We systematically characterized the relative phototoxicity of 488nm and 546nm light on cell cycle progression of untransformed human (RPE1) cells. Unlabelled cells were irradiated by a 100 W high pressure mercury lamp on a Leica DMRE epifluorescence microscope through Leica L5 or Red-GFP band-pass filters and a 20X, 0.4 NA lens. Light intensities at the specimen plane were 13.6mW/cm² for 488nm and 20.6mW/cm² for 546nm. Mitotic shake off cells were plated on coverslips and 2 hours later (early G1) were given single dose irradiations ranging from 0.5 – 2.5 minutes. Irradiated fields were continuously followed for 48 hours (~2 normal cell cycles) to determine how many cells progressed to the next mitosis. Reduction in cell cycle progression was our measure of phototoxicity. All control cells entered mitosis under these conditions. For 488nm light we observed a dose dependent reduction on the percentage of cells that progressed to mitosis with only 16.4% dividing after 2.5 minute irradiations, as well as a dose-dependent delay in the time cells do reach mitosis. In contrast, equivalent irradiations of 546nm light (normalized for photons/second/cm²) resulted in 83% of cells progressing to mitosis. Preliminary results suggest that the introduction of a long-pass filter into the illuminating path to diminish possible leakage of <430nm wavelengths through the excitation filters produces no increase in the fraction of cells progressing to mitosis for any light dose of either wavelength. We also characterized the effect of spreading the total irradiation durations out into a series of 10 second pulses as well as conducting single longer, but lower intensity, exposures. Neither regime made a significant difference in the percentage of cells that progress into mitosis relative to the single acute dose regimes. Lastly, cells

expressing GFP-centrin 1 showed increased sensitivity to single 488nm exposures with 10% less cells entering mitosis at each exposure tested. In contrast, cells expressing mCherry-centrin 1 did not exhibit a significant change after single 546nm doses compared to WT cells.

Orientation-Independent Differential Interference Contrast (OI-DIC) Microscopy can detect Mouse Sperm Acrosome Reaction.

B. Ozkosem^{1,2}, C.M. O'Flaherty^{1,3}, M. Shribak²;

¹McGill University, Montreal, QC, ²Marine Biological Laboratory, Woods Hole, MA, ³McGill Univ Hlth Ctr, Montreal, QC

The quality of sperm has an effect not only on the IVF and ICSI outcomes but also on the incidence of abnormalities in their protoplasmic compartment and in the predisposition to genetic and epigenomic errors, which increases with oxidative stress. Before IVF and ICSI sperm quality must be estimated to assure normal embryo development. Unfortunately, most of the techniques used to investigate sperm cells are highly invasive and cannot be adopted to select the fertilizing spermatozoon.

We recently developed a new imaging mode called Orientation Independent Differential Interference Contrast Microscopy (OI-DIC). New system is implemented on research grade upright and inverted Olympus microscopes BX61 and IX81. The OI-DIC system can switch DIC shear directions by 90° and change bias in about 50 msec. Within 1 sec the OI-DIC captures 6 raw DIC images with two orthogonal shear directions and three different biases. Then the obtained raw images are processed to generate the high resolution quantitative optical path length and gradient images in very thin optical section. In this study, we demonstrated that using OI-DIC microscope, the acrosomal status of mouse spermatozoa can be distinguished, and acrosome reacted spermatozoa can be selected for IVF and ICSI. Sperm were capacitated in BWW medium supplemented with (5mg/ml BSA and 20 uM bicarbonate) and then; acrosome reaction was induced with either Ca²⁺-ionophore, A23187 (5 uM) or progesterone (10 uM). The presence of acrosome (acrosome intact) in spermatozoa was visualized with OI-DIC system. Acrosome integrity was evaluated using Fluorescein conjugated *Pisum sativum* Agglutinin (PSA-FITC) with supravitality stain, Propidium Iodide (PI) by fluorescent illumination using 520–540 nm and 620 nm filters. Acrosome integrity assay, A23187 Ca²⁺-ionophore induced acrosome reaction was evaluated with PSA-FITC/PI double staining showed that reacted acrosome were present in (90.98 ± 0.7003, n=5) of viable spermatozoa. Using OI-DIC system, we observed that (91.50 ± 0.5000, n=5) of viable spermatozoa with reacted acrosome. There was a strong correlation (r= 0.8639) between these two methods. This study suggests that non-invasive imaging of intact and reacted acrosomes by OI-DIC microscopy technique can be used as criterion for healthy sperm selection. The use of the proposed instrumentation for ICSI could represent not only a diagnostic tool but also an accurate and novel method for sperm selection. This study could provide not only a strategy guiding the criteria for sperm selection but also a tool to better understand about sperm physiology, especially nuclear integrity. The evaluation of sperm head using OI-DIC and birefringence in sperm cells could expand the limitations of

current sperm selection criteria for ART procedures by contributing additional information on sperm acrosomal status after sperm capacitation and potential in the routine evaluation of the male factor, as well as modifying the technique of sperm preparation.

Rapid 3D Tissue Synthesis by Chemically Programmed Assembly.

Z.J. Gartner^{1,2};

¹Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, ²Center for Systems and Synthetic Biology, University of California, San Francisco, San Francisco, CA

Methods to construct three-dimensional tissues of defined structure, from multiple cell types, with single-cell spatial resolution, and within physiologically relevant extracellular matrices (ECM) would greatly advance the study of developmental biology, cancer, and regenerative medicine. Here, we combine microscale direct writing of oligonucleotides with DNA-programmed assembly to reconstruct a tissue from the bottom-up and across centimeter distances in a manner that is amenable to long-term culture and imaging. The process begins by chemically remodeling the adhesive properties of individual cells with degradable oligonucleotide glue, allowing them to rapidly and specifically adhere to objects coated with complementary DNA sequences. Living cells are then rapidly assembled, layer-by-layer, onto a DNA-patterned substrate. Treatment with DNase releases fully assembled tissues directly into ECM gels for three-dimensional (3D) culture and observation. We demonstrate that this method enables the synthesis of diverse tissues with precise size, shape, composition and spatial arrangement within a slab of ECM. Finally, we demonstrate the use of the method to quantitatively analyze competitive and cooperative interactions between malignant and non-malignant mammary epithelial cells in the same tissue, as well as to assemble a precisely structured multicomponent tissue incorporating combinations of primary and transformed human endothelial, epithelial, and fibroblast cells into a single integrated 3D tissue.

Dynamic micropatterning of cells on nanostructured surfaces using a cell-friendly photoresist.

J. Doh¹, S. Kweon², K. Song¹;

¹Department of Mechanical Engineering, POSTECH, Pohang, Korea, ²1-Bio, POSTECH, Pohang, Korea

Nanoscale topographical features of the extracellular matrix (ECM) influence the behavior of cells including cell differentiation, migration, and proliferation. While how nanoscale topographical structures

affect various cellular behaviors has been active area of research, dynamics of cells on nanostructured surfaces has not been systematically examined. Here, we developed a new micropatterning method to control cellular dynamics on nanostructured surfaces using a cell-friendly photoresist poly(2,2-dimethoxy nitro-benzyl methacrylate-r-methyl methacrylate -r-poly(ethylene glycol) methacrylate) (PDMP), and studied how nanotopography influences spreading dynamics of cells. Surfaces containing nanoscale ridge/groove structures were fabricated by replicating a mold using a UV-curable resin polyurethane acrylate (PUA). The PUA substrates were coated with gelatin and subsequently spincoated with PDMP. Then, Microscope projection photolithography (MPP) was performed by illuminating light through a photomask inserted in a field diaphragm of the microscope. UV-exposed areas of PDMP thin films were selectively removed and nanostructured surfaces coated with gelatin were exposed. Cells seeded onto the patterned surfaces were selectively attached onto the UV-exposed area, resulting in single cell array formation. Finally, PDMP thin films surrounding cells were removed by briefly illuminating UV without photomask to trigger spreading of cells. And spreading dynamics of HeLa cells on nanostructured surfaces were monitored by interference reflection microscopy (IRM). In addition to the simple groove/ridge structures, spreading dynamics of complex nanostructured surfaces were quantitatively analyzed. This method will be useful to understand cellular behaviors under complex microenvironments.

NovaMatrix-3D: an alginate-based 3D cell culture system.

T. Andersen¹, M. Dornish¹;

¹FMC BioPolymer/NovaMatrix, Sandvika, Norway

NovaMatrix[®]-3D is an alginate-based cell culture system comprising an alginate foam matrix and an alginate immobilizing solution. Cells are first suspended in a solution of sodium alginate that is then applied to the foam. As the foam absorbs the cell suspension, gelation occurs in situ as calcium ions are donated from the foam which effectively cross-links the added alginate. A hydrogel forms in the pores of the foam entrapping the cells throughout the foam. Cell immobilization occurs at room temperature and physiological pH. Cell localization and multi-cellular structures formed within the transparent gel can be visualized using confocal microscopy after vital staining of cells within the gel. A unique aspect of using an alginate-based foam matrix for 3D cell growth is that cells and intact multi-cellular structures can be retrieved for further analysis by adding calcium chelating agents such as citrate that dissolves the gel.

Results: We have cultured 22 different cell lines and primary cells in NovaMatrix[®]-3D. All cell lines tested formed multi-cellular structures. Cells do not have receptors that recognize alginate and for some cell types this may promote spheroid formation as the gel will be inert. Other cells require cell-matrix interaction to proliferate. This is achieved by using a peptide such as RGD (Arg-Gly-Asp) coupled to alginate, thereby facilitating a signaling cascade via integrin-RGD interactions. For some cell lines, the addition of RGD-alginate induced dramatic changes in cell proliferation and formation of multi-cellular

structures. In a separate set up experiment, the effect of x-ray radiation on cells cultured under different oxygen concentrations was investigated. The growth of spheroids inside the 3D matrix was determined by evaluating changes in spheroid volume. Spheroids cultured under 20% oxygen showed a significant reduction in volume increase after irradiation with 15 Gy, compared to the spheroids cultured under 5% oxygen. This study indicates that hypoxia increases the resistance of NHIK 3025 (human cervical carcinoma) spheroids against x-ray radiation and demonstrates the utility of the matrix in dose-response experiments.

Conclusions: NovaMatrix[®]-3D mimics a 3D model with the potential to approximate cell proliferation and architecture within tissues or tumors. Cells are uniformly entrapped into the foam matrix by a gentle and fast technique, and visualization can easily be performed. Cells form multi-cellular structures within the matrix and intact structures may be isolated under physiologic conditions. The immobilized cells can be treated with drugs or other agents since the alginate matrix is permeable for small and medium sized molecules, making NovaMatrix[®]-3D a versatile 3D cell culture system.

PDMS-based 3D microfluidic in vitro culture System for cornea disease research model.

J. Ju¹, S. Choi², G. Lee³, S. Lee¹;

¹Biomedical Engineering, Korea University, Seoul, Korea, ²Medicine, Yonsei University, Seoul, Korea,

³NBIT, Ku-kist graduate school of converging science and technology, Korea University, Seoul, Korea

TGFBI (transforming growth factor- β -induced gene)-linked corneal dystrophy is an autosomal dominant disorder caused by a point mutation in TGFBI gene on chromosome 5q31. Age-dependent progressive accumulation of mutant-TGFBI protein in the corneal stroma is a hallmark of TGFBI-linked corneal dystrophy and interferes with corneal transparency. A prevalence of granular corneal dystrophy type 2, major type of TGFBI-linked corneal dystrophy, has been estimated 8.25 per 10,000 persons in South Korea. Ideally the effect of pathologically determined this disease should be examined in the whole cornea of a living organism. However, no animal model of TGFBI-linked corneal dystrophy replicates the accumulation of mutant-TGFBI protein in cornea as the complex pathophysiological changes seen in patients. This is a severe limitation in the pathological and therapeutic implication studies of TGFBI-linked corneal dystrophy. Additionally, development and analysis of animal models can also be time-consuming and costly. Miniaturization technology, in particular microfluidics, has shown promise in overcoming these limitations and disadvantages. We report simple microfluidics 3-dimensional (3D) compartmentalized culture systems which have employed mixed culture of Keratocyte cells and epithelial cells in 3D gels (e.g., collagen I). This microfluidics system enables information-rich in vitro assays.

Microfluidics devices were fabricated using soft lithography. Polydimethylsiloxane (PDMS, Sylgard 184 Silicon Elastomer Kit, Dow Corning) was molded over the SU-8 master and sandwiched between

transparency film and weights to allow access to the ports. For compartmentalization, a “trident” shaped channel was designed. Human cornea fibroblast cells and epithelial cells cultured in DMEM supplemented with 10% FBS and penicillin/streptomycin. All cultures were maintained at 37°C in a humidified atmosphere containing 5% CO₂. For collagen sample preparation, the cells were trypsinized and counted (concentration 1×10⁶ cells/ml). Collagen was prepared at concentration of 1.3 mg/ml initially by an acidic collagen solution. To neutralize collagen using HEPES buffer, the buffer was mixed with same amount of acidic collagen solution (1:1 ration).

The cornea fibroblast cells (Keratocyte) and epithelial cell was cultured in microfluidic system. And also collagen was stained by immunocytochemistry. We presented a simple compartmentalized 3D culture model that supports the Keratocyte and Epithelial cell *in vitro*. In conclusion, our PDMS-based 3D microfluidics cell culture system may help overcome barriers to a limitation in a scientific method to investigate pathogenesis and treatments of TGFBI-linked corneal dystrophy

Probing cancer cell migration on topographically reconstituted ECM nanofibers.

V.P. Sharma^{1,2}, J.K. Williams³, E. Leung¹, M.R. Padgen³, R.J. Eddy¹, J. Castracane³, J.S. Condeelis¹;
¹Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ²Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, ³SUNY College of Nanoscale Science and Engineering, Albany, NY

Intravital imaging has emerged as the dominant imaging modality for the visualization of tumor cell migration *in vivo*. Intravital imaging has identified the phenotypes of cell behavior *in vivo* at single cell resolution. However, the complexity of the tumor microenvironment makes mechanistic analysis of its contributions to cell phenotype uncertain. Previously, we utilized micro-patterned extracellular matrix (ECM) substrates to study cancer cell migration properties in 1D, but due to the flat nature of ECM substrate on the glass coverslip, we could not faithfully capture the 3D topography of ECM substrate which cells encounter *in vivo*. Here, we developed a more realistic *in vitro* system using reconstituted ECM with cylindrical substrate topography as found in the tumor microenvironment *in vivo* and demonstrate that it supports the phenotypes of cell migration seen *in vivo*. First, we investigated the *in vivo* tumor ECM architecture in two mouse models: PyMT- and breast carcinoma cell-derived mammary tumors, using second harmonic intravital imaging. Tumor cells were found to move on fibronectin associated collagen I fibers. We found a wide distribution of collagen I diameters with the major peak falling in the range, 1.5-2 μm . Based on these *in vivo* observations, we engineered cylindrical poly(lactic-co-glycolic acid) (PLGA) nanofibers matching *in vivo* dimensions and coated them with fluorescently-labeled ECM components (collagen I, fibronectin). Remarkably, all of the emergent tumor cell behaviors seen *in vivo* were recapitulated on the 1.5-2 micron fibers suggesting that the fiber topography is a key contributor to cell behavior *in vivo*. Tumor cells in the presence of macrophages formed linear assemblies of alternating tumor cells and macrophages, resembling streams found *in vivo*. Average cell speed on these fibers reached 1 $\mu\text{m}/\text{min}$, with maximum speed reaching 4 $\mu\text{m}/\text{min}$, consistent with

previous observations made for tumor cell speed *in vivo*; and two times faster than speeds seen on 2D surfaces. Surprisingly, we discovered dynamic nuclear deformations during carcinoma cell migration on nanofibers, similar to nuclear deformation observed in cells squeezing through a narrow opening *in vivo*, suggesting that carcinoma cell nucleus is inherently plastic and ECM space constraint is not required for nuclear deformation.

Osteogenic environment provided by hybrid scaffold comprised of stickyapatite and collagenous membrane.

C. Kim¹;

¹Kyung Hee University, Lab of Tissue engineering, Yongin-si, Geonggi-do, Korea

For covering large bone defect and controlling the morphology of regenerated tissues, scaffold is essential in tissue engineering. For bone tissue engineering, osteo-conductivity is essential characteristic of bone scaffold to help bone regeneration, and inorganic ceramic materials are main player in exhibiting osteo-conductivity of scaffold. So, inorganic ceramic materials such as hydroxyapatite are essential composition for bone scaffold. However, ceramic biomaterials itself show demerit of brittleness. In biological bone, polymeric structure of collagen counterbalance brittleness of hydroxyapatite. In our study, molecular linker was introduced on the surface of hydroxyapatite microcrystals by surface modification, so that they can participate in polymerization reaction with organic polymer. Those surface-modified hydroxyapatite was named as 'Stickyapatite'. Composite of stickyapatite and organic polymer was constructed on small intestinal submucosa based on layer-by-layer approach, to mimick the hybrid structure of biological bone. In etopic bone marrow model, the hydroxyapatite-chitosan composite showed excellent bone and marrow formation. We expect this sheet-type osteogenic composite construction can be utilized not only for bone regeneration but also for osteo-chondral graft formation. This work was supported by the Basic Science Research Program funded by the Korean Ministry of Science ICT and Future Planning (NRF-2011-0009391) and a grant of the Korean Health Technology R&D Project(HI13C1479), Ministry of Health and Welfane, Republic of Korea.

P852**Board Number: B166****Utilizing Novel Methodologies to Recapitulate the In Vivo Tissue Microenvironment in Cell Culture.**W. Holmes¹, S. Haddad¹, L. Connolly¹, M. Stanton², C. Lambert², R. Bellin¹;¹Biology, College of the Holy Cross, Worcester, MA, ²Chemistry and Biochemistry, Worcester Polytechnic Institute, Worcester, MA

Growing mammalian cells in culture is an invaluable tool for biomedical research. Researchers can study specific effects in a highly controlled environment by growing cells outside of their native tissue. While growing cells in culture has led to the development of significant medical advances, most cells grown in culture do not completely resemble cells in their native tissue. This is often due to the fact that cells are typically cultured on a flat, two-dimensional (2D) dishes, while native tissues are structured in an intricate three-dimensional (3D) arrangement including an extra cellular matrix (ECM). This has led to the development of commercially available 3D cell culture materials, however these are cost-prohibitive and limiting for large scale, high-throughput study

The goal of this project is to develop a novel method of growing cells in culture that mimics the 3D microenvironment of native tissue. In this study, we utilized a polymer of polydimethylsiloxane (PDMS) that is cast on a rough surface, creating a unique textured microenvironment for cells to grow within. Previous results demonstrate that cells grown on these rough PDMS surfaces change their morphology depending on the surface they grow on. Here, we show that these effects are not limited to cell type, but significant morphology changes are observed on three of the most common cell lines used (HeLa, NIH-3T3, and Cos7). It is our hypothesis that these cells will express characteristics similar to that of cells in tissue. To determine this, we compared morphological changes to cells grown on different surfaces, including a 3D matrix (Matrigel). We also assessed changes in the actin cytoskeleton and our results show a significant decrease of actin stress fiber formation on rough PDMS surfaces, similarly seen in cells grown in a 3D matrix. Overall, our studies begin to establish that cells grown on a rough PDMS surface may provide cells with an efficient, cost-effective method to produce a more *in vivo* like environment and allow more findings in cell culture to be translated to the whole organism.

P853**Board Number: B167****Automated Platform for Analysis of Cell-Matrix Adhesions in 2D and 3D Environments.**N. Diggins¹, J. Broussard², S. Hummel³, W. Georgescu^{3,4,5}, V. Quaranta⁶, D. Webb^{1,4,7};

¹Department of Biological Sciences, Vanderbilt University, Nashville, TN, ²Biological Sciences, Vanderbilt University, Nashville, TN, ³Center for Cancer Systems Biology, Vanderbilt University, Nashville, TN, ⁴Vanderbilt Institute for Integrative Biosystems Research and Education, Vanderbilt University, Nashville, TN, ⁵Department of Biomedical Engineering, Vanderbilt University, Nashville, TN, ⁶Vanderbilt University School of Medicine, Nashville, TN, ⁷Department of Cancer Biology, Vanderbilt University, Nashville, TN

Cell-extracellular matrix adhesions are of great interest because of their influence on many biological processes, including cell migration, survival, proliferation, differentiation, tissue morphogenesis, wound healing, and tumorigenesis. Adhesions are dynamic structures that have been traditionally characterized on two-dimensional (2D) substrates, although the need to analyze adhesions in more physiologic three-dimensional (3D) environments is being increasingly recognized. However, progress in this area has been greatly hindered by the lack of available tools to analyze adhesions in 3D environments. To address this, we have developed a platform for the automated analysis, segmentation, and tracking of adhesions (PAASTA). This platform enables the quantification of adhesion dynamics and other adhesion characteristics, such as lifetime, location, size, distribution, and shape, in both 3D and 2D environments. We manually validate our platform by analyzing adhesions on 2D substrates and comparing results obtained with PAASTA to traditional analysis methods. Moreover, we use PAASTA to determine rate constants for adhesion assembly and disassembly for cells embedded in 3D type I collagen matrices. Therefore, this platform can be used to analyze multiple characteristics of adhesions and will provide a valuable tool for investigating the molecular mechanisms that regulate adhesion dynamics in 3D environments.

P854**Board Number: B168****Sub-domain FRAP of cell surface molecules to monitor cell surface topography in living cells.**M. Aljumaa¹;¹IMEM, Cardiff University, Cardiff, United Kingdom

It is becoming increasingly clear that many cells have a reservoir of excess plasma membrane in the form of cell surface wrinkles and micro-ridges. The released of these surface structures allow cells to change shape rapidly by permitting an apparent increase in cell surface area eg during phagocytosis or cell spreading. Although indirect methods point to this conclusion, it is only possible to visualise the cell surface topography under scanning electron microscopy and therefore cannot be used to follow surface

topography changes to be monitored in living cells during changes in cell morphology. In this abstract, we describe a novel methodological approach which allows this using the measurement of fluorescence recovery after photobleaching in subdomain at defined 2 dimension distances from the bleach front. Assuming that the diffusion of the fluorescent molecules is constant to rate of recovery at defined points reflects the diffusion distance and hence indicates the surface topography between the bleach front and the measurement domain. Human neutrophils were isolated from blood and their plasma membrane labelled with DiI (DiI C16(3) MWt 877). The dye can be excited using a 543nm laser line and effectively photobleached using the 488nm line transiently elevated. A photo-bleaching zone across the region of the cell of interest was chosen and the image of the cell recording during bleaching and recovery. The bleach/recovery cycle could be repeated. This approach was shown to reflect the cell surface topography by experimentally increasing the wrinkledness of the cell surface using hyperosmotic media. The measured apparent diffusion length increased in the increased wrinkled state and was returned to close to its pre-shrunk value by restoration of isotonicity. The methodology showed that whereas the body of neutrophils has significant ridge-like topographical features, the phagosome and the extending pseudopodia are smooth. This method also showed that elevation of cytosolic Ca²⁺ (by uncaging IP3) influenced the cell surface topography. This methodology opens a novel way of monitoring an important cell characteristic which has not been possible to study previously.

Measurement with multi-electrode array system for analysis of temperature-dependent beating rate of cardiomyocytes.

T. Kaneko¹;

¹Department of Frontier Bioscience, Hosei University, Tokyo, Japan

The beating rate of cardiomyocytes is known to change by environmental temperature. To characterize the beating rate of cardiomyocytes depending on temperature, we measured the beating rate of cardiomyocytes derived from chick embryo (E13) with multi-electrode array (MEA) system. MEA system could be noninvasively measure the extracellular field potential of excitable cells for long-term experiment. The waveforms of the extracellular field potential of cardiomyocytes could be easily detected Na⁺ peak triggered for beating of cardiomyocytes. The interval of between Na⁺ peak and next Na⁺ peak was shown to inter-spike interval (ISI) for the beating rate of cardiomyocytes. The amplitude of Na⁺ peak was shown to the field potential amplitude (FPA) for the activity of Na⁺ channel. Cardiomyocytes cultured on MEA chip were measured with MEA systems after starting the temperature rises from 15°C to 32°C. As a result, the ISI and FPA were recovered synchronous sigmoidal increasing as temperature rises after lag time of several minutes. The stationary phase of the beating rate of cardiomyocytes was constant at a repeated procedure of several times. These results suggested that cardiomyocytes could possess an inherent beating rate corresponding to surrounding environments.

P856**Board Number: B170****Extracellular potential recording of cardiomyocytes derived from chick embryo for drug screening with multi electrode array system.**Y. Shin¹, T. Kaneko²;¹Graduate school of science and engineering, Hosei University, Tokyo, Japan, ²Department of Frontier Bioscience, Hosei University, Tokyo, Japan

Cardiac toxicity testing is essential for drug discovery to consider the effects on the human body in safety pharmacological studies. An electrocardiographic QT interval often extends just before fatal arrhythmia such as torsades de pointes (TdP) caused by the dosage of drugs. A number of drugs are known to cause the electrocardiographic QT interval prolongation by suppressing the rapid delayed rectifier current (IKr), human ether-a-go-go related gene (hERG) channel that functions as a major constituent of K⁺ current. Recently, multi electrode array (MEA) system has been used to measure the field potential duration (FPD) equivalent of QT interval. To examine the availability of MEA system with cardiomyocytes derived from chick embryo (E13) for detect arrhythmogenicity of drugs, we applied K⁺ blocker E-4031 to the cardiomyocytes with this system. As a result, the FPD was extended to 1.2 times compared with control at a final concentration of 10 nM E-4031. Moreover, the Short Term Variability (STV) that is the index of incidence of fatal arrhythmias is increased about 2 times at a final concentration of 10 nM E-4031 and about 10 times at a final concentration of 100 nM E-4031 compared to before addition of drugs. This is the same result in case of cardiomyocytes derived from human ES cells. These results suggested that this MEA system with chick embryonic cardiomyocytes was useful for detection of arrhythmogenicity of drugs. Next, to analyze the drug effect, we applied anticancer drug cisplatin that had been reported having arrhythmia and heart failure as side effects in clinical to this MEA system. There were no effect of cisplatin to the FPD and STV. This result suggested that cisplatin might have no acute toxicity at least for chick embryonic cardiomyocytes.

P857**Board Number: B171****Optimization of medium condition for toxicity testing with multi electrode array system.**Y. Kamei¹, T. Kaneko²;¹Graduate school of science and engineering, Hosei university, Tokyo, Japan, ²Department of Frontier Bioscience, Hosei University, Tokyo, Japan

Multi electrode array (MEA) system is a simple and noninvasive technique to measure the extracellular field potential of excitable cells, and has the possibility to solve the various problems of the toxicity testing. It is known that torsade de pointes (TdP) causes the variation of QT interval on electrocardiogram just before occurring arrhythmia. The variation of QT interval is important to be

detected for the toxicity testing. MEA system could be detected the field potential of cardiomyocytes to analyze the field potential duration (FPD) that equivalent to QT interval and inter spike interval (ISI) that is beating interval. Because its optimum protocol for the toxicity testing is not established, it is necessary to explore medium condition to stably measure the FPD and ISI. In the case of standard Dulbecco's modified Eagle's medium (DMEM), the ISI and FPD often largely vary and are unstable. To stable the pH in the medium, DMEM including HEPES buffer (DMEM with HEPES) and CO₂ independent medium were applied to cardiomyocytes on the MEA chip. We measured the FPD and ISI of cardiomyocytes derived from chick embryo (E13) with MEA system. In the case of pH changes in the medium, DMEM with HEPES was more mildly changed than standard DMEM, and CO₂ independent medium hardly changed. In the waveform of extracellular field potential of cardiomyocytes, the variations of the FPD and ISI were sequentially increased in standard DMEM. However the variations of the FPD and ISI were decreased in DMEM with HEPES and CO₂ independent medium, and the FPD and ISI were stably measured at least for 2 hours. As a result, we found that pH changes in the medium had a negative influence on cardiomyocytes. Therefore, it was suggested that the medium suppressing pH changes could be used for a toxicity testing during several hours.

Micro-Cavity based Force Sensors for Cell-biological Studies.

N.M. Kronenberg¹, P. Liehm¹, A. Steude¹, M.C. Gather¹;

¹School of Physics and Astronomy, University of Saint Andrews, Saint Andrews, Scotland

Mechanics is increasingly recognized as an important factor in numerous biological processes. Monitoring the mechanical properties of cells and tissue is considered a key factor to the understanding of a range of fundamental biological processes and may enable more accurate diagnosis in a range of diseases.

Today, Traction Force Microscopy (TFM) is the most widely-used method to investigate cellular forces exerted on 2D substrates. Until recently, it was assumed that vertical forces can be neglected in the analysis of cell mechanics. However so-called 2.5D TFM studies have now shown that the out-of-plane and in-plane forces exerted by cells are of the same order of magnitude. Although 2.5D TFM has contributed to our understanding of vertical forces for different cell types, it suffers from several immanent limitations: The need to perform 3D confocal laser scanning for bead tracking and associated photo-toxic effects limit temporal resolution and restrict the field of view when performing time-lapse measurements. The need to take zero-force images at the end of each experiment complicates the measurement further.

Here, we present a completely new approach to measure cellular forces which overcomes the limitations of 2.5D TFM by interferometrically detecting deformations of an elastic probe rather than by tracking bead displacement. The centrepiece of our innovation is a novel optical micro-cavity sensor that enables fast force mapping across a large field of view by analysing changes in resonance wavelength.

Our approach avoids any phototoxic effects and therefore allows the measurement of cellular forces at high frame rates over hours or days. Being based on wide-field imaging, our new method measures the deformation at each point of the image simultaneously and with diffraction limited lateral resolution. Vertical displacements are detected with accuracy far beyond conventional confocal microscopy (5 nm or better). Force maps can be recorded without the need for zero-force images, increasing throughput, eliminating the need to detach non-migrating cells after force mapping and allowing measurements of multiple cells on one substrate. Additionally, the optics needed for the readout of the new biosensor can be readily integrated with a conventional inverted microscope.

In this presentation we will discuss the fabrication of our micro-cavity sensors and provide detailed investigations of force and spatial resolution of the device by means of AFM indentation analysis. Cell mechanical measurements of different cell lines, including human neuronal cells and primary immune cells, will be presented and links between recorded force patterns and subcellular structures labelled by fluorescence staining will be discussed.

Nanoparticles and the blood-brain barriers in vitro: Carriers as well as barrier modulators.

H. Galla¹, S. Cramer², R.G. Rempe¹;

¹Biochemistry, Univ Muenster, Muenster, Germany, ²Biochemistry, University of Münster, Münster, Germany

Nanoparticles are widely used in different areas as food, cosmetics, surface protective in clothes and biomedical products. Moreover they are proposed to be useful carriers to overcome biological barriers. But besides the widespread use and favorable characteristics of nanoparticles (NP) there has been some concern about their biological safety. New techniques have to be emerged to fast and reliably determine possible interferences with barrier properties. The electrical resistance together with the electrical capacitance is such a useful technique In vivo studies in rats have shown that e.g. silver-NPs accumulate in various organs including the brain after both oral exposure and inhalation. Since the mechanism of brain transfer is not known it is important to study the effects of Ag-NPs on the barriers of the central nervous system, namely the blood-brain barrier (BBB) and the blood-cerebrospinal fluid (CSF) barrier. The aim of the present in vitro study was to analyze the effects of two differently modified Ag NPs (Ethylene oxide [EO] and Citrate) on primary porcine brain capillary endothelial cells (PBCEC) and, for the first time, on primary capillary choroid plexus epithelial cells (PCPEC) (Cramer et al 2014) The effect to weaken the barrier may be used for drug targeting to the brain if barrier opening occurs in a given short time window and is reversible. This will be demonstrated by the use of poly-butylcyanoacrylate-NPs. We will show that these nanoparticles open the blood-brain-barrier in a time window of about 2 hours which allows a drastic flux of even larger molecules by passive diffusion through the tight junctions (Rempe et al 2011) Here we will present the useful application of a new technique called Impedance spectroscopy to investigate barrier properties of cells grown on permeable filters to quantify the barrier

properties. Correlation to permeability changes and cellular responses like cytotoxicity, oxidative stress and inflammation will be shown.

3D isotropic volume imaging and reconstruction of biological samples using SEM.

G. Kiss¹, B. Lich², F. Boughorbel^{1,2}, L. Hekking², E. Korkmaz²;

¹FEI, Hillsboro, OR, ²FEI, Eindhoven, Netherlands

In recent years there has been a considerable advancement in SEM-based methods for 3D reconstruction of large tissue volumes. Serial Block-Face SEM (SBF-SEM) involves combination of imaging and in-situ sectioning of plastic embedded tissue blocks within the SEM vacuum chamber, allowing for automated imaging and subsequent reconstruction of volumes of tissue. With a novel solution for high spatial resolution and throughput SEM volume imaging overcoming the resolution limits set by mechanical slicing by combining it with virtual sectioning. Virtual slicing is realized by Multi-Energy Deconvolution SEM (MED-SEM), a non-destructive technique that allows high resolution reconstruction of the top layers of the sample. This cycle of physical and virtual sectioning offers isotropic datasets with excellent z-resolution and can be fully integrated and automated. For experiments where even greater isotropic resolution is needed, DualBeam systems excel offering up to 3nm isotropic resolution in 3D volume dataset. DualBeam scanning electron microscopes are equipped with both ion- (FIB) and electron-beam (SEM) and offer a new solution to explore subsurface structure of biological tissues. It not only provides high resolution SEM imaging, but also enables precise cross sectioning or slicing with the FIB on selected positions on the sample. With the new advanced detection technologies available, low kV imaging enables the acquisition of series of images of the tissue block face without charging. Using the automated software solutions, the acquisition of the high quality 3D dataset needs minimal user intervention, and so offers instant and high yield productivity. Furthermore the potential combination of the 3D imaging systems with fluorescence microscopes opens new doors for site specific structural analysis. In this work we demonstrate the process what the eukaryotic cells using to eliminate foreign object from themselves. The details of the endocytotic pathway are revealed in a live and dynamic environment using fluorescently labelled foreign objects. Then using correlative light and electron microscopy approach the region of interest was located. Then the lysosome structure with the fluorescence foreign object was examined in a 3D with high resolution details using scanning electron microscopy.

P861**Board Number: B175****Intracellular delivery by cell squeezing is affected by perturbation of actin cytoskeleton and lipid rafts.**M.P. Stewart¹, X. Ding¹, K. Jensen², A. Sharei¹, R.S. Langer¹;¹Koch Institute for Integrative Cancer Research, Massachusetts Institute of Technology, Cambridge, MA,²Chem Eng, Massachusetts Institute of Technology, Cambridge, MA

Cell squeezing is a new intracellular delivery modality based on rapid mechanical deformation of cells passaging through precisely fabricated constrictions in a microfluidic device. Delivery of molecules is achieved by diffusion through membrane disruptions, however, little is known about how the properties of the cell surface affect the membrane disruption and recovery behavior. Using specific inhibitors in conjunction with flow cytometry to assess delivery efficiency, we uncover roles for actin and lipid rafts in the cell response. While perturbation of rafts decreased cell robustness and recovery, inhibitors of actin dynamics exhibited variable effects, with some even improving membrane recovery. We anticipate continued studies on these underlying mechanisms should yield insight into the mechanical response to rapid cell deformations and lead to improved efficiency in delivery applications.

