy
- Synthetic biology
- Naturally evolved cellular circuits

The poster will show examples of student work from a mid-course "capstone" project involving modeling the Luria-Delbrück experiment via simulation-based likelihood maximization. The project is partly open-ended; examples will be shown of work by students who have never done computer programming prior to this course, as well as more sophisticated students who took the assignment farther. Outcomes include student reports of improved ability to gain research positions as undergraduates, and greater effectiveness in such positions, as well as students enrolling in more challenging later courses than they would otherwise have chosen.

Board Number: B140

The FUTURE Program: Ensuring that underserved populations become the scientific and civic leaders of tomorrow.

C.B. Favero¹, R.L. Lyczak¹, R.A. Roberts¹;

¹Biology, Ursinus College, Collegeville, PA

The Center for Science and the Common Good (CSCG) at Ursinus College provides a framework for all Ursinus science majors to think, speak, and write about the impact of science on the common good. One target group of the CSCG is the FUTURE Students (Fellowships in the Ursinus Transition to the Undergraduate Research Experience), members of underserved populations in science who are given research opportunities early and often to ensure that they can become scientific and civic leaders. We include underrepresented minorities (URMs), women, first-generation college students, and disabled students in this program. Students in the program enter a research experience during the summer prior to or directly after their first college year. During this time, they participate in a team-taught course titled "Science and Mathematics in Society" and are closely mentored by a faculty member and an upper class FUTURE Mentor. FUTURE students are encouraged to continue in research following the summer experience, to become FUTURE Mentors, and to participate fully in the CSCG. The CSCG was founded in 2012 through an HHMI grant and we have run two successful summer experiences to date. All FUTURE participants have continued in STEM fields. Through use of the national survey of undergraduate research experiences (SURE), we have shown that students who have participated in the FUTURE program show gains in all areas that are at or above the national average. Some positive impacts on students include: making them more resolute in their career choice, giving them confidence in their ability to communicate and make connections with faculty members, and increasing their awareness of the role of science in the common good.

P828**Board Number: B141****Isolating and analyzing bacteriophages with first year Biology students at Saint Joseph's University.**J.Y. Lee-Soety¹, C. King-Smith²;¹Biology, Saint Joseph's University, Philadelphia, PA, ²Department of Biology, Saint Joseph's University, Philadelphia, PA

Saint Joseph's University has been a member of the SEA-PHAGES (Science Education Alliance-Phage Hunters Advancing Genomics and Evolutionary Science, supported by the HHMI) consortium since 2009. We are in our fifth year of leading novice scientist, first year students majoring in Biology, Chemical-Biology, Math, and Environmental Sciences, in isolating, naming, sequencing, and genomic annotation of bacteriophages. From collecting soil to calling genes over the course of an academic year, the students are involved in authentic research using cutting-edge techniques. In the first semester, students isolate and purify novel phages from soil samples; they then characterize the phages by electron microscopy, DNA restriction digests, and pulsed-field gel electrophoresis. In the second semester, fully sequenced phage genomes are annotated using bioinformatics tools. We have now isolated 54 mycobacteriophages that infect *Mycobacterium smegmatis*, and 11 of those have been completely sequenced and analyzed. Five fully annotated sequences have been published on GenBank (Mycobacteriophages Daisy, BPBiabs31, Flux, Winky, and Oaker). This year, we have ventured to explore a new bacterial host – *Arthrobacter* sp. Both *Arthrobacter* sp and *M. smegmatis* are soil bacteria and from the same Actinomycetales order. So far, we have isolated 22 *Arthrobacter* phages and sequenced two. In addition to experiencing first hand research, students are exposed to primary journal articles and presenting their work orally and in writing; all of these activities building upon interests in the sciences and help with student retention in the STEM majors.

P829**Board Number: B142****Integrating authentic research in cell biology into an undergraduate liberal arts curriculum to enhance the pace of rare disease gene discovery for underserved populations and promote STEM retention.**R.N. Jinks¹, B.K. Davis¹, D.M. Roberts¹, E. Rice¹, K.W. Brigatti¹, E.G. Puffenberger², K.A. Strauss²;¹Franklin Marshall College, Lancaster, PA, ²Clinic for Special Children, Strasburg, PA

Next-generation sequencing accelerates disease gene discovery, especially for orphan diseases, though at present it outpaces functional studies needed to provide 'proof of causation.'

Working from a small, community-based, clinical laboratory, the Clinic for Special Children has identified more than 130 allelic variants associated with disability, disease, or untimely death among the Amish and Mennonite (Plain) populations of North America. In collaboration with the Clinic, we developed an

HHMI-funded program that integrates functional studies of novel disease gene alleles into our undergraduate curriculum. Roughly 150 students per year in our introductory cell biology and neuroscience courses clone human disease genes and study the functional impacts of gene variants through expression in mammalian cell culture. We use these authentic research experiences to teach key concepts in cell biology, genetics, and neuroscience. Students later build upon this experience in upper-level courses in cell biology, neuroscience, genetics, cancer biology, and immunology in which they engage in semester-long research projects in small teams. Teams conduct functional studies of disease gene variants or study novel cellular or animal models of disease. These experiences engender talented undergraduates to assume greater research responsibility through independent study and summer research projects that transition them into the role of co-PI for their project. Data published through this project (PLoS ONE 7:e28936) were recently used by another institution to diagnose a critically-ill, non-Plain newborn with lethal neonatal seizure-rigidity syndrome (Sci Transl Med 4:154ra135). This provides important proof-of-concept for integrating novel disease gene functional studies into a carefully structured undergraduate research curriculum. Students in our Public Health program are collaborating with the Clinic to develop handbooks to help parents care for children with special medical needs with the goal of producing one to two high-quality disease handbooks annually. Our program represents a model for engaging undergraduates in meaningful research at the front lines of biomedical science and public health in ways that directly impact the diagnosis and care of children with rare inherited disorders and promote STEM retention.

Board Number: B143

Development of a novel, inquiry-based curriculum for the undergraduate cell biology laboratory.

O.M. Kielbasa¹;

¹Department of Science and Mathematics, Biology Program, Alvernia University, Reading, PA

Research in undergraduate scientific education has shown that the most effective methodology in teaching laboratory-based science is to utilize an applied approach that emphasizes both inquiry and the use of the scientific method to solve “real world” problems. Student learning is most positively impacted by the design and execution of longer-term projects that more closely mirror the types of investigations that are carried out by actual research scientists. This is in contrast to a “cookbook-like” sampling of techniques, which are often taught in succession without a direct context for application to scientific research. Muscle differentiation is a complex process that provides a unique opportunity for undergraduate students to explore various aspects of cell biology in the laboratory. The work presented here describes the development of a novel inquiry-based undergraduate cell biology laboratory course focused on the examination of muscle cell differentiation. In this innovative curriculum, students were involved in the entire scientific process, from asking the experimental question to designing and performing the experiments, and then analyzing the results. They utilized a variety of complimentary techniques (including fluorescence microscopy, western blotting, and polymerase chain reaction) to

examine the morphological and genetic changes that occur during muscle cell differentiation in culture. Unlike typical labs which usually have an objective that is met in one or two class sessions, the students engaged in a longer-term project that spanned eight weeks during the semester. Students were assessed on the quality of their laboratory notebooks, including how thoroughly they documented each experiment and answered related discussion questions regarding the techniques and results. Ultimately, students compiled their work into an individually written research report, the format of which paralleled typical journal articles published in the field of cell biology. Overall, the design of this curriculum allowed students to explore fundamental cell biology topics while learning key experimental techniques. Furthermore, this was placed into the context of a conventional research experience to more effectively engage students in learning through direct inquiry and investigation.

MULTI-MICROBEAM SYSTEM FOR LOCALIZED INDUCTION OF DNA DAMAGE BY MULTIPLE TYPES OF RADIATION AND LIVE CELL IMAGING OF CELLULAR RESPONSES.

J. . Stap¹, J. Aten², J. Verhoeven³, C. van Oven², R. Hoebe², R. Meindert⁴, P. Krawczyk²;

¹Cell Biology / Van Leeuwenhoek Center for Advanced Microscopy, Academic Medical Center, Amsterdam, Netherlands, ²Cell Biology / Van Leeuwenhoek Center for Advanced Microscopy, Academic Med Ctr, Amsterdam, Netherlands, ³Kamerlingh Omnes Laboratory, Leiden Institute of Physics, University of Leiden, Leiden, Netherlands, ⁴Cluster 3 workshop, Academic Med Ctr, Amsterdam, Netherlands