P862**Board Number: B176****Why only stretch when you can also see? Correlative optical Tweezers-Fluorescence Microscopy (CTFM) as a versatile tool for cell biology.§.**A. Candelli^{1,2}, J. Block³, I. Brouwer¹, I. Heller¹, G. Sitters^{1,2}, O.D. Broekmans¹, M. Modesti⁴, S. Köster³, E.J. Peterman^{1,2}, O.T. Heyning², G.J. Wuite^{1,2};¹Department of Physics and Astronomy, VU University Amsterdam, Amsterdam, Netherlands, ²LUMICKS bv, Amsterdam, Netherlands, ³Georg-August-Univ Gottingen, Gottingen, Germany, ⁴Institut National de la Santé et de la Recherche Médicale, Marseille, France

Correlative optical Tweezers-Fluorescence Microscopy (CTFM), combines optical tweezers with confocal fluorescence and STED nanoscopy. CTFM is a promising approach for the investigation of biological systems, because it uniquely allows to simultaneously manipulate, sense and visualize individual molecules with exquisite sensitivity and resolution. Here we present our efforts to broaden the applicability of CTFM technology by developing an integrated instrument that allows turn-key operation with ease of use, without compromising performance. Using this instrument, we carry out a series of demonstration experiments, exploring applications of CTFM in DNA-protein interactions, nano-mechanics of intermediate filaments, synthetic models of signal transduction, membrane fusion and molecular motors. These experiments show that the technological advances in hybrid single-molecule methods allow the development of an easy-to-use and stable instrument that can be applied in many research areas and operated by researchers with diverse training and background.

P863**Board Number: B177****Cell proliferation studies with a bioadhesive hydrogel for intervertebral disc tissue regeneration.**A. Nitzl¹, E. England¹, T. Christiani^{1,2}, J. Vernengo^{1,2}, J. Kadlowec^{1,3}, C. Iftode¹;¹Biological Sciences, Rowan University, Glassboro, NJ, ²Chemical Engineering, Rowan University, Glassboro, NJ, ³Mechanical Engineering, Rowan University, Glassboro, NJ

The goal of our research is to develop a three-dimensional culture system for use in intervertebral disc tissue engineering. As such, thermosensitive biomimetic hydrogels will be designed to support long-term viability and differentiation of adipose stem cells towards the nucleus pulposus (NP) phenotype. Our first objective is to produce a polymeric scaffold with superior mechanical strength and bioadhesive properties, while remaining biocompatible with the stem cells it envelopes. Previously, we reported on the cytoviability of a base polymer consisting of 5% poly-N-isopropylacrylamide grafted chondroitin sulfate (PNIPAAm-g-CS). In our current work, we present cell studies performed with a new bioadhesive scaffold synthesized by blending alginate microparticles with PNIPAAm-g-CS. The new polymer was designed to achieve increased bioadhesive properties, a crucial requirement for prevention of dislocation of intervertebral disc implants. Both qualitative (LiveDead) and quantitative (XTT) viability tests performed with this new composite polymer show that it supports HEK-293 and adipose-derived stem cell (ASC) survival to approximately 85% of that of PNIPAAm-g-CS alone. In preliminary studies, we have also found that increasing the alginate particle size (> 89.8 microns) doubles polymer tensile strength and enhances cell proliferation of HEK-293 cells in direct comparison with particles sizes less than 16 microns. Future work includes differentiation of ASCs in the PNIPAAm-g-CS-alginate polymer toward the NP phenotype and confirmation NP marker expression by immunohistochemistry and RT-PCR.

P864**Board Number: B178****Novel particles for transportation of active proteins into cellular nuclei.**C.L. Minchew^{1,2}, V.V. Didenko^{1,2};¹Baylor Coll Med, Houston, TX, ²Michael E. DeBakey Veterans Affairs Medical Center, Houston, TX

We describe a new type of multifunctional fluorescent nanoparticle for the targeted induction of cell death in the specified cell types, such as cancer cells. The particles employ a novel internal architecture and are structured assemblies of fusion proteins and cationic polymers. They have interchangeable targeting moieties with the ability to be re-targeted to a variety of cell types. After injection into the tumor site, they can penetrate tumor cell membranes and selectively passage into their nuclei. Being fluorescent, the new nanoparticles can simultaneously signal the response to the therapy. The new

development is applicable in anticancer research which uses cell-specific delivery and fluorescence imaging.

Reversible protein inactivation by optogenetic trapping in cells.

S. Lee¹, H. Park², T. Kyung², N. Kim², S. Kim², J. Kim², W. Heo^{3,4};

¹Inst Basic Science, Daejeon, Korea, ²Dept Biological Sciences, KAIST, Daejeon, Korea, ³KAIST, Daejeon, Korea, ⁴IBS, Daejeon, Korea

The precise inhibition of target proteins can serve as an effective means to dissect complex signaling networks or to identify new therapeutic targets. Here we present a versatile platform to inactivate proteins in living cells using light, light-activated reversible inhibition by assembled trap (LARIAT), which sequesters target proteins into complexes formed by multimeric proteins and a blue light-mediated heterodimerization module. Using LARIAT, we inhibited diverse proteins that modulate cytoskeleton, lipid signaling and cell cycle with high spatiotemporal resolution. Use of single-domain antibodies extends the method to target proteins containing specific epitopes, including GFP.

Cas9 driven by an optimal promoter improves gene editing in eukaryotic cell lines when paired with synthetic crRNA and tracrRNA.

A. Haupt¹, E. Anderson¹, Z. Strezoska¹, H. Machado¹, S. McClelland¹, M. Mayer¹, A. Rocker¹, A. Vermeulen¹, A. Birmingham¹, M. Kelley¹, A. Smith¹;

¹Research and Development, Dharmacon, Part of GE Healthcare, Lafayette, CO

Genetic engineering of living cells is of critical importance to understanding how genes influence organisms. Recently, the CRISPR-Cas9 system has gained popularity in the gene editing field due to its relative elegance and ease of use compared to other gene editing methods. This system requires a complex of the Cas9 protein with a gene-targeting CRISPR RNA (crRNA) and a trans-activating RNA (tracrRNA), to introduce DNA breaks at specific locations in the genome in a single- or multi-gene fashion.

Presented here are results on the efficiency of using synthetic crRNA and tracrRNA to introduce gene editing events when co-transfected with a plasmid expressing Cas9. Expressing humanized Cas9 from different promoters (e.g., human and mouse CMV and EF1alpha, PGK, CAG), along with synthetic crRNA and tracrRNA, results in varying amounts of gene editing in different cell lines and cell types. The efficiency of gene editing can be improved with the use of the optimal promoter in chosen cell lines, demonstrating the importance of choosing the most active promoter in the cell line of interest.

Additionally, the Cas9 gene can be expressed with either a puromycin selection marker or a red fluorescent protein for FAC sorting to allow enrichment of transfected cells. Both methods result in enrichment of cells with gene editing events by at least two-fold as measured by a mismatch-specific nuclease assay. Importantly, results demonstrate that the use of synthetic crRNA and tracrRNA offers a simplified and faster method for gene editing of one or more genes without requiring any cloning steps. By virtue of its simplicity, this three-component CRISPR-Cas9 system is amenable to high-throughput genome editing applications.

Integration of Linear and Dendritic Actin Nucleation in Nck-Induced Actin Comets.

S. Borinskaya¹, L.M. Loew¹, B.J. Mayer²;

¹Center for Cell Analysis and Modeling, University of Connecticut Health Center, Farmington, CT,

²Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT

We propose that the Nck adaptor protein can serve as an integrator of linear and branched nucleation in actin comet tails. In our studies we characterize comet tails induced by experimental aggregation of Nck-SH3 domains at the membrane. They are extremely similar in their shape and dynamics to *Vaccinia* comets and serve as a good model to study the role of Nck adaptor in signaling to the actin cytoskeleton and maintenance of the comet tail phenotype. Experimentally shifting the tight unbranched/branched nucleation balance altered morphology and dynamics of Nck-SH3-induced actin comets. Inhibition of linear formin-based nucleation with the small molecule inhibitor SMIFH2 resulted in formation of predominantly circular actin structures with decreased mobility. The proline-rich FH1 domain of formins recognizes Src-homology 3 (SH3) domains. We overexpressed FH1 domain to inhibit the binding of endogenous full-length formin on Nck-SH3-induced actin comets. As a result, cells produced less dynamic and mostly circular actin structures. Additionally, enhancement of branched Arp2/3-mediated nucleation, caused by N-WASP overexpression, similarly caused loss of the typical actin comet tail shape. These results indicate that formin-based linear actin polymerization is critical for the formation of Nck-dependent actin comet tails and maintenance of their phenotype. In fact aggregation of only branched active Nucleation Promoting Factor (VCA domain of N-WASP) with the density and turnover similar to that of N-WASP in Nck comets, does not reconstitute dynamic elongated actin comets. The ratio of linear to dendritic nucleation activity may, thus, serve to distinguish the actin structures induced by viral and bacterial pathogens.

P868**Board Number: B183****Cordon Bleu serves as a platform at the basal region of microvilli where it regulates microvillar length through its WH2 domains.**J. Wayt¹, A.P. Bretscher¹;¹Cornell University, Ithaca, NY

Cordon Bleu (Cobl) is a WH2-containing protein believed to act as an actin nucleator. We show that it has a very specific localization in epithelial cells at the basal region of microvilli, a localization unlikely to be involved in actin nucleation. The protein is localized by a central region between the N-terminal COBL domain and the three C-terminal WH2 domains. Ectopic expression of Cobl shortens apical microvilli, and this requires functional WH2 domains. Proteomic studies reveal that the COBL domain binds several BAR-containing proteins, including SNX9, PACSIN-2/Syndapin-2 and ASAP1. ASAP1 is recruited to the base of microvilli by binding the COBL domain through its SH3. We propose that Cobl is localized to the basal region of microvilli to participate in both length regulation and to recruit BAR proteins that associate with the curved membrane found at the microvillar base.

P869**Board Number: B184****A coupled in vitro-in vivo approach to dissect APC-Diaphanous mediated actin assembly.**O. Molinar¹, R. Jaiswal², E. Kunttas-Tatli¹, A. Rankova², V. Stepanik¹, B.L. Goode², B.M. McCartney¹;¹Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA, ²Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

The multifunctional Adenomatous polyposis coli (APC) proteins are known for their roles in negatively regulating Wnt signaling, stabilizing microtubules, and indirectly regulating actin through effectors such as Asef and IQGAP. Most recently, we have shown that through their basic domains both vertebrate APC (vAPC) and *Drosophila* APC1 can bundle and nucleate actin filaments, and collaborate with the formin Diaphanous (Dia) to efficiently nucleate actin assembly *in vitro*. In addition, *Drosophila* APC2 (which lacks a basic domain) and Dia bind directly and are required for actin furrow extension in the fly embryo. APC1 does not function in actin furrow extension. Together these data suggest that APC-Dia collaborations are an evolutionary conserved mode of actin filament assembly regulation. However, significant gaps exist in our understanding of both mechanism and physiological relevance. While we have investigated the mechanism underlying the vAPC/APC1-Dia collaboration in detail, how APC2 affects Dia activity without a basic domain is not known. Here we demonstrate that APC2 interacts with Dia through its β -catenin binding 20 amino acid repeats (20Rs), and that 20R phosphorylation by GSK3 β regulates APC2's actin furrow activity. Contrary to our predictions that APC2 promotes Dia's actin assembly activity in the embryo, APC2 specifically inhibits the actin assembly activity of both APC1 and

Dia in vitro. We are currently working to reconcile these results and develop a deeper mechanistic understanding of APC2-APC1-Dia interactions. As a complement to these analyses, we are dissecting the role of APC-Dia collaborations *in vivo*. Many coordinated actin-mediated processes occur during *Drosophila* oogenesis making this a great physiologically relevant system in which to study actin assembly. In stage 10B egg chambers, an array of cytoplasmic actin bundles (actin baskets) form around each nucleus in the nurse cells to secure them. Loss of these baskets disrupts oogenesis resulting in small, round, inviable eggs. Here we show that APC1 and Dia are required for the proper assembly of these actin baskets. In *APC1* or *dia* mutants, the actin baskets fail to form at stage 10B, but surprisingly they are present at stage 11. This delay may suggest that APC1-Dia function can be compensated for by other assembly factors. Alternatively, APC1 and Dia may be able to carry out actin assembly alone in the absence of the other partner, but with reduced efficiency resulting in assembly delay. In conclusion, the *Drosophila* APC-Dia collaborations represent an evolutionarily conserved, experimentally tractable system in which to dissect both molecular mechanisms and physiological relevance.

Calponin-like protein isoforms regulate actomyosin contractility in *C. elegans*.

K. Ono¹, T. Obinata², S. Yamashiro¹, Z. Liu¹, S. Ono¹;

¹Pathology, Emory University, Atlanta, GA, ²Biology, Chiba University, Chiba, Japan

Calponins and calponin-related proteins are present widely in eukaryotes and regulate stability of actin filaments and contractility of actin and myosin. Although a number of biochemical studies suggest their regulatory roles for actin cytoskeleton, little is known about their *in vivo* functions. In mammals, calponins and calponin-related proteins have a calponin-homology (CH) domain at the N-terminus and one or three calponin-like (CLIK) motifs at the C-terminus. In the nematode *Caenorhabditis elegans*, UNC-87 is a unique calponin-related protein with seven CLIK motifs and no CH domain and has been shown previously to stabilize actin filaments in striated muscle (Goetinck and Waterston, 1994; Yamashiro et al., 2007). Here, we report that multiple isoforms of calponin-like proteins are expressed in *C. elegans* and have functions to regulate actomyosin contractility in striated and non-striated muscles. The *unc-87* gene has two alternative first exons, which are used to generate two UNC-87 isoforms (Goetinck and Waterston, 1994): UNC-87A with a longer N-terminal sequence and UNC-87B with a shorter N-terminal sequence. A promoter-reporter analysis showed that UNC-87A and UNC-87B are expressed in different tissues. UNC-87A was expressed in pharynx, uterine muscle, and neurons, whereas UNC-87B was expressed in body wall muscle and the somatic gonad. *In vitro*, UNC-87A and UNC-87B bound to actin filaments and bundled them. They also bound to myosin and inhibited actin-activated myosin ATPase. Both UNC-87A and UNC-87B induced large actomyosin bundles that are resistant to ATP-induced disassembly. In these *in vitro* experiments, UNC-87A exhibited stronger binding to actin and myosin than UNC-87B, suggesting that these isoforms have different regulatory functions for actin and myosin. In addition, *C. elegans* has another gene *clik-1*, which encodes a protein with seven CLIK motifs and a 46 % identical sequence to UNC-87B. Although a single knockout of *clik-1* did not cause

any detectable phenotypes, knockdown of *clik-1* in *unc-87* mutants caused paralysis and defective egg laying. Simultaneous depletion of *unc-87* and *clik-1* also caused excessive contraction of the myoepithelial sheath in the somatic gonad, suggesting that they have overlapping functions to inhibit actomyosin contractility. These results suggest biological significance of calponin-related proteins with CLIK motifs in actomyosin regulation.

The actin crosslinking protein palladin modulates force generation and mechanical sensing by cells.

M. Azatov¹, S. Goicoechea², R.F. Hwang³, C.A. Otey², A. Upadhyaya⁴;

¹University of Maryland, College Park, MD, ²Univ North Carolina Sch Med, Chapel Hill, NC, ³Anderson Cancer Center, University of Texas, Houston, TX, ⁴Physics and IPST, University of Maryland, College Park, MD

Pancreatic tumor-associated fibroblasts (TAFs) have been shown to promote the progression of pancreatic tumors, metastasis, and the resistance to therapy. Mechanisms by which these cells stimulate invasiveness and metastasis of cancer cells are not well understood. It is known that the actin-crosslinking protein, palladin, is upregulated in TAFs, but the precise role of palladin in these cells is unknown. Several lines of evidence suggest that the misregulation of actin reorganization resulting from enhanced palladin levels may contribute to aberrant cellular behavior. In this study we use human pancreatic tumor associated fibroblasts (TAFs) to investigate the role of palladin in regulating the plasticity of the actin cytoskeleton and cellular force generation in response to alterations in substrate stiffness. Traction force microscopy revealed that TAFs are sensitive to substrate stiffness as they generate larger forces on substrates of increased stiffness. Contrary to expectations, knocking down palladin increased the forces generated by cells accompanied by significant differences in the actin organization palladin knock down cells. Our results suggest that the actin crosslinkers such as palladin and myosin motors coordinate for optimal cell function and to prevent aberrant behavior as in cancer metastasis.

Calcium-regulated actin bundling activity of human plastins.

C. Schwebach^{1,2}, M.B. Mohamed¹, S.N. Pawela¹, E. Kudryashova¹, D.S. Kudryashov^{1,2};

¹The Department of Chemistry and Biochemistry, The Ohio State University, Columbus, OH, ²Molecular and Cellular Developmental Biology Program, The Ohio State University, Columbus, OH

The actin cytoskeleton is an extensive and intricate network that is tightly regulated by a vast array of actin binding proteins. Plastins are one such family of proteins that are conserved throughout eukaryotic

life with three isoforms expressed in mammals. Each of these isoforms is tissue-specific: plastin 1 (PLS1) is expressed in the intestines and kidneys, plastin 2 (PLS2) is expressed in hematopoietic cells and malignant tumors, while the most abundant plastin 3 (PLS3) is present in solid tissues. The three isoforms are involved in distinct functions including epithelium strengthening, cell migration, and differentiation. Plastins crosslink actin filaments into tight bundles essential for cellular structures such as microvilli, lamellipodia, and filopodia. This bundling is implemented by two tandem actin binding domains (ABDs) and regulated by an N-terminal domain containing two EF hand motifs. Binding of Ca^{2+} to the EF hands inhibits the bundling activity of all isoforms, however, a detailed molecular mechanism of this inhibition is not understood. Recently, it has been reported that the isolated EF-hands of PLS3 have two different affinities to Ca^{2+} (low $K_d \sim 10 \mu\text{M}$ and high $K_d \sim 0.4 \mu\text{M}$); whereas both EF-hands of PLS2 bind Ca^{2+} with similar high affinity ($K_d \sim 1 \mu\text{M}$). Based on this observation it has been proposed that PLS3 is more suitable for maintaining static cytoskeleton, while PLS2 is more suitable for dynamic rearrangements characteristic for actively migrating immune cells. In the present study we readdress this subject by using full-length proteins and monitoring functional effects of Ca^{2+} interaction with plastin. To this end, we employed light scattering to directly monitor Ca^{2+} -induced disassembly of actin bundles formed by the three plastin isoforms. Phosphorylation of Ser5 on PLS2 has been shown to dramatically improve its binding to actin. Accordingly, only the phosphomimetic mutant of PLS2, but not the wild-type protein, bundled actin in our assays. Intriguingly, we found that all three isoforms of recombinant human plastins have similar sensitivity to Ca^{2+} within the physiologically relevant pCa 6.3-6.5. While efficiently dismantling actin bundles, Ca^{2+} did not substantially affect binding of any of the three isoforms to actin suggesting that binding of only one of the domains (ABD1 or ABD2) is inhibited by EF hands. Interestingly, a construct of PLS3 lacking the C-terminal actin binding domain (ΔABD2) bound actin in Ca^{2+} -independent manner with an affinity similar to that of full-length PLS3. This result indirectly implies that binding of ABD2 rather than ABD1 is inhibited by the EF hands. Work is ongoing to further characterize the effect of Ca^{2+} on plastin binding to filamentous actin and to decipher a detailed Ca^{2+} regulatory mechanism.

Regulation of macrophage motility, morphology and activation by the actin-bundling protein L-plastin.

E.M. Todd¹, J.Y. Zhou¹, L.E. Deady¹, S. Morley^{1,2};

¹Pediatrics, Washington University School of Medicine, St. Louis, MO, ²Pathology and Immunology, Washington University School of Medicine, St. Louis, MO

Macrophage motility requires precise spatiotemporal control of actin dynamics. The actin-bundling protein L-plastin (LPL; also called fimbrin) is highly enriched in macrophage podosomes. Essential functions for LPL in macrophage biology have not yet been fully described. Prior work has demonstrated reduced motility and transmigration in lymphocytes lacking LPL. Investigation of the cellular mechanisms underlying the increased susceptibility of mice genetically deficient for LPL (LPL^{-/-} mice) to pulmonary

infection with the bacteria *Streptococcus pneumoniae* revealed a developmental defect in alveolar macrophages. Alveolar macrophages are a tissue-specific, developmentally unique population of phagocytes critical to normal lung innate immunity. Building upon these prior observations, we now report the requirement for LPL in macrophage morphology, motility, and activation. Alveolar macrophages derived from LPL^{-/-} mice demonstrated reduced spreading on glass coverslips compared to macrophages sufficient for LPL. Actin recruitment to sites of vinculin aggregation was impaired in LPL^{-/-} alveolar macrophages, revealing impaired podosome formation. Peritoneal macrophages from LPL^{-/-} mice were defective in transmigration across collagen-coated Transwell inserts. These morphologic and motility defects correlated with activation defects in LPL^{-/-} alveolar macrophages. Using the NLRP3 inflammasome activator ATP after LPS priming, we demonstrated reduced production of IL-1-beta by LPL^{-/-} alveolar macrophages. IL-6 production was also reduced but secretion of TNF-alpha was unimpaired, suggesting selective activation defects in the absence of LPL. The mechanistic link between disruption of cytoskeletal regulation and NLRP3 inflammasome activation in cells lacking LPL is an area of active investigation. Transcripts of IL-1-beta were reduced in LPL^{-/-} alveolar macrophages, suggesting that LPL may be required to maintain cells in a "readiness" state to receive and respond appropriately to activation signals. Further investigation of macrophages from LPL^{-/-} mice will reveal novel insights into the molecular mechanism by which actin cytoskeletal elements regulate immune cell activation.

The function and dynamics of the apical scaffolding protein E3KARP is regulated by cell cycle phosphorylation.

C. Sauvanet¹, D. Garbett¹, A.P. Bretscher¹;

¹Cornell University, Ithaca, NY

Scaffolding proteins, often containing PDZ domains, bring together other proteins to facilitate their collective activity. Here we examine the apical protein E3KARP/NHERF2 and find that its function and dynamics is cell cycle regulated, but in a mechanistically different manner from its paralog EBP50/NHERF1. The identification of novel phospho regulatory sites has allowed us to investigate their functional significance. Phosphorylation at serine 303 in the tail region of E3KARP greatly enhances the in vivo dynamics of E3KARP in cells during mitosis. Phosphomimetic S303D enhances the dynamics and compromises the ability of E3KARP to complement the function of EBP50 in generating microvilli on interphase cells. S303D enhances the dynamics of the isolated E3KARP tail in vivo, and, in contrast to EBP50, the presence of the PDZ domains does not regulate the dynamics. However, in vitro, the interaction of E3KARP with active ezrin is unaffected by S303D, indicating the involvement of another factor that enhances in vivo dynamics. Inhibitor, knockdown and localization studies indicate that A-Raf is required for S303 phosphorylation in mitotic cells. Interestingly, in both cases the mechanisms regulating dynamics involve the tails, which are the most diverged region of the paralogs, and probably evolved independently after a gene duplication event that occurred early in vertebrate evolution.

P875**Board Number: B190****Septin 9 is an actin binding protein which bundles F-actin through a unique N-terminal domain.**C. Smith¹, R. Van Sciver¹, L. Dolat², E.T. Spiliotis², V.E. Galkin¹;¹Eastern Virginia Medical School, Norfolk, VA, ²Biology, Drexel University, Philadelphia, PA

Septins are GTP-binding proteins that are crucial for cell division and nervous system development. They are structurally related to the Ras GTPases but unlike the monomeric small GTPases, septins readily polymerize into filaments, bundles and rings comprised of tissue specific septin isoforms. SEPT9 is a unique septin that possess an N-terminal extension (NTE) domain that is missing in the other septin isoforms. Recently it has been shown that septins interact with both actin filaments and microtubules. *Drosophila* septin complexes form curved bundles out of actin filaments, while human SEPT9 is capable of promoting bundle formation out of both microtubules and F-actin. We used electron microscopy and image analysis to show that SEPT9 bundles F-actin via its NTE, and that the basic domain of the NTE is responsible for the actin bundling. We also show that GTP-binding domain (G-domain) of SEPT9 readily binds but does not bundle F-actin. Both the NTE-domain and the G-domain may compete with the NTE for the same binding site of the F-actin surface. Our structural data indicate that SEPT9 might directly affect acto-myosin contractility and participate in regulation of cell motility.

P876**Board Number: B191****Structural Basis of the Vinculin–F-actin Interaction.**L.Y. Kim¹, P. Thompson², S. Campbell², G.M. Alushin¹;¹CBPC, NIH/NHLBI, Bethesda, MD, ²Biochemistry and Biophysics, UNC, Chapel Hill, NC

The essential protein vinculin is a key component of cell–matrix and cell–cell adhesions, acting as a linker between these connection points and the actin cytoskeleton. Accumulation of vinculin is necessary for adhesions to sustain high traction forces, and its direct interaction with F-actin is required for mechanotransduction. Due to its physiological significance, the molecular determinants of this interface have been under scrutiny for some time, yet conflicting structural models are present in the literature, largely because of the absence of high-resolution analysis. We have obtained a subnanometer-resolution (8.5 Å, gold-standard FSC 0.143) cryo-EM reconstruction of vinculin’s C-terminal “tail” domain (Vt) bound to F-actin, sufficient for constructing an unambiguous pseudo-atomic model of the interface by flexible docking of crystallographic structures of the components. Our findings support a recent experimentally derived model of the interaction (Thompson et al., *Structure* 2014). Additionally, we find that Vt undergoes a substantial conformational change upon actin binding, characterized by a twisting of helices 4 and 5 and unfolding of helix 1 from the bundle, a segment of which makes a novel contact with the surface of the actin filament. We postulate that this structural

transition enables additional interactions between vinculin and binding partners upon actin engagement.

P877

Metavinculin alters the mechanical properties of F-actin and attenuates the bundling activity of vinculin.

Z.A. Durer¹, H. Kang², W.A. Elam², R.M. McGilivray¹, C.L. Vizcarra¹, D. Hanein³, E. De La Cruz², E. Reisler^{1,4}, M.E. Quinlan^{1,4};

¹Chemistry and Biochemistry, University California-Los Angeles, Los Angeles, CA, ²Yale University, New Haven, CT, ³Bioinformatics and Systems Biology Program, Sanford Burnham Medical Research Institute, La Jolla, CA, ⁴Molecular Biology Institute, University California-Los Angeles, Los Angeles, CA

Metavinculin is a longer and muscle specific splice variant of vinculin. Despite the link between mutations in the tail of metavinculin (MVT) and human cardiac disease, the function of MVT remains elusive. Recent work proposed that MVT severs F-actin. Therefore, we characterized this activity and the structural changes in F-actin that manifest upon MVT binding. Using mutagenesis, site-directed fluorescent labelling and TIRF microscopy, we found that MVT alters the actin arrangement of actin interprotomer contacts and fragments F-actin most potently at half binding densities. However, we did not observe MVT's severing activity under real time conditions. This raises the possibility that the fragmentation observed in our equilibrium assays may result from an MVT induced change in F-actin bending mechanics. Consequently, we assessed the flexibility of F-actin decorated with MVT by measuring the bending persistence length. Indeed, we observed a difference. Finally, we explored the interplay between VT and MVT by monitoring the F-actin bundle formation using TIRF microscopy. Our results on MVT induced changes in actin filament flexibility and altered actin filament organization will be presented.

Cyclase Associated Protein Regulates Alpha-Actinin Function in Epithelia.

J.P. Kemp Jr¹, W.M. Brieher²;

¹Univ Illinois Urbana-Champaign, Urbana, IL, ²Cell and Developmental Biology, University of Illinois-Urbana-Champaign, Urbana, IL

Alpha-Actinin is a well-known actin binding and bundling protein. It has been shown to localize to many known actin structures including stress fibers, adherens junctions, lamellipodia, and the cortical actin cytoskeleton. Understanding the actinin interactome will help us better understand its role in and regulation of each of the structures it localizes to. With this in mind, we performed a pull down of kidney extract using recombinant actinin as bait. The main hit from our pull down was Cyclase

Associated Protein 1, CAP1. CAP1 has been shown in our lab as well as others to facilitate depolymerization of actin filaments in vitro and to both increase and decrease the amount of actin in different actin structures in cells by as yet unknown mechanisms. In MDCK cells, a canine kidney epithelia cell line, CAP1 was localized to cell-cell borders, actin protrusions, and basal fibers. Actinin also localizes to these structures, however, when we examined the localization of the two proteins along stress fibers they were predominantly not colocalized. We then knockdown CAP1 in MDCK cells and found that the actin signal at the basal surface increased as well as the actinin signal. This is consistent with a new model where CAP1 either sequesters or buffers the amount of actinin to modulate stress fibers. We are currently testing this model further with in vitro biochemistry.

Quantitative comparison of human Cofilin-1, Cofilin-2, and ADF effects on actin dynamics.

S. Chin¹, S. Jansen¹, B.L. Goode²;

¹Brandeis University, Waltham, MA, ²Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

Cofilin/Actin-Depolymerizing Factor (ADF) family proteins bind to actin filaments and actin monomers and perform essential in vivo roles in driving the dynamic remodeling and turnover of the actin cytoskeleton. Mammals express three different Cofilins: Cofilin-1, Cofilin-2, and ADF. Cofilin-1 and ADF are more ubiquitous and often co-expressed in the same cell types, whereas Cofilin-2 is muscle-specific. Here, we performed a direct and quantitative comparison of the activities of all three human Cofilins on actin filament and monomer dynamics in vitro using both TIRF microscopy and bulk fluorescence assays. Our results show that all three Cofilins bind actin monomers with similar affinities ($K_d \sim 1.3 \mu\text{M}$) and block nucleotide exchange. However, Cofilin-2 and ADF sever filaments with higher efficiency than Cofilin-1. Further, in the presence of Aip1 and Cor1B, Cofilin-2 and ADF disassembled filaments more efficiently than Cofilin-1. We have also engineered cysteine residues in each Cofilin to generate fluorescently labelled functional molecules for multi-wavelength TIRF experiments aimed at directly visualizing and comparing the interactions of each Cofilin with actin filaments. Finally, we have begun comparing the activities of each Cofilin on branched versus bundled actin filament networks.

P880**Board Number: B195****GMF β controls branched actin content and lamellipodial retraction in fibroblasts.**E.M. Haynes¹, S.B. Asokan¹, S.J. King¹, C. Wu^{1,2}, I.P. Lebedeva^{1,2}, J.E. Bear¹;¹UNC Lineberger Comprehensive Cancer Center, Department of Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC, ²Howard Hughes Medical Institute, Chevy Chase, MD

The process of cell migration is integral to both organism development and disease. In order to migrate, cells rely on the lamellipodium, a fan-like structure comprised of Arp2/3 nucleated branched actin which generates the force necessary for leading edge protrusion. Polymerization of actin at the leading edge is relatively well understood; however, much less is known about branched actin disassembly/remodeling and how it influences migration. In order to respond to extracellular cues, a cell must be able to quickly remodel its actin cytoskeleton, a process which relies on actin severing and pruning of branches. The cofilin homolog GMF has been implicated in disassembly of branched actin mainly by in vitro work. We sought to understand the role of the ubiquitous mammalian GMF isoform, GMF β , in lamellipodial dynamics and cell migration. We found that GMF β (but not GMF γ) is expressed in fibroblasts and localizes to the leading edge of the cell. Modulation of GMF β by depletion or overexpression resulted in significant phenotypes in lamellipodial dynamics, branched actin content and migration. Specifically, depletion of GMF β resulted in larger lamellipodia with reduced ability to retract, and a higher fraction of the cell periphery positive for Arp2/3. GMF β overexpressing cells were smaller and had a reduced fraction of Arp2/3 positive cell periphery. These data are consistent with the notion of GMF β as an antagonist of branched actin, but does not differentiate between GMF β 's two proposed mechanisms of action: debranching and preventing nucleation promoting factors from binding to Arp2/3. In order to address whether branch lifetime itself was affected by GMF β , we performed a wash-in using the Arp2/3 inhibitor CK666. Based on previous studies (Hetrick et al 2013) CK666 binds free Arp2/3 and prevents formation of new branches, but branches that are already formed will not disassemble in the presence of CK666. GMF β depletion increased the time required for Arp2/3 signal to dissipate from the cell edge after CK666 wash-in, suggesting that GMF β is important for debranching. In addition, we created a mutation in GMF β analogous to a mutation in budding yeast GMF (Ydenberg et al 2013) which severely reduces debranching activity. This mutant cannot rescue the observed phenotypes of depletion of wild type GMF β . Finally, we tested if the changes we observed in the branched actin content in these cells affected directional migration. While both GMF β depleted and GMF β overexpressing cells could detect a gradient of soluble cue (chemotaxis), we found that both cell lines were unable to detect a gradient of bound extracellular matrix (haptotaxis). This corroborates previous results from our lab that the branched actin generated by Arp2/3 is necessary for haptotaxis.

P881**Board Number: B200****Sid2 phosphoregulation of anillin-related Mid1 nuclear localization and fission yeast cytokinesis.**A.K. DeWitt¹, P. Schneider¹, G. Foa¹, K.L. Gould², D.M. Clifford Hart¹;¹Cell and Molecular Biology, Grand Valley State University, Allendale, MI, ²Cell and Developmental Biology, Vanderbilt Univ Med Sch/HHMI, Nashville, TN

Cortical nodes assemble during interphase and serve as the foundation to generate a contractile ring for fission yeast cytokinesis. The anillin-related protein Mid1 serves as a central organizer of cytokinesis by anchoring cortical nodes to the cell membrane and recruiting proteins that incorporate into the contractile ring. Interestingly, Mid1 dissociates from the cell cortex prior to contractile ring constriction. However, it remains unclear if Mid1 departure influences ring function. Given that localization of Mid1 to the cell cortex is phosphorylation dependent, we hypothesized that Mid1 departure from the cell cortex may be similarly controlled. Indeed we find that Sid2 kinase directly phosphorylates Mid1. Phosphosite mapping and phenotypic analyses of phosphosite mutants reveal defects in Mid1 nuclear accumulation following septation and during interphase. Instead, Mid1 remains concentrated in the cytoplasm and appears to localize as cortical nodes. Strikingly, a reproducible percentage of phosphosite mutants display two contractile rings and/or disorganized contractile rings. To further examine Mid1 localization, we combined the Mid1 phosphosite mutant with a temperature-sensitive mutation that arrests cells at anaphase when Mid1 should be concentrated in the nucleus. In the phosphosite mutant, Mid1 fails to move from the cytoplasm to the nucleus. Instead Mid1 accumulates in punctate clusters or remains in rings that are often abnormal. We conclude that Sid2 phosphoregulation of Mid1 nuclear accumulation during interphase promotes proper contractile ring function in mitosis.