KEY WORDS: DNA damage, live cell imaging

Cellular DNA damage responses (DDR) are important in cancer induction, diagnostics and treatment. Therefore, understanding of DDR pathways is crucial for improvement of existing and development of novel anti-cancer therapies. “Localized” DNA damage, induced in a small volume of the cell nucleus, is an important tool because signaling and repair responses triggered by the localized DNA damage can be studied in great detail using microscopical techniques not only in fixed cells, but also in living cells with fluorescently-tagged DNA repair-related factors. Induction of DNA damage using focused UV laser beams is a commonly applied technique, but there is a growing concern about the poor characterization of the DNA lesions produced by these sources. This is an important issue, since different repair processes are taking care of different types of DNA damage. In order to overcome this drawback, we constructed a novel type of instrument, coined the multi-microbeam (MMB). This instrument can be equipped with various irradiation sources to induce specific DNA damage. An ultra-soft X-ray source is used to induce DNA double-strand breaks (DSBs). The ultra-soft X-ray source is positioned under an

ultra-thin bottom culture dish containing adherent cells. A metal mesh filter with a dense array of micro apertures is positioned between the radiation source and the culture dish, enabling local irradiation of cells. A Leica SP5 confocal microscope, equipped with a water dipping objective, is positioned above the source, allowing real-time observation of cellular responses. A large part of the microscope and the irradiation source is enclosed in an incubator with CO₂ and temperature control. Using the MMB the accumulation kinetics of a number of DSB factors on sites of DNA damage can be analyzed. The system also allows Fluorescence recovery after photo-bleaching (FRAP) experiments to establish the residence time of proteins at the damaged DNA. A prototype of the MMB was already used to detect recruitment of heterochromatin protein 1 to DSBs. We expect that MMB irradiation will serve as a standard, given the well-characterized damage spectrum of the irradiation sources.

This project is funded by a NWO middelgroot grant (2010) and two grants from the Maurits en Anna de Kock stichting (2011).

Live cell imaging of cytoplasmic mRNP complexes in response to HIV-1 infection.

J.T. Becker¹, S.L. Fricke¹, A. Bates², L.E. Dougherty¹, N.M. Sherer¹;

¹Department of Oncology, University of Wisconsin, Madison, WI, ²University of Arkansas - Pine Bluff, Pine Bluff, AR

In mammalian cells, dynamic cytoplasmic messenger ribonucleoprotein (mRNP) complexes form in response to cellular stressors, including viral infection. These mRNPs include processing bodies (PBs) and stress granules (SGs), sites of RNA decay and suppression, respectively. Many RNA viruses have evolved mechanisms to evade or coopt PB and/or SG machineries, including the human immunodeficiency virus type 1 (HIV-1). To directly monitor the effects of HIV-1 infection on cytoplasmic mRNPs, we generated stable cell lines expressing visible versions of PB markers (APOBEC3G, Ago2, and Dcp1a) and SG markers (TIA1 and G3BP) and infected these cell lines with HIV-1 or the murine leukemia virus (MLV), both retroviruses, or the picornavirus rhinovirus A. Cells were monitored over the course of infection (over 72 hours) for changes to the quantity, morphology, and distribution of PBs and SGs over time. For HIV-1, this approach yielded single cell dynamics for HIV-mediated downregulation of the antiviral PB protein A3G by the HIV-1 protein Vif. We found this process to take more than 60 minutes per cell. In the absence of the HIV-1 Vif protein, infection led to remarkable relocalization of A3G from PBs and the cytoplasm to the plasma membrane. We observed A3G aggregating in large, 1-2µm diameter mRNP complexes at the cell surface containing the HIV-1 Gag capsid protein. Interestingly, we also noted that HIV infection can induce the transient formation of SGs and, unexpectedly, causes a marked condensation of TIA1 into bright nuclear foci at late times post-infection. Taken together, we have generated a tractable visual system for monitoring single cell RNP responses to viral infection, and confirm that HIV-1 infection can trigger dynamic remodeling of PBs and SGs of potential relevance to the viral life cycle.

P833**Board Number: B147****Super-constriction precedes GTP-hydrolysis dependent conformational changes in dynamin polymers during plasma membrane fission.**A.C. Sundborger¹, J.E. Hinshaw²;¹NIH, NIDDK, Bethesda, MD, ²NIH/NIDDK, Bethesda, MD

Dynamin is a mechanochemical enzyme that assembles into short scaffolds on necks of budding vesicles to mediate plasma membrane fission during clathrin-mediated endocytosis. Recent structural data has revealed key features of dynamin function during fission: 1) stalk-driven oligomerization into polymers with helical symmetry 2) dimerization of G domains that stabilizes the transitions-state of the GTP hydrolysis-reaction, a pre-requisite for productive fission, and 3) a GTP-dependent conformational change in the polymer referred to as the dynamin powerstroke. We show that dominant-negative dynamin mutant, K44A, is defective in stimulated GTP hydrolysis due to its inability to stabilize the GTP hydrolysis transition state. K44A polymers are trapped in a pre-fission state, capable of “super-constricting” necks of budding vesicles to the point of spontaneous fission. Super-constriction is achieved by K44A adopting a 2-start helical symmetry, which allows the polymer to constrict the underlying lipid bilayer to an inner luminal diameter of only 3.7 nm. We further show that super-constricted K44A is trapped in a ground state-configuration, which indicates that GTP binding is sufficient to promote an initial conformational change in the polymer, prior to GTP hydrolysis. In the super-constricted state, half of the PH domains are tilted out of the membrane compared to the non-constricted dynamin polymer. This suggests that upon super-constriction, the PH domain re-arranges its orientation in the outer leaflet of the bilayer, which may contribute to destabilization of the lipid, and act to promote fission. To understand how GTP hydrolysis ultimately promotes fission we performed time resolved studies of WT dynamin using cryo-EM. We show that like K44A, WT dynamin assembles into a 2-start helix in the presence of GTP that super-constricts the underlying lipid to the point of spontaneous fission. We further show that super-constriction is followed by a series of distinct conformational changes that ultimately lead to twisting, super-coiling, disassembly and fragmentation of protein-decorated lipid tubes. Therefore, we suggest that a fundamental function of dynamin is to assemble into a 2-start helix around necks of budding vesicles. This allows for super-constriction of the neck, optimizes G domain organization in the polymer, and evokes stimulated GTP hydrolysis that triggers a series of conformational changes; the BSE powerstroke, PH domain re-arrangement, loosening of the polymer and ultimately fission.

P834**Board Number: B148****Measuring mesoscale dynamics in chromosome organization with single-molecule tracking correlation spectroscopy.**C. Limouse¹, C. Fuller², J. Bell², A.F. Straight³, H. Mabuchi⁴;¹Stanford University, Stanford, CA, ²Biochemistry, Stanford University, Stanford, CA, ³Biochemistry, Stanford School of Medicine, Stanford, CA, ⁴Applied Physics, Stanford University, Stanford, CA

Numerous cellular processes involve conformational changes occurring at the scale of tens to hundreds of nanometers. The most compelling example is perhaps genomic organization where transient contacts between remote loci separated by hundreds or thousands of bp are ubiquitous and essential for transcription regulation. These processes are difficult to probe both *in vivo* and *in vitro* because they are sub-diffraction limit yet too large to be easily accessible by precise single-molecule methods such as FRET. I discuss the application of single-molecule fluorescence correlation techniques, as well as single-molecule tracking as a way to resolve conformational dynamics on these length scales. I present a proof-of-principle experiment where we measured the end-end dynamics of short DNA fragments freely diffusing in solution. Finally I discuss future applications to the detection of DNA looping induced by CTCF and other DNA binding proteins.

P835**Board Number: B149****Determination of sample preparation parameters critical for optimal Structured Illumination Microscopy (SIM).**C. Arvanitis^{1,2}, N.J. Dolman³, J.Z. Rappoport^{2,4};¹Pathology, Northwestern University, Chicago, IL, ²Center for Advanced Microscopy, Northwestern University, Chicago, IL, ³Molecular Probes Labeling and Detection Technologies, Thermo Fisher Scientific, Eugene, OR, ⁴Department of Cell and Molecular Biology, Northwestern University, Feinberg School of Medicine, Chicago, IL