P882**Board Number: B201****CARMIL proteins exhibit isoform-specific spatial and temporal expression patterns during zebrafish development.**B.C. Stark¹, J.A. Cooper¹;¹Department of Cell Biology and Physiology, Washington University School of Medicine, Saint Louis, MO

Actin assembly is essential for many cellular processes, including cell migration during development, an immune response, and metastasis. Assembly occurs primarily at barbed ends of actin filaments, and the generation of new barbed ends is highly regulated. Capping protein binds to actin barbed ends and stabilizes the filament, preventing loss or addition of actin subunits. CARMIL proteins are a major regulator of capping protein. They are found throughout vertebrates and in some lower eukaryotes including *Acanthamoeba* and *Dictyostelium*. CARMILs bind to and inhibit capping protein via an

allosteric mechanism. Most exciting, they are able to remove capping protein from barbed-ends and thereby generate a new, free barbed-end. CARMILs are large, multi-domain proteins. Vertebrate genomes contain three conserved genes that encode three CARMIL isoforms. Prior to my work, only one CARMIL isoform had been confirmed in zebrafish. I have identified two additional CARMIL genes in the zebrafish genome. All three isoforms of CARMIL in zebrafish are highly conserved with respect to other vertebrates. All three are expressed during development. The CARMIL 1 and CARMIL 3 isoforms are expressed both maternally and zygotically, whereas the CARMIL 2 isoform is expressed zygotically. RNA in situ hybridizations reveals differential expression patterns for all three genes within the developing embryo. Morpholino-mediated knockdowns of CARMIL 2 and CARMIL 3 result in isoform-specific phenotypes. CARMIL 2 knockdown results in embryonic lethality in 90% of fish by 24 hpf. CARMIL 3 knockdown results in cardiac defects and death by 5 dpf.

Board Number: B202

A temporally ordered mechanism for actin filament disassembly involving mammalian Coronin, Cofilin, AIP and Srv2/CAP.

S. Jansen¹, A. Collins¹, D. Breitsprecher¹, B.L. Goode²;

¹Brandeis University, Waltham, MA, ²Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

The actin cytoskeleton is a self-organizing, dynamic polymer system that drives important biological processes such as endocytosis, cell migration and morphogenesis, and relies on balanced actin filament assembly and disassembly. How actin disassembly is regulated is still not well understood. One of the most well characterized components of the disassembly machinery is Cofilin/ADF, which binds cooperatively to filaments and induces severing. However, Cofilin binds F-actin with surprisingly slow kinetics, has relatively inefficient severing activity, and produces free (uncapped) barbed ends, which leads to assembly instead of disassembly. These enigmas have long suggested that additional cellular factors may be required in vivo for rapid and efficient F-actin disassembly. Here, we used three-color TIRF microscopy single molecule analysis to investigate the mechanism by which mammalian Coronin, AIP1 and Srv2/CAP (cyclase-associated protein) work with Cofilin to promote actin disassembly. We show that these four proteins work in a specific order on ADP-F-actin and together produce ultra-fast disassembly. Coronin binds first to filaments and rapidly recruits Cofilin. Then, AIP1 arrives and induces highly efficient severing. After severing, AIP1 remains associated with the newly generated barbed ends, blocking growth and promoting disassembly even under assembly conditions. Srv2/CAP makes a distinct mechanistic contribution to disassembly by binding autonomously to filament sides and altering F-actin structure to enhance Cofilin-dependent severing. Finally, in a reconstituted assembly-disassembly system, we could directly visualize formins rapidly polymerizing filaments, counterbalanced by equally rapid severing and depolymerization by the disassembly factors working in concert.

P884**Board Number: B203****Tropomodulin4-deficient mice exhibit compensatory upregulation of tropomodulin1 and altered thin filament activation in skeletal muscle.**D.S. Gokhin¹, J. Ochala², A.A. Domenighetti³, V.M. Fowler¹;¹Department of Cell and Molecular Biology, The Scripps Research Institute, La Jolla, CA, ²Centre of Human and Aerospace Physiological Sciences, King's College of London, London, United Kingdom,³Department of Orthopaedic Surgery, University of California, San Diego, La Jolla, CA

Simultaneous control of thin filament lengths, thin filament activation, and actomyosin crossbridge formation is essential for efficient contractile function of skeletal muscle fibers. Thin filament pointed ends in skeletal muscle sarcomeres are capped by a combination of two sarcomeric tropomodulin (Tmod) isoforms, Tmod1 and Tmod4, both of which interact with the N-terminus of tropomyosin and regulate actin subunit dynamics *in vitro*. However, to date, only Tmod1 has been directly implicated in the specification of muscle-specific thin filament lengths, formation of actomyosin crossbridges, and contractile stress generation *in vivo*. To better understand the *in vivo* functions of Tmod4 and distinguish Tmod4's functions from Tmod1's functions, we first compared Tmod1 vs. Tmod4 protein levels across various muscle types using quantitative western blotting. The ratio of Tmod4:Tmod1 protein levels ranged from ~9.5:1 in a representative fast muscle (tibialis anterior) to ~4:1 in a representative slow muscle (soleus), suggesting that sarcomeric Tmod isoform distributions are muscle-specific, analogous to tropomyosin, troponin, and myosin isoform distributions. This is partly due to muscle-specific differences in gene expression, as RNA sequencing analysis identified ~2-fold greater *Tmod4* mRNA levels in tibialis anterior muscle than in soleus muscle, but markedly lower *Tmod1* mRNA levels in both of these muscle types. Next, we investigated the functional role of Tmod4 *in vivo* by characterizing the skeletal muscle phenotype of a novel *Tmod4*^{-/-} mouse. *Tmod4*^{-/-} mice exhibit no overt myopathic features, with normal myofibril organization and unchanged thin filament lengths, due to compensatory upregulation of Tmod1 of a magnitude sufficient to repopulate nearly all of the pointed ends vacated as a result of Tmod4 deletion. Thus, Tmod4 is dispensable for specification of thin filament lengths *in vivo*. However, the switch from pointed-end capping by Tmod1 and Tmod4 in wild-type muscle to exclusively Tmod1 in *Tmod4*^{-/-} muscle resulted in a trend toward reduced and more variable Ca²⁺ sensitivity during thin filament activation, although the kinetics of actomyosin crossbridge cycling, the total number of myosin heads bound, and maximal isometric stress generation were all unchanged. We propose that muscle-specific isoform distributions of Tmod1 and Tmod4 may enable muscle-specific, collaborative fine-tuning of thin filament lengths and thin filament activation, possibly mediated by long-range effects initiated by Tmod-tropomyosin interactions at the pointed end.

P885**Board Number: B204****Comparison of actin-binding activity between MyBP-C (myosin-binding protein-C) isoforms.**S. Wakatsuki¹, T. Obinata¹, N. Sato¹;¹Department of Nanobiology, Chiba University, Graduate school of Advanced Integration Science, Chiba, Japan

Myosin-binding protein-C (MyBP-C/ C-protein) is one of the major myosin-binding proteins and has three isoforms, cardiac (cMyBP-C), fast-skeletal (fMyBP-C) and slow-skeletal type (sMyBP-C) in vertebrate striated muscles. MyBP-C locates at the C-zone of A-band in sarcomeres of vertebrate striated muscles. The fMyBP-C and sMyBP-C are composed of 3 fibronectin type III (FNIII) repeats and 7 immunoglobulin (Ig) domains. The cMyBP-C has an extra Ig domain (C0) at the N-terminus. A linker sequence between domain 1 and 2 is named MyBP-C motif and contains unique phosphorylation sites in the cardiac isoform, which imply additional functions compared with the skeletal isoforms; e.g., mutation of human cMyBP-C causes to hypertrophic cardiomyopathy. It has been demonstrated that the N-terminal domains of cMyBP-C interact with actin filaments and S2 subfragment of myosin, on the other hand, the C-terminal domains interacts with light meromyosin and connectin/titin. Through these domains, cMyBP-C modulates myosin assembly, actin-myosin interaction, and stabilizes thick filaments. However, it is unclear whether fMyBP-C and sMyBP-C bind to actin filaments and affect actomyosin interaction. In this study, we prepared N-terminal fragment encoding mouse cMyBP-C (domain 0 to domain 3), that of fMyBP-C (domain 1 to domain 4) and that of sMyBP-C (domain 1 to domain 4) in an *E. coli* expression system. Cosedimentation assays and other experiments revealed that not only cMyBP-C but also fMyBP-C and sMyBP-C bind to actin filaments by a cross-linking (or bundling) manner, and also bind to myosin filaments at the N-terminal regions. When the fMyBP-C fragment and actin were incubated in a molar ratio of 0.25:1, the fMyBP-C elevated actin-activated myosin ATPase activity significantly. To determine the actin filaments and myosin filaments binding site of fMyBP-C precisely, we prepared several deletion fragments of fMyBP-C. The result indicated that fMyBP-C interacts with actin filaments and myosin filaments through its MyBP-C motif.

P886**Board Number: B205****Arginylation of beta actin is dynamically regulated during cell migration.**D. Volgin¹, A.S. Kashina¹;¹Department of Animal Biology School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA

Our previous work has uncovered that beta actin is arginylated in non-muscle cells and that this arginylation is required for leading edge formation during cell migration, but the underlying mechanisms are not understood. Here we used a newly developed antibody to arginylated beta actin

and found that arginylation dynamically increases in cells that are actively migrating and reduces during resting period, and that arginylated beta actin is concentrated in the leading lamella in a zone located right behind the leading edge actin network. Lack of arginylation results in a dramatic reduction of actin polymer levels in the lamellipodia. Our data suggest that arginylation of beta actin is a tightly regulated process that occurs in response to cell migration stimuli and is required for the massive polarized growth of the actin filaments that facilitates leading edge protrusion.

Arginylation regulates brain development, neuronal patterning, and growth cones.

D. Volgin¹, J. Wang¹, A.S. Kashina¹;

¹Department of Animal Biology School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA

Arginylation is an emerging posttranslational modification that has been recently found to affect actin cytoskeleton and regulate cell migration in non-muscle cells. Here we studied the effect of the brain-specific knockout of arginyltransferase (Ate1) on mouse development and the morphology and behavior of neurons in a conditional knockout model with Ate1 deletion driven by brain-specific Nestin (Nes) promoter. Such Nes-Ate1 mice exhibit high rates of perinatal lethality accompanied by prominent structural and behavioral retardation. Cultured Ate1 knockout neurons isolated from embryos and neonates exhibit delayed growth cone development. Immunofluorescence studies show that arginylated beta actin prominently accumulates in developing wild type neurons and appears to target specifically to the growth cones during branching, following only the protruding neurites. Our results suggest that Ate1-mediated arginylation of beta actin is actively involved in neuron development and outgrowth and that its abolishment leads to several neuronal impairments at cellular and organismal level.

Regulation of pheromone-induced cell polarization by the polarisome proteins in yeast.

H. Lai¹, T. Zyla¹, D.J. Lew¹;

¹Department of Pharmacology and Cancer Biology, Duke University Medical Center, Durham, NC

The ability to polarize is essential for the function of many cell types. During mating, haploid budding yeast cells polarize growth to generate mating projections (shmoo) towards each other in order to fuse and form diploids. Such pheromone-induced cell polarization and morphogenesis is thought to be regulated by the “polarisome” proteins Bni1, Bud6, Pea2, and Spa2. These proteins are thought to act

primarily by localizing formin activity, which acts to orient actin cables that deliver secretory vesicles to the polarity site. In turn, polarisome components are themselves targeted to the polarity site by the master polarity regulators, Cdc42 and Bem1. Here we report interdependencies between Spa2, Pea2, and Bni1 for localization to the polarity site. In addition, we find that loss of Spa2 or Pea2 may alter the distribution of upstream regulators, as well as weakening downstream vesicle targeting. Vesicle accumulation at the shmoo tip was most severely reduced in cells lacking the formin Bni1. However, we found that loss of all formins did not block polar growth or the formation of mating projections, suggesting that secretory vesicles can be directed to the polarity site independent of actin cables.

CD44/Integrin α v β 3 signaling: Role in Prostate Cancer Invasion/Metastasis and Osteoclastogenesis.

M. Chellaiah¹;

¹Department of Oncology and Diagnostic Sciences, Univ Maryland Dental Sch, Baltimore, MD

Pathological skeletal fractures develop in prostate cancer patients as a result of bone loss induced by androgen deprivation therapy and bone metastases. In this regard, bone-resorbing osteoclasts (OCs) are essential in mediating bone loss induced by metastatic prostate cancer cells homing to the skeleton. Therefore, there is a critical need for novel pharmacotherapeutic approaches to control this debilitating disease. We have previously demonstrated that prostate cancer cells secrete receptor activator of NF- κ B ligand (RANKL), a protein essential for OC differentiation and activation. The objective of our study is to inhibit the expression and function of RANKL in metastatic prostate cancer cells. We used prostate cancer cells lines derived from a variety of anatomic metastases. We found a significant increase in the expression of CD44, a cell surface receptor in prostate cancer cells derived from human bone metastases (PC3) as compared with those derived from brain (DU 145) or lymph node (LNCaP) metastases. CD44 expression is very negligible or not observed in LNCaP cells. We show here that CD44 / Src signaling which involves cortactin-WASP-Arp2/3 axis plays an important role in the formation of invadopodia and invasion of PC3 cells. Knock down of CD44 and expression of kinase defective Src in PC3 cells reduces invasive property of PC3 cells. RUNX2 and Smad 5 proteins are involved in the regulation of expression of RANKL. CD44 and α v β 3 signaling pathways support RANKL expression by phosphorylation of RUNX2 and Smad 5 proteins, respectively. RUNX2-Smad 5 complex formation and intranuclear targeting of RUNX2 are functionally required for this process. An inhibitor to integrin α v and SiRNA to CD44 attenuated the expression of RANKL in PC3 cells. Immunohistochemistry analysis of tissue microarray sections containing primary prostatic tumor (grade2-4) detected predominant localization of RUNX2 and phosphorylated Smad 5 in the nuclei. Small molecular weight CD44 peptides have the potential to block RANKL expression/secretion and conditioned media from these cells blocked OC formation in vitro although at different levels. These results provide an experimental basis for the development of anti-invasive/metastasis peptide agent to block pathways possibly involved in invadopodia formation and osteoclastogenesis.

P890**Board Number: B209****Spatiotemporal mathematical modeling of myocardin-related transcription factor-A signaling.**B. Spar¹, Q.K. Chen², C. Nelson^{2,3};¹Computer Science, Princeton University, Princeton, NJ, ²Chemical and Biological Engineering, Princeton University, Princeton, NJ, ³Dept. of Molecular Biology, Princeton University, Princeton, NJ

Myocardin-related transcription factor-A (MRTF-A; also known as Mkl1, MAL, BSAC) is involved in many cellular processes including migration, organogenesis and tumor metastasis. MRTF-A is activated by nuclear translocation, which is regulated by the nucleocytoplasmic distribution of monomeric and filamentous actin. The current conceptual model is that MRTF-A is only exported from the nucleus when bound to G-actin, and only imported when unbound. To test the robustness of this conceptual model, we transfected MRTF-A under a strong constitutive promoter into NIH-3T3 fibroblasts. MRTF-A nuclear localization was quantified using immunostaining.

Surprisingly, we found that the nuclear localization of MRTF-A was altered in cells expressing ectopic protein compared to endogenous. Specifically, treatment with cytoskeletal disruptors such as jasplakinolide or cytochalasin D, or stimulation with serum, had different effects on localization of ectopic versus endogenous MRTF-A. Computational kinetic modeling of the MRTF-A/actin regulatory axis using systems of differential equations was unable to quantitatively explain these results. Stochastic kinetic modeling using the slow-scale stochastic simulation algorithm, a variant of the Gillespie algorithm, was unable to reproduce this distribution using physiologically relevant protein copy numbers. Taken together, our results show that the currently accepted conceptual model of MRTF-A nucleocytoplasmic shuttling does not sufficiently explain MRTF-A kinetics.

P891**Board Number: B210****Multilevel crosstalk between Myocardin-related transcription factor (MRTF) and TAZ, two major cytoskeleton-regulated transcriptional coactivators: role in myofibroblast transition.**P. Speight¹, A. Kapus²;¹Keenan Research Center for Biomedical Science, Toronto, ON, ²University of Toronto, Depts Surgery, Biochemistry, Keenan Research Center for Biomedical Science, Toronto, ON

The cytoskeleton impacts gene transcription and thus cell plasticity by regulating the nucleocytoplasmic traffic of mechanosensitive transcription factors. Of these, the Rho effector MRTF and the Hippo pathway target TAZ have emerged as key molecules linking actin dynamics and gene expression. While the nucleocytoplasmic shuttling of MRTF is regulated by its direct binding to G-actin, the mechanism

whereby the cytoskeleton controls TAZ remains unknown. Since we noticed that MRTF contains a C-terminal WW domain-binding motif, while TAZ has a WW domain, we asked if MRTF and TAZ might associate and if MRTF could confer actin-sensitivity to TAZ via a piggyback mechanism. Here we show that MRTF and TAZ indeed bind each other but MRTF is not responsible for the actin-dependent nuclear uptake of TAZ. However, MRTF and TAZ do impact each other at multiple levels, influencing (either unilaterally or reciprocally) the expression, nuclear traffic, mobility and transcriptional activity of the partner. Coimmunoprecipitation studies revealed that MRTF and TAZ associate both in the cytoplasm and in the nucleus. Mutation of the WW-binding motif caused 60% reduction in TAZ binding to full-length MRTF and abolished binding to the isolated C-terminus. MRTF silencing drastically reduced TAZ mRNA and protein expression, indicating that MRTF is a key transcription factor for TAZ. Knockdown of TAZ did not affect MRTF expression, but doubled MRTF's cytosolic mobility (as measured by FRAP) and strongly facilitated its stimulus-induced nuclear accumulation. Cytosolic retention of MRTF by TAZ required the WW-binding motif. Conversely, silencing of MRTF enhanced the nuclear accumulation of heterologously expressed TAZ. Since our previous studies have shown that both MRTF and TAZ impact the expression of the myofibroblast marker α -smooth muscle actin (SMA), we examined their transcriptional effects on the SMA promoter, which harbors side-by-side cis-elements for MRTF (CArG boxes) and TAZ (Tead-binding elements, TBE). MRTF (strongly) and TAZ (weakly) stimulated the SMA promoter through CArG and TBE, respectively, while they reciprocally inhibited each other's effect. TAZ suppressed the MRTF-induced activation of the wild type promoter, while inactivation of the CArG boxes strongly augmented the effect of TAZ. In contrast, TAZ conferred sensitivity for the TGF β effector, Smad3 through Smad-binding elements. Based on these findings, we propose a model in which MRTF and TAZ/Smad3 represent two alternative modes of regulation of SMA expression, which may be linked to wound healing-associated (MRTF) vs. fibrogenic (TAZ/Smad3) programming of myofibroblasts. Selective targeting of these pathways offers a new strategy to interfere with SMA expression only in aggressive myofibroblasts.

Dystroglycan depletion inhibits the functions of differentiated Kasumi-1 cells.

M. Escárcega Tame¹, I. Martínez-Vieyra^{1,2}, B. Cisneros³, S.J. Winder⁴, D. Cerecedo^{1,2};

¹laboratorio de Hematobiología, Instituto Politécnico Nacional, Mexico, Mexico, ²laboratorio de Hematobiología, Instituto Politécnico Nacional, Mexico DF, Mexico, ³Genetics and Molecular Biology, CINVESTAV, Mexico, D.F., Mexico, ⁴Biomedical Science, University of Sheffield, Sheffield, United Kingdom

Hematopoiesis is a complex process, requiring self-renewing and pluripotent stem cells, differentiated progenitor and precursor cells, as well as supportive stroma, adipose tissue, vascular structures, and extracellular matrix. The extracellular matrix guides their division, growth, and development, determining functions. The dystroglycan comprises two glycoproteins; the N-terminal peripheral membrane protein α -dystroglycan that links to the extracellular matrix via several ligands, whereas the

transmembrane β -dystroglycan links α -dystroglycan to the actin cytoskeleton via dystrophin or utrophin. Dystroglycan is widely expressed and heavily glycosylated, the glycosylation pattern of dystroglycan varies with development and tissue and is essential for its function. The central role of dystroglycan as a link between cytoskeleton and extracellular matrix clearly defines dystroglycan as an adhesion molecule. Dystroglycan has recently been characterized in blood tissue cells, as part of the dystrophin glycoprotein complex but to date nothing is known of its role in the induction of macrophagelike cells. We have characterized the pattern expression and cellular distribution of dystroglycans in Kasumi-1 cell line, a human acute myeloid leukaemia cell line differentiated to macrophagelike cells and we have investigated the role of dystroglycan during the differentiation process. Depletion of dystroglycan by RNAi resulted in altered morphology and reduced properties of differentiated Kasumi-1 cells, including chemotaxis, phagocytic activities and expression of markers of differentiation. These findings strongly implicate dystroglycan as a key membrane adhesion protein involved in the differentiation process in Kasumi-1 cells and so is therefore of considerable functional importance.

MIEN1 drives breast cancer invasion by regulating cytoskeletal dynamics.

M.F. Kpetemey¹, J.K. Vishwanatha¹;

¹Molecular and Medical Genetics, Univ North Texas Hlth Sci Ctr, Fort Worth, TX

Introduction: The emergence of metastases remains the primary cause of cancer mortality and morbidity. Active migration of tumor cells is a prerequisite for tumor-cell invasion and metastasis. We identified Migration and Invasion Enhancer 1(MIEN1) as a novel promoter of cell migration/invasion. Previously known as C35, C17orf37, RDX12 and MGC14832, MIEN1 is a novel gene located in the chromosomal region 17q12-21. While absent or low in normal tissues, MIEN1 is abundantly expressed in multiple cancers; including breast, prostate, oral and gastrointestinal carcinomas. A membrane-bound signaling adaptor, MIEN1 localizes to the leading edge of migrating cells and promotes migration and invasion by increasing filopodium formation. While MIEN1 is shown to promote motility through filopodia formation, little is known on the mechanisms by which MIEN1 influence the actin cytoskeleton. Exploring underlying mechanisms, we show that MIEN1 associates with the actin cytoskeleton during motility and directly influence actin polymerization. **Methods:** We performed immunofluorescence, migration and invasion assays using breast cancer cell lines, MDA-MB 231 and MCF10CA1a to investigate the mechanisms by MIEN1 potentiate cell motility.

Results: Ablation of MIEN1 inhibited cell migration, and altered the expression of downstream targets. Immunofluorescence staining with FITC- conjugated-phalloidin confirmed that MIEN1 induced-migration is associated with actin filaments and the knockdown of MIEN1 disturbs the actin cytoskeleton in both MDA-MB231 and MCF10CA1a breast cancer cells. Examination of F-actin and G-actin contents in MIEN1 knocked-down cells showed that the mean ratio of F-actin to G-actin was significantly lesser than control cells. **Conclusion:** Our results show that MIEN1 is a critical regulator of cell motility. The importance of MIEN1 in tumor cell dissemination is well established; understanding the

molecular mechanisms aiding the processes involved will enable designing novel and effective treatments for metastatic tumors

Board Number: B213

Role of Grb2 in muscle differentiation.

P. Mitra¹, T. Thanabalu¹;

¹School of Biological Sciences, Nanyang Technological University, Singapore, Singapore

Grb2 (Growth Factor Receptor bound protein-2) is an adaptor protein which is known to interact with tyrosine phosphorylated- Epidermal Growth Factor Receptor (EGFR) through its SH2 domain and N-WASP through its SH3 domain. N-WASP belongs to the Wiskott Aldrich Syndrome Protein (WASP) family which regulates actin cytoskeleton remodeling through activation of Arp2/3 complex. Reorganization of actin cytoskeleton is critical for various processes such as muscle differentiation, endocytosis, cancer cell migration and invasion, etc. N-WASP has been shown to be required for the process of muscle differentiation, which involves step wise fusion of mono-nucleated myoblasts to form multi-nucleated myotubes. However the role of Grb2 in myogenesis has not been elucidated. In order to study the role of Grb2 in myogenesis we generated a Grb2 knocked down C2C12 cell line (Mouse myoblast) and found that knocking down Grb2 enhanced myogenic differentiation even though the expression of Grb2 was found to be relatively unchanged during myogenic differentiation. This suggests that Grb2 might have an inhibitory role in myogenic differentiation. We are currently generating Grb2 overexpressing C2C12 cells to characterize the inhibitory role of Grb2 in myogenesis. Identifying the role of Grb2 in muscle differentiation will give us a better understanding about the role of N-WASP-Grb2 complex in repair and ageing.

USP7 inhibitors for the treatment of malignancies.

M. Kodrasov¹, M. Eddins¹, S. Agarwal¹, J.G. Marblestone¹, J. Wu¹, J. LaRocque¹, Z. Butt¹, M.R. Mattern¹, J. Weinstock¹, S. Kumar¹;

¹RandD, Progenra Inc., Malvern, PA

Ubiquitylation and deubiquitylation control the stability, localization and activity of many cellular proteins. Deubiquitylation is performed by a family of ~80 enzymes (DUBs) including USP7, which removes ubiquitin selectively from HDM2, Foxp3, claspin and various other therapeutically relevant substrates. Importantly, USP7 is overexpressed in prostate cancer and human multiple myelomas and the expression level of USP7 is inversely correlated with prognosis in multiple myeloma patients. Previously, we reported the discovery and characterization of P0005091 a USP7 inhibitor which exhibited anti-tumor activity in in vitro and in vivo models of multiple myeloma. Additionally, we

reported that P0005091 inhibits USP47, a closely related DUB that is an emerging oncology target in its own right. Furthermore, a structural analog of P0005091, P0022077 has recently been reported by another research group to inhibit neuroblastoma growth in an orthotopic mouse model, suggesting that in addition to hematological tumors, solid tumors may be treatable via inhibition of USP7. To obtain additional starting points for a USP7 or a USP7/USP47 selective drug discovery program we recently conducted a new screening campaign. By utilizing a biophysical assay platform we were able to exclude compounds that bind to the active site of USP7, thereby increasing the possibility of identifying allosteric modifiers of USP7 activity. Hits from this screen are currently the subject of hit to lead optimization and will be evaluated in biophysical and biochemical assays as well as in vitro and in vivo models of hematological and solid tumors. Data will be presented describing these results.

Dexamethasone And Azathioprine Promote Cytoskeleton Changes And Affect MSCs Migratory Behavior.

N. Schneider¹, F. Gonçalves¹, F.O. Pinto^{2,3}, P.L. Lopez⁴, A. Araujo⁵, M. Lamers⁶, A.D. Paz^{2,3};

¹Graduate Program in Gastroenterology and Hepatology Sciences, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil, ²Morphological Sciences, Universidade Federal Do Rio Grande Do Sul, Porto Alegre- RS, Brazil, ³Experimental Pathology Unity, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil, ⁴Experimental Research Center, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil, ⁵Umbilical Cord Blood Bank, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil, ⁶Morphological Sciences, Universidade Federal Do Rio Grande Do Sul, Porto Alegre- RS, PA

Glucocorticoids and immunosuppressive drugs are commonly used to treat inflammatory disorders, such as Inflammatory Bowel Disease (IBD) and, despite few improvements, the remission of IBD is still difficult to maintain. Due to its immunomodulation properties, Mesenchymal Stem Cells (MSCs) have emerged as regulators of immune response, and its viability and activation of migratory properties are essential for successful cell therapy. However, little is known about the effects of immunosuppressant drugs used on IBD treatment on MSCs behavior. The aim of this study was to evaluate MSC viability, nuclear morphometry, cell polarity, F-actin distribution and cell migration properties in the presence of the immunosuppressive drugs Azathioprine (AZA) or Dexamethasone (DEX). After initial characterization, MSCs were treated with DEX (10 μ M) or AZA (1 μ M) for 24 hrs or 7 days. Both drugs had no effects on cell viability or nuclear morphometry. However, AZA treatment induced a more elongated cell shape and increased the presence of ventral actin stress fibers, while DEX was associated to a more rounded cell shape with high presence of ventral actin stress fibers and a decrease on protrusion stability. After 7 days of treatment, AZA improved cell the spatial trajectory (ST) and increased migration speed (24.35%, $P < 0.05$, $n = 4$) while DEX impaired ST and migration speed after 24 hrs and 7 days treatment (-28.69% and -25.37%, respectively; $P < 0.05$, $n = 4$). In conclusion our data suggests these immunosuppressive drugs can differently affect MSCs morphology and migration capacity, possibly impacting the success of cell therapy.

14-3-3 β , but not 14-3-3 γ , Supports Nuclear Transport of Synaptopodin 2 (Myopodin).

M. Abootorabi Ardestani¹, N.F. Linde¹, S. Papadopoulos¹, G. Pfitzer¹, M. Schroeter¹;

¹Institute of Vegetative Physiology, Cologne, Germany

Multiple actin binding proteins shuttle between the nucleus, the cytoplasm, or the membrane, depending on environmental and cell differentiation parameters. Synaptopodin 2 (SYNPO2 in the sequel) is one of these proteins. Via expression of ECFP or EYFP tagged proteins, as well as with a fluorescence complementation assay (BIFC), we were able to confirm the validity of earlier in vitro observations within the intact cellular environment. Rat synaptopodin 2 (syn. myopodin), importin α , and 14-3-3 β/γ , were cloned into conventional pECFP and pEYFP vectors, as well as into complementary split-EYFP vectors. In HEK293 cells transfected with the conventional vectors, confocal microscopy localized EYFP-SYNPO2 to the cytoplasm and to the nucleus, with accumulation in the nucleoli. Importin α and 14-3-3 β were also found in the nucleus, however, this was not the case for 14-3-3 γ . The BIFC-assay revealed that SYNPO 2 formed cytoplasmically located dimers and also interacted with importin α and 14-3-3 β/γ . In the nucleus, we did not observe SYNPO 2 dimers or an interaction of SYNPO 2 with 14-3-3 γ . However, SYNPO 2 formed stable intra-nuclear complexes with importin α and 14-3-3 β , which participated in loop-formation and had the appearance of actin-loops. While in vitro studies and our cellular BIFC-assays demonstrated that 14-3-3 β supports nuclear translocation of SYNPO 2, we did neither detect 14-3-3 γ -SYNPO 2 complexes in the nucleus nor did we find intra-nuclear 14-3-3 γ complexes. This is surprising since 14-3-3 γ , at least in smooth muscle cells, is abundant and we expected that it may substitute there for the less abundant 14-3-3 β . Thus, while SYNPO 2 is able to interact with both isoforms of 14-3-3 β and γ , in the cytosol, only the β -isoform appears to trigger nuclear translocation of SYNPO 2.

P898**Board Number: B217****Comparison Of Incorporation of Wild Type And Mutated Actins Into Sarcomeres in Skeletal Muscle Cells: A Fluorescence Recovery After Photobleaching (FRAP) study.**J. Wang¹, Y. Wang¹, J.M. Sanger¹, J.W. Sanger¹;¹Cell and Developmental Biology, SUNY Upstate Med Univ, Syracuse, NY

Our long-term goals are to understand how the highly ordered arrangements of myofibrils form and how this complex of interacting proteins is maintained over a lifetime of contractile activity. Failure to achieve optimal assembly and function can be caused by many factors, among the most serious of which are mutations in myofibrillar proteins that cause severe myopathies. Analyzing such mutated proteins in live muscle cells undergoing myofibrillogenesis should yield insights into the molecular effects of these mutated proteins. The actin mutation, G15R, is located in the nucleotide-binding pocket and causes a severe actin myopathy in human skeletal muscle cells. When expressed in cultured skeletal muscle cells, G15R is incorporated into the sarcomeres in a pattern initially indistinguishable from wild type actin. However, patches of mutant actin resembling patches found in patient biopsies subsequently form. FRAP analysis of incorporation of mutant actin localized in myotubes shows major differences from incorporation of wild type sarcomeric actin when the data are plotted not as average FRAP recovery, but as a function of the fast-growing ends of the actin filament in the Z-band, versus the slow growing ends of the thin filaments in the middle of the sarcomeres. In cultured skeletal muscle, wild type actin shows a markedly faster rate of incorporation at the plus (+) ends of actin filaments than at the minus (-) ends of the filaments. By comparison with wild type actin, the incorporation of mutated actin-G15R molecules is reduced at the plus (+) ends and increased at the minus (-) ends. The same relationship of incorporation is seen in cytochalasin-D inhibited myofibrils: decreased dynamics at the plus (+) ends and increased dynamics at minus (-) ends of actin filaments. We speculate that the imbalance of the normal polarized assembly of actin filaments creates excess monomers that form actin patches. Our results indicate that normal actin plus (+) end dynamics are needed to maintain actin thin filament stability in the myofibrils.

P899**Board Number: B218****Biochemical and Biological Properties of Dictyostelium Cortexillin III and Its Complex(es) with DGAP1.**S. Shu¹, X. Liu², S. Yu², D. . Lee³, G. Wang², M. Gucek², E.D. Korn²;¹NHLBI, National Institutes of Health, Bethesda, MD, ²NHLBI, NIH, Bethesda, MD, ³NIH/NHLBI, Bethesda, MD

Cortexillins I, II and III are members of the α -actinin/spectrin sub-family of Dictyostelium calponin homology proteins. We report the biochemical properties of recombinant cortexillin III, the complexes formed by FLAG- and GFP-tagged cortexillin III expressed in Dictyostelium, and the properties of cortexillin III-null cells. Purified recombinant cortexillin III is an unstable monomer, unlike recombinant cortexillins I and II which form stable homodimers in vitro. However, cortexillin III forms more stable heterodimers when co-expressed in E. coli with either cortexillin I or cortexillin II, and co-expressed cortexillin I and cortexillin II also form stable heterodimers. All of the recombinant homodimers and heterodimers bind weakly to F-actin and none affects actin polymerization in vitro. As determined by both co-immunoprecipitation, and by affinity chromatography and gel filtration, cortexillin III expressed in Dictyostelium heterodimerizes with both cortexillin I and II. The heterodimers form one or more complexes with DGAP1, a Dictyostelium GAP protein. Like cortexillins I and II, GFP-cortexillin III expressed in wild-type Dictyostelium localizes with F-actin in the cortex of vegetative cells, the leading edge of motile cells, and the cleavage furrow of dividing cells. However, although expressed cortexillin III localizes with F-actin in both cortexillin I and cortexillin II single-null cells, cortexillin III is diffuse in the cytoplasm when expressed in cortexillin I/ II double-null cells and also when expressed in DGAP1-null cells. We conclude from these data that cortexillin III localizes with F-actin in vivo only as a heterodimer with either cortexillin I or cortexillin II complexed to DGAP1-complex. As neither homodimers nor heterodimers of recombinant cortexillin I and cortexillin II bind with high affinity to F-actin in vitro, we speculate that localization of cortexillin I and cortexillin II with F-actin in vivo may occur only when complexed to DGAP1 or GAPA (a Dictyostelium GAP protein to which cortexillins I and II, but not cortexillin III, also bind).

Deletion of cortexillin III affects chemotaxis and development. Although individual cortexillin III-null cells chemotax normally in a cAMP gradient they form unstable streams, and starved cortexillin III-null cells form much smaller mounds and fruiting bodies than wild-type cells. Also, cortexillin III-DGPA1 complexes may be negative regulator of pinocytosis, phagocytosis, cytokinesis and cell growth as all are enhanced in cortexillin III-null cells.

P900**Board Number: B219****MARVELD1 Alters Malignant Phenotype of Lung Cancer Cell via Modulating Cell Adhesion Signaling.**Y. Yao¹;¹School of Life Science and Technology, Harbin Institute of Technology, Harbin, China

MARVELD1 (MARVEL domain-containing 1) is a member of MARVEL (MAL and related proteins for vesicle trafficking and membrane link) family. Recently, we reported MARVELD1 inhibited cell migration and regulated cell adhesion in epithelial cells. However, how MARVELD1 functions in lung tumorigenesis is still not understood. We now demonstrate that low MARVELD1 expressing lung cancer cells have significant defects in cell spreading as well as increased cell metastasis. The MARVELD1-mediated Integrin β signaling activated downstream adhesion molecules FAK, Talin and Paxillin, and suppressed matrix metalloproteinases MMP2 and MMP3. In addition, we also found MARVELD1-mediated Integrin signaling regulated filopodial length and density of lung cancer cells. The numerous filopodia that induced by MARVELD1 expression may be a prerequisite for the cells to form adherens junctions. Scanning electron microscope (SEM) analysis further determined that MARVELD1 expression reduced the aggressive character of lung cancer cells. Collectively, our data showed MARVELD1-mediated Integrin signaling alters the malignant phenotype of lung cancer cells, suggesting MARVELD1 has a potential to be developed as a therapeutic target for lung carcinoma.