Super-resolution microscopy is a term used to describe a variety of techniques that bypass the diffraction limited resolution of a light microscope (~250nm). Structured Illumination Microscopy (SIM) is a super-resolution microscopy technique by which one can obtain roughly double the resolution of standard light microscopy. SIM accomplishes this by using a grid to generate a Moiré pattern on the sample. The grid is moved and rotated resulting in a total of 9-15 images, which are then computationally reconstructed to generate a final image with a resolution of roughly 125 nm. The quality, and resolution of this final image is highly dependent on sample preparation. Photobleaching, signal from out of the focal plane, spherical aberration (introduced by cell structures such as nuclei or poor quality mounting media) and low signal to noise can result in images which are filled with artifacts or not resolved. To date there are no studies which determine the optimal mounting media for SIM

microscopy, in particular across different samples and SIM imaging platforms. Here we compare results from two different SIM microscopes (Nikon N-SIM and GE OMX) using both sub resolution beads and fluorescently labeled cells mounted in media from a variety of manufactures, as well as a homemade buffered glycerol solution containing p-Phenylenediamine (PPD). For bead preparations, we measured maximal resolution using full width half max (FWHM) measurements in four channels (405, 488, 561 and 640 excitation). To model more relevant biological samples, cells were grown on coverslips loaded with 20nm red FluoSpheres and labeled with Alexa Fluor 488 phalloidin. FWHM measurements were taken on both the FluoSpheres as well as actin filament diameter to compare resolution within cells. Results from each of the different sample preparations are presented.

Combination of Stimulated Depletion Emission (STED) microscopy with Electron Microscopy (EM) to image the uptake and trafficking of A β oligomers into murine Microglia.

C.M. Chalouni¹, M. Reichelt¹, R. Patnaik², O. Foreman¹, J. Webster¹, P. Steiner³;

¹Pathology Department, Genentech, South San Francisco, CA, ²Bioengineering Department, Columbia University, New York City, NY, ³Neurosciences Department, Genentech, South San Francisco, CA

The diffraction limit (D_{xy}) is the minimum distance required between two objects to resolve them individually and is defined by the wavelength of the excitation light (λ) and the numerical aperture of the lens (NA) ($D_{xy} = \lambda / 2NA$). Microscopy has entered a new era with technological advances in super-resolution imaging which allows for the achievement of a resolution beyond the lateral diffraction limit of 250 nm. One of these approaches is STED microscopy based on Stefan Hell's concept, in which the resolution further depends on the ratio of the intensity of the excitation laser versus the intensity of the depletion laser (I_{sat}): $D(xy) = \lambda / 2NA (1 + \sqrt{1 + I/I_{sat}})$. The Leica SP8 STED 3X system can image samples labeled with up to 3 different fluorescent tags down to maximal xy and z resolutions of 45 nm and 130 nm, respectively. This increased resolution dramatically improves discrimination, description, and quantification of sub-cellular compartments. Cell trafficking is a crucial question relevant to numerous biological fields of investigation. In this study, we show that gated STED imaging allows to routinely increase the lateral resolution by a factor of 2 compared to confocal imaging and that further deconvolution using Huygens software improves the resolution an additional 3 fold. We have applied this technology to study the internalization of A β oligomers by murine microglia. A β oligomers are considered as one of the hallmarks of Alzheimer's disease and have been suggested to contribute to disease pathophysiology. In addition, uptake of A β oligomers by microglia is thought to be involved in oligomer clearance from the brain and may play a critical role in disease progression. Here, we studied A β oligomers uptake and intracellular trafficking into microglia using 3 dimensional STED imaging. We performed double immunofluorescence for A β oligomers in combination with endocytic markers such as clathrin, caveolin, LAMP, EEA1 as well as the autophagocytic marker LC3 in microglia. The specificity of the markers was further confirmed by immuno-electron microscopy. Correlating STED images with

electron microscopy images (CLEM) provides additional cellular morphological information and context. Altogether, these results demonstrate the feasibility of combining STED and CLEM and allow the identification of the subcellular trafficking of A β oligomers in microglia at a resolution never achieved previously.

iSERS Microscopy: Multiplexed Protein Localization for Tissue-based Cancer Diagnostics by Surface-Enhanced Raman Scattering.