P901**Board Number: B220****Arp2/3 Complex Inhibition Radically Alters Lamellipodial Actin Architecture, Suspended Cell Shape, and the Cell Spreading Process.**J.H. Henson¹, H. Geist², M. Pais²;¹Dickinson Coll, Carlisle, PA, ²Dickinson College, Carlisle, PA

Recent studies have investigated the dendritic actin cytoskeleton of the cell edge's lamellipodial (LP) region by experimentally decreasing the activity of the actin filament nucleator and branch former the Arp2/3 complex. Here we extend these studies via pharmacological inhibition of the Arp2/3 complex in sea urchin coelomocytes, cells that possess an usually broad LP region and display correspondingly exaggerated centripetal flow. Using light and electron microscopy, we demonstrate that Arp2/3 complex inhibition via the drug CK666 dramatically altered LP actin architecture, slowed centripetal flow, drove a lamellipodial to filopodial shape change in suspended cells, and induced a novel actin structural organization during cell spreading. A general feature of the CK666 phenotype in coelomocytes was transverse actin arcs and arc generation was arrested by a formin inhibitor. We also demonstrate that CK666 treatment produces actin arcs in other cells with broad LP regions, namely fish keratocytes and *Drosophila* S2 cells. We hypothesize that the actin arcs made visible by Arp2/3 complex inhibition in

coelomocytes represent an integral feature of the LP cytoskeleton and may correspond to the elongate mother filaments that serve as the scaffold for the production of the dendritic actin network.

14-3-3 controls cell cortical tension in human cells.

Q. Zhou¹;

¹Missouri State University, Springfield, MO

The cell cortex is mainly composed with a thin meshwork of actin filaments, myosin and associated proteins that lie beneath the plasma membrane. The tension is created by the active myosin motors when they slide actin filaments with respect to one another in the network. The tension is regulated by the myosin motor activity and the stiffness of actin network which is regulated by other associated proteins. At cellular level, the tension of cell cortex is tightly regulated spatially and temporally during cell shape change of any cellular process, such as cytokinesis and directional migration. At tissue level, the cell cortical tension may also underlie part of the tissue surface tension, which is one of the most direct biomarker for physicians to differentiate tumor tissue from normal surrounding tissues. In our previous study, we found that 14-3-3 regulates cell cortical tension in *Dictyostelium* cells, where 14-3-3 down-regulation leads to decrease of cortical tension and cytokinesis failure. In this study, we investigated 14-3-3's role in cortical tension regulation in mammalian cells. Our preliminary data indicates that when 14-3-3 sigma is knocked down by siRNA in Hela S3 cells, cell cortex becomes much softer when comparing with control cells. In the near future, cell transwell migration assay will be used to study how 14-3-3 may impact cell migration capability and survival rate of cells growing with shear stress will be assessed when 14-3-3 is down-regulated as well. We hypothesize that down-regulation of 14-3-3 leads to decrease of cell cortical tension, which may increase the migration capability and yet reduce the survival rate when cells are stressed with shear stress. Our study may suggest 14-3-3's complicated roles in cancer cell metastasis.

Regulation of Actin Dynamics 2

The formin INF2 is a focal adhesion protein that promotes dorsal stress fiber and fibrillar adhesion formation to drive extracellular matrix assembly.

C.T. Skau¹, S.V. Plotnikov^{1,2}, C. Waterman¹;

¹National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD, ²Cell and Systems Biology, University of Toronto, Toronto, ON

The dynamic connection between actin and focal adhesions (FA) is essential for driving cell migration and tissue morphogenesis. Actin and FA frequently behave as an integrated system, and exhibit remarkable plasticity in form, with actin establishing dendritic meshworks and contractile and non-contractile bundles, and FA maturing from tiny nascent adhesions, to focal complexes, mature FA, and fibrillar FA. Some actin/FA systems are well understood, for example, Arp2/3 mediating the formation of a lamellipodium containing nascent FA that is required for cell guidance by haptotaxis. However, motile cells display a number of other actin-based structures, such as contractile arcs and dorsal stress fibers in the lamella, TAN lines over the nucleus, and ventral stress fibers under the cell body, yet the mechanism of their formation and how they interface with FA to specify function is not known. The formin family of actin nucleators is thought to be critical for formation of many linear actin structures, including dorsal SF at FA, however none of these family members have been found to localize to FA. We previously identified the formin INF2 in a proteomic screen of FA proteins, and thus sought to analyze its role in FA and SF in mouse embryonic fibroblasts. We found that INF2 localized to FA in the lamella at their junction with SF, as well as to protruding lamellipodia. siRNA to decrease INF2 protein levels revealed that INF2 KD cells lacked stress fibers in their lamellae and possessed wider lamellipodia. Furthermore, actin filament barbed end localization and photobleach marking of remnant SF in INF2 KD cells showed that INF2 promotes actin polymerization from free barbed ends at FA to form stress fibers. We then determined the role of INF2 in FA functions. Analysis of INF2 and paxillin dynamics showed that INF2 is recruited to FA during elongation, suggesting that it may be required for FA maturation and function. Depletion of INF2 showed that in contrast to growth and elongation of FA in control cells, FA in INF2 KD cells maintained an immature size and shape, yet still contained markers of mature FA including vinculin, zyxin, and tensin. This indicates that INF2 is required for morphological but not compositional maturation of FA. Indeed, although cells lacking INF2 showed only minor defects in migration and traction force generation, they were unable to remodel or generate a dense ECM, indicating that fibrillogenesis requires morphological but not compositional maturation. Collectively, our results show that INF2 is critical to specifying the function of a distinct stress fiber/FA cohort, and reveal the critical role of stress fibers in the maturation of FA to mediate ECM remodeling.

P904**Board Number: B223****Microtubule end-binding protein CLIP170 and formin mDia1 interact to form a barbed end-tracking complex that accelerates actin polymerization.**J.L. Henty-Ridilla¹, A. Rankova², J.A. Eskin², B.L. Goode²;¹Brandeis University, Waltham, MA, ²Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

Strict coordination of actin and microtubule (MT) dynamics is critical for many cellular processes, including directed cell migration, axon guidance, and cell and tissue morphogenesis. However, the mechanistic basis of actin-MT crosstalk is still not well understood. We identified sequences in CLIP-170 (cytoplasmic linker protein 170) homologous to formin-interacting motifs found in yeast Smy1, which led us to investigate CLIP-170 effects on formin-mediated actin assembly. Purified full-length CLIP-170 increased the rate of mDia1-dependent actin polymerization by 3.5-fold (from ~55 to 180 subunits s⁻¹ μM⁻¹) specifically in the presence of profilin. However, CLIP-170 had no effects on actin dynamics in the absence of mDia1, and failed to regulate the activities of formins Bni1 and Bnr1. Similar activities on mDia1 were observed for all three alternatively spliced isoforms of CLIP-170, suggesting that this formin-regulating function may be universal for CLIP-170. Using multi-wavelength single molecule TIRF microscopy, we observed SNAP-547-mDia1 molecules persisting on the growing ends of actin filaments during CLIP-170-accelerated polymerization. SNAP-649-CLIP-170 molecules transiently associated with mDia1-capped filaments, and correlated with enhanced rates of elongation. CLIP-170 also increased the ability of mDia1 to protect actin filament ends from capping protein. Together, these results suggest that CLIP-170 and mDia1 interact to form barbed-end tracking complexes that support extremely rapid polymerization (0.5 μm s⁻¹ μM⁻¹ profilin-actin) and protect growing actin filament ends from being capped. We are now investigating the effects of microtubule and EB1 binding on CLIP-170-mDia1 activities, and testing whether CLIP-170 coordinates MT and actin polymer dynamics *in vivo*.

P905**Board Number: B224****V-1/Myotrophin Regulates Capping Protein Activity in Vivo.**G. Jung¹, C.J. Alexander*², B. Chen³, E. Betzig³, J.A. Hammer⁴;¹NIH/NHLBI, Bethesda, MD, ²NHLBI, NIH, Bethesda, MD, ³HHMI/Janelia Farm Research Campus, Ashburn, VA, ⁴LCB, NIH/NHLBI, Bethesda, MD

Mammalian myotrophin/V-1 is a ~13 kDa, ankyrin-repeat protein that binds Capping Protein (CP) *in vitro* with an affinity of ~20 nM, creating a 1:1 complex that has no affinity for the barbed end. V-1 has the potential, therefore, to influence actin polymerization *in vivo* by reducing the extent of barbed end capping. *Dictyostelium discoideum* (*D.d.*) contains a single gene encoding a 13 kDa protein with high sequence similarity to mouse V-1. Like mouse V-1, *Dd* V-1 binds CP, is present in cells at a ~four-fold molar excess over CP, and no longer binds CP when a function-blocking point mutation (FBM) is

introduced into the first ankyrin loop (FBM *Dd V-1*). Consistent with V-1's ability to sequester CP, over-expression of *Dd V-1* results in an elevation in total cellular F-actin content that scales positively with the degree of over-expression. Importantly, over-expression of FBM *Dd V-1* does not alter cellular F-actin levels, arguing that the effect of V-1 over-expression is due to its ability to sequester CP. The over-expression of *Dd V-1*, but not FBM-*Dd V-1*, also induces the formation of actin-rich, filopodial-like structures that scales positively with the degree of over-expression. In contrast to over-expression, *Dd V-1* null cells created by homologous recombination exhibit a large decrease in cellular F-actin content. Moreover, these cells exhibit significant decreases in growth rate, macropinocytosis rate, random motility rate, polarity during migration, and chemotactic streaming efficiency. Importantly, these defects are rescued by wild type V-1 but not by FBM *Dd V-1*. Together, these results argue that V-1 plays a major role in regulating actin assembly in cells. Moreover, the fact that FBM V-1 neither induces over expression phenotypes nor rescues null cell phenotypes argues that V-1 exerts its effects on the actin cytoskeleton by buffering cellular CP. We conclude, therefore, that reductions and elevations in cellular CP activity caused by the over-expression and knock out of V-1, respectively, result in changes in cellular actin content that are consistent with CP's barbed end capping activity. Moreover, the functional consequences of these changes, which involve alterations in numerous cellular activities that depend on actin assembly, indicate that V-1 is physiologically important.

Board Number: B225

A Mechanism for Accelerated Actin Filament End-Shortening and Direct Visualization of Rapid Treadmilling.

A. Johnston¹, A. Collins², B.L. Goode¹;

¹Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA, ²Brandeis University, Waltham, MA

A fundamental property of cytoskeletal networks is their ability to be dynamically assembled and disassembled. While microtubules are inherently unstable polymers and abruptly transition to states of rapid depolymerization, actin filaments are inherently stable and undergo relatively slow depolymerization that must be enhanced *in vivo* by other factors. One mechanism for accelerating actin filament turnover is severing by cofilin, but the slow dissociation of subunits from severed filament ends remains rate-limiting. Here, we describe a complementary mechanism, mediated by Twinfilin, which accelerates loss of polymer mass specifically from filament ends. Twinfilin alone causes 3-fold faster shortening at barbed ends of filaments, and working in concert with Srv2/CAP causes 26-fold faster shortening at pointed ends. This end-shortening activity is conserved in evolutionarily distant yeast and mouse homologs of Twinfilin and Srv2/CAP, and specifically acts on 'aged' ADP-F-actin. Single molecule analysis reveals that Twinfilin processively associates with the shortening barbed ends, and also associates with filament sides. Ultrastructural analysis shows that Twinfilin induces major changes in actin filament structure. Finally, accelerated shortening at pointed ends continues even under assembly

conditions, concurrent with barbed end growth, allowing direct visualization of rapid actin filament treadmilling.

Modification of VASP architecture reveals a fundamental difference between actin-filament elongation in solution or when clustered on a surface.

S. Bruehmann¹, D. Ushakov¹, U. Curth¹, R.B. Dickinson², J. Faix¹;

¹Hannover Med School, Hannover, Germany, ²Chemical Engineering, University of Florida, Gainesville, FL

The only proteins known so far that directly enhance filament elongation by interaction with the growing barbed end and recruitment of monomeric actin for polymerization are formins and Ena/VASP proteins. However, despite the relevance of Ena/VASP proteins for many actin-based processes, we in fact still know rather little about their molecular mode of action as compared to formins. Based on previous analyses of chimeras from fast and slow elongating VASP proteins by in vitro TIRF microscopy, kinetic and thermodynamic measurements we showed that the rate of VASP-mediated filament elongation depends primarily on the G-actin recruitment motif (GAB). Based on these experiments we were able to formulate a testable mathematic model of Ena/VASP-mediated actin-filament elongation. It suggests that at steady state one polypeptide chain of the VASP tetramer is bound to the filament terminal subunit by its GAB, leaving a number (N) of free GABs to capture actin monomers from solution for subsequent filament incorporation. Global fitting of the experimental data yielded N=3, suggesting that a single VASP tetramer operates at a growing filament tip. However, previous work revealed that single VASP tetramers are rather poorly processive, as opposed to surface-clustered VASP which allows long lasting and robust filament elongation even in the presence of high concentrations of capping protein. Since the number of free GABs (N) was obtained by fitting, we began experimentally testing the model by manipulation of VASP oligomerization by deleting or replacing the tetramerization motif of the fast elongating hVASP chimera with the oligomerization motifs of different proteins yielding synthetic VASP monomers, dimers, trimers and hexamers. Analyses of these VASP oligomerization mutants in solution showed that the number of free GABs (N) directly correlated with the elongation rate, and is in excellent agreement with model predictions. Interestingly, when clustered in high density on beads, the elongation rate of the same mutants was highly similar suggesting that surface tethered elongation operates at a fixed rate. These findings further indicate that the elongation rate on a surface may be limited to a defined number of contributing GABs, which in turn could be contributed by different VASP molecules and operate together around a central actin filament.

P908**Board Number: B227****Capping Protein Function in Cells requires an interaction with a CPI –motif protein.**M. Edwards¹, P. McConnell², D.A. Schafer³, J.A. Cooper²;¹Cell Biology, Washington University School of Medicine, St. Louis, MO, ²Department of Cell Biology and Physiology, Washington University School of Medicine, Saint Louis, MO, ³University of Virginia, Charlottesville, VA

Capping protein, CP, a ubiquitous heterodimeric actin binding protein, plays an essential role in actin assembly in vivo and in vitro. CP binds the barbed end of actin filaments with high affinity, blocking the addition and loss of actin subunits. Previous models for CP function in cells assumed that CP is constitutively active, diffusing freely to find and cap barbed ends. However, the discovery of CP-binding proteins with CPI (Capping Protein Interacting) motifs raises the possibility that, in order to function properly in cells, CP might need to be targeted to specific cellular locations or have its capping activity decreased.

CPI motifs are found in a diverse group of proteins with the consensus sequence LXHXTXXRPKX₆P. CPI-motif proteins bind CP and decrease but do not abolish its affinity for barbed ends of filaments. They promote the dissociation of bound CP from the barbed end of actin filaments.

Here we tested the activity in cells of a mutant form of CP that cannot bind to the CPI motif. This CP mutant binds and caps barbed ends as well as wild type CP does. However, the mutant displays little to no function in cells; it failed to rescue loss-of-function phenotypes in CP-depleted cells. Overexpression of the CP mutant had a dominant negative effect in cells, phenocopying the depletion of CP from cells. In addition, the CP mutant failed to localize properly in cells.

Our results indicate that, in cells, CP does not function unless it can bind to a CPI-motif protein. The reason that this interaction is essential may be because CP must be targeted to a location and / or that the capping activity of CP must be decreased. Regardless, these findings will require a major change in models for actin assembly in cells.

P909**Board Number: B228****Identification of kinases that phosphorylate Xenopus Slingshot phosphatase during oocyte maturation.**S. Iwase¹, S. Ono², H. Abe¹;¹Nanobiology, Chiba University, Chiba, Japan, ²Pathology, Emory University, Atlanta, GA

We have previously demonstrated that Xenopus Slingshot phosphatase (XSSH), an activator for Xenopus ADF/cofilin, is hyperphosphorylated just after GVBD. This phosphorylation is accompanied by

dephosphorylation of XAC that has been mostly phosphorylated in immature oocytes. This XAC dephosphorylation after GVBD is completely suppressed by latrunculin B, an actin monomer-sequestering drug. On the other hand, jasplakinolide, an F-actin-stabilizing drug, induces dephosphorylation of XAC. Effects of latrunculin B and jasplakinolide are reconstituted in cytostatic factor-arrested extracts (CSF-extracts), and the XAC dephosphorylation is abolished by depletion of XSSH from CSF-extracts, suggesting that XSSH functions as an actin filament sensor to facilitate actin filament dynamics via XAC activation. In this study, in order to clarify the precise role of XSSH phosphorylation, we first explored the kinases that phosphorylate its tail domain during oocyte maturation and found that XSSH is phosphorylated at multiple sites within the tail domain by different kinases during oocyte maturation. The tail domain was divided into two regions, designated as GST-N-tail and GST-C-tail, and each were assayed for mobility shift with CSF-extracts. Although both regions were phosphorylated to represent striking mobility shifts, we found that GST-N-tail was more sensitive to phosphorylation using serially diluted CSF-extracts. This mobility shift of GST-N-tail was mostly suppressed in interphase-extracts but recovered by addition of α N85-cyclin B to the interphase extracts, indicating that the phosphorylation of GST-N-tail occurs specifically at both meiotic and mitotic phases. By a combination of kinase inhibitors, biochemically isolated kinases and site-directed mutagenesis, we conclude that MPF, p90RSK and p38MAPK, which are reported to be deeply involved in oocyte maturation, directly phosphorylate the tail domain, and identified their phosphorylation sites in the N-tail region.

Board Number: B229

Dynamic regulation of actin filaments by ADF/cofilin is required for the assembly of microtubule-organizing center and meiotic spindles in *Xenopus laevis* oocytes.

Y. Yamagishi¹, H. Abe¹;

¹Nanobiology, Chiba University, Chiba, Japan

Oocyte maturation is defined by resumption of meiosis to release oocytes from arrest in meiotic prophase I. This process starts with the breakdown of the nuclear envelope of the germinal vesicle, a giant nucleus specifically formed in oocytes, (i.e., germinal vesicle breakdown (GVBD) or nuclear envelope breakdown). In *Xenopus* oocytes, a disc-shaped organelle called the microtubule-organizing center and transient microtubule array (MTOC-TMA) assembles at GVBD to capture chromosomes and transport them to the animal cortex. Thereafter, the MTOC-TMA disappears and chromosomes are aligned on the spindle microtubules. We previously demonstrated that phosphorylation of *Xenopus* Slingshot (XSSH), a *Xenopus* ADF/cofilin (XAC)-specific phosphatase, at multiple sites within the tail domain occurs immediately after GVBD and is accompanied by dephosphorylation of XAC that has been mostly phosphorylated in immature oocytes. Injection of the anti-XSSH antibody, which blocks full phosphorylation of XSSH after GVBD, inhibits both meiotic spindle formation and XAC dephosphorylation. Co-injection of the constitutively active XAC with the antibody suppresses this phenotype. Treatment of oocytes with jasplakinolide also impairs spindle formation. These results strongly suggest that elevation of actin dynamics by XAC activation through XSSH phosphorylation is

required for the meiotic spindle assembly in *Xenopus laevis*. However, the precise role of XAC on cellular actin organization that regulates microtubule structures has still remained unclear. In this study, we show that the orderly formation of microtubule structures requires dynamic reorganization of cytoplasmic and intranuclear actin filaments by XAC regulated through XSSH. Surrounding the germinal vesicle (GV) in immature oocytes, cytoplasmic actin filaments reorganized to accumulate beneath the vegetal side of GV, where MTOC-TMA assembled, just before GV breakdown (GVBD). Immediately after GVBD, MTOC-TMA developed well and intranuclear actin filaments began to disassemble from the vegetal to animal side. Suppression of XAC dephosphorylation by anti-XSSH antibody injection inhibited these actin filament dynamics. Interestingly, antibody-injected oocytes lacked proper formation and localization of MTOC-TMA and meiotic spindles. We further confirmed that while both XAC and XSSH are diffusely distributed throughout the cytoplasm, only XAC is exclusively absent from the base region of MTOC-TMA where cytoplasmic actin filaments have already assembled. As constitutively active S3A-cofilin-injection could disrupt cytoplasmic actin filaments and MTOC-TMA, the cytoplasmic actin filaments associated once with MTOC could be protected from XAC under regulation. Taken together, XAC appears to reorganize cytoplasmic actin filaments required for precise assembly of MTOC and to regulate intranuclear actin filament dynamics essential for the formation of meiotic spindles.

The development of a chiral pattern of actomyosin was revealed by studying the self-organization of the actin cytoskeleton in human fibroblasts confined to cell-sized circular adhesive islands. We identified several distinct stages of actin cytoskeleton evolution, starting with the formation of a radially symmetrical system of actin bundles. Myosin-II-deficient alpha-actinin-enriched radial fibers grew centripetally from peripheral focal adhesions, while myosin-IIA-enriched transverse fibers moved centripetally along radial fibers. Formin inhibitor blocked the formation of radial fibers while myosin II inhibitor suppressed formation of both radial and transverse fibers. This radial pattern evolved spontaneously into the chiral pattern as a result of the synchronous and unidirectional tilting of all radial fibers. Subsequently transverse fiber movement acquires a tangential component. We propose a novel mechanism of myosin IIA-driven retrograde flow where contractile stresses within transverse fibers drive their movement along radial fibers. Computational modeling demonstrated that this mechanism can explain the pattern transition from radial to chiral. Remarkably, the chiral pattern is characterized by

a defined handedness. This directionality could be reversed by overexpressing full-length alpha-actinin-1. Expression of a truncated alpha-actinin-1 construct lacking actin binding domain abolished formation of radial fibers, but resulted in the formation of a new type of long actin fibers containing myosin IIA and anchored at focal adhesions. These actin fibers also tilt unidirectionally, preserving the handedness of the direction of tilt similarly to the radial fibers in control cells. Expression of an alpha-actinin fragment containing the integrin-binding site also perturbed the development of radial fibers. Depletion of alpha-actinin-1 via siRNAs resulted in phenotypes analogous to those observed in cells expressing these dominant-negative alpha-actinin-1 constructs. Taken together, these results suggest that while the crosslinking function of alpha-actinin-1 is not essential for the initiation of the chiral asymmetry of the actin cytoskeleton, it is essential for the alteration of the chirality seen in alpha-actinin-1 overexpressing cells. We hypothesize that the handedness of the chiral pattern depends on the intrinsic helical symmetry of actin filaments, which is transformed (with the aid of formin and alpha-actinin-1) into a unidirectional torque that triggers the transition of unstable radial system to chiral rotation. Thus, self-organization of the actin cytoskeleton can provide built-in machinery that potentially allows cells to distinguish between left and right.

Traffic Jam regulates actin protrusions of migrating border cells through PKC δ in the *Drosophila* ovary.

F. Gunawan¹, M. Lu¹, D. Godt^{1,2};

¹Department of Cell and Systems Biology, University of Toronto, Toronto, ON, ²University of Toronto, Toronto, ON

The migrating border cell cluster (BCC) in the *Drosophila* ovary is a simple, genetically-tractable system to study cell migration in vivo. The BCC, which contains 6-8 migratory cells, invades the germline cyst and migrates toward the oocyte during mid-oogenesis. To generate the force needed to push the cluster forward, extension of actin-based cellular protrusions by the leading cell is crucial. Not surprisingly, a number of actin-regulating factors have been shown to be necessary for proper BCC motility. Our previous work identified the *Drosophila* large Maf transcription factor Traffic Jam (Tj) as an important regulator of BCC migration. We recently discovered that Tj acts as a negative regulator of actin protrusions in the BCC. Increased Tj expression leads to a significant decrease in the number of prominent protrusions extended by the BCC, which in turn causes a severe delay of BCC migration. In contrast, reduced Tj expression causes cells within the BCC to extend extra protrusions in multiple directions. To find downstream targets of Tj that regulate the actin cytoskeleton, we conducted a microarray screen using RNA from isolated border cells with normal, reduced, and increased Tj activity. *Drosophila* Protein Kinase C δ (PKC δ), a serine/threonine kinase, was identified as a putative activation target of Tj in this screen. Similar to Tj, altering PKC δ expression leads to abnormal actin organization: PKC δ loss-of-function causes an increased number of radially-arranged protrusions, whereas PKC δ gain-of-function leads to a decreased number of prominent actin protrusions. Analysis of the epistatic

relationship between Tj and PKC δ indicates that PKC δ is an important downstream factor through which Tj exerts its effects on actin. We further identified a putative target of PKC δ activity, the actin-polymerizing factor Enabled (Ena)/VASP, which is known to be important for BCC migration. Ena is normally localized cortically along the periphery of the cluster, and enriched in the leading protrusion. Tj or PKC δ reduction leads to mis-localization of Ena to the cytoplasm and failure of Ena to be enriched in the protrusions. Overexpression of Tj or PKC δ seems to cause stronger and more punctate cortical localization of Ena. Based on our data, we propose a new pathway needed to regulate actin dynamics in the BCC: the transcription factor Tj directly or indirectly upregulates the expression of the kinase PKC δ , which is needed for proper formation of actin protrusions, a function that might be mediated through proper localization of the actin-regulating factor Ena.

Chapel Hill, NC, ³Department of Epidemiology, University of Iowa College of Public Health, Iowa City, IA,

⁴Department of Genetics, University of North Carolina, Chapel Hill, NC

Actin remodeling must be tightly regulated during both development and adult tissue homeostasis. While prostaglandins (PGs), lipid signals produced downstream of cyclooxygenase (COX) enzymes, are known to regulate actin dynamics in cultured cells and platelets, their roles during development remain largely unknown. Previously, we identified the *Drosophila* COX-like enzyme, Pxt, and found that loss of Pxt causes numerous actin remodeling defects during late-stage oogenesis. Here, we define a new role for PG signaling during oogenesis—temporal restriction of actin remodeling. Loss of Pxt results in the early onset of actin remodeling, causing the formation of extensive actin filaments and aggregates in the posterior nurse cells of stage 9 (S9) follicles. Wild-type follicles exhibit similar structures at a low frequency. We performed a screen to identify actin-binding proteins that localize to early actin structures in *pxt* mutant, but not wild-type, S9 follicles in order to identify the factor(s) responsible for promoting early actin remodeling in the absence of PG signaling. Using this approach, we found that Enabled (Ena), an actin elongation factor, preferentially localizes to early actin structures in *pxt* mutants, suggesting that PG signaling is required to restrict Ena localization/activity during S9. Consistent with this model, we find that reduced levels of *ena* are sufficient to strongly suppress early actin remodeling in *pxt* mutants. Additionally, a parallel pharmaco-genetic interaction screen revealed that heterozygous loss of either *ena* or its functional antagonist *capping protein*, strongly sensitizes follicles to the effects of COX inhibition during S10B. Consistent with these results, we find that Ena localization to the barbed ends of actin bundles during S10B is reduced in *pxt* mutants. Together, these data lead us to propose a model in which PG signaling temporally regulates actin remodeling during *Drosophila* oogenesis, in part,

by differentially controlling Ena localization/activity, such that PG signaling inhibits Ena-dependent actin remodeling during S9, while promoting it during S10B. As PG-dependent regulation of Ena's mammalian homologs (Mena, EVL, and VASP) is poorly understood, *Drosophila* oogenesis provides an ideal system to elucidate the conserved mechanisms by which PG signaling regulates this family of proteins to temporally control actin remodeling.

Abiotic fungal biofilms of *C. albicans* secrete factors that remodel the actin cytoskeleton in keratinocytes and fibroblasts.

T.U. Woellert¹, G.M. Langford¹;

¹Biology, Syracuse University, Syracuse, NY

Candida albicans is an opportunistic fungal pathogen that causes candidiasis in humans. Many infections caused by *C. albicans* are a direct consequence of its ability to form biofilms. The intracellular signaling pathways that are triggered in human epithelial cells by the adhesion of *C. albicans* and by secreted virulence factors released by biofilms are poorly understood. In a previous study, we showed that the virulence factors, secreted aspartyl proteases (Saps), produced by *C. albicans* target the actin cytoskeleton and its associated proteins in keratinocytes. In this study, a new *in vitro* assay was developed to determine the virulence of medically relevant *C. albicans* biofilms and evaluate changes of the actin cytoskeleton in human keratinocytes and mouse fibroblasts in the presence of these biofilms. Abiotic fungal biofilms were created by addition of yeast cells obtained from overnight *C. albicans* cultures to cell culture dishes followed by incubation in keratinocyte serum free medium for 3 hours. We used OKF6/TERT-2 cells, an immortalized cell line of human oral keratinocytes and 3T3 fibroblasts co-cultured with hyphae-forming wild-type *C. albicans* (SC5314) and *efg1D/efg1D* and *sap4-6D/sap4-6D* mutants. The actin remodeling was determined at 0.5, 1, 2 and 3 hours by high-resolution fluorescence microscopy and quantitative image analysis. OKF6/TERT-2 cells and 3T3 fibroblasts exposed to biofilms formed by wild-type *C. albicans* showed a dynamic remodeling of the actin cytoskeleton compared to untreated cultures. Coculture of OKF6/TERT-2 cells with *C. albicans* stimulated the formation of lamellipodia at 1 hour followed by the accumulation of actin retraction fibers at the cell edges between 2 and 3 hours. In addition, an increase in the formation of cell-cell adhesions was observed after 1 hour and newly formed cell-cell adhesions began to disintegrate after 3 hours. Coculture of 3T3 fibroblasts with *C. albicans* resulted in the formation of actin retraction fibers and in the decrease of focal adhesions. 80-90% of all cells exhibited this behavior. Interestingly, we did not detect internalized hyphae with OKF6/TERT-2 cells during coculture with *C. albicans*. The latter observation suggests that changes in the actin cytoskeleton and its associated proteins are primarily caused by secreted virulence factors by *C. albicans*. *C. albicans* mutants *sap4-6D/sap4-6D* and *efg1D/efg1D* with diminished virulence and reduced abilities to form biofilms were found to elicit attenuated changes in keratinocyte and fibroblasts responses compared to those that were cocultured with wild-type *C. albicans*. The induction of actin remodeling in keratinocytes by pathogenic *C. albicans* may constitute an important first step in

the invasion mechanism and these observations could lead to improvements in the prevention and treatment of biofilm-based infections.

Reciprocal regulation of actin remodelling and cell migration by Calcium and Zinc: role of H₂O₂ and TRPM2 channels.

F. Li¹, p.T. Manna², A. Sivaprasadarao³;

¹School of Biomedical Sciences, Faculty of biological sciences, University of Leeds, Leeds, United Kingdom, ²Infectious diseases, University of Cambridge, Cambridge, United Kingdom, ³Multidisciplinary Cardiovascular Research Centre, School of Biomedical Sciences, University of Leeds, Leeds, United Kingdom

H₂O₂ is a signalling molecule thought to play a role in cell migration by remodelling actin cytoskeleton. However, the mechanisms remain unclear. Here, we investigated the role of the H₂O₂-sensitive transient receptor potential-melastatin 2 (TRPM2) cation channel in cell migration using the HeLa and PC-3 cell lines. Dynamics of actin cytoskeleton and focal adhesions that regulate cell migration were monitored using confocal microscopy. Actin was stained with Alexa⁴⁸⁸-phalloidin, and focal adhesions with anti-paxillin antibodies. Cell migration was monitored using the agarose spot assay, where the agarose spot contained test substances. Exposure of cells to H₂O₂ caused filopodia-like protrusions, loss of stress fibres and disassembly of focal adhesions. Consistent with these changes, H₂O₂ promoted cell migration. Inhibition of TRPM2 channels with pharmacological agents and small interference RNA targeted to TRPM2 channels prevented all cellular changes induced by H₂O₂. H₂O₂ activation of TRPM2 channels increased the cytosolic levels of both Ca²⁺ and Zn²⁺. To distinguish the role of individual ions, we raised the intracellular levels of Ca²⁺ and Zn²⁺ using ionophores, A23187 and pyrithione respectively. The results showed remarkable differences in how Ca²⁺ and Zn²⁺ affect the cytoskeleton and cell migration: Zn²⁺ promoted filopodia-like protrusions, loss of stress fibres, disassembly of focal adhesions and cell migration, while Ca²⁺ displayed the complete opposite effects. Thus, our findings demonstrate a novel role for TRPM2 channels in cell migration where Zn²⁺ and Ca²⁺ affect the actin cytoskeleton and focal adhesions in a reciprocal fashion.

P917**Board Number: B236****Wave-like actin dynamics for contact guidance.**W. Losert¹, C. Guven², S. Das², X. Sun³, A. Carlsson⁴, J. Fourkas³;¹Dept of Physics, University of Maryland, College Park, MD, ²Dept of Physics and Institute for Physical Science and Technology, University of Maryland, College Park, MD, ³Dept of Chemistry and Biochemistry, University of Maryland, College Park, MD, ⁴Physics, Washington University School of Medicine, St Louis, MO

How do cells sense and follow the texture of their surrounding environment in the natural world? In rapidly moving cells, *Dictyostelium* and neutrophils, we discovered that cells utilize actin waves to sense and follow surface nanotopography. The wave-like character of the sensing allows cells to follow topographical features on the 100s of nm scale, larger than proteins or macromolecular clusters that are involved in other sensing tasks.

Specifically, cells use actin polymerization waves that propagate isotropically in eukaryotic cells when migrating on flat surfaces. We find that exposing cells to nanofabricated ridges hundreds of nm wide breaks the symmetry of actin waves and results in guided polymerization. We present quantitative measurements of the speed and orientation of actin waves generated in *Dictyostelium discoideum* cells and neutrophils in contact with such nanoscale ridges for a broad range of conditions. We find that spatially periodic, ~300-nm wide nanoridges spaced ~1.5 microns apart, slightly larger than typical actin wave sizes, lead to the best contact guidance of the migrating cells. Through measurements of the distribution of actin-wave speeds and directions relative to the nanoridges we show that actin polymerization is preferentially localized to nanoridges over a range of spatial periodicities, and that the speed of actin polymerization waves is increased along the nanoridges.

A stochastic growth model of actin polymerization dynamics reproduces these key observations, if nanoridges are modeled as locally increasing the concentration of nucleation promoting factors. We use this model together with experiments to demonstrate that the propagation speed of actin waves due to the underlying nanotopography decreases when the concentration of actin monomers decreases. We show that the effect of nanoridges on actin polymerization can be modeled as a local positive feedback on the actin polymerization machinery.

Our proposed actin based dynamic contact guidance mechanism utilizes ubiquitous cytoskeletal machinery and may thus be operational in a broad range of cell types and natural contexts. Part of this work appeared in *ACS Nano* **8**, 3546, (2014).