J. Wissler¹, S. Schlücker¹;

¹Physical Chemistry, University Essen-Duisburg, D-45141 Essen, Germany

Optical localization of proteins by microscopy is often performed by usage of fluorescent labels. Proteins can be labeled with fluorescent dyes directly or indirectly by antigen-recognizing fluorophore-labeled antibodies (immuno-fluorescence). In cases where multiple targets have to be colocalized, the number of distinct fluorophores is limited. This is due to the huge overlap of the broad spectral emission profiles of available fluorescent dyes. Parallel detection of more than four fluorescence colors is therefore very challenging. In contrast, Raman emission profiles are characterized by narrow line widths and can even be used parallel to established fluorescence detection. In combination with Raman-active noble metal nanoparticles, the surface-enhanced Raman scattering effect (SERS) can be exploited which results in an increase of the vibrational Raman intensity by several orders of magnitude.^[1] This offers multiplexed and quantitative detection of numerous cellular entities which can be performed with up to dozens of different Raman-"colors" using a single laser excitation wavelength. The properties of the colloidal SERS probes, like signal brightness, stability and robustness, are important for this task. Multiple SERS-labeled antibodies can be used for the parallel detection of numerous antigen targets on tissue biopsies, enabling fast multi-testing of different cancer antigens by immuno-SERS microscopy (iSERS).^[2] Two-(Raman)-color iSERS experiments localizing the tumor suppressor p63 and prostate-specific antigen (PSA) on prostate tissue samples show the possibility of fast cancer antigen detection on large biopsy areas. The differentiation of histological subclasses, like p63(+) basal epithelium and p63(-) secretory epithelium, is visible in high resolution iSERS-images.^[3] Results of multiplex-iSERS imaging experiments on tissue samples, targeting different protein antigens, are presented.

P838**Board Number: B152****Novel mouse xenograft model for noninvasive in vivo imaging of human tumor cell and tissue in the auricle.**S. Kita¹, H. Higuchi¹;¹Physics, The University of Tokyo, Tokyo, Japan

We developed methods of preparing xenograft model and imaging GFP-expressing cells to observe noninvasively cells in mouse auricles. In the previous studies, we imaged invasively the tumor exposed by dissection of skin and epithelium. By the dissection, blood flow was blocked, resulting in lack of supply of oxygen and nutrient. We, however, concern if homeostasis of their cells is maintained to elucidate biological phenomenon in imaging under ischemic condition. Therefore, we developed new noninvasive imaging methods. We selected the ear auricle of mouse for observation of tumor cells because of very thin (about 150-200 μ m) and limited hypodermal tissue. We have developed a novel xenograft model which has tumor in auricle. SCID mice of 8-12 weeks old were used in our experiments. We injected five kinds of human cancer cell lines into the ear auricle of SCID mice; breast cancer cell lines named KPL4-EB1-GFP and MDA-MB-231, MDA-MB-231-EB1-GFP and MDA-MB-231-GFP-tub, and glioma cells line U87MG. Tumor was successfully formed 100% of injected mice at incitation of $> 4.6 \times 10^6$ cells of KPL4-EB1-GFP, which is known to form tumor tissue easily on subcutaneous. On the other hand, MDA-MB-231 cell line had been difficult to form tumor at subcutaneous of mouse back. Surprisingly, we successfully develop the xenograft about 100 % of injected mice by inoculation of $> 4.0 \times 10^6$ cells of MDA-MB-231, MDA-MB-231-EB1-GFP and MDA-MB-231-GFP-tub in the ear auricle of mice. Tumor formation rate of U87MG which is known as cancer having high malignancy was 100% at injected more than 0.8×10^6 cells. The tumor and cells in auricle were noninvasively imaged by spinning disk confocal (CSU) system equipped with automatic positioning stage, piezo actuator for objective and an EMCCD camera. We imaged GFP fluorescence in the MDA-MB-321-GFP-tub cells in tumor of ear auricle without injuring mice. The individual two cells in tumor were distinguished faintly with bright background of tumor fluorescence. We also took a montage view of tumor cover wide area (3x2 mm). The shape of a tumor appeared faintly at the depth $> 40 \mu$ m, suggesting the shape is background of a tumor located deeper. There are several bright spots in the diameter of about 20 μ m in the enlarged image, indicating those are single cells. We could successfully perform real time observation of GFP fluorescence in the breast cancer cells in noninvasive condition by a CSU system.

P839**Board Number: B153****Multiplex imaging of DNA damage in cell suspensions.**A. Didenko^{1,2};¹Vivid Technologies Inc, Houston, TX, ²Tufts University, Medford, MA

We developed a new approach to study cellular reactions in cell suspensions via multiplex imaging of DNA alterations. The approach detects conditions of individual cells by visualizing DNA-centered biomarkers. For this, the cells are initially immobilized on a set of selective capture membranes and are then analyzed *in situ* for the presence of specific types of DNA breaks, which indicate apoptosis, phagocytosis or non-lethal DNA damage. The methodology is fast and cost-effective. It is advantageous in research using complex cellular suspensions composed of cell types with dissimilar responses to stressors. The method is a new multiplex imaging tool useful in molecular and cell biology.