P918**Board Number: B237****A quantitative, FRET-based method for observing changes in non-muscle myosin II phosphorylation in living cells.**M.L. Markwardt¹, M.A. Rizzo¹;¹Physiology, University of Maryland School of Medicine, Baltimore, MD

Phosphorylation of the non-muscle myosin II regulatory light chain (RLC) enables association of myosin fibers with the actin cytoskeleton and filament contraction. Tight spatial and temporal regulation of RLC phosphorylation is thus necessary to generate vectorial force during cell migration. Here we report a method for observing, and quantifying, phosphorylation-induced changes in myosin II conformation in living cells using fluorescent protein-tagged RLC. In the absence of phosphorylation, we observe fluorescence resonance energy transfer (FRET) between tagged-RLCs using fluorescence polarization microscopy. Homotransfer decreases upon stimulation of RLC phosphorylation by plating cells on fibronectin. Similar changes in homotransfer are observed by mutating RLC phosphorylation sites to aspartate, and inhibited by mutation of these same sites to alanines. Further, low-FRET (phosphorylated) cellular regions co-localize with phospho-RLC antibody staining. These results are consistent with FRET-based reporting of phosphorylation-induced RLC conformational changes. Dynamic changes were observed in response to myosin-light chain kinase activation, via application of KCl in cells co-expressing mCherry-RLC and an optimized MLCK reporter containing mCerulean3. Addition of nitric oxide to stimulate myosin phosphatase increased myosin-RLC FRET, consistent with promotion of RLC dephosphorylation. Further, we observed changes in RLC FRET consistent with phosphorylation on the leading edge of spreading membranes, and FRET changes consistent with RLC dephosphorylation prior to retraction of cellular structures. These studies demonstrate the utility of a single color FRET-based approach for resolving spatio-temporal changes in non-muscle myosin II phosphorylation states in living cells.

P919**Board Number: B238****TRPM4 channels are required for biomechanical remodeling during wound healing.**L. Ortiz¹, T. Recabarren^{1,2}, A. Colombo², E. Leiva-Salcedo¹, A. Romero¹, J. Rivas¹, I. Silva¹, G. Flores¹, A. Álvarez¹, M. Cáceres¹, O. Cerda¹;¹Programa de Biología Celular y Molecular, Facultad de Medicina, Universidad de Chile, Santiago, Chile,²Programa de Anatomía y Biología del Desarrollo, Facultad de Medicina, Universidad de Chile, Santiago, Chile

Cellular migration and contractility are fundamental processes in wound healing that are regulated by a variety of concerted mechanisms such as cytoskeleton rearrangements, focal adhesion turnover, protein

kinase/phosphatase activities, and Ca^{2+} oscillations. TRPM4 is a Ca^{2+} -activated non-selective cationic channel (Ca^{2+} -NSCC) that conducts monovalent cations and localizes at focal adhesion complexes. Here, we show that suppression of TRPM4 in MEFs impacts turnover of focal adhesions, serum-induced Ca^{2+} influx, focal adhesion kinase (FAK) activity, and results in reduced cellular spreading, migration and contractile behavior *via* regulation of FAK and Rac GTPase activities. Finally, we demonstrate that TRPM4 activity regulates cellular contractility and migration *in vivo*, impacting morphogenetic movements during development and wound closure in zebrafish, and regulating the re-epithelialization and granulation tissue formation during cutaneous wound healing in mice. Together, these findings provide the first evidence for a TRP channel specifically localized to focal adhesions, where it performs a central role in modulating cellular migration, contractility and biomechanical remodeling during development and wound healing.

Actin depolymerisation and crosslinking join forces with myosin II to drive secretion via compression of fused secretory vesicles.

P. Miklavc¹, K. Ehinger¹, A. Sultan¹, W. Close¹, T. Felder¹, P. Paul², K.E. Gottschalk², M. Frick¹;

¹Inst. of Gen. Physiology, University of Ulm, Ulm, Germany, ²Inst. of Experimental Physics, University of Ulm, Ulm, Germany

In recent years it has become evident that actin-based forces are required for secretion of poorly soluble vesicle contents. It is now well established that actin and myosin are specifically recruited to the surface of exocytic vesicles following fusion with the plasma membrane and promote active extrusion of cargo. Yet, little is known about the molecular mechanisms that regulate actin coat formation and drive coat contraction on fused granules. We have recently demonstrated that actomyosin dependent compression of fused lamellar bodies (LBs) is essential to drive secretion of pulmonary surfactant. Here we provide a detailed kinetic analysis of the molecules regulating actin coat contraction on fused LBs. We demonstrate that Rock1 and myosin light chain kinase (MLCK) translocate to fused LBs and activate myosin II on actin coats. Yet, myosin II activity is not sufficient for efficient actin coat contraction. In addition, Rock1 regulates cofilin-1 activity. Regulated actin depolymerisation by cofilin-1 and actin crosslinking via α -actinin is essential for full contraction of the actin coat. In summary, our data support a model in which actin depolymerisation and crosslinking join forces with myosin II to contract actin coats around fused secretory vesicles to drive secretion.

14-3-3 proteins tune non-muscle myosin II assembly, providing a possible bridge between cell mechanics and cancer metastasis.

H. West-Foyle¹, J. Osborne¹, D. Robinson^{1,2};

¹Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine, Baltimore, MD

The 14-3-3 family comprises a group of small acidic regulatory proteins which are essential, ubiquitous, and highly conserved across eukaryotic species. These proteins have roles in numerous core cellular processes such as DNA damage repair, cell cycle control, apoptosis prevention, and certain signaling pathways. Generally 14-3-3s act as tumor suppressors and consequently, are down-regulated in many cancers. By contrast, overexpression of 14-3-3s sigma, epsilon, zeta, and eta correlate with a higher metastatic potential and poorer clinical outcomes in breast, liver, and pancreatic cancers. The literature has no unified theory on how 14-3-3 proteins that are normally tumor suppressors become oncogenes. However, we have uncovered a role for 14-3-3s in regulating the assembly of non-muscle myosin II. This demonstrates that 14-3-3s could tune cell mechanics directly, and therefore, contribute to the progression of metastatic cancers. Here, we examine the entire landscape of myosin II assembly regulation by 14-3-3 in *Dictyostelium* (one 14-3-3, one non-muscle myosin II) and humans (seven 14-3-3s and three non-muscle myosin IIs). In *Dictyostelium*, 14-3-3 mediates a pathway between microtubules and racE small GTPase to regulate myosin II assembly, and 14-3-3's expression levels negatively correlate with BTF accumulation. *In vitro* assembly assays using purified myosin II tail fragments and 14-3-3 demonstrate that this interaction is direct and phosphorylation-independent. We then extended our analysis to the seven human 14-3-3 paralogs and the three non-muscle myosin IIs. We found that the seven human paralogs of 14-3-3 affect the assembly of myosin II filaments in different ways, broadly clustering into those that cause myosin II overassembly and those that cause its solubilization. Assemblers and solubilizers can directly compete to govern the overall level of myosin II assembly. Examining assembled myosin II filaments by EM confirms that the average filament size correlates with the overall assembly level. Furthermore, we mapped three critical residues which differ between the two classes and discovered that mutating any of these residues converts an assembler to a solubilizer. Our findings demonstrate a novel phosphorylation-independent method for regulating myosin II assembly that is mechanistically conserved from amoebas to humans. These findings imply that altered 14-3-3 expression profiles could directly modulate cell mechanics in metastatic cancers, which would be of great interest for basic and clinical sciences alike.

P922**Board Number: B242****Counting molecules in non-muscle myosin II filaments.**X. Wan¹, C. Patino Descovich¹, D.A. Applewhite¹, S. Rogers¹, P.S. Maddox¹, A.S. Maddox¹;¹Department of Biology, University of North Carolina, Chapel Hill, NC

Non-muscle (NM) myosin II is involved in many important cellular processes, including migration, adhesion and cytokinesis. Like its muscle counterpart, NM myosin II assembles into bipolar filaments; this multimerization is thought to be essential for acto-myosin contractility. The classical sliding filament hypothesis for cytokinesis states that NM myosin II acts in cytokinesis by sliding actin. However, recent studies implicate its actin crosslinking role as being more important for cytokinesis. Since each head in a myosin filament can bind F-actin, the number of heads per filament will affect the balance among its bundling, crosslinking and sliding activities, as well as the load-dependent feedback on these activities. Electron microscopy studies of interphase cells from different species have shown NM myosin II filaments contain 16-30 heads, but the size of filaments has never been determined in cytokinesis.

We first studied the number of NM-myosin II in meiotic and mitotic *C. elegans* zygotes. GFP was tagged at the tail of NM myosin heavy chain, so that the fluorescence from the tags on all myosin molecules in a filament contributed to a single diffraction-limited focus. Myosin was imaged by TIRF microscopy until the fluorescence signal was completely bleached. We developed a novel, yet very simple approach to measure the number of bleaching events in the fluorescence decay curves from cells with different level of GFP expression. We found that the total number of myosin molecules in a single filament is 100 – 150. As an independent assessment of myosin filament size, we also measured filament length in cultured *Drosophila* cells using super-resolution microscopy. We measured the distance between diffraction-limited foci containing GFP-tagged regulatory light chain (RLC) at the two ends of myosin filaments, with nm accuracy. On average, myosin filaments are approximately 380 nm long. This method also allowed us to determine the orientation and size of the RLC myosin head foci. Interestingly, increased myosin filament length correlated with more parallel filament head foci. We will combine these measurement techniques with genetic perturbations to understand how NM myosin II filament assembly is controlled and how interaction with actin influences myosin filament structure.

P923**Board Number: B243****Fission yeast UCS protein Rng3p provides surveillance of myosin-II motor function during cytokinesis.**L.W. Pollard¹, B.C. Stark¹, V. Sirotkin², M.J. Lord¹;¹Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, ²Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

UCS (Unc-45-/Cro1p-/She4p-related) proteins are known to participate in the folding and maturation of myosin-II motors. Fission yeast myosin-II (Myo2p) and UCS protein Rng3p are essential for actomyosin ring formation and cytokinesis. Previous studies suggested that Rng3p is a chaperone for Myo2p given that Rng3p function is critical for the isolation of active Myo2p from fission yeast. Here we employed a combination of in vivo and in vitro studies to understand how Rng3p regulates Myo2p and actomyosin ring function during cytokinesis. Rng3p localizes transiently to both pre-assembled and assembled rings where it contributes to ring assembly, constriction, and Myo2p turnover at the ring. Elevation of Myo2p expression levels influences Rng3p localization and suppresses cytokinesis defects associated with loss of Rng3p function, indicating that Myo2p is the key substrate for Rng3p. We engineered a Myo2p-Rng3p fusion to enforce constitutive association of Rng3p with its substrate in vivo. While the fusion supports growth, it led to obvious morphological defects in cytokinesis characterized by significantly reduced rates of ring assembly, constriction, and disassembly. Current in vitro mechanistic studies are centered on understanding the potential role of Rng3p in destabilization of aged Myo2p motors. Collectively our studies point to a critical role for Rng3p in Myo2p motor homeostasis in the cell.

P924**Board Number: B244****Motor activity is required for stacking of non-muscle myosin II filaments.**A.M. Fenix¹, J. Lewis¹, D.T. Burnette¹;¹Cell and Developmental Biology, Vanderbilt University School of Medicine, Nashville, TN

The molecular motor, myosin II, is best known for driving muscle contraction. Myosin II is a hexamer comprised of 2 heavy chains, 2 regulatory light chains, and 2 essential light chains. The two heavy chains create a C-terminal coiled-coil domain forming a rod on one end of the molecule and two N-terminal motor domains on the other end. Myosin II molecules form bipolar contractile-competent filaments by binding each other through their rod domains. In skeletal muscle, myosin II filaments are organized into regularly spaced stacks within sarcomeres. This organization facilitates efficient muscle contraction. However, how stacks of myosin II filaments develop is not well understood. We have recently used structured illumination microscopy (SIM) to resolve individual motor domains of non-muscle myosin IIA filaments in live U2OS cells to reveal that filament stacks result from the expansion of a single filament. Here we use this system as a model to test if the motor activity of myosin II is required for filament stack formation. Previous studies have reported that treatment with relatively high doses (e.g., 50 μ m) of the

myosin II ATPase inhibitor, blebbistatin, dramatically reduces the number of myosin II filaments in both U2OS and other cell types. We sought to find a concentration of blebbistatin that reduced stack height but kept the number of filaments relatively the same. After allowing U2OS cells to spread for 2 hours on Laminin, we treated cells for 1 hour with different concentrations of blebbistatin and then labeled endogenous myosin IIA filaments by immuno-fluorescence. We found that cells treated with 1 μ m and 10 μ m concentrations of blebbistatin had similar number of myosin II filaments as controls cells. However, there was a marked reduction in stack height after treatment. Specifically, there was a 49.3 +/- 13.7% and 34.8 +/-14.1% reduction in the number of stacked myosin II filaments in 10 μ m and 1 μ m blebbistatin treated cells, respectively. Our results suggest that the expansion of a myosin II filament into a stack is more sensitive to changes in motor activity than the initial filament formation.

EGF stimulation of MDA-MB-231 breast cancer cells results in the transient phosphorylation of S1943 on the nonmuscle myosin-IIA heavy chain (NMHC-IIA), which enhances myosin-IIA filament disassembly and promotes cell migration in vitro. Using reverse phase protein arrays (RPPAs) and a phosphospecific antibody against S1943, we have extended these observations to show that EGF-stimulated NMHC-IIA S1943 phosphorylation occurs in multiple breast cancer cell lines. In addition, immunohistochemical studies indicate that S1943 phosphorylation is detected at the invasive edge of human breast tumors. To test the role of NMHC-IIA in tumor metastasis, we produced MDA-MB-231 breast cancer cells expressing wild-type, phosphomimetic (S1943E) and non-phosphorylatable (S1943A) mutants. Expression of the S1943E NMHC-IIA markedly increased metastasis in an experimental metastasis assay. Cell biological studies demonstrated that NMHC-IIA S1943 phosphomimetics (S1943 D/E) enhance myosin-IIA filament turnover in vivo and inhibit EGF receptor internalization. In addition, EGF-stimulated S1943 phosphorylation is blocked by inhibitors of Class IA PI 3-kinases as well as inhibitors of casein kinase 2. Altogether, these data suggest that EGF-mediated phosphorylation of NMHC-IIA is linked to invasive behavior and tumor metastasis, and suggest that NMHC-IIA S9143 phosphorylation might serve as a diagnostic marker for metastatic tumors.

P926**Board Number: B246****Conditional Deletion of Nonmuscle Myosin II-A Leads to Squamous Cell Carcinoma of the Tongue.**M. Conti¹, A. Saleh², S. Cornelius², C. Van Waes², R.S. Adelstein¹;¹Laboratory of Molecular Cardiology, Genetics and Developmental Biology Center, NHLBI/NIH, Bethesda, MD, ²Clinical Genomics Unit and Tumor Biology Section, Head and Neck Surgery Branch, NIDCD/NIH, Bethesda, MD

In an effort to investigate the contribution of nonmuscle myosin II-A (NMII-A) to early cardiac development we crossed Myh9 floxed mice and Nkx2.5 cre recombinase mice. Nkx2.5 is expressed in the early heart and later in the tongue epithelium and in a mosaic pattern in the stomach, and spleen. Mice homozygous for deletion of NM II-A (A^{Nkx}/A^{Nkx}) were born at the expected ratio but were 50% smaller than control littermates probably due to insufficient nutrition. Although the hearts developed normally, the conditionally deleted mice developed invasive squamous cell carcinoma (SCC) of the tongue as early as embryonic day 17.5. In general the mice survived for 2-3 months at which time they were sacrificed for humane reasons due to a failure to thrive. In some cases the SCC progressed slowly and the mice survived for up to 2 years of age. In order to assess the reproducibility of these results a second, independent line of Aflox mice was derived from the original, targeted embryonic stem cells. The homozygous floxed mice expressing cre in this second line were also smaller than control littermates and also developed a SCC that was indistinguishable from that of the original cell line and showed a similar timing of tumor formation and lethality. The same phenotype was observed in mice in which one allele was null for II-A and the other allele conditionally ablated by Nkx 2.5 cre expression. In an effort to rescue the phenotype by expression of a second NMHC, mice were generated in which one allele of NMHC II-A was replaced by NMHC II-B under control of the NMHC II-A promoter, but these mice also developed tumors of the tongue. Schramek et al. (Science. 2014, 343, 309-13) have reported that RNAi mediated deletion of NMII-A leads to SCC of the skin in a tumor susceptible background by a mechanism involving p53 stabilization. In our A^{Nkx}/A^{Nkx} mouse tongue epithelium, genetic deletion of NMII-A does not affect the stabilization of p53 in the nucleus after gamma irradiation of mice. Additionally, an in vitro FRET based assay of p53 activation and binding to p21 target sequences in human UMSCC-1 and UMSCC-74A cell lines indicates that siRNA-mediated deletion of II-A itself induces p53 activation. This activation is further enhanced in the presence of DNA damaging agents that induce a p53 response.

P927**Board Number: B247****Non-muscle myosin IIB is critical for nuclear translocation during 3D invasion.**D.G. Thomas¹, T.T. Egelhoff¹, J. Lammerding², C.M. Denais³;¹Cellular and Molecular Medicine, Cleveland Clinic Lerner Research Institute, Cleveland, OH,²Department of Biomedical Engineering, Cornell University, Ithaca, NY, ³Weill Institute, Cornell University, Ithaca, NY

Tumor metastasis is a complex process that involves the migration of a tumor cell from the primary tumor to a secondary site, involving the formation of leading edge protrusions and the translocation of a bulky nucleus through restrictive spaces. A major component to cellular migration is the motor protein, non-muscle myosin II (NMII). NMII is expressed in all cell types to regulate cellular structure and cytoskeletal dynamics during migration. There are three isoforms of the heavy chain (IIA, IIB and IIC), encoded by three separate genes. Treatment of the murine epithelial cell line, NMuMG, with TGF β 1 induces an increased invasive behavior as well as a dramatic up-regulation of NMIIB at both mRNA transcript and protein levels. This observation led us to investigate NMIIB's role in invasion of tumor cells through a three-dimensional collagen matrix. We used a collagen invasion assay to enhance migration through a collagen gel. In this assay, knockdown of either NMIIA or NMIIB via shRNA caused a dramatic reduction in invasion compared to control, in both the human breast carcinoma cell line MDA-MB 231 and the murine mammary tumor line 4T1. We then analyzed NMIIB's role in nuclear translocation through restrictive spaces. MDA-MB 231 cells were analyzed in three-dimensional chemotaxis chambers that contain 5 micron constriction points. Knockdown of NMIIB but not NMIIA resulted in an increase in the nuclear transit time through constriction points. These data suggest a role for NMIIB in squeezing the nucleus through resistive openings. Rescue of NMIIB expression in the NMIIB shRNA background with a GFP-NMIIB fusion construct restored collagen invasion and normal nuclear translocation rates. Furthermore, perinuclear stress fibers of GFP-NMIIB were visible as the nucleus passed through the 5 micron constrictions. We then tested if NMIIB is essential for the development of traction forces required to constrict the nucleus. During spreading on polyacrylamide gel coated with 50 μ g/ml fibronectin, knockdown of NMIIA but not NMIIB ablates traction force generation during the first hour of spreading. To control for active migration and protrusions, fibronectin was patterned in 30 μ m² grids on polyacrylamide and traction forces were measured after 1 and 16 hours. NMIIB shRNA had modest effect on traction force at one hour compared to control, but dramatically reduced traction force at 16 hours. The converse was true for NMIIA shRNA, where traction force was greatly diminished at 1 hour, but normal at 16 hours. These data suggest that NMIIA is involved in generating traction force during early stage active spreading and protrusion formation, while NMIIB is involved in generation of long-term traction stress in a static condition to maintain cell morphology.

P928**Board Number: B248****Tuning myosin driven sorting on cellular actin networks.**R.F. Hariadi¹, R. Sommese¹, S. Sivaramakrishnan¹;¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

Unconventional myosin function in cellular processes emerges from the interaction of multiple myosins on an organelle scaffold with the complex actin cytoskeleton. Currently, the role of myosins in membrane sorting has been extensively studied in reconstituted systems, but these have focused almost exclusively on understanding single actin-myosin interactions. To bridge the gap between single molecule and cellular function, we pair DNA origami scaffolds, containing a defined number of antagonistic myosins, with a model cellular actin network. Scaffolds with antagonistic myosins (V and VI) exhibit unidirectional motion, unlike the bi-directional movement previously reported for groups of kinesin and dynein. For scaffolds with equal numbers of myosin V and VI, minus and plus-end directed movement is equally favored. This two-dimensional flux is significantly lower than that of single filament, emphasizing the importance of actin architecture on myosin behavior. In ensembles with asymmetric motor composition, the net flux of trajectories can be finely tuned by the relative number of myosin V and myosin VI. Thus, modulating the relative number of motor engagement sites represents an elegant sorting mechanism in cells. Finally, the net flux is dependent on the structural properties of the myosin lever arm. Our study demonstrates a novel regulatory function for the myosin lever arm beyond its canonical function as a structural amplifier in the chemomechanical cycle.

P929**Board Number: B249****Mechanical Coordination of Motor Ensembles Revealed Using Engineered Artificial Myosin Filaments.**R.F. Hariadi¹, R. Sommese¹, S. Sivaramakrishnan¹;¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

Force production and contraction in muscle are driven by interactions between actin and myosin filaments. While the individual actin-myosin cross-bridge has been extensively characterized, coordination within myosin ensembles remains poorly understood. Here, we engineer an artificial myosin filament using a polymerizable DNA nanotube scaffold that provides control over motor number and spacing. For both myosin V and myosin VI filaments, neither myosin density nor total myosin number has an effect on the gliding speed. We propose a simple model wherein myosin ensembles function as an energy reservoir that buffers individual stochastic events to provide smooth continuous motion. We find that the compliance of individual cross-bridges has been tuned to enhance mechanical coupling between motors, while minimizing Brownian effects.

P930**Board Number: B250****Dynamic actin filaments are capable of fine-tuning myosin processivity in a filament age-dependent manner.**D. Zimmermann¹, A. Janik², D.R. Kovar^{1,2}, R.S. Rock²;¹Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, ²Biochemistry and Molecular Biology, University of Chicago, Chicago, IL

Unlike a static and immobile skeleton, the actin cytoskeleton is a highly dynamic network of filamentous actin (F-actin) polymers that continuously turn over. In addition to generating mechanical forces and sensing mechanical deformation, dynamic F-actin networks are utilized as cellular “tracks” along which specialized processively moving myosin motors transport molecular cargoes such as organelles and RNA. Unfortunately, the vast knowledge about how processive myosins function derives almost exclusively from *in vitro* studies where myosin motility was studied on pre-assembled and artificially stabilized *static* F-actin tracks. In this study we addressed the role of actin dynamics in myosin motility using a novel *in vitro* assay by which myosins traveling *dynamic* assembling F-actin can be studied over time at the single molecule level. For this, we chose the two well-characterized and highly processive motors myosin V and VI, which are heavily involved in various transport processes. We found that on dynamic F-actin the barbed end-directed motor myosin V is 1.5-fold more processive (i.e., increased runlength), whereas its pointed end-directed counterpart myosin VI is turned less processive (1.7-fold) compared to the motility behavior on static F-actin. Furthermore, our data indicate differences in myosin processivity along the length of an aging actin filament. While myosin V is more likely to take longer runs on ADP/P_i-rich (young) portions of the growing filament, myosin VI travels longer distances along ADP-rich (old) F-actin, suggesting a fine-tuning mechanism by which myosins sense the nucleotide-state of the track they are walking on. Taken together, these experiments indicate that processive myosins may gain quite different transport properties solely depending on whether a myosin travels ADP/P_i or ADP F-actin, adding a novel mechanism of how myosin traffic may sort on different F-actin networks.

P931**Board Number: B251****The mechanosensory proteome of the mammalian actin cytoskeleton.**E.S. Schiffrhauer¹, T. Luo², X. Qian², K. Mohan³, P. Iglesias³, D. Robinson^{1,4};¹Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ³Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD, ⁴Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine, Baltimore, MD

Cells have a remarkable ability to sense and respond to their mechanical environment; this ability directs a host of cellular and global processes, such as metastasis, engulfment, blood vessel constriction, and tissue development. However, the direct mechanism by which the components of the cortical

cytoskeleton assemble and interact to exert force on the membrane in response to mechanical perturbations remains unclear. The cytoskeleton is comprised of a dynamic network of actin filaments, myosin motors, and actin crosslinking proteins which generate a tunable feedback system for controlling the resting cortical tension of a cell, as well as its viscoelastic response to an added load. Here, we define the in vivo kinetics of 20 cytoskeletal and signaling proteins in response an applied external stress and identify a number of structural elements that accumulate to regions of the cell under shear or dilational forces. Prominent among the responsive proteins of the mammalian cytoskeleton are the three non-muscle myosin II paralogs, the actin bundling protein α -actinin 4, and the orthogonal actin crosslinking protein filamin B. All three myosin paralogs, as well as α -actinin 4, accumulate to the tip region of the aspirated cell, which experiences primarily dilational force. Filamin B, however, accumulates to the tip and the neck region, demonstrating that it responds to both sheared and dilated microenvironments. These differences in response can be directly related to the actin binding characteristics and distinct mechanism of force response for each protein. Interestingly, a mutation in α -actinin 4 at lysine 255, known to be the cause of the human kidney disorder Focal Segmental Glomerulosclerosis (FSGS), displays a characteristic disorganization in the actin cytoskeleton. In the proposed wild-type model, lysine 255 participates in a salt bridge that allows for a change in protein confirmation under load and a subsequent increase in the protein's actin binding affinity. This model predicts that destruction of this bridge would lead to tighter baseline binding to the actin network and, therefore, to lower turnover. Indeed, we observe much slower accumulation kinetics to the site of stress in the FSGS-associated α -actinin 4 mutant K255E. The accumulation of cytoskeletal motors and crosslinking proteins under mechanical load represents a mechanism by which cells can concentrate structural components to reduce strain or retract from a local environment of high stress. Understanding how cortical protein dynamics intrinsically give rise to the self-tuning nature of the cell will not only offer insight into the mechanisms underlying major human diseases, but also the basic nature of mechanically-dependent cell processes.

An unconventional myosin mediates crosstalk between the actin and microtubule cytoskeletons.

S. Wu¹, M. Bezanilla¹;

¹Univ Massachusetts-Amherst, Amherst, MA

Plant cells divide using the phragmoplast, a microtubule-based structure that directs vesicles secretion to the nascent cell plate. The phragmoplast forms at the cell center and expands to reach a specified site at the cell periphery, tens or hundreds of microns distant. The mechanism responsible for guiding the phragmoplast remains largely unknown. Here, using both moss and tobacco, we show that myosin VIII associates with the ends of phragmoplast microtubules and together with actin guides phragmoplast expansion to the cortical division site. Our data lead to a model whereby myosin VIII links phragmoplast

microtubules to the cortical division site via actin filaments. Myosin VIII's motor activity along actin provides a molecular mechanism for steering phragmoplast expansion.

AMPK-related protein kinase UNC-82/ARK5/SNARK/NUAK associates with myosin and regulates myosin organization in *Caenorhabditis elegans* striated muscle.

N.R. Schiller¹, E. Manzon¹, C.D. Duchesneau¹, P.E. Hoppe²;

¹Biology, Western Michigan University, Wyoming, MI, ²Western Michigan University, Kalamazoo, MI

In *Caenorhabditis elegans* striated muscle, the UNC-82 serine/threonine kinase is required for maintaining the organization of myosin filaments and internal components of the M-line during development. The pathology of *unc-82(0)* mutants is consistent with a failure to adapt myosin filament placement in response to embryonic cell shape change (Hoppe et al., 2010). The mechanism of UNC-82 kinase activation, the signal that promotes activation and the identities of UNC-82 targets have not been established. Antibody staining of *unc-82* mutant alleles revealed that ectopic accumulations of paramyosin occur in a kinase domain missense mutant, but not in the presumptive null. An UNC-82::GFP fusion containing the missense mutation in the kinase domain (*e1220*) shows wild-type localization in an N2 background, but localization to ectopic structures that contain paramyosin in the *unc-82* null background, suggesting paramyosin may be a substrate. The hypothesis that the kinase-impaired UNC-82 protein drives formation of these distinctive paramyosin accumulations is supported by the observation that similar paramyosin structures present in *unc-98* mutants do not form in the *unc-82*; *unc-98* double mutant. We tested for physical interaction between UNC-82 and other M-line or thick-filament proteins by using strains in which myosin, paramyosin or UNC-82 is ectopically localized within muscle cells, and determining which proteins are recruited to the ectopic structures. Our results suggest that UNC-82 physically interacts, either directly or indirectly, with one or more of these three proteins: myosin, paramyosin, and UNC-98, which is a potential chaperone required for the incorporation of paramyosin into thick filaments (Miller et al., 2008). UNC-82::GFP localized to ectopic myosin accumulations, which result from mutation of potential phosphorylation sites in the myosin nonhelical tail piece, and do not contain detectable paramyosin. Antibody staining of double mutant embryos expressing truncated myosin and homozygous for *unc-82(0)* revealed an increase in ectopic accumulations of myosin. These data suggest that UNC-82 physically associates with myosin and regulates myosin localization in a manner that does not require the myosin tailpiece. Further evidence of the role of UNC-82 in regulating myosin filament localization is further demonstrated in double mutants with the M-line kinase UNC-89/obscurin, which exhibit novel elongated myosin structures outside of the contractile apparatus. Our data are consistent with the model that misregulation of the incorporation of myosin and paramyosin into filaments is the underlying defect in *unc-82* mutants.

P934**Board Number: B254****Hat1, a lysine acetyltransferase, affects cytoplasmic mRNA storage granules.**A. Kindsfather¹, N. Rothbard¹, S. Robins¹, A. Hilliker¹;¹Biology, Univ Richmond, University of Richmond, VA

mRNAs are constantly shifting between translation and translation repression or degradation. Repressed mRNAs can accumulate with proteins in cytoplasmic foci, such as processing (P) bodies and stress granules. Ded1 is a DEAD-box RNA helicase that is essential in yeast and conserved from yeast to humans. The human homolog to Ded1, DDX3, is misregulated in several cancers and is used by both hepatitis C and HIV to promote viral life cycles.

Our previous results suggest a two-step model through which Ded1 returns repressed mRNAs to translation. First, Ded1 transitions repressed mRNAs, such as those that accumulate in P-bodies, into a pre-48S initiation complex that can accumulate in stress granules. Second, Ded1 hydrolyzes ATP and allows the mRNA to continue into translation. We hypothesize that Ded1 first recruits translation initiation factors to an mRNA and then acts as an ATP-dependent switch to allow that mRNA to recruit the ribosome. Consistent with this model, Ded1 directly binds translation initiation factors eIF4E and eIF4G. Presumably, both steps of Ded1 function are regulated to control translation of mRNAs.

In the search for regulators of Ded1, we conducted a genetic screen in order to identify factors from the yeast genome that, when overexpressed, would suppress the severe growth defect caused by *DED1* overexpression. This screen identified the histone acetyltransferase *HAT1*. We used this genetic assay to screen other lysine acetyltransferases and deacetylases for genetic interactions with *DED1*.

Hat1 shows both nuclear and cytoplasmic localization, suggesting that it could affect cytoplasmic proteins. We did not observe acetylation of Ded1 *in vivo*, as assayed by affinity purification and western blot. We also tested whether the absence or overexpression of *HAT1* affects mRNA storage granules. When visualized using fluorescence microscopy under various stress conditions, the deletion of *HAT1* increases the number and intensity of stress granules and P-bodies, suggesting that Hat1 normally either promotes the disassembly or antagonizes the formation of cytoplasmic granules. This effect on granules occurs within minutes of the stress, which is likely too short of a time span to result from nuclear changes in chromatin state and transcriptional changes. While the direct target of Hat1 acetylation is unknown, its effect on cytoplasmic granules suggests that acetylation plays a role in the regulation of cytoplasmic mRNA. These data broaden the role for a lysine acetyltransferase that is assumed to only modify histones.

P935**Board Number: B255****Investigating the Effects of Arginine Methylation on the Role of Ded1, a DEAD-Box Helicase.**N. Rothbard¹, A. Winters¹, A. Hilliker¹;¹Biology, Univ Richmond, University of Richmond, VA

Translational control is a fast and reversible way that cells respond to their environment. mRNAs can be translated, or translationally repressed and stored in cytoplasmic mRNA storage granules, such as P- (processing) bodies or stress granules. Stored mRNAs can be degraded or shuttled back into active translation. mRNA regulation can shift within minutes of a stress and the proteins that promote mRNA regulation are known to be affected by post-translational modifications.

Ded1 is an RNA helicase that has been implicated in moving translationally-repressed mRNAs into translation (1). Our previous data suggests the following two-step model: First, Ded1 promotes the movement of repressed mRNAs, such as those in P-bodies, into a pre-initiation complex that can accumulate in stress granules. Second, Ded1 hydrolyzes ATP to promote translation. Regulation of both of these functions of Ded1 is important to the regulation of mRNA translation.

Post-translational modifications represent one possible way to regulate Ded1 function. Ded1 was recently shown to be methylated at 4 arginine residues. Methylation of Ded1 increases the interaction between Ded1 and Npl3, a protein involved in mRNA export (2). We acquired mutations at one of these four arginines as an intergenic suppressor of Ded1 mutants that were impaired in the Ded1's second function in translation.

We are testing whether Ded1's arginine methylation affects Ded1's function in translation. We mutated each affected residue to lysine by site-directed mutagenesis. *DED1* is an essential gene. We are testing whether these mutant *ded1* alleles are able to complement a *ded1* null and whether these mutants confer any growth defect to yeast cells.

Subsequent experiments using these constructs will seek to determine the effects, if any, of Ded1's arginine methylation on the formation of cytoplasmic mRNA storage granules or Ded1's accumulation in stress granules. Additionally, we will test whether methylation affects Ded1's role in translation, as well as other defined biochemical roles of Ded1.

P936**Board Number: B256****How is the motor force regulated in skeletal muscle contraction?.**B. Chen¹;¹Zhejiang Univ, Hangzhou, China

How the force of a molecular motor is regulated to perform the mechanical work in living systems is fascinating. Contrary to the conventional wisdom, recent experiments suggested that the motor force maintains ≈ 6 pN during skeletal muscle contraction at the steady state. Through analysis, we show that this rather precise regulation in an essentially chaotic system can be due to that a “working” motor is arrested in a transitional state. We then suggests that the motor force can be self-regulated through chemomechanical coupling. This work provides insights to understanding the coordinated function of multiple molecular motors existing in various physiological processes.

P937**Board Number: B257****Myosin Superfamily Classification using the Conserved Domain Database (CDD) Resource at NCBI.**R.A. Yamashita¹, A. Marchler-Bauer¹, S. Bryant¹;¹NIH/NCBI, Bethesda, MD

The Conserved Domain Database (CDD) at NCBI is a repository of manually curated and computationally derived protein domain families from various sources including Pfam, SMART, TIGRFAM, and COG. CDD curators use a number of tools including CDTree, CN3D, CDART, VAST, and Pubmed to create evolutionary hierarchies with detailed protein descriptions, PMIDs, annotations with graphical displays of protein-ligand interactions. We have applied these methods to create a current classification system of the ever growing myosin motor domain. We will present a comparison of our analysis with that of recent work from other researchers. A full suite of Conserved Domains and Protein Classification resources can be found here: <http://www.ncbi.nlm.nih.gov/Structure/cdd/cdd.shtml>

P938**Board Number: B258****Cellular and biochemical studies of the *Dictyostelium* alpha kinases, myosin heavy chain kinase D and alpha kinase 1.**E. Lehman¹, K. Burgett¹, A. Herring¹, P. Steimle¹;¹Biology, Univ North Carolina-Greensboro, Greensboro, NC

Contraction-dependent processes such as cytokinesis and cell migration rely on the proper assembly and localization of myosin II bipolar filaments. In *Dictyostelium* cells, as well as in mammalian cells, myosin II filament disassembly can be driven by phosphorylation of the myosin II heavy chain (MHC) "tail". MHC phosphorylation in *Dictyostelium* is catalyzed by at least three kinases (MHCK-A, -B, and -C) that share homologous alpha-kinase catalytic and WD-repeat domains. In the current study, we examined the cellular and biochemical characteristics of two other *Dictyostelium* alpha kinases - MHCK-D and Alpha kinase 1 (AK1). We report here that over-expression of MHCK-D slows suspension growth, with cells becoming large and multinucleated over time; a phenotype consistent with a role for MHCK-D in driving myosin II filament disassembly. Moreover, in vitro kinase experiments revealed that MHCK-D phosphorylates MHC to a stoichiometry of ~0.6 mol/mol MHC and in manner that leads to myosin II filament disassembly. RT-PCR analysis of expression revealed that MHCK-D, unlike the other MHCKs, is expressed only during *Dictyostelium* multicellular development (peak expression at ~16h). We also found that in live *Dictyostelium* cells GFP-tagged MHCK D exhibits robust and persistent localization to the leading edges of cellular extensions. By contrast, a truncation of MHCK-D lacking the WD-repeat domain localizes mainly to the cytoplasm, suggesting that the WD-repeat domain is involved in the targeting the kinase to cellular protrusions. Taken together, these results indicate that MHCK-D is a bone fide myosin II heavy chain kinase that is likely to function in myosin II filament turnover at the leading edges of migrating *Dictyostelium* cells.

Like MHCK-D, the AK1 protein shares sequence homology with the catalytic domains of the MHCK family, and thus may also play a role in regulating myosin II function in the cell. To explore this possibility, we have engineered a recombinant plasmid for planned studies of AK1 over-expression in *Dictyostelium* cells and for eventual affinity purification of AK1 for studies of the enzyme's catalytic activity. Collectively, our studies MHCK-D and AK1 have the potential to impact our understanding of the basic cellular functions of these two novel proteins in a variety of cellular contexts, including cell division and cell migration, both of which are impaired in cancer cells that exhibit uncontrolled multiplication and metastasis.

P939**Board Number: B259****Differential roles of myosin 1c and myosin 1b during exocytosis in alveolar type II cells.**N. Kittelberger¹, M. Breunig¹, R. Martin², H. Knoelker², P. Dietl¹, P. Miklavc¹;¹Inst. of Gen. Physiology, University of Ulm, Ulm, Germany, ²Department of chemistry, Technische Universität Dresden, Dresden, Germany

Class 1 myosins are molecular motors with actin-binding head and lipid-binding C-terminal domain, which function as linkers between actin network and membranes. Myosin 1 isoforms have different tension sensing properties and are thought to mediate different functions in the cell. We investigated the role of myosin 1c and 1b for exocytosis of surfactant-containing secretory vesicles (lamellar bodies) in primary isolated alveolar type II cells. Both myosin 1 isoforms are expressed in type II cells and localize to fused lamellar bodies in immunofluorescence experiments. Live cell imaging on cells expressing fluorescently coupled myosin constructs showed that myosin 1c and 1b have profoundly different recruitment kinetics to fused vesicles. Myosin 1c translocation closely followed PIP₂ on the vesicle membrane, whereas myosin 1b translocation was largely PIP₂ independent. Inhibition of myosin 1c using a dominant-negative tail domain significantly decreased exocytosis after ATP stimulation, which did not happen after myosin 1b inhibition. We confirmed this finding by using myosin 1c inhibitor pentachloropseudilin, which also resulted in significantly lowered exocytosis. Efficient surfactant extrusion requires formation and compression of actin coat on fused vesicles and we investigated the influence of myosin 1c and 1b on these processes. Inhibition of myosin 1c slowed down vesicle compression, whereas inhibition of myosin 1b had no such effect. In summary, myosin 1c and 1b are both present on lamellar body membrane after fusion, however myosin 1c appears to be the one with a more prominent function for secretory vesicle exocytosis in alveolar type II cells.

P940**Board Number: B260****Myosin II controls cellular branching morphogenesis and migration in 3D by responding to and minimizing cell surface curvature.**R.S. Fischer¹, H.L. Elliott², K.A. Myers³, R.A. Desai⁴, C.S. Chen^{5,6}, R.S. Adelstein⁷, C. Waterman⁸, G. Danuser⁹;

¹Cell and Tissue Morphogenesis, NHLBI/NIH, Bethesda, MD, ²Image and Data Analysis Core, Harvard Medical School, Boston, MA, ³Department of Biological Sciences, Misher College of Arts and Sciences, University of the Sciences, Philadelphia, PA, ⁴MRC NIMR, London, United Kingdom, ⁵Biomedical Engineering, Boston University, Boston, MA, ⁶Wyss Institute for Biologically Inspired Engineering, Harvard University, Boston, MA, ⁷Laboratory of Molecular Cardiology, Genetics and Developmental Biology Center, NHLBI/NIH, Bethesda, MD, ⁸National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD, ⁹Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX

Cell shape is integral to cell function, tissue formation, and regulation of intracellular signaling. An important program of cell shape control in neuronal, endothelial, and cancer cells is branching morphogenesis, in which migratory cells invade a 3D extracellular matrix (ECM) by developing a complex arboreal morphology with a spindle-shaped cell body and branch-like protrusions extending into the ECM. While it has been shown that actin polymerization can drive branch formation and that myosin II inhibits branching, three central questions remain unresolved regarding the control of 3D cell shape by actomyosin. First, how is the molecular-scale activity of myosin II motors related to the cell-scale shape? Second, does cell shape feed back to regulate actomyosin? And third, how is actomyosin spatially and temporally controlled to mediate branching and guide migration? We utilize high-resolution imaging, computer vision, and 3D mathematical morphology measurements to quantify branching morphogenesis and migration in primary endothelial cells in 3D collagen ECMs. We find that myosin-II motor activity regulates micro-scale cell surface curvature to control cell-scale branch complexity and orientation. Myosin-II preferentially assembles onto cortical regions of minimal surface curvature while also acting to minimize local curvature. Using micropatterned chambers, we demonstrate that myosin II assembly is biased by local cortical curvature. We also find that curvature-dependent cortical assembly of myosin II could be separated from its ability to generate tension by inhibiting myosin II force generation with either blebbistatin or a mutant myosin II heavy chain (R702C) with impaired motor function. Using automated 3D curvature mapping and branch analysis of live cell migration in 3D demonstrates that cycles of exploratory branching followed by branch pruning and cell body advance are driven by cycles of myosin-II dissociation from the cortex that allow plasma membrane curvature to increase, followed by myosin-II cortical recruitment to drive curvature minimization. Differential association of myosin to outer low-curvature and inner high-curvature surfaces of branches controls branch orientation, linking local curvature control to global directional control of migration. Thus, cell surface curvature minimization is a central mechanism that translates the molecular activity of myosin-II at the cortex into dynamic shape control for guiding cell migration in 3D.

Kinesins 1

Board Number: B261

Why is Kinesin-2 KIF3AC so Processive?.

S. Guzik-Lendrum¹, K.C. Rank², I. Rayment², S.P. Gilbert¹;

¹Department of Biological Sciences, Rensselaer Polytechnic Institute, Troy, NY, ²Department of Biochemistry, University of Wisconsin, Madison, WI

Mammalian KIF3AC is a heterotrimeric kinesin-2 that consists of two non-identical N-terminal motor polypeptides that dimerize and bind a nonmotor kinesin-associated-protein (KAP) to form the C-terminal cargo-binding domain. KIF3AC is best known for its roles in neuronal tissue for organelle transport and remodeling of the microtubule cytoskeleton, yet *in vitro* studies to characterize its single molecule behavior are lacking. We report that kinesin-2 KIF3AC is highly processive with run lengths at $1.23 \pm 0.09 \mu\text{m}$ which match those exhibited by conventional kinesin K560 at $1.26 \pm 0.1 \mu\text{m}$ in comparative experiments. This result was unexpected because KIF3AC exhibits the canonical kinesin-2 neck linker sequence that has been reported to be responsible for the shorter run lengths observed for kinesin-2 KIF3AB. KIF3C also contains a long extension in surface loop L11 not present in KIF3A or B, or other processive kinesins. Loop L11 is a component of the kinesin microtubule interface and has been implicated in activation of ADP release when kinesin collides with the microtubule. KIF3AC encoding a truncation in KIF3C L11 (KIF3AC Δ L11) is even more processive than wildtype KIF3AC at $1.55 \pm 0.09 \mu\text{m}$. This observation suggests that loop L11 also plays a role in determining the run length. Steady-state ATPase experiments show that shortening L11 does not alter the k_{cat} , consistent with the observation that single molecule velocities are not affected by shortening loop L11. However, shortening loop L11 does significantly increase microtubule affinity: $K_{1/2,MT} = 232.8 \pm 26.6 \text{ nM}$ for KIF3AC and $169.3 \pm 14.4 \text{ nM}$ for KIF3AC Δ L11. Analysis of the homodimers KIF3CC and KIF3CC Δ L11 reveals that both are processive but exceedingly slow. The run length of KIF3CC at $0.57 \pm 0.03 \mu\text{m}$ is shorter than that of KIF3CC Δ L11 at $0.75 \pm 0.03 \mu\text{m}$, and the steady-state ATPase $K_{1/2,MT}$ for KIF3CC at $44.3 \pm 7.4 \text{ nM}$ is weaker than the $K_{1/2,MT}$ for KIF3CC Δ L11 at $8.4 \pm 0.2 \text{ nM}$. These results reveal that processivity can be regulated in part by loop L11 length, consistent with the interpretation that loop L11 becomes ordered upon microtubule collision to activate ADP release. These studies also expand our understanding of motor processivity and point to alternative structural and mechanistic modulators of processivity. Supported by NIH grants to I. Rayment (R01-GM086351) and S. P. Gilbert (R37-GM54141). K. C. Rank was supported by NIH training grant (T32-GM07215).

P942**Board Number: B262****Cargo-mediated dimerization of mammalian Kinesin-3 motors results in superprocessive motion.**V. Soppina¹, S. Norris², A.S. Dizajia¹, M. Kortusa¹, S.L. Veatch², M. Peckham³, K.J. Verhey⁴;¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, ²Biophysics, University of Michigan, Ann Arbor, MI, ³Univ Leeds, Leeds, England, ⁴Department of Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI

The kinesin-3 family is one of the largest among the kinesin superfamily and its members play important roles in a wide range of cellular transport activities, yet the molecular mechanisms of kinesin-3 regulation and cargo transport are largely unknown. We performed a comprehensive analysis of mammalian kinesin-3 motors from three different subfamilies (KIF1, KIF13, and KIF16). Using Forster resonance energy transfer microscopy in live cells, we show for the first time to our knowledge that KIF16B motors undergo cargo-mediated dimerization. The molecular mechanisms that regulate the monomer-to-dimer transition center around the neck coil (NC) segment and its ability to undergo intramolecular interactions in the monomer state versus intermolecular interactions in the dimer state. Regulation of NC dimerization is unique to the kinesin-3 family and in the case of KIF13A and KIF13B requires the release of a proline-induced kink between the NC and subsequent coiled-coil 1 segments. We show that dimerization of kinesin-3 motors results in superprocessive motion, with average run lengths of $\approx 10 \mu\text{m}$, and that this property is intrinsic to the dimeric kinesin-3 motor domain. This finding opens up studies on the mechanistic basis of motor processivity. Such high processivity has not been observed for any other motor protein and suggests that kinesin-3 motors are evolutionarily adapted to serve as the marathon runners of the cellular world.

P943**Board Number: B263****A novel system for assembling multi-kinesin complexes in live cells reveals independent action of kinesins in complex.**S. Norris¹, V. Soppina², D. Cai², S. Sivaramakrishnan², K.J. Verhey³;¹Biophysics, University of Michigan, Ann Arbor, MI, ²Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, ³Department of Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI

Processive molecular motors such as kinesin and dynein are largely responsible for the trafficking and organization of subcellular cargoes, including organelles, vesicles, mRNA particles, and even viruses, in eukaryotic cells. Although the biophysical and biochemical properties of individual motor proteins are well-characterized, how motors coordinate their motility when attached to the same cargo is largely unknown. To study the emergent properties of multi-motor complexes, we developed a novel protein-

based system to assemble defined complexes of kinesin motors inside living cells. We first characterized protein segments that can serve as a scaffold for assembling complexes or as linkers for attaching kinesin motors to the scaffold. We next tested the effectiveness of ten different fluorescent proteins for two-color imaging of kinesins in complex and found that EGFP, monomeric EGFP, tagRFPT, and mApple resulted in a population of motors with aberrant run length behavior. Finally, we applied the system to study the cooperation between slow kinesin-1 motors and fast kinesin-3 motors attached to the same complex. We find that the motors act independently (neither hinder nor help each other), both in vitro in cell lysates and in live COS7 cells, and that the motors can alternate their actions. We find that slow kinesin-1 motors dominate the motility of the complex in vitro on homogeneous microtubules but that kinesin-3 can dominate in live COS7 cells where microtubule heterogeneity provides tracks that kinesin-1 does not engage with. We find that motors can merge with and separate from the scaffold during motility events, suggesting a force-dependent release of motor-cargo linkages.

Kinesin-5 acts as a microtubule stabilizer, polymerase and plus-tip tracker.

Y. Chen^{1,2}, W.O. Hancock^{1,3};

¹Department of Biomedical Engineering, Pennsylvania State University, University Park, PA, ²Cell and Developmental Biology, Pennsylvania State University, University Park, PA, ³Interdisciplinary Graduate Degree Program in Bioengineering, Pennsylvania State University, University Park, PA

Kinesin-5 slides antiparallel microtubules apart during mitosis and is necessary for bipolar spindle formation. Besides its unique homotetrameric configuration, determined by the coiled-coil domain, kinesin-5 motor domains also possess specific properties optimal for their spindle organizing function. To study properties intrinsic to the kinesin-5 motor domain, we generated functional kinesin-5 dimers by fusing the kinesin-5 head and 18-residue neck linker to the coiled-coil rod of kinesin-1. In ATP this kinesin-5 dimer decorated plus-ends of taxol-stabilized microtubules and slowed depolymerization of GMPCPP microtubules. On dynamic microtubules, kinesin-5 dimer increased the microtubule growth rate by more than a factor of two and reduced the catastrophe frequency three-fold. These findings suggest kinesin-5 can stabilize microtubules and acts as a microtubule polymerase. To understand this polymerase mechanism, TIRF microscopy was used to visualize individual GFP-labeled kinesin-5 dimers on immobilized microtubules. Motors walked to the ends of microtubules and remained bound there for 7 seconds, much longer than the 0.1 s motor step time. A more processive kinesin-5 dimer, made by shortening the neck linker to 14-residues, tracked the plus-ends of growing microtubules and had similar end-binding durations. These data suggest that after walking to microtubule plus-ends, kinesin-5 waits there instead of dissociating, and will resume walking if additional tubulin dimers are incorporated. We hypothesize that kinesin-5 promotes microtubule polymerization by stabilizing longitudinal interactions between tubulin subunits on a single protofilament. Consistent with this protofilament stabilization hypothesis, fluorescence analysis suggested that microtubule plus-ends are more tapered in the presence of kinesin-5. Furthermore, curved and looped ends were observed, which occasionally

resolved into straight microtubules, consistent with kinesin-5 stabilizing long protofilament bundles. These findings suggest that when sliding apart antiparallel microtubules in the mitotic spindle, kinesin-5 pauses at and promotes microtubule polymerization of dynamic microtubule plus-ends. Both of these activities enhance the ability of kinesin-5 to establish and maintain spindle pole separation during mitosis.

Solution of the complete kinesin-2 hydrolysis cycle provides insight into bidirectional transport.

G. Chen¹, D. Arginteanu¹, W.O. Hancock^{1,2};

¹Department of Biomedical Engineering, Pennsylvania State University, University Park, PA,

²Interdisciplinary Graduate Degree Program in Bioengineering, Pennsylvania State University, University Park, PA

The kinesin-2 family motor KIF3A/B coordinates with dynein in the bidirectional transport to deliver intraflagellar particles, melanosomes, neuronal vesicles, and mitotic spindle apparatus. In stark contrast to the conventional kinesin, the run length of kinesin-2 shows stronger force sensitivity, suggesting that the function of kinesin-2 is specifically adapted for bidirectional transport. To interpret the physiological behavior of kinesin-2 from a microscopic aspect, we investigated the kinetics of a functional homodimer of mouse KIF3A that exhibits similar motility to full-length KIF3A/B. By referring to the scheme developed for kinesin-1, we solved a hydrolysis model of the kinesin-2 with our kinetic assays, which are in agreement with the precedent measurements in velocity, run length, randomness, and microtubule affinity assay. This study provides direct evidence in that kinesin-2 resides longer in weak-binding state (~50%), which explains its higher force sensitivity.

Kinesin-12 Kif15 targets kinetochore-fibers via an intrinsic two-step mechanism.

E.G. Sturgill¹, D.K. Das², Y. Takizawa¹, Y. Shin³, S. Collier¹, M.D. Ohi¹, W. Hwang^{4,5}, M.J. Lang², R. Ohi⁶;

¹Cell and Developmental Biology, Vanderbilt University, Nashville, TN, ²Department of Chemical and Biomolecular Engineering, Vanderbilt University, Nashville, TN, ³Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, ⁴Department of Biomedical Engineering, Texas AM, College Station, TX, ⁵School of Computational Sciences, Korea Institute for Advanced Study, Seoul, Korea, ⁶Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

Proteins that recognize and act on specific subsets of microtubules (MTs) enable the varied functions of the MT cytoskeleton. We recently discovered that Kif15 localizes exclusively to kinetochore-fibers (K-fibers), or bundles of kinetochore-MTs within the mitotic spindle. It is currently speculated that the MT-

associated protein TPX2 loads Kif15 onto spindle MTs, but this model has not been rigorously tested. Here, we show that Kif15 accumulates on MT bundles as a consequence of two salient biochemical properties. First, Kif15 is self-repressed by its C-terminus. Second, Kif15 harbors a non-motor MT-binding site, enabling dimeric Kif15 to crosslink and slide MTs. We further show that two-MT-binding activates Kif15, resulting in its accumulation on and motility within MT bundles but not on individual MTs. We propose that Kif15 targets K-fibers via an intrinsic two-step mechanism involving molecular unfolding and two-MT-binding. This work challenges the current model of Kif15 regulation and provides the first account of a kinesin that specifically recognizes a higher order MT array.

Src Phosphorylation Regulates the Human Kinesin 5, Eg5, and Disrupts the Binding of Eg5 Inhibitors.

K.M. Gifford¹, J.S. Waitzman¹, T.A. Poor², B.J. Mann³, M.C. Gonzalez¹, P. Wadsworth³, S.E. Rice¹;
¹Department of Cell and Molecular Biology, Northwestern University, Chicago, IL, ²Molecular Biosciences, Northwestern University, Evanston, IL, ³Department of Biology, Molecular and Cellular Biology Graduate Program, University of Massachusetts Amherst, Amherst, MA

Eg5 is a human kinesin-5 that drives spindle pole separation during the early phases of mitosis. While a substantial body of work has revealed the role that Eg5 plays during mitosis, relatively little is known about how Eg5 activity is regulated throughout the cell cycle. Our data shows that endogenous Eg5 in HEK cells is phosphorylated on tyrosine residues. *In silico* predictors suggest three tyrosines in the Eg5 motor domain as targets of Src kinase phosphorylation. We show that these residues are phosphorylated specifically by Src kinase, but not by Wee1 kinase *in vitro*. Furthermore, cells expressing Eg5 constructs with a phosphomimetic mutation of Y211 to glutamate (Y211E) show significantly higher percentages of monopolar spindles than cells expressing wild-type Eg5. The Y211E mutation also significantly decreases Eg5 ATPase rates and motility *in vitro*. The proximity of the potential phosphorylation sites to the binding sites of small molecule inhibitors targeting Eg5 suggested that phosphorylation may interfere with drug binding. Isothermal calorimetry experiments show that phosphomimetic Eg5 constructs have significantly decreased affinity for S-trityl-L-cysteine (STLC). Together, these data suggest a role for the mitotic kinase Src in regulating Eg5 throughout the cell cycle by directly altering its motor characteristics. Such a role for post-translational modifications has not yet been investigated in Eg5. Additionally, the effect of phosphomimetic mutations on STLC binding suggests that phosphorylation may decrease the efficacy of Eg5 inhibitors that are currently in clinical trials. Future work will seek to confirm Src kinase as a regulator of Eg5 activity in cells and investigate phosphorylation as a potential cancer resistance mechanism.

P948**Board Number: B268****The C-terminal region of MCAK controls structure and activity through a conformational switch.**J.P. Welburn¹, S. Talapatra¹, B. Harker¹, A. Bertin²;¹Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, Scotland, ²Inst Curie- Umr CNRS 168, Paris, France

Motor proteins in the Kinesin-13 family are potent microtubule depolymerases that trigger microtubule catastrophe. The non-motor regions flanking the motor domain regulate Kinesin-13 function through phosphorylation. However the molecular basis for the regulation of their activity is not well understood. Here using X-ray crystallography and electron microscopy, we report that the kinesin-13 MCAK forms a compact structure in solution, unlike canonical kinesins. This compact structure of MCAK is held auto-inhibited by an interaction with its C-terminus to prevent non-productive ATP hydrolysis and reduce the affinity of MCAK for microtubules in vitro. The C-terminus of MCAK promotes motor head dimerization, favoring a double lockdown inhibitory mechanism, similarly to Kinesin-1 inhibition. The X-ray structure of MCAK bound to the C-terminus at 3Å reveals that the binding of the ATPase domains as dimers, with the C-terminus binding at the interface between the two ATPase domains. Finally, we show that phosphorylation of the C-terminus of MCAK alleviates MCAK auto-inhibition and induces a large conformational rearrangement. We propose that this regulatory mechanism allows phosphorylation-dependent spatial and temporal activation of MCAK depolymerase activity during mitosis.

P949**Board Number: B269****Sensitivity of Multiple-Kinesin Transport to Microtubule Lattice Defects.**J. Xu¹;¹Univ California-Merced, Merced, CA

Microtubules are fundamental biopolymers in cells, formed via self-assembly of tubulin dimers. Defects in microtubule lattices have been observed, including point defects (missing tubulin dimers) and line defects (protofilament disruption). Microtubule-based molecular motors enable long-range transport in cells. Potential impact of microtubule lattice defects on intracellular transport is not yet understood. Here we vary microtubule polymerization conditions to uncontrollably tune defect presence in microtubule lattices, and use single-molecule-type optical trapping experiments to investigate the impact of such defect on multiple-kinesin transport. We find that kinesin-based cargoes pause preferentially at specific locations along individual microtubules investigated, and that the pause frequency and duration increase with increasing presence of defects in microtubules. Additionally, we find that the dissociation rates of multiple-kinesin-based cargoes are also strongly dependent on the specific microtubules they travel along. Taken together, our study highlights a previously unexplored, and important role of microtubule polymerization condition in regulating intracellular transport.

P950**Board Number: B270****Loss of fission yeast kinesin-14 pkl1p results in aneuploidy via chromosome cut.**V. Syrovatkina¹, P. Tran^{1,2};¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA, ²CNRS UMR144, Institut Curie, Paris, France

Fidelity of chromosome segregation requires the proper formation of the bipolar mitotic spindle. The spindle – organized by microtubules, motors, and microtubule-associated proteins – consists of the spindle poles which nucleate microtubules and focus the microtubule minus ends, the interpolar microtubules which form the spindle midzone containing crosslinked antiparallel overlapping microtubule plus ends, and the kinetochore microtubules which make kinetochore-microtubule attachment for subsequent chromosome segregation. Defects in spindle pole microtubule focusing have led to defects in chromosome segregation, resulting in aneuploidy, a hallmark of cancer cells. However, the mechanism of how unfocused spindle poles lead to aneuploidy is not well understood. Here we show that fission yeast kinesin-14 pkl1p focuses the minus ends of microtubules at the poles during mitosis. The absence of pkl1p (pkl1Δ) leads to fragmentation of the spindle poles, unfocused microtubule minus ends, and aberrant microtubule protrusions away from the spindle axis. The microtubule protrusions are produced by kinesin-5 cut7p, located at the spindle midzone, sliding microtubules apart. Surprisingly, chromosome segregation proceeds normally during mitosis in pkl1Δ cells. However, at the end of mitosis, some long minus end microtubule protrusions can reach the cell tip cortex and push the properly segregated chromosome mass toward the medial cell division site, where the contractile ring can “cut” the chromosome and produce aneuploidy. This novel pathway for aneuploidy may be particularly dangerous, as it bypasses the known checkpoints that ensure chromosome segregation fidelity.

P951**Board Number: B271****Defective axonal transport increases Aβ production downstream from kinesin-1-assisted phosphorylation of amyloid-β precursor protein by JNK.**V. Muresan¹, Z. Ladescu Muresan¹;¹Pharmacology and Physiology, New Jersey Medical School - Rutgers University, Newark, NJ

Stress transiently impairs normal cellular function; prolonged, or repeated stress episodes, occurring throughout life, could lead to cancer or neurodegenerative diseases, including Alzheimer's disease (AD). Here we show that, in neurons, stress impairs axonal transport, which triggers a signaling cascade that delays the folding, and the export from the endoplasmic reticulum (ER), of the Amyloid-β Precursor Protein (APP), a transmembrane protein relevant to AD. We find that, normally, APP is transported from the soma to the neurites by recruiting kinesin-1 via the adaptor protein Fe65, an interactor of APP, and

of the cargo binding subunit of kinesin-1, the KLC. A fraction of APP is proteolytically cleaved into fragments, including the amyloid- β peptide (A β); in AD, the increased generation and accumulation of A β oligomers is neurotoxic. APP is phosphorylated by c-Jun NH2-terminal kinase (JNK) at Thr668, an event that increases its susceptibility to amyloidogenic cleavage. With cultured neurons, we find that the phosphorylation of APP is enabled by kinesin-1, which mediates - via its two KLCs - recruitment of JNK to APP. We show that APP phosphorylation requires the divalent KLCs, which provide the platform for recruiting JNK - via JIP-3 (a JNK scaffold) - and enable its anchoring to APP - via Fe65. Silencing the expression of Fe65, JIP-3, or KLC reduces, whereas the moderate overexpression of any of them increases, the levels of phosphorylated APP. We find that the kinesin-1-assisted phosphorylation of APP does not require the motor activity of kinesin-1, or its binding to microtubules. By contrast, APP phosphorylation is enhanced in conditions of impeded axonal transport, when APP, Fe65, kinesin-1, JIP-3, and JNK are retained in the soma, and form a complex at the ER/ER-Golgi-intermediate compartment (ERGIC). We also find that the phosphorylated APP that is generated in the soma upon blocking of transport is rapidly cleaved by secretases via the amyloidogenic pathway, with subsequent accumulation and oligomerization of A β in the ER lumen, a situation that - we show - reproduces the intraneuronal accumulation of A β in the AD brain. Finally, we show that the above-described mechanism for the generation of A β , following phosphorylation of APP at the ER, is a direct consequence of impeded axonal transport, caused by a variety of forms of stress: genotoxic, osmotic, oxidative, or metabolic. Overall, this study reveals a novel, motor-independent role of kinesin-1 in cargo phosphorylation. It also uncovers an ER stress mechanism leading to the overproduction of A β in response to impeded axonal transport, which could lead to the development of AD. Supported by NIH award AG039668 (Z.M.) and by New Jersey Health Foundation awards (ZM, VM).

²Department of Biomedical Engineering, Pennsylvania State University, University Park, PA,

³Interdisciplinary Graduate Degree Program in Bioengineering, Pennsylvania State University, University Park, PA

The human genome codes for 45 kinesins that contain a highly conserved kinesin motor domain and divergent tail domains for their specific functions. Genetic methods such as RNAi and overexpression of dominant negative species have been used to explore the cellular roles of different kinesins. These methods have yielded valuable information, but are slow acting and prone to off-target effects and hence not suitable to address complex and dynamic biological questions. The identification of small molecule inhibitors specific to different kinesins is highly desirable, yet only a handful of such inhibitors

have been identified due at least in part to the high conservation of the kinesin motor domain. Here we demonstrate that the kinesin motor domain can be engineered to maintain motility yet be inhibited by small, cell permeable molecules. Using kinesin-1 as a prototype, we pursued two strategies to obtain inhibitable motors: I) We inserted the six amino acid tetracysteine tag into surface loops of the motor domain such that binding of biarsenic dyes conformationally distorts and thereby inhibits motility. II) We fused DmrB dimerization domains to the motor heads such that addition of B/B homodimerizer cross-links the motor domains and inhibits motor stepping. We show using cellular assays that the engineered kinesin-1 motors are able to transport artificial cargoes similarly to the wild type motor, but are efficiently inhibited by the addition of inhibitor. *In vitro* assays revealed that inhibitor addition reduces the number of active motors on the microtubule, with minor effects on motor run length and velocity. Future studies will enable us to deploy the inhibitable kinesin-1 motors in cells and animals to study cellular kinesin function with high specificity and temporal resolution. It is likely that these inhibition strategies can be successfully applied to other members of the kinesin superfamily, owing to the high conservation of the kinesin motor domain. MFE was supported by an early postdoc mobility fellowship (PBZHP3_141433) from the Swiss National Science Foundation.

Antioxidant signaling involving the microtubule motor KIF12 is an intracellular target of nutrition excess in beta cells.

W. Yang¹, Y. Tanaka¹, M. Bundo¹, N. Hirokawa²;

¹Dept Cell Biol Anat, Univ Tokyo Grad Sch Med, Tokyo, Japan, ²Cell Biology and Anatomy, Univ Tokyo Grad Sch Med, Tokyo, Japan

Beta cell injury due to oxidative stress is a typical etiology of diabetes caused by nutritional excess, but its precise mechanism remains largely elusive. Here, we demonstrate that the microtubule motor KIF12 mediates a novel antioxidant cascade in beta cells as an intracellular target of excess fat intake or 'lipotoxicity'. Newly generated KIF12-knockout mice suffer from hypoinsulinemic glucose intolerance due to increased beta cell oxidative stress. Using this model, we identified an antioxidant signaling cascade involving KIF12 as a scaffold for the transcription factor Sp1. The stabilization of nascent Sp1 appeared to be essential for proper peroxisomal function by enhancing Hsc70 expression, and the pharmacological induction of Hsc70 expression with teprenone counteracted the oxidative stress. Because KIF12 is transcriptionally downregulated by chronic exposure to fatty acids, this newly identified antioxidant cascade involving KIF12 and Hsc70 is proposed to be a critical target of nutritional excess in beta cells in diabetes.

P954**Board Number: B274****Regulation of the kinesin Kif15 by the microtubule associated protein TPX2.**S. Balchand¹, B.J. Mann², H.M. Jordan³, P. Wadsworth²;¹Department of Biology, University of Massachusetts, Amherst, Amherst, MA, ²Department of Biology, Molecular and Cellular Biology Graduate Program, University of Massachusetts Amherst, Amherst, MA,³University of Massachusetts Amherst, Amherst, MA

The proper assembly of a bipolar mitotic spindle is essential for the faithful segregation of chromosomes. The plus-end directed motor Eg5 is known to be required in many organisms for formation of a bipolar spindle. Recently, another plus-end directed motor, Kif15, was shown to be capable of compensating for loss of Eg5 function under certain conditions. It has also been shown that Kif15 stabilizes the spindle microtubules in metaphase and makes the spindle resistant to STLC treatment. Interestingly, *in vitro* experiments have shown that the microtubule associated protein TPX2 reduces the stepping of both Eg5 and Kif15 on microtubules thereby regulating them. However, the requirements for Kif15 binding to microtubules and its regulation in cells are yet to be completely understood. So, we set out to examine whether the microtubule binding protein TPX2 regulates the function of Kif15 in cells. We observe that fluorescently tagged Kif15 remains cytosolic in interphase and localizes to spindle microtubules in mitosis. GFP-Kif15 cells are sensitive to STLC when treated for short times and become resistant to STLC following longer treatments. Resistance to STLC was not dependent on the presence of K-fibers presumably because of the overexpression of Kif15. But, when TPX2 is depleted using siRNA, GFP-Kif15 cells regain sensitivity to STLC treatment. Expressing truncated constructs of TPX2 lacking some residues in the C terminus does not rescue the functionality of Kif15 in these cells. In microtubule pelleting assays, the C terminal tail fragment of Kif15 pellets with the microtubules only in the presence of TPX2. Together these results demonstrate that TPX2 is required for the localization and function of Kif15 *in vivo*, and that residues in the C-terminal region of TPX2 are necessary for Kif15 function.

Microtubule Dynamics and Its Regulation

Generating the chemical complexity of tubulin: insights into the mechanism of tubulin post-translational modification enzymes.

A. Szyk¹, A. Deaconescu², J. Spector¹, M. Valenstein¹, B. Goodman¹, V. Kormendi¹, N. Grigorieff³, A. Roll-Mecak¹;

¹Cell Biology and Biophysics, NINDS/NIH, Bethesda, MD, ²Department of Molecular Biology, Cell Biology and Biochemistry, Brown University, Providence, RI, ³Janelia Farm Research Campus, Howard Hughes Medical Institute, Ashburn, VA

Microtubules are dynamic polymers that grow through the GTP dependent addition of tubulin dimers. Cells constantly adjust the balance between dynamic, short-lived and stable, long-lived microtubules. Microtubules are decorated with abundant, chemically diverse and evolutionarily conserved posttranslational modifications that serve to mark subpopulations of microtubules for specialized functions in cells. Other than viruses and clathrin cages, microtubules are the only known hollow polymers in eukaryotic cells. Acetylation on α -tubulin Lys40 stands out as the only known tubulin posttranslational modification located in the microtubule lumen. It marks stable, long-lived microtubules and is required for polarity establishment and directional migration. Tubulin acetyltransferase (TAT) presents a puzzle: its activity is stimulated by microtubules, yet the luminal location of Lys40 hinders access by the enzyme. TAT was proposed to access its substrate by diffusing from microtubule ends, accessing the Lys40 loop from the exterior of the microtubule or by gaining access to the lumen through openings or defects in the microtubule lattice. To elucidate substrate access by TAT and to uncover the molecular basis for the *in vivo* correlation between acetylation and microtubule age, we combined X-ray crystallography, electron microscopy, biochemical and single-molecule fluorescence analyses, and modeling. We report the first crystal structure of TAT in complex with a tubulin peptide–ac-CoA bisubstrate analog that together with structure-based functional analyses constrains the active enzyme to the microtubule lumen and reveal the structural determinants for Lys40 loop recognition. Unexpectedly, we find that acetylation by TAT proceeds stochastically along the microtubule without a preference for ends despite the luminal location of the acetylation site. Consistent with this, single-molecule fluorescence imaging reveals that TAT efficiently and stochastically scans the microtubule, while modeling and kinetic analyses demonstrate that TAT catalytic activity, rather than diffusion through the lumen, is rate-limiting. Consistent with this, our high-resolution 1.35Å X-ray complex crystal structure reveals that the TAT active site is suboptimal for supporting the proton transfer required for acetylation. Thus, by virtue of its preference for the microtubule geometry and its low catalytic rate, TAT alone can function as an enzymatic timer for microtubule lifetimes.