P840**Board Number: B154****Optogenetic Control of Fibroblast Growth Factor Receptor Signals.**M. Lee¹, N. Kim², J. Kim¹, C. Kim¹, K. Chang², W. Heo^{1,2};¹KAIST, Daejeon, Korea, ²IBS, Daejeon, Korea

Fibroblast growth factor receptors (FGFRs) regulate diverse cellular behaviors such as proliferation, growth, differentiation, migration, survival, and apoptosis. Here, we present a synthetic approach to modulate FGFR signaling by light in a highly spatiotemporal manner. We engineered an optically controlled FGFR (optoFGFR1) by exploiting cryptochrome 2, which homointeracts upon blue light irradiation. OptoFGFR1 can regulate the signaling pathways of FGFR by light in a rapid and reversible manner with subcellular resolution. At the single cell level, localized effect of optoFGFR1 induced changes in the cytoskeleton. Utilizing the precision control of optoFGFR1, we can induce cell polarization and directed cell migration. With the same scheme of optoFGFR1, we developed optoFGFR2, optoFGFR3 and optoFGFR4 (optoFGFRs) for investigating FGFR subtypes mediated signaling pathways. The genetically modified light-inducible FGFRs, optoFGFRs, shed us a potential on the study of FGF signaling in various biological systems.

P841**Board Number: B155****Live-cell imaging of RNAs fused to Spinach using fluorescent microscopy in *Saccharomyces cerevisiae*.**J.A. Zinskie¹, M. Bruist¹, C.J. Janetopoulos², K.A. Myers³;¹Chemistry Biochemistry, University of the Sciences, Philadelphia, PA, ²Biological Sciences, Univ of the Sciences, Philadelphia, PA, ³Department of Biological Sciences, Misher College of Arts and Sciences, University of the Sciences, Philadelphia, PA

A wide array of options exists for live-cell imaging of RNA, however each option has its own drawback. A recent development in the field of RNA imaging is the development of a small -RNA aptamer, Spinach, which interacts with a fluorophore to produce fluorescence. To test this system in *Saccharomyces cerevisiae*, yeast, a small-nucleolar gene, SNR30, was fused to the Spinach aptamer. The gene fusion was expressed in and imaged using fluorescent microscopy. Spinach did not affect RNA localization and yielded a high quantum yield of fluorescence. Additional small-RNAs have been tagged with the Spinach aptamer, expressed in yeast and visualized using fluorescent microscopy.

The ability to visualize subcellular organelles in yeast cells has required fixation due to Brownian motion. Immobilization by embedding live yeast on the surface of 2% agarose has been used, but gives poorer resolution than fixation. Agarose also reduces the signal intensity, yielding a less than optimal image. To combat this reduction in image quality, a new microcompressor has been used for live-cell fixation; considerable subcellular detail can be captured from such mechanically fixed cells.

P842**Board Number: B156****Signaling Events and Cellular Processes Modulated by Ultra-small Integrin-targeted Silica Nanoparticles in a Concentration-dependent Manner.**M. Benezra¹, M. Pauliah¹, M.H. Overholtzer², U. Wiesner³, M.S. Bradbury^{1,4};¹Department of Radiology, Memorial Sloan-Kettering Cancer Center, New York, NY, ²Cell Biology Program, Memorial Sloan Kettering Cancer Center, New York, NY, ³Department of Materials Science and Engineering, Cornell University, Ithaca, NY, ⁴Molecular Pharmacology and Chemistry Program, Sloan Kettering Institute, New York, NY