P956**Board Number: B277****Combinatorial Regulation of Microtubule Dynamics by Microtubule Associated Proteins.**

A. Hibbel¹, I. Ibarlucea Benitez², A.R. Tipton³, D. Feliciano⁴, R. Garner⁵, M. Zanic⁶, J. Kondev⁷, J. Howard⁸;
¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ²University of California, Berkeley, CA, ³Oklahoma Medical Research Foundation, Oklahoma City, OK, ⁴Physiology Course at Marine Biological Laboratory, Woods Hole, MA, ⁵Stanford University, Stanford, CA, ⁶Vanderbilt University, Nashville, TN, ⁷Department of Physics, Brandeis University, Waltham, MA, ⁸Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

The lengths of spindle and astral microtubules are tightly regulated for proper eukaryotic cell division. Microtubule associated proteins (MAPs) control microtubule dynamics to tune microtubule length distributions. The roles that individual MAPs play in the regulation of microtubule dynamics have been successfully characterized using *in vitro* reconstitution. However, how combinations of MAPs work together to regulate microtubule length is often poorly understood.

During the 2014 MBL Physiology course in Woods Hole, we reconstituted the interactions of three sets of MAPs that co-localize on microtubules. We studied the effect of the budding yeast plus-end tracking protein complex Kip2p-Bik1p-Bim1p on microtubule dynamics. Both Kip2p and Bim1p promoted growth by increasing the microtubule growth rate. Addition of Bim1p, Bik1p or both to Kip2p did not further enhance microtubule growth rate or microtubule length. Furthermore, we reconstituted the competition between the budding yeast polymerase Kip2p and the depolymerase Kip3p. At equimolar concentrations of these proteins, microtubules were longer than in the absence of Kip2p and Kip3p, indicating that Kip2p had won. This result qualitatively agrees with a random walk model of microtubule dynamics and suggests that the growth promoting activity of Kip2p is dominant over the depolymerase activity of Kip3p. Finally, we examined the role of *Xenopus laevis* TPX2 and XMAP215 on microtubule nucleation. Both TPX2 and XMAP215 individually increased the number of nucleation events and TPX2 alone decreased the lag time between microtubule catastrophe and growth. Combined however, TPX2 and XMAP215 additively increased the number of nucleation events and decreased the lag time between growth events.

These studies show that the interplay of MAPs on microtubules can give rise to differences in microtubule length control beyond the effects of the individual components.

P957**Board Number: B278****A combined cell biological and biophysical strategy to analyze actin/microtubule crosstalk and its relation to cytoplasmic streaming.**M. Drechsler¹, R. Goldstein², I.M. Palacios¹;¹Department of Zoology, University of Cambridge, Cambridge, United Kingdom, ²DAMTP, University of Cambridge, Cambridge, United Kingdom

The actin and microtubule (MT) cytoskeletons constitute versatile and highly dynamic protein networks regulating a broad variety of processes like cargo transport or cellular motility. While there is a good understanding of the roles of either type of filament, knowledge about how actin and MTs interact remains rather elusive. Therefore, understanding fundamental concepts of cytoskeletal crosstalk constitutes an important task in cell biology.

We use the *Drosophila* oocyte as model of cytoskeletal crosstalk and dynamics. One major function of these two cytoskeletons in the oocyte is the asymmetric distribution of key developmental determinants. In addition to cargo transport, MTs and the motor Kinesin-1 (Kin) are essential for the induction of major bulk movements of the cytoplasm – a process known as cytoplasmic streaming. We applied particle image velocimetry (PIV) to monitor and quantify cellular fluid dynamics in living oocytes. With this technique we could detect even subtle changes in Kinesin activity and found that flow features strongly correlate with the architecture of the MT cytoskeleton^[1]. We now aim to understand how flows feedback on the MT network and how the cell maintains cytoskeletal organization, by simultaneously monitoring MT dynamics and flows in living oocytes, and subsequent analysis by PIV.

Additionally to Kin and MTs, streaming and cargo localization is regulated by a cytoplasmic F-actin mesh through a yet unknown mechanism. The formation of this actin mesh is developmentally regulated. When it is present, oocytes display slow unorganized cytoplasmic flows, while streaming becomes fast and directed when the mesh dissolves later on. The major task is now to understand how exactly the actin mesh influences Kin activity and the organization of the MT network, as well as the biophysical properties of the cytoplasm. In particular we concentrate on the function of actin-MT crosslinking proteins that might be involved in the interaction of both cytoskeletons. Preliminary data, obtained from live microscopy, suggest that the absence of flows causes an ectopic correlation between the actin mesh and MT bundles, indicating an association of both filament types.

The characterization of flows by PIV, in combination with live video microscopy, FRAP and photoconversion approaches constitutes a novel straight forward experimental setup to gain mechanistic insights into the crosstalk between F-actin and MTs in relation to cytoplasmic flows.

P958**Board Number: B279****A novel microfluidics assisted assay for microtubule dynamics directly links cap transitions and stability.**C. Duellberg¹, N.I. Cade², T. Surrey², D. Holmes³;¹Microtubule Cytoskeleton Laboratory, London Research Institute, London, United Kingdom, ²Cancer Research UK London Research Institute, London, United Kingdom, ³London Centre for Nanotechnology, University College London, London, United Kingdom

Switching between growth and shrinkage is an important property of microtubule ends. The molecular mechanism underlying this switch is still not well understood. Using a novel microfluidics-assisted total internal reflection fluorescence microscopy assay, we directly tested predictions of the most prominent current models of dynamic instability. We found that the mechanism of catastrophe induction cannot be explained satisfactorily by recently proposed models. We combined our microfluidics assay with novel tools to manipulate GTPase cycle-associated transition kinetics. Faster kinetics directly accelerated the disappearance of the stabilizing end structure at microtubule ends after microfluidics-assisted tubulin removal. This is the first and most direct experimental demonstration of how the lifetime of a transiently existing stabilizing end structure determines overall microtubule stability. We further show that a conformational cap recognized by EB proteins is (or at least is the major part of) the stabilizing end structure. This allowed us to directly visualize the time course of cap decay on the single filament level after microfluidics assisted tubulin removal. Cap density and lifetime - rather than total cap length - are most crucial for microtubule stability. Fluctuations in cap density likely explain microtubule lifetime distributions at steady state and after rapid tubulin wash-out. Our results provide a simple, yet powerful conceptual framework that explains the molecular mechanism of catastrophe induction.

P959**Board Number: B280****p150Glued-interacting domains of TRAPPC9 reveal regulatory function of TRAPPC9 at the centrosome.**W. Gan¹, M. Zong¹, A. Satoh², H. Chan³, S. Yu¹;¹Chinese University of Hong Kong, Hong Kong, Hong Kong, ²Okayama Univ, Okayama, Japan, ³Epithelial Cell Biology Research Center, School of Biomedical Sciences, Faculty of Medicine, The Chinese University of Hong Kong, Hong Kong, Hong Kong

The vesicle tethering factor TRAPP (Transport protein particle) complex has been implicated in cellular processes other than vesicle trafficking. Increasing evidence suggests that TRAPP has microtubule-related functions. We have recently discovered TRAPPC9, a subunit of TRAPPII, interacts with CTGlued, the cargo-binding, carboxyl terminal domain of p150Glued, a subunit of dynactin. Here, we identify three TRAPPC9 domains that mediate this interaction - p150Glued-interacting domains 1, 2 and 3 (GID1,

2 3). Purified recombinant GID1 and GID3 could interact with CTGlued in vitro, demonstrating a direct, physical interaction. Pre-incubation of GID3 with CTGlued competitively reduced the interaction between CTGlued and GID1, suggesting GID1 and GID3 bind to CTGlued at the same site. Unexpectedly, GFP-GID1 and GFP-GID3 targeted to the centrosome and affects the formation of microtubule bundles originating from the organelle. Endogenous TRAPPC9 signal also targeted to the centrosome when its Golgi-localization signal was removed by the detergent digitonin. In human skin fibroblast isolated from an individual with mental retardation and microcephaly, mutant TRAPPC9 caused increased number of centrosomes, and thus, higher chromosome ploidy level. Taken together, our results imply that TRAPPC9 plays important roles in microtubule-based axonemes, in addition to its well-documented function in vesicle traffic.

Role of molecular motors and microtubule-binding proteins in cell polarity and regeneration of *Stentor*.

T. Makushok¹, W. Marshall¹;

¹Biochemistry and Biophysics Dept., University of California, San Francisco, San Francisco, CA

Every living cell performs a multitude of operations during its cell cycle. These may include attachment to substrate, movement, division, etc. All of these processes are affected by physical properties of the cells and by their capacity to generate force. Forces are mostly generated within cells via the action of molecular motors pushing and pulling on diverse cytoskeletal structures. The unicellular ciliate *Stentor* is an excellent model system for studying force generation due to its giant size, wide range of behaviors, extraordinary level of structural regularity of its cytoskeleton, and amenability to microsurgical manipulation. Importantly, *Stentor* has the capacity to regenerate any of its parts, which gives access to studying the development of force generation structures over time and the role of these structures in regeneration. In this study, we used RNAi to analyze the role of *Stentor* cytoskeleton and molecular motors in cell motility, cell shape control, intracellular transport, and regeneration. We showed that proteins controlling microtubule dynamics have dramatic effects both on the morphology of *Stentor* cells and on their dynamic behaviors.

P961**Board Number: B282****Dynein-generated forces bend and reorient microtubules by acting upon stationary pinning points.**I.A. Kent¹, P. Rane², A.J. Ladd², T.P. Lele¹, R.B. Dickinson¹;¹Chemical Engineering, University of Florida, Gainesville, FL, ²Chemical Engineering, Univ Florida, Gainesville, FL

Microtubules dynamically bend in living cells, but the mechanisms by which microtubule shape is determined are not well understood. Polymerization forces, microtubule motor proteins, and myosin have all been implicated in microtubule bending. In porcine kidney epithelial cells stably expressing GFP- α -tubulin, we observed that microtubules were able to bend along their length even as their tips grew far away from the cell periphery. Crucially, this indicates that microtubule plus ends do not need to be held stationary for bends to form. We used photobleaching to create fiduciary markers along the lengths of microtubules under the nucleus and found that the majority of microtubule bends were formed by plus-end directed (anterograde) translation of a microtubule segment towards another, stationary microtubule segment, or pinning point. Simulations predicted that bends of the sizes observed in living cells cannot be produced by tangential forces without the presence of a pinning point. Pinning points were found to be transient in nature, sometimes releasing a microtubule and allowing for relaxation of an adjacent bend past where the microtubule was initially pinned. Inhibition of dynein caused a reduction in the proportion of bends caused by anterograde translation as well as in the overall incidence of microtubule bending, suggesting that dynein is providing the tangential force necessary to bend microtubules at pinning points. Myosin inhibition, on the other hand, had no effect on anterograde bending of microtubules. We propose a mechanism by which bending at pinning points can contribute to dynein-dependent deflection of growing microtubule tips. A growing plus end near a pinning point rotates around the pinning point as a bend forms. As the tip continues to grow, friction with the surrounding cytomatrix stabilizes its new direction, so that even if the pinning point dissipates and the bend relaxes, the microtubule cannot relax completely to its original direction. Simulations verified that pinning points near growing plus ends and dynein motor activity are sufficient to cause changes in microtubule direction.

P962**Board Number: B283****The yeast kinesin Kip2p promotes microtubule growth through polymerase and anti-catastrophe activities.**A. Hibbel¹, A. Bogdanova¹, D. Liakopoulos², J. Howard³;¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ²CRBM-CNRS, Montpellier, France, ³Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

The lengths of individual microtubules need to be tightly controlled for cytoskeletal functions such as mitotic spindle positioning. Length control requires a precise balance between microtubule growth and shrinkage, but how this is achieved is poorly understood. In budding yeast, the orphan kinesin Kip2p is suggested to promote microtubule growth, as deletion of this kinesin results in shorter, less abundant cytoplasmic microtubules. However, how Kip2p promotes microtubule growth is not known.

We studied the effect of Kip2p on microtubule dynamics *in vitro*, using reconstitution assays combined with total internal reflection fluorescence (TIRF) and differential interference contrast (DIC) microscopy. In the presence of ATP, Kip2p increases the growth rate and inhibits the catastrophe rate of microtubules grown from either pig or yeast tubulin. These activities increase the mean length of dynamic microtubules, thereby promoting microtubule growth.

To investigate the molecular mechanism by which Kip2p controls microtubule dynamics, we determined biophysical properties of Kip2p on stabilized and dynamic microtubules in single-molecule experiments. In the presence of ATP, Kip2p is a highly processive motor that transports tubulin to the microtubule plus-end. In the presence of the non-hydrolyzable ATP analog AMP-PNP, Kip2p is stationary on the lattice and microtubule growth is no longer promoted. The flux and end-residence time of Kip2p on dynamic microtubules indicate that the mechanism by which Kip2p promotes microtubule growth is primarily by tubulin subunit addition while Kip2p is at the microtubule plus-end. The targeting of tubulin to the end by Kip2p plays a relatively small role in growth promotion.

Our results provide evidence that a kinesin motor can act directly as a microtubule polymerase and anti-catastrophe factor in the absence of accessory proteins.

P963**Board Number: B284****Human Kinesin-8 Kif18A is a Microtubule Depolymerase and Catastrophe Factor.**H. Petzold¹, J. Howard²;¹MPI-CBG, Dresden, Germany, ²Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

Members of the kinesin-8 family of microtubule motors regulate the lengths of mitotic spindles in yeast, fly and mammalian cells. Kip3p, the budding yeast kinesin-8, has microtubule-depolymerizing and catastrophe-promoting activities *in vitro*, activities which accord with Kip3p's ability to regulate

microtubule length. By contrast, there are contradictory results in the literature on the activity of Kif18A, the mammalian kinesin-8: some labs have reported that it depolymerizes microtubules while others have reported that it inhibits catastrophe by pausing microtubule growth. These contradictory results raise the possibility that kinesin-8 function is not conserved, despite the high sequence similarity.

To elucidate how Kif18A affects microtubule dynamics, we studied its effect on stabilized and dynamic microtubules *in vitro*, using reconstitution assays combined with total internal reflection fluorescence (TIRF) microscopy. We found that, when added to dynamic microtubules, Kif18A increases the catastrophe rate in a concentration- and ATP-dependent manner. Furthermore, Kif18A depolymerizes GMPCPP- and taxol-stabilized microtubules.

Our results show that Kif18A is a microtubule depolymerase and catastrophe factor like its budding yeast ortholog Kip3p.

EB1 and cytoplasmic dynein mediate protrusion dynamics for efficient three-dimensional cell migration.

A. Giri¹, H. Jayatilaka¹, N. Trenton¹, P. Wu¹, D. Wirtz^{2,3};

¹Johns Hopkins University, Baltimore, MD, ²Physical Sciences-Oncology Center, Johns Hopkins University, Baltimore, MD, ³Department of Pathology and Oncology and Sydney Kimmel Comprehensive Cancer Center, Johns Hopkins University School of Medicine, Baltimore, MD

Microtubules have long been targeted to control tumor growth and, more recently, metastatic disease, for which a critical step is the local invasion of tumor cells into the 3D collagen-rich stromal matrix. Here we show that to migrate in collagen matrices human fibrosarcoma and breast cancer cells exploit the dynamic formation of highly branched protrusions, which are composed of a microtubule-filled core surrounded by actin filaments that is largely absent in the same cells flattened on 2D substrates. Microtubule plus-end tracking protein EB1 and microtubule-associated motor protein dynein critically modulate 3D cell migration, not by regulating vesicular trafficking, but by regulating both speed and persistence through regulation of protrusion branching itself regulated by differential assembly dynamics of microtubules in the protrusions. These proteins do not regulate conventional 2D migration. An important consequence of the prominent role of microtubules in 3D migration is that the treatment of fibrosarcomas by commonly used cancer drug paclitaxel, which stabilizes microtubules, is dramatically more effective in 3D than in 2D, uniformly and completely blocking 3D cell migration. This work reveals the central role that microtubule dynamics plays in cell migration in more pathologically-relevant 3D collagen matrices and suggests that cancer drugs targeting microtubule dynamics to mitigate migration should be further tested in 3D microenvironments.

P965**Board Number: B286****Understanding the regulation of +TIP complexes of microtubules.**K. Trogden¹, S. Rogers²;¹Biology, University of North Carolina, Chapel Hill, NC, ²Department of Biology, University of North Carolina, Chapel Hill, NC

Dynamic microtubules are necessary for many cellular functions, including cell motility, morphogenesis, and mitosis. MT dynamics are regulated by a conserved set of proteins, termed +TIPs, which interact primarily with the MT plus end. +TIPs encompass a number of protein families; some promote MT dynamics while others stabilize MTs. In *Drosophila*, the scaffolding proteins EB1 and Sentin promote MT dynamics by recruiting the TOG domain protein Mini spindles (Msps). Msps acts an "anti-pause" factor in S2 cells. It is known that the *Xenopus* homolog, XMAP215, can both processively add tubulin to growing ends and drive MT depolymerization in vitro and are thought to have the same activities in cells. Orbit is another +TIP that functions to stabilize MTs by suppressing dynamic instability. The goal of my project is to understand how the cell regulates these antagonistic activities using *Drosophila* S2 cells as a model system. Our data indicate that the ability of +TIPs to interact are regulated in S2 cells. This regulation, in part, is through the kinase GSK3 β downstream of Rac. GSK3 β can affect the localization of Orbit, similar to what has been seen in mammalian cells in which the Orbit homolog CLASP has been shown to be directly phosphorylated by GSK3 β . We found that in *Drosophila*, this pathway is conserved and also regulates Msps localization. Downstream of this pathway, Orbit is necessary to allow Msps to switch from tip to lattice localization of the microtubule. We also show that Msps and Orbit can interact through the scaffolding protein Sentin. We hypothesize that this interaction is important for proper microtubule dynamics in cells.

P966**Board Number: B287****Spatiotemporal control of microtubule dynamics by patterned illumination.**J. van Haren¹, H. Wang², K.M. Hahn², T. Wittmann¹;¹Department of Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA,²Department of Pharmacology, University of North Carolina, Chapel Hill, NC

Reorganization of membranes, organelles and other intracellular components during complex cell dynamics such as cell division or directed migration relies on a tight spatial and temporal control of microtubule (MT) dynamics and interactions. Here we present three different light-activated microtubule modulators that we have designed to interrogate the functional relevance of local regulation of microtubule dynamics and interactions. +TIPs are a diverse class of proteins that associate specifically with the ends of growing MTs, and regulate MT dynamics, or mediate MT interactions with other intracellular structures such as kinetochores, organelles and the cell cortex. +TIPs therefore play an important role in spatially organizing the cell. End-binding proteins (EBs) are key elements of the

growing MT end, as these +TIPs recruit the majority of other +TIPs to MT ends. Several other EB-dependent +TIPs have been found to localize to other structures besides the MT end, such as for example CLASPs that localize to the cell cortex independently of MTs and capture MTs at the cell cortex. The interaction of CLASPs with MT ends at the cell cortex is spatially controlled by a gradient of GSK3- β activity. Polarized distribution/activation of +TIPs is likely a general mechanism for the establishment of a polarized MT network, and hence polarized cellular responses. Utilizing blue light controllable dimerization modules, LOV2/ZDK1 and Cry2/CIB1, we constructed light-controllable EBs, which we can use to spatiotemporally control intracellular +TIP or microtubule interactions. In addition, MT polymerization dynamics are spatiotemporally regulated in cells, and we utilized light-controlled inhibition of the small MT destabilizer Op18/stathmin to directly influence MT polymerization. These light-controlled MT modulators have advantages over knockdown approaches, since our systems can be used to locally control microtubule dynamics, and are fully reversible, and will allow to directly ask longstanding questions about intracellular microtubule function. We are currently testing how local control of MT dynamics by patterned illumination affects cellular behaviors.

Role of TACC3 in Axon Elongation and Guidance.

B. Erdogan¹, M.F. Evans¹, B.U. Nwagbara¹, L.A. Lowery¹;

¹Biology, Boston College, Chestnut Hill, MA

Axon outgrowth and guidance are two essential phenomena in establishing proper neural connection for a functioning nervous system. Navigating to the proper target requires the communication and coordination of the environmental guidance cues and cytoskeletal polymers at the growing tip of the axon, the growth cone. Microtubules are dynamic cytoskeletal polymers in the growth cone. The dynamic behavior of the microtubule is regulated by its plus end and a conserved family of proteins called 'plus-end tracking proteins' (+TIPs) located on these ends.

Our focus is to understand how +TIPs regulate dynamic behavior of microtubules during axon outgrowth and guidance. We are investigating the role of the +TIP TACC3 in axon outgrowth and guidance. Here we show that TACC3 is expressed in vertebrate neuron. Overexpression of it increases axon length while knocking it down reduces both axon length and number in *Xenopus laevis* growth cones. In addition to its effect on axon outgrowth, we also investigated its role in axon guidance. We performed in vitro stripe assays in which the neural tube and eye explants from *Xenopus laevis* embryos were cultured in a dish in the presence of stripe of the repulsive axon guidance cue, ephrin. The responsiveness of the growth cones of these explants were evaluated quantitatively by comparing the localization behavior of the growth cones as it navigates through the ephrin stripes. Our findings reveal that TACC3 functions as an axon outgrowth promoting factor in vivo in embryonic spinal cord neurons and it is required for proper axon navigation during optic nerve projection to the brain.

P968**Board Number: B289****TACC3 is a microtubule plus-end tracking protein that promotes axon elongation and also regulates microtubule plus-end dynamics in multiple embryonic cell types.**B.U. Nwagbara¹, B. Erdogan¹, E. Bearce¹, P. Ebbert¹, M. Evans¹, E. Rutherford¹, L.A. Lowery¹;¹Biology, Boston College, Chestnut Hill, MA

Proper neural connections, essential to nervous system function, depend upon precise navigation by the neuronal growth cone. A fundamental problem in growth cone cell biology is how guidance pathways are integrated to coordinate cytoskeletal dynamics, thus driving accurate steering. To address this question, we focus on the plus-ends of microtubules, which explore the growth cone periphery and play a key role in growth cone steering. Microtubule plus-end dynamics are regulated by a conserved family of proteins called 'plus-end-tracking proteins' (+TIPs). Yet, it is still unclear how +TIPs interact with each other and with plus-ends to control microtubule behavior, especially in the developing nervous system.

The centrosome-associated protein TACC3, a member of the transforming acidic coiled coil (TACC) domain family, has been previously implicated in regulating several aspects of microtubule dynamics. However, TACC3 has not been shown to function as a +TIP in vertebrates. Here, we show that TACC3 promotes axon outgrowth and also regulates microtubule dynamics by increasing microtubule plus-end velocities in vivo. We also demonstrate that TACC3 acts as a +TIP in multiple embryonic cell types, and that this requires the conserved C-terminal TACC domain. Using high-resolution live-imaging data of tagged +TIPs, we reveal that TACC3 localizes to the extreme microtubule plus-end, where it lies distal to the microtubule polymerization marker, EB1, and directly overlaps with the microtubule polymerase, XMAP215. TACC3 also plays a role in regulating XMAP215 stability and localizing XMAP215 to microtubule plus-ends. Together, our results implicate TACC3 as a +TIP that functions with XMAP215 to regulate microtubule plus-end dynamics.

P969**Board Number: B290****Mcp1p tracks microtubule plus ends to destabilize microtubules at cell tips.**F. Zheng¹, T. Li¹, M. Cheung¹, V. Syrovatkina², C. Fu³;¹Department of Biochemistry, Univ Hong Kong, Pokfulam, Hong Kong, ²Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA, ³Department of Biochemistry, Univ Hong Kong, Hong Kong, Hong Kong

Microtubule plus ends are dynamically regulated by a wide variety of proteins for performing diverse cellular functions. Here, we show that the fission yeast *Schizosaccharomyces pombe* uncharacterized protein mcp1p is a microtubule plus-end tracking protein which depends on the kinesin-8 klp6p for

transporting along microtubules towards microtubule plus ends. In the absence of mcp1p, microtubule catastrophe and rescue frequencies decrease, leading to an increased dwell time of microtubule plus ends at cell tips. Thus, these findings suggest that mcp1p may synergize with klp6p at microtubule plus-ends to destabilize microtubules.

Board Number: B291

The novel microtubule-regulating protein, MTCL1, crosslinks and stabilizes noncentrosomal microtubules on the Golgi membrane.

Y. Satoh¹, A. Suzuki²;

¹Medical Science, Yokohama City University, Yokohama-City, Japan, ²Medical Life Science, Yokohama City University, Yokohama, Japan

Recent studies have revealed the presence of a microtubule (MT) subpopulation called Golgi-derived MTs that support the Golgi ribbon formation required for maintaining polarized cell migration. CLASPs and AKAP450/CG-NAP are involved in their formation, but the underlying molecular mechanisms remain unclear. We have recently identified a novel MT-regulating protein, MTCL1, which crosslinks MTs through its N-terminal MT-binding region and subsequent coiled-coil motifs, and revealed its indispensable roles in accumulating the noncentrosomal MTs along the lateral membrane of polarized epithelial cells. In the current study, we demonstrate that MTCL1 colocalizes with the Golgi membrane through interactions with CLASPs and AKAP450/CG-NAP, and plays indispensable roles in the development of the Golgi-derived MTs. Correspondingly, MTCL1-depleted cells fail to develop the stable perinuclear MTs and Golgi ribbon. Interestingly, not only the N-terminal MT-binding region, which promotes MT accumulation around the Golgi membrane, but also the C-terminal MT-binding region showing a novel MT-stabilizing activity, are required for rescuing these defects in MTCL1-depleted cells. Taken together, the present results suggest that MTCL1 cooperates with CLASPs and AKAP450/CG-NAP for the formation of the Golgi-derived MTs, and mediates their development into a stable Golgi-associated MT network along which the Golgi stacks extend to form the Golgi ribbon. These results reveal a novel role of MTCL1 in organizing another kind of noncentrosomal MTs and clarify how the Golgi-associated MTs are specifically stabilized.

P971**Board Number: B292****A Role for Microtubules in Lens Fiber Cell Elongation and Lens Morphogenesis.**C.M. Logan¹, L. Zhang¹, S. Menko²;¹Anatomy, Thomas Jefferson University, Philadelphia, PA, ²Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA

Tissue development and regeneration involve high-ordered morphogenetic processes that are governed by elements of the cytoskeleton in conjunction with cell adhesion molecules. Such processes are particularly important in the lens whose structure dictates its function. Microtubules have many roles in the cell, among them as determinants of directional migration and as the highways for vesicle transport. Here we investigated the possible role of microtubules and their interactions with N-cadherin in providing directionality to fiber cell elongation. Through co-immunoprecipitation analysis using chick embryo lenses microdissected into four distinct zones of differentiation we demonstrated that N-cadherin interacts with tubulin and acetylated-tubulin primarily in the cortical fiber zone, where lens fiber cells elongate. Disassembly of microtubules with the microtubule depolymerizing drug nocodazole affected lens fiber cell elongation and directionality. High doses of nocodazole also affected interactions between fiber cells and epithelial cells along the epithelial-fiber interface (EFI). These effects were accompanied by a dramatic loss of association between N-cadherin and acetylated tubulin in the cortical fiber zone, as well as changes in levels of F-actin and phospho-myosin. These results provide the first demonstration of a role for microtubules in lens fiber cell elongation, lens morphogenesis and the maintenance of lens tissue integrity.

P972**Board Number: B293****Persistence of microtubule polymerization controls cell migration in 3D matrix.**B. Bouchet¹, I. Noordstra¹, A. Akhmanova¹;¹Cell Biology, Faculty of Science, Utrecht University, Utrecht, Netherlands

Cooperation between the actin and microtubule cytoskeleton is essential for cell migration, but the underlying mechanisms differ depending on the cell type and cell culture conditions. In 2D cultures, actin polymerization typically drives spreading of lamella while actomyosin-based contractility translocates the cell body towards the leading edge. In this context, microtubules are thought to have primarily a regulatory function linked to the control of signaling and focal adhesion dynamics. In more physiologically relevant 3D culture models, cells do not form flat lamella but instead can extend long pseudopods that penetrate the matrix and form adhesions. Also in these conditions, the actomyosin network is essential for cell protrusion and translocation, but the role of microtubules is still poorly understood. Here, we investigated whether microtubule dynamics is an important factor in 3D migration. We used inactivation of SLAIN2, a recently identified interphase-specific plus-end recruitment factor for the microtubule polymerase ch-TOG, to disrupt persistent microtubule polymerization. When

SLAIN2 is inactivated, interphase microtubules grow slowly and undergo frequent catastrophes, but the organization and maintenance of microtubule network is relatively normal and cell divide normally, because SLAIN2 plays no role in the formation of the mitotic apparatus. Surprisingly, we found that processive microtubule growth is dispensable for cell spreading and migration in 2D, but is completely essential for the mesenchymal cell movement in 3D matrix. When persistent microtubule polymerization is reduced, the formation of long pseudopods that initiate cell movement in 3D is dramatically inhibited. Short term treatments with very low doses of microtubule-targeting agents that induced similar perturbation of microtubule growth without destroying microtubule network caused rapid retraction of the existing pseudopods, indicating that also the maintenance of cell protrusions in 3D depends on persistence of microtubule growth. We further found that rapid microtubule polymerization antagonizes myosin II-based contractility during pseudopod extension in 3D matrix. Finally, we showed that persistent microtubule growth is a prerequisite for pseudopod-based invasion induced by complete epithelial-mesenchymal transition (EMT) in human breast epithelial cells, a process that is crucial for both normal development and cancer cell metastasis. Our results demonstrate that, independently from microtubule network maintenance, the microtubule polymerization processivity is a critical factor required for the elongation of pseudopods that initiate cell motility in 3D matrix.

Paxillin interacts with and inhibits HDAC6 to regulate microtubule acetylation, Golgi integrity and polarized cell migration.

N.O. Deakin¹, C.E. Turner¹;

¹Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Polarized cell migration is of fundamental importance for organism development and maintenance, including tissue patterning, wound healing and immune surveillance. However, the dissemination of cancer cells from the primary tumor to generate distant metastases also requires navigation of cells through the tissue stroma to the lymphovascular system. A hallmark of directional migration is the repositioning of a cohesive Golgi apparatus ahead of the nucleus to facilitate trafficking of pro-migratory factors to the appropriate cellular locales. Furthermore, spatiotemporal regulation of dynamic cell-extracellular matrix interactions is also essential for cells to generate the traction forces necessary for cell movement. Importantly, these aforementioned key events in directional migration can all be regulated by the microtubule cytoskeleton. Paxillin localizes to sites of cell-extracellular matrix interaction, termed adhesion contacts, where it serves to integrate a diverse array of signaling and structural proteins. Historically, paxillin has been shown to function at adhesion contacts to predominantly serve as a hub for Rho GTPase family protein signaling to coordinate the actin cytoskeleton. Herein we report a new role for paxillin in regulating the microtubule network and cell polarization machinery through its interaction with and inhibition of HDAC6 in both normal and cancer cells. Using a combination of FRET and proximity ligation assays we determined that while a small percentage of the paxillin-HDAC6 complexes were found in and around adhesion contacts, the majority

was distant from these sites of robust paxillin enrichment. Furthermore, through inactivation of HDAC6, paxillin, is able to regulate polarized cell migration/invasion in both 2D and 3D microenvironments by controlling the microtubule acetylation-dependent cohesion and repositioning of the Golgi apparatus. We also determined that the proline-rich region of paxillin is necessary for the interaction with and inhibition of HDAC6. This study has identified a new and ubiquitous role for paxillin as a key regulator of the microtubule network and cell polarization machinery.

Effects of Rev Protein on Microtubule Arrays in Living Cells.

N. Nikumbh¹, J. Chang¹, M.W. Miller²;

¹Biological Sciences, Wright State University, Dayton, OH, ²Wright State University, Dayton, OH

The HIV protein Rev regulates the expression of essential viral proteins during the course of infection by a mechanism that is well understood. It promotes nuclear export of viral transcripts, normally retained in the nucleus owing to the presence of introns, by interacting with host cell transport factors. However, over-expression of Rev in cells leads to defects in cell cycle progression, specifically slowing growth and impairing progression through mitosis (Miyazaki et al., 1995, Exp. Cell Res. 219:93-101, data shown here). While it is possible that Rev may be altering the proteins in transport pathways, cell cycle defects may be attributed to Rev's interactions with other proteins.

In vitro experiments show that highly purified Rev has a high and specific affinity for α and β tubulin present either as free heterodimers or polymerized into microtubules (MTs) (Watts et al., 2000, J. Cell Biol. 150:349-360). Moreover, Rev rapidly depolymerizes MTs *in vitro* producing intermediates that closely resemble the products of depolymerization reactions triggered by a variety of experimental conditions. Owing to structural similarities, Rev hypothetically depolymerizes MTs by a mechanism used by Kinesin-13 (Kin-13) proteins that are potent MT depolymerizing enzymes.

To determine whether Rev is interacting with MTs in a Kin-13-like manner, point mutations were introduced into Rev substituting alanine for amino acids shared with Kin-13. Mutant proteins were tagged with YFP, over-expressed in HeLa cells and cell cycle progression was monitored. In contrast to expression of Rev, which lengthened doubling times and all stages of the cell cycle, each point mutant partially corrected the defect. These results are consistent with Rev acting in a manner similar to Kin-13.

To determine whether Rev over-expression affects MT dynamics in cells, MT arrays were experimentally depolymerized and allowed to recover. If Rev inhibits MT nucleation or promotes depolymerization, then MT arrays in cells expressing Rev should require more time to recover. Results show that MT arrays recover from depolymerization equally well in presence and absence of Rev. Because wild-type Rev accumulates largely in the nucleus and nucleoli, we attempted to increase the cytoplasmic levels of Rev by introducing M4 and M6 mutations that impair Rev multimerization and nuclear import, respectively. However, neither M4 nor M6 expression affected MT recovery after depolymerization.

These results suggest that the cell cycle defects observed in Rev-expressing cells are not mediated by Rev's ability to alter the polymerization state of MT.

NuSAP stabilizes kinetochore microtubules by attenuating MCAK depolymerization activity.

C. Li¹, Y. Liou¹;

¹Department of Biological Science, National University of Singapore, Singapore, Singapore

NuSAP (Nuclear and Spindle Associated Protein), a novel Microtubule Associated Protein (MAP), functions as a microtubule stabilizer. Depletion of NuSAP leads to severe mitotic defects. However, it remains unclear how NuSAP stabilizes microtubules in cells during mitosis. In this paper, we dissect the function of NuSAP in stabilizing kinetochore microtubules during metaphase and present the first evidence of the direct interaction of NuSAP and a MT depolymerizer, MCAK. NuSAP tightly regulates the localization, dynamics and depolymerization activity of MCAK. Furthermore, we demonstrate that Aurora B kinase regulates the functional complex of NuSAP and MCAK at kinetochore region. Aurora B significantly enhances the interaction of NuSAP with MCAK and further modulates the effects of NuSAP on the localization and depolymerization activity of MCAK. Thus, we provide new insights into the complex regulation of kinetochore microtubules dynamics during metaphase to ensure proper tension at kinetochore and establish the attachment of kinetochore microtubules to promote precise cell division.

Kinetochore microtubule dynamics are controlled by microtubule length and centromere tension forces in the *S. cerevisiae* mitotic spindle.