Ultra small multifunctional silica nanoparticles may provide a highly versatile disease-directed platform for delivery of therapeutic drugs. Of critical importance to the clinical advancement of such platforms is the need to completely characterize novel particle probes at the cellular and molecular levels, and elucidate how particle surface chemistry potentially modulates key biological properties of these probes. In this study, we characterized these new fluorescent particles, termed Cornell dots (or C dots surface-functionalized with polyethylene glycol (PEG) chains for conjugation of cyclic arginine-glycine-aspartic acid-tyrosine (cRGDY) peptide ligands). We have previously shown high binding affinity, and

enhancement of potency, and multivalency with this ultra small, inorganic nanoparticle platform. In this work we investigate mechanism of action, subcellular internalization, and expression levels of key signaling pathway intermediates in the alpha-v-beta-3 ($\alpha v\beta 3$) integrin-expressing human melanoma (M21) and umbilical vein endothelial (HUVEC) cells as a baseline for future therapeutic work. Concentration- and time-dependent binding was observed by flow cytometry and gamma counting using cRGDY-PEG-C dots in M21 and HUVEC cells. PEG-C dots served as the control. Saturating conditions were achieved at room temperature after incubating M21 and HUVEC cells with 100 nM of the dots for 4 hours. Binding specificity of the targeted platform was also demonstrated relative to the control probe by integrin receptor blocking using the native cRGD peptide as a competitor. Importantly, we observed activation of multiple signaling pathways in M21 cells upon targeted particle binding. Phosphorylation of focal adhesion kinase (FAK), led phosphorylation of Src, accompanied by additional phosphorylation of FAK. FAK phosphorylation induced activation of downstream signaling pathways. Addition of a FAK inhibitor to M21 cells incubated with cRGDY-PEG-C dots blocked phosphorylation of FAK and multiple downstream effectors. Additionally, enhanced in vitro migration rates were seen upon addition of cRGDY-PEG-C dots to both HUVEC and M21 cells, and a higher percentage of M21 cells were observed in S phase relative to that measured under control conditions. Furthermore, observed alterations in the adhesion and spreading properties of M21 cells, manifested, as cellular morphologic changes in a competitive binding assay, may, in part, be the result of pathway modulation upon particle exposure. Taken together, these data suggest that multiple FAK-mediated, integrin-stimulated signaling pathways are activated in M21 and HUVEC cells after exposure to particles. These changes, in turn, modulate key biological processes- cell migration, adhesion/spreading, and proliferative activity- known to be critical to angiogenesis, metastatic invasion, and wound healing.

Bioluminescence resonance energy transfer (BRET) image analysis of Ras-Raf interaction in live cells using NanoLuc luciferase and Venus yellow fluorescent protein by bioluminescence microscopy.

K. Ogoh¹, T. Takahashi¹, A. Miyawaki², H. Suzuki¹;

¹OLYMPUS Corporation, Hachioji-shi, Japan, ²RIKEN Brain Sci Inst, Wako City, Japan

NanoLuc (Promega) is a new luciferase originated from deep sea shrimp and emits blue bioluminescence utilizing imidazopyrazinone substrate. Since NanoLuc is approximately 150 fold brighter than firefly luciferase, a bioluminescent image of cells expressing NanoLuc can be captured within a sub-second exposure time by a bioluminescence microscope, LV200 (Olympus) equipped with an electron multiplying (EM)-CCD camera (ImagEM, Hamamatsu Photonics). We used NanoLuc and a yellow-emitting mutant of *Aequorea* GFP (Venus) as the donor and acceptor of bioluminescence resonance energy transfer (BRET), respectively, to image activation of Ras, a small G protein that transduces signaling from receptor tyrosine kinase to Raf (MAP kinase kinase kinase) at the inner part of cell membrane. H-Ras and Ras-binding domain (RBD) of Raf-1 were fused to Venus and NanoLuc,

respectively. Venus-Ras and RBD-NanoLuc were co-expressed in HeLa cells. After substrate administration, bioluminescent images through the donor (435-495 nm) and BRET (530 nm long pass) channels were captured alternately using LV200 equipped with ImagEM. This experimental system allowed us to image Ras-Raf interaction with a temporal resolution of 10 seconds. Immediately after stimulation with EGF (epidermal growth factor), an increase in BRET signal occurred on the plasma membrane (PM). BRET increases due to Ras-Raf association were not only the PM but also intracellular vesicle. We clearly identified another increase in BRET signal appearing inside the cytoplasm at approximately 10 min after EGF stimulation. The latter activation of Ras involved endomembranous structures, such as Golgi apparatus and recycling endosome. To map the Ras activation locations more precisely, BRET-imaged samples are being subjected to immunocytochemical experiments that use organelle-specific antibodies. In this way, we demonstrate that BRET imaging using NanoLuc with the help of LV200, and ImagEM is a powerful means for studying spatiotemporal pattern of cellular events in live cells.