J.M. Chacon¹, M.K. Gardner¹;

¹University of Minnesota, Minneapolis, MN

During metaphase, dynamic kinetochore microtubules grow and shrink to align sister chromosomes on opposite halves of a mitotic spindle. Proper chromosome alignment is necessary to ensure their faithful segregation to daughter cells during anaphase, and requires fine-tuning of the kinetochore microtubule transition frequencies between growing and shortening states (rescue and catastrophe). In budding yeast, both mechanical tension as well as microtubule length-dependent regulatory proteins likely contribute to this alignment process. However, the relative importance of these effects remains unclear. Thus, we quantified the dynamics of single kinetochore microtubules with high temporal and spatial resolution to determine the relative contributions of microtubule length and tension force to metaphase kinetochore positioning. Quantification of dynamics in wild-type cells demonstrated that microtubule

switching frequencies were affected by both microtubule length and tension, although microtubule length had a more substantial effect on transition frequencies than the effect of tension. Regardless, increased tension values were correlated with both increased rescue frequency and reduced catastrophe frequency, and longer microtubule lengths were correlated with both reduced rescue frequency and increased catastrophe frequency. We conclude that both tension and kinetochore microtubule length contribute to metaphase kinetochore positioning in budding yeast.

The CHE-12 protein family uses a TOG domain array to regulate microtubules in the primary cilium.

A. Das^{1,2}, D. Dickinson³, C. Wood³, B. Goldstein³, K.C. Slep³;

¹Department of Biochemistry and Biophysics, University of North Carolina, Chapel Hill, NC, ²Molecular and Cellular Biophysics Program, University of North Carolina, Chapel Hill, NC, ³Department of Biology, University of North Carolina, Chapel Hill, NC

Primary cilia are microtubule-based projections from the cell surface, critical for normal development, sensation, and homeostasis. A solitary primary cilium is present in most mammalian cell types, where it acts as a cellular antenna to sense the extracellular environment. Defects in cilia architecture and function yield a host of diseases collectively termed ciliopathies. Cilia consist of basal, middle and distal zones, characterized by triplet, doublet and singlet microtubules, respectively. The catalog of factors that regulate ciliary microtubules and their respective mechanisms are poorly understood. The XMAP215 and CLASP families are key TOG domain array-based regulators of cytoplasmic microtubules, but whether TOG array proteins regulate cilia structure and function remains to be determined. We have identified a conserved protein family unique to ciliated/flagellated organisms that use a tetrameric TOG domain array to regulate ciliary microtubules, defined by the *C. elegans* member CHE-12. *che-12* worms lack singlet microtubules in cilia distal segments and have defective doublet architecture, resulting in aberrant chemotaxis. We present the crystal structure of mammalian CHE-12 (mCHE-12) TOG2 revealing a canonical TOG fold with conserved tubulin-binding determinants. We have shown that mCHE-12 localizes to the distal tip of primary cilia in mammalian cell culture and can also bind along cytoplasmic microtubules when over-expressed. Using a light scattering assay, we demonstrate that mCHE-12 TOG domains promote microtubule polymerization in vitro. We used the recently developed Cas9-triggered homologous recombination method to introduce mutations in the endogenous *che-12* genetic locus in *C. elegans*, and demonstrated that CHE-12's TOG domain-dependent tubulin-binding activity is essential for proper amphid sensory cilia development. Taken together, our findings suggest that CHE-12 uses its TOG domain array to bind tubulin and regulate microtubule organization in primary cilia. Thus, the CHE-12 family expands the TOG domain array-based MT regulatory paradigm with key implications for cilia structure and function.

P978**Board Number: B303****CLASP1 Differentially Regulates Microtubule Growth Dynamics in Response to ECM Composition and Density.**N. Caesar¹, K.A. Myers¹;¹Biological Sciences, University of the Sciences, Philadelphia, PA

Angiogenesis is the process by which endothelial cells (ECs) are signaled to polarize, extend branches, and migrate with directional specificity to establish new vascular networks from existing vasculature. To establish a polarized morphology, ECs extend branched protrusions, a process that requires the differential regulation of microtubule (MT) dynamics. Regulation of MT dynamics is accomplished by Microtubule Associated Proteins (MAPs), which function by promoting MT growth, MT stability, or MT disassembly. CLASP1 is a MAP that associates with MTs with regional specificity to promote MT stability, and in doing so contributes to cell polarization. In addition to MAPs, interactions with the extracellular matrix (ECM) are known to differentially influence MT dynamics. For example, variations in ECM dimensionality and compliance cause marked differences in MT growth dynamics, resulting in altered EC branching morphologies. Nevertheless, it is not known if, or how, CLASP1 contributes to ECM-engagement-mediated regulation of MT growth. We tested the hypothesis that CLASP1 promotes the regional regulation of MT growth dynamics in response to ECM engagement in order to drive EC branching. HUVECs were cultured on either high-density (90ug/mL) or low-density (45ug/mL) 2D collagen-I ECMs, and were compared to HUVECs cultured on either high-density (100ug/mL) or low-density (10ug/mL) 2D fibronectin ECMs. Our results show that HUVEC engagement of fibronectin ECMs resulted in significantly faster and longer-lived MT growth than engagement of collagen, independent of ECM density. On fibronectin ECMs, CLASP1 expression resulted in significantly slower and shorter-lived MT growth, independent of ECM density. In HUVECs cultured on low-density collagen ECMs, CLASP 1 expression promoted fast MT growth with no effect on MT growth lifetimes. However, on high-density collagen ECMs, CLASP1 expression promoted significantly slower and longer-lived MT growth. Regional analysis comparing the branched periphery versus the cell center revealed that CLASP1 expression promoted slower MT growth speeds in the cell periphery but had no effect on MT growth lifetimes, independent of ECM composition or ECM density. Analysis of HUVEC branching revealed that only HUVEC engagement of high-density fibronectin ECMs significantly increased branch number, and that CLASP1 expression on high-density fibronectin ECMs further increased branch number. Together, these results suggest that CLASP1 differentially regulates MT dynamic instability in response to both ECM composition and ECM density, and suggest that CLASP1 regional regulation of MT growth dynamics contributes to HUVEC branching by promoting slow and short-lived MT growth in response to HUVEC engagement of high-density fibronectin ECMs.

P979**Board Number: B304****Dissecting the role of microtubule poleward flux in correction of kinetochore mis-attachment.**E. Roscioli¹, B. He¹, H. Bomberger¹, M. Shen¹, G. Civelekoglu-Scholey², D. Cimini¹;¹Biological Sciences, Virginia Bioinformatics Institute, Virginia Tech, Blacksburg, VA, ²Department of Molecular and Cellular Biology, University of California, Davis, CA

Microtubule (MT) poleward flux refers to a specific aspect of MT dynamics by which individual tubulin subunits within mitotic spindle MTs translocate poleward. This behavior is thought to arise from MT depolymerization at the minus end (spindle pole), MT polymerization at the plus end, and concomitant motor-dependent poleward sliding of the MT lattice. In this process, kinesin 13s (KLP10A in *Drosophila*, Kif2a in vertebrates) at the spindle poles act as the major MT minus end depolymerases. The biological role of MT poleward flux has been long debated, given that it is only observed in certain model systems. Previous studies indicated that suppression of poleward flux results in an increased rate of chromosome mis-segregation in the form of anaphase lagging chromosomes (Ganem and Compton, *Curr. Biol.*, 2005) and increased desynchronization of chromosome poleward movement (by distribution of poleward forces across the spindle; Matos et al., *J. Cell Biol.*, 2009). However, in the study by Ganem and Compton, suppression of poleward flux could only be performed in cells co-depleted of the plus end depolymerase MCAK and, in Matos et al., KLP10A and CLASP were knocked down simultaneously and their quantitative model did not account for MT dynamic instability or kinetochore (KT) attachment state. We have recently developed a comprehensive mathematical model of chromosome dynamics that includes MT plus and minus end dynamics and poleward flux, as well as an experimental approach (microinjection of Kif2a antibodies) to suppress MT poleward flux independent of other perturbations. Here, we combined these approaches to investigate the role of MT poleward flux in correction of KT mis-attachment. Computer simulations of metaphase in the absence of poleward flux indicated that KT-MT attachments become more stable, resulting in higher numbers of kinetochore MTs (kMTs) with increased kMT half-life. Given that kMT turnover is required for the correction of KT mis-attachments, these results suggest that inhibition of poleward flux alone is enough to impair this mechanism of correction. To test this prediction, we examined chromosome segregation by time-lapse microscopy in cells microinjected with Kif2a antibodies and found that more than 40% (15/35) of the cells displayed anaphase lagging chromosomes as opposed to 13% (4/30) in buffer-injected cells. These results strongly support the idea that MT poleward flux plays a key role in correction of KT mis-attachment. We are currently investigating additional effects suppression of MT poleward flux may have on overall organization of the metaphase spindle.

P980**Board Number: B305****Xenopus Dppa2 is an embryo-specific inhibitor of microtubule growth required for nuclear assembly.**J. Xue¹, M. Takata¹, H. Funabiki¹;¹Laboratory of Chromosome and Cell Biology, Rockefeller University, New York, NY

Dppa2 is a member of a gene family expressed exclusively in embryonic and pluripotent tissues, originally cloned through coexpression with Oct4. Dppa2 orthologs are found throughout vertebrates, and we identified *Xenopus* Dppa2 in a proteomic screen for novel chromatin-binding proteins. Interestingly, despite its exclusive localization to chromatin, Dppa2 contains a microtubule-regulatory activity in its C-terminal domain spanning 97 amino acids. Here we present our studies analyzing the effects of recombinant Dppa2 on the dynamics of in vitro microtubules. In a dose-dependent manner, Dppa2 inhibits growth from pre-existing microtubule seeds and appears to suppress rescue frequency. In vivo, Dppa2 disassembles the remnants of metaphase microtubules around chromatin at the transition from metaphase to interphase and is required for the assembly of normal, replication-competent nuclei. In the absence of Dppa2, nuclei are smaller and have distorted morphology. This phenotype is mimicked by taxol treatment and rescued by nocodazole, confirming the importance of regulated microtubule dynamics during nuclear assembly. Dppa2 expression is limited to the early *Xenopus* embryo, which is notable both for its large size (1 mm diameter) and its rapid cell divisions (once every 30 minutes). We propose that rapid cell cycles in large cells pose unique challenges to the mitotic apparatus, necessitating specific solutions that maintain tight spatial and temporal control of cytoskeletal dynamics.

P981**Board Number: B306****SUMO-2/3 modification regulates the stability of microtubules.**S. Hong¹, W. Law¹, K. Middleton¹;¹Cytoskeleton, Inc., Denver, CO

Microtubule undergoes post-translational modifications (PTMs), which diversify its functional regulations on intracellular transport, cell shape, motility and differentiation. Various PTMs on microtubules are well documented in literature, but SUMOylation of microtubule has not been clearly demonstrated so far. In this study, we have detected microtubule structure, SUMOylated by endogenous SUMO-2/3, in HeLa cells. For the first time, we visualized cytoplasmic network, targeted by SUMO-2/3, with immuno-fluorescent staining. This network is densely populated near the perinuclear region and emanates to the periphery of cells, which is well co-localized with microtubules. Clearly, SUMO-2/3 modifies either directly microtubule (or tubulin) or microtubule-associated proteins (MAPs). Interestingly, this SUMOylated microtubule structure shows strong resistance against Nocodazole treatment (10uM for 1hr), which may indicate that SUMOylation by SUMO-2/3 is involved in formation

and/or maintenance of stable microtubules rather than dynamic ones. Up to now, it is not clear if SUMO-2/3 preferentially targets stable microtubules or if SUMO-2/3 modified tubulins form stable microtubules. However, our observation that paclitaxel treatment (Taxol, 1 μ M for 4hrs) does not increase the level of SUMOylated microtubule may indicate that the latter is more possible scenario than the former. Next, we treated HeLa cells with Trichostatin A (TSA, 5 μ M for 4hrs), which inhibits Histone Deacetylase6 (HDAC6). While acetylated microtubules are greatly increased and form solid structures, most of SUMOylated microtubules are fragmented and long cable-like networks disappeared. Taken together, our data shows that endogenous SUMO-2/3 modifies microtubule structure and this SUMOylation regulates the stability of microtubules. Further studies on the cross-talk of SUMOylation with other PTMs will provide insights into the regulatory mechanism of dynamics and stability of microtubule.

TLL6 Promotes Slow MT Growth at the Leading Edge of Polarized Endothelial Cells.

F. Buslig¹, K.A. Myers²;

¹Biological Sciences, University of the Sciences, Philadelphia, PA, ²Department of Biological Sciences, Misher College of Arts and Sciences, University of the Sciences, Philadelphia, PA

Angiogenesis is the formation of new vasculature from existing vasculature. During angiogenesis, endothelial cells migrate to specific locations to form new blood vessels. In order to migrate with directional specificity, endothelial cells (ECs) generate a polarized morphology by establishing a leading and trailing edge. EC polarization requires the coordinated re-organization of the microtubule (MT) array, a process that is accomplished through the careful regulation of MT dynamics by various families of MT associated proteins (MAPs). Mitotic Centromere Associated Kinesin (MCAK) is a MAP that binds to MT plus ends and induces MT disassembly. One method used by cells to control MCAK-mediated MT disassembly is through recruitment of MCAK to specific, post-translationally modified regions of the MT lattice. MCAK binding to MTs is promoted by tubulin tyrosination, while polyglutamylation of MTs inhibits MCAK association. Tubulin Tyrosine Ligase-Like 6 (TLL6) is an enzyme that functions to post-translationally glutamylate MTs; however, it is not known what effects TLL6-mediated glutamylation has on MT growth dynamics, or how TLL6-mediated glutamylation regulates MCAK-mediated MT disassembly. To investigate these questions, we performed high-resolution live-cell imaging of polarized, wound-edge Human Umbilical Vein Endothelial Cells (HUVECs) either expressing mApple-EB3 alone (Control) or co-expressing mApple-EB3 with TLL6 or MCAK. We analyzed MT growth speeds and growth lifetimes of whole cell, leading edge and trailing edge regions using an automated MatLab based MT tracking program. Our results show that TLL6 promoted slow MT growth speeds compared to Control cells or compared to cells expressing MCAK. Regional analysis of MT dynamics in the leading and trailing edges of wound-edge HUVECs revealed that MCAK expressing cells had significantly faster MT growth speeds specifically within the leading edge when compared to Control HUVECs. Additionally,

in TLL6 expressing HUVECs, leading edge MT growth speeds were significantly slower than trailing edge MT growth speeds, suggesting that TLL6 mediates differential regulation of MT growth dynamics at the leading and trailing edge of the cell. MCAK expression reversed this phenotype, by promoting fast MT growth within the leading edge of wound-edge HUVECs. Thus, MT glutamylation by TLL6 promotes slow and short-lived MT growth globally throughout the cell, while at the leading edge of the cell, TLL6 promotes the slowest MT growth speeds, and this effect can be reversed by MCAK overexpression. Together, these data suggest that TLL6 glutamylation may function to inhibit MCAK with regional specificity at the leading edge of wound-edge HUVECs.

Compliance Myosin-II-dependent ECM Mechanosensing Regulates Microtubule Dynamics Through a MCAK-Mediated Signaling Pathway.

L.C. D'Angelo¹, K.A. Myers²;

¹Biological Sciences, Univ of the Sciences in Philadelphia, Philadelphia, PA, ²Department of Biological Sciences, Misher College of Arts and Sciences, University of the Sciences, Philadelphia, PA

Directed cell migration relies on soluble guidance cues, as well as, the physical/mechanical attributes of the extracellular matrix (ECM). Transmission of ECM physical properties, compliance (softness) and dimensionality, to intracellular signaling events occurs largely through reorganization of the actin-myosin and microtubule (MT) cytoskeletons. Changes in MT dynamics are mediated in part by MT-associated proteins such as Mitotic Centromere Associated Kinesin (MCAK), a MT depolymerizer, and changes in myosin-II-dependent contractility via ECM mechanosensing. Here, we examined the effect of MCAK expression levels on MT growth speed and growth lifetime, and branching morphology in Human Umbilical Vein Endothelial Cells (HUVECs) cultured on stiff (55 kPa) and soft (0.7 kPa) collagen-coupled polyacrylamide ECMs. MT assembly dynamics were analyzed using high-resolution live-cell microscopy and MT plus end-end tracking software. Our data demonstrate that on stiff ECMs, MCAK expression results in slow, shorter-lived MT growth while on compliant ECMs, MCAK expression resulted in fast MT growth but had no effect on growth lifetime. On stiff ECMs, inhibition of myosin-II contractility with 20 μ M blebbistatin resulted in fast, shorter-lived MT growth, independent of MCAK expression. However, on compliant ECMs, myosin-II inhibition resulted in slow, shorter-lived MT growth only in MCAK-expressing HUVECs. These results suggest that the effects of MCAK on MT growth speed and growth lifetime are sensitive to myosin-II contractility specifically in response to ECM compliance mechanosensing. Regional analysis of MT dynamics revealed that growth speeds were similar in branched regions as compared to the whole cell, while growth lifetimes were significantly longer-lived within HUVEC branches. This effect was independent of ECM compliance or MCAK expression. Analysis of MT growth dynamics within branched regions revealed that myosin-II inhibition promoted fast MT growth only on stiff ECMs, but did not significantly affect MT growth lifetimes. Under conditions of myosin-II inhibition, MCAK expression significantly reduced MT growth speeds independent of stiffness, but reduced MT growth lifetimes only on stiff ECMs. Analysis of branching morphology revealed that

MCAK expression increased branch number on stiff substrates but reduced branch number on compliant ECMs, while MCAK expression in myosin-II inhibited cells resulted in reduced branch number on both stiff and compliant ECMs. These data suggest that, within HUVEC branches, myosin-II-dependent regulation of MT growth dynamics functions to promote slow MT growth through a MCAK-dependent pathway. However, when myosin-II is inhibited on compliant substrates, MT growth lifetimes become insensitive to MCAK-mediated regulation.

Hereditary Neuralgic Amyotrophy Mutations Alter the Microtubule Bundling Properties of Septin 9.

T. Knox¹, E.T. Spiliotis², X. Bai²;

¹Drexel University, Philadelphia, PA, ²Biology, Drexel University, Philadelphia, PA

Hereditary neuralgic amyotrophy (HNA) is a rare, autosomal dominant neuropathy that is characterized by sudden onset of severe pain in the shoulder girdle, together with arm and shoulder muscle degeneration (atrophy). To date, the only gene associated with HNA is septin9 (SEPT9). Missense mutations of SEPT9 (R88W and S93F) and partial duplication of SEPT9 sequence have been reported in HNA patients. Septins are oligomeric, GTP-binding proteins and SEPT9 was found to associate and bundle microtubules (MTs) and regulate asymmetric neurite growth. By incubating the SEPT9i3 or its mutants with pre-polymerized microtubules and sedimenting the complexes at 39,000xg (high speed pelleting) or 8,000xg (low speed pelleting), we tested the ability of the proteins to bind and bundle microtubules, respectively. The high speed pelleting assay shows that neither the missense mutations nor the partial duplication (aa19-233) of SEPT9i3 alter microtubule binding to SEPT9i3. The low speed pelleting assay suggests that R88W and S93F missense mutations significantly decrease microtubule bundling, relative to wild type levels. The SEPT9 and HNA associated mutations/microtubule relationship was also investigated with a visual assay. Rhodamine-MT was incubated with wild type SEPT9i3, SEPT9i3R88W, SEPT9i3S93F or SEPT9_i3(aa19-233). Wild type SEPT9i3 has been previously shown to induce bright and long MT bundles. SEPT9R88W/S93F show a decrease in length of MT bundles, and, alternatively, SEPT9i3(aa19-233) shows an increase in length of MT bundles relative to wild type SEPT9i3. Collectively, our data suggest that the HNA-associated mutations alter the MT bundling properties of SEPT9. On-going studies aim at determining the effects of HNA-linked SEPT9 mutants on neuronal morphogenesis and function.

P985**Board Number: B310****Tenovin-treated cells show defects in mitosis and cytokinesis and tubulin cytoskeleton abnormalities in interphase.**M. . Carmena¹, C. Breunig², O. Molina¹, I. van Leeuwen³, M. Ladds³, S. Lain³, W.C. Earnshaw¹;¹Wellcome Trust Centre for Cell Biology, The University of Edinburgh, Edinburgh, United Kingdom,²University of Bayreuth, Bayreuth, Germany, ³Karolinska Institutet, Stockholm, Sweden

Sirtuins (SirT) are NAD(+)-dependent acetyl-lysine deacetylases known to be involved in the control of cellular metabolism and maintenance of cellular homeostasis. Despite being classified as Class III histone acetyltransferases (HDACs) these enzymes act upon both histone and non-histone substrates. SirT1 was reported to regulate the transcriptional activity of p53, suggesting that Sirtuin inhibition could result in improved tumour suppression and leading to exploration of the therapeutic potential of Sirtuin inhibitors.

Tenovin 1, which was identified in a screen for small molecule activators of p53 is the founder member of the Tenovin family of Sirtuin inhibitors. Tenovin 6 (T6), a more potent, water-soluble analogue inhibits the activity of SirT1 and SirT2 *in vitro* (Lain et al, 1998). T6 reduces tumour growth *in vivo* (melanoma and neuroblastoma xenografts) and contributes to eliminate leukemic stem cells (Li et al 2012; Li et al., 2014). The Tenovin D3 derivative (TD3) shows higher specificity for SirT2 *in vitro* (McCarthy et al 2013).

We have determined the phenotypic consequences of inhibiting SirT1/SirT2 in human cultured cells (RPE-1 and HeLa) using T6 and TD3. Treatment of p53 defective cells with either compound does not lead to cell cycle arrest in interphase. Our studies revealed the presence of defects in both mitosis and cytokinesis in T6 and TD3-treated cells. The most common defect observed in treated cells was the presence of chromatin bridges in late mitosis and cytokinesis. We also detected misaligned chromosomes in prometaphase and lagging chromatids in anaphase at lower frequencies.

Although the actin cytoskeleton appeared normal in Tenovin-treated cells, we observed increased levels of acetylated tubulin (a SirT2 substrate) throughout mitosis, with levels particularly high at midbodies in cytokinesis. Interestingly, we found an increased frequency of binucleated cells in which nuclei remained connected by chromatin bridges. This phenotype was frequently accompanied by an abnormal accumulation of tubulin between the nuclei, consistent with an increased stability of the microtubules in this area. Drug-treated cells also showed elongated cytoplasmic extensions containing abnormal projections of acetylated tubulin.

Finally, we studied the effect of treatment with T6 and TD3 in the levels of Histone acetylation and we found that the levels of H3K9ac are significantly elevated in drug-treated cells compared to controls.

Our results shed new light on the phenotypic effects of Tenovin treatment in cell cycle progression and genomic stability in different cell lines.

A novel role for Drosophila KASH domain protein Klarsicht in microtubule stability during collective cell migration.

M. Myat¹, R. RN¹, D. Manna², N. Xu³, M.A. Welte²;

¹Biology Department, Medgar Evers College-CUNY, Brooklyn, NY, ²Dept. of Biology, University of Rochester, Rochester, NY, ³Natural Science Department, LaGuardia Community College, Long Island City, NY

During collective migration of the Drosophila embryonic salivary gland, cells rearrange to form a tube of a distinct shape and size. Here, we report a novel role for Drosophila KASH (Klarsicht-Anc-Syne-Homology) domain protein, Klarsicht (Klar), in the regulation of microtubule (MT) stability and integrin receptor localization during salivary gland migration. In wild-type salivary glands MTs become progressively stabilized as gland migration progressed. In klar mutant embryos, salivary gland cells failed to rearrange and migrate, and these defects were accompanied by decreased MT stability and altered integrin receptor localization. Overexpression of Spastin (Spas), a MT severing protein, in otherwise wild-type salivary glands disrupted cell rearrangement and integrin localization, like loss of klar. Promoting MT stability by reducing spas gene dosage in klar mutant embryos rescued the integrin localization, cell rearrangement and gland migration defects. Klar genetically interacts with the Rho1 small GTPase in salivary gland migration and is required for the subcellular localization of Rho1. We also show that Klar co-immunoprecipitates with tubulin from whole embryo lysates and binds tubulin directly in vitro. Our studies provide the first evidence for klar in regulation of the MT cytoskeleton and integrin localization during collective cell migration.

Intraflagellar transport (IFT), a bidirectional transport system between the ciliary base and tip, delivers ciliary precursors and turnover products for cilia assembly and maintenance as well as signaling molecules for signal transduction. The anterograde transport from the ciliary base to tip is powered by kinesin-II whereas the retrograde transport is driven by cytoplasmic dynein. The motors carries protein complexes called IFT particles comprising IFT-A and –B complexes that serves as cargo adaptors for ciliary components. IFT is regulated both at the ciliary base and ciliary tip. Kinesin-II is activated and carries IFT particles to enter the cilium at the ciliary base. At the ciliary tip, IFT particles are unloaded and kinesin-II is inactivated. However, the regulatory mechanism is unknown. We have found that CrCDPK1 phosphorylates kinesin-II motor subunit FLA8/KIF3B at the conserved residue S663 and regulates the activity of kinesin-II, and loading and unloading of IFT particles at the ciliary base and tip. We show that FLA8/KIF3B is a substrate of CrCDPK1, that IFT-B loading and kinesin-II/IFT ciliary entry require FLA8 dephosphorylation, and that FLA8 phosphorylation is needed for IFT-B unloading at the ciliary tip. Moreover, changes of the cellular level of phosphorylated FLA8 are associated with IFT entry rate during cilia assembly. These results suggest that phosphorylation of FLA8/KIF3B mediated by CrCDPK1 controls IFT entry and turnaround. .

How to specialize a cilium: MT glutamylation and tubulin composition regulate axonemal ultrastructure.

M.S. Silva¹, R. O'Hagan², K. Nguyen³, D.H. Hall³, M.M. Barr¹;

¹Rutgers University, Piscataway, NJ, ²Genetics, Rutgers University, Piscataway, NJ, ³Nruroscience, Albert Einstein College of Medicine, Bronx, NY

Cilia are morphology and functionally diverse microtubule (MT) based organelles that are vital for human development and health. To understand ciliary specialization, we compared two morphologically distinct cilia types in *C.elegans*: sinusoid shape cephalic male (CEM) and rod shaped amphid channel cilia. MT ultrastructure of CEM and amphid cilia was significantly different. The transition zone (TZ) consists of nine MT doublets, comprised of a 13-protofilament A-tubule and, 11-protofilament B-tubule,

anchored to the membrane by proteinaceous Y-links. TZ immediately give rise to the 'middle segment', in which nine MT doublets devoid Y-links. Middle segment give rise to the distal segment, which is comprised of MT singlets and projects to the tip of the cilium. These singlets are the A-tubules of the MT doublets. B-tubules in MT doublets abruptly stop at the end of the middle segment.

In contrast to the amphid cilium, the CEM cilium has a longer TZ and a shorter middle segment. Nine MT-doublets in the middle segment give rise to 18 MT-singlets, which arise via splitting and extension of both A- and B-tubules doublets at the end of middle segment. Similar MT-doublet splitting is observed in human spermatozoa¹. Some CEM distal MT singlets fuse at the distal ciliary tip, a feature that has been not described before.

We found that CEM axonemal ultrastructure is modulated MT post-translational modifications. CCPP-1 is a tubulin deglutamylase that is required for B-tubule stability². We found that the TTL-11 glutamylase antagonizes CCPP-1 function in CEM neurons. In a ttl-11 mutant background, distal B-tubules in the CEM cilia are stabilized as nine doublets. Combined, our results indicated that A-B tubule spans in CEM cilia are modulated by glutamylation state.

Alpha tubulin-6 (tba-6) is required to establish MT ultrastructure in CEM cilia. By serial section TEM analysis of tba-6 mutants, we found that B-tubules in MT doublets fail to extend as separate singlets and terminate at the end of the middle segment. A-tubule singlets appeared unaffected. These results suggest that A- and B-tubule singlets are of different tubulin composition, and that B-tubules require tba-6.

The Pleiotropic Phenotypes of a Chlamydomonas Mutant Defective in a Flagellar Nucleoside Diphosphate Kinase.

X. Zhu¹, R. Gopal², S.M. King³, P. Yang¹;

¹Department of Biological Sciences, Marquette University, Milwaukee, WI, ²Department of Cell and Molecular Biology, The Scripps Research Institute, La Jolla, CA, ³Department of Molecular, Microbial and Structural Biology, University of Connecticut Health Center, Farmington, CT

Large quantities of ATP and GTP are continually consumed in reactions central to various cilia and flagella functions, such as trafficking, tubulin turnover, signaling, protein folding and rhythmic beating. While mitochondria located near the flagella base could be the source of these nucleotides, flagella also harbor enzymes involved in NTP generation. To understand the metabolic schemes used to supply

these energy-requiring activities, we investigated a conserved nucleoside diphosphate kinase, NDK5, that is a constitutive subunit of the axonemal radial spoke complex in *Chlamydomonas* flagella. NDKs act to maintain the balance of nucleotide species by transferring γ -phosphate from copious NTP species to NDP of the scarcer ones. Curiously, while a mutant lacking the entire radial spoke has only paralyzed flagella, wild type transgenic strains expressing inactive NDK5_{H121A}-His that is incapable of phosphate transfer generate half-length, paralyzed flagella. A newly recovered *ndk5* mutant also generates paralyzed flagella, missing NDK5 and two additional radial spoke subunits - RSP1 in the head module and HSP40 that is thought to refold the head-neck region of the radial spoke precursor assembled in the cell body after it has been delivered to the flagellar tip. After deflagellation, the *ndk5* mutant regenerated shorter flagella and at a slower pace than the control. In minimal media lacking acetate that could be used for energy metabolism, flagellar length was dramatically reduced. Surprisingly, NDK5-deficient gametes also cannot mate. These data suggest that NDK5 is a critical member of an overlapping enzymatic network designed to couple nucleotide metabolism with radial spoke assembly and thus to meet the fluctuating energy demands of these complex organelles.

An assay for clogging the ciliary pore complex distinguishes mechanisms of cytosolic and membrane protein entry.

D. Takao¹, J.F. Dishinger¹, H.L. Kee¹, J.M. Pinsky¹, B.L. Allen¹, K.J. Verhey¹;

¹Department of Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI

As a cellular organelle, the cilium contains a unique protein composition. Entry of both membrane and cytosolic components is tightly regulated by gating mechanisms at the cilium base, however, the mechanistic details of ciliary gating are largely unknown. We previously proposed that entry of cytosolic components is regulated by mechanisms similar to those of nuclear transport and is dependent on nucleoporins (NUPs) which comprise a ciliary pore complex (CPC). To investigate ciliary gating mechanisms, we developed a system to clog the pore by inhibiting NUP function via forced dimerization. We targeted NUP62, a component of the central channel of the nuclear pore complex (NPC), for forced dimerization by tagging it with the homodimerizing Fv domain. As proof of principle, we show that forced dimerization of NUP62-Fv attenuated active transport of bovine serum albumin into the nuclear compartment and of the kinesin-2 motor KIF17 into the ciliary compartment. Using the pore clogging technique, we find that forced dimerization of NUP62 attenuated the gated entry of cytosolic proteins but did not affect entry of membrane proteins or diffusional entry of small cytosolic proteins. We propose a model in which active transport of cytosolic proteins into both nuclear and ciliary compartments requires functional NUPs of the central pore whereas lateral entry of membrane proteins utilizes a different mechanism that is likely specific to each organelle's limiting membrane.

P991**Board Number: B317****PI3K/Akt signaling regulates ciliogenesis initiation via Rab11-effector vesicular trafficking switch.**V. Walia¹, C. Insinna (Kettenhofen)¹, Q. Lu¹, S. Specht¹, C.J. Westlake²;¹LCDS, National Cancer Institute-Frederick, Frederick, MD, ²National Cancer Institute-Frederick, Frederick, MD

Defects in primary cilium formation and signaling are associated with a growing list of genetic diseases and have been linked to certain cancers. A critical step in the initiation of ciliogenesis requires pre-ciliary vesicle trafficking to the mother centriole. Previously, we showed that serum starvation induced rapid association of Rabin8, a Rab8 GEF, with Rab11 pre-ciliary vesicles, a step needed to initiate ciliogenesis. We hypothesized that pre-ciliary trafficking depends on growth factor signaling. To test this hypothesis, we screened growth factors in RPE cells cultured in serum-free condition and identified lysophosphatidic acid (LPA) and TGF- β as novel inhibitors of ciliogenesis. Interestingly, only LPA blocked Rabin8 pre-ciliary trafficking suggesting that LPA functions specifically at the ciliogenesis initiation step. We show that the LPAR1 receptor, but not LPAR2-5, functions in the inhibition of pre-ciliary trafficking and ciliogenesis. Using chemical inhibitors against LPAR1 downstream pathways, we determined that inhibition of PI3K/Akt signaling induced Rabin8 pre-ciliary trafficking and promoted ciliogenesis, whereas other LPAR1 signaling pathways (Ras, Rac, or PLC) had no effect. Inhibition of PI3K/Akt signaling also promotes ciliogenesis in other cell lines suggesting that this pathway is a global regulator of cilia formation. To understand how Akt regulates pre-ciliary trafficking, we examined Akt-phosphorylation on Rab11 and Rabin8. While Rabin8 was found to be an Akt substrate, there was no observed effect of this site on Rab11 binding or ciliogenesis. We next theorized that Akt-phosphorylation regulates Rab11-Rabin8 interaction indirectly via a Rab-effector switch. RNAi studies for Rab11-effectors demonstrated that WDR44/Rabphilin-11 ablation promotes Rabin8 centrosomal trafficking in the presence of serum. WDR44 is the first reported Rab11 effector but its function is not well understood. We mapped Akt sites on WDR44 within the Rab11 binding domain and showed that phosphorylation status of WDR44 coincided with Rab11-Rabin8 interaction upon serum starvation. Importantly, a phospho-mimetic WDR44 mutant showed stronger binding to Rab11 and inhibited ciliation upon serum starvation. Together these findings uncover a novel role for a growth factor signaling network mediated by Akt kinase and its downstream substrate, WDR44, in the regulation of pre-ciliary vesicle trafficking and ciliogenesis initiation.

P992**Board Number: B318****Cryo-electron tomography reveals the 3D structure of the ciliary tip.**A.L. Mleczak¹, P. Kiesel¹, J. Mahamid², O. Filina¹, L. Stepanek¹, G. Marini¹, G. Pigino¹;¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ²Max Planck Institute of Biochemistry, Martinsried, Germany

Eukaryotic cilia are microtubule-based organelles that allow cells to move and sense extracellular signals. The way the cell assembles the cilium and its complex axonemal structure is not completely understood. It is known that building blocks of the axoneme are transported by the intraflagellar transport trains at the tip of the cilium (1) where the assembly takes place (2). However, the mechanism and the molecular machinery that regulates this process are largely unknown. William Dentler and collaborators observed typical capping structures at the plus end of axonemal microtubules in a number of species (3). These structures might be involved in the regulation of axonemal assembly and disassembly.

Here we used cryo-electron tomography to reveal the 3D architecture of the ciliary tip in the free-living protozoan *Tetrahymena thermophila*. We confirm the presence of ciliary capping structures in membranated cilia that are preserved in a near-native, hydrated state, typical of the cryo-vitrification technique. Also, for the first time we show the 3D arrangement of these structures. A Central Microtubule Cap (CMC), which terminates the Central Pair of Microtubules (CP MTs) consists of two plugs inserted into the lumen of CP MTs, a density between the CP MTs, a plate located perpendicularly to CP MTs, and a bead at the very end of CMC. This globular structure is tightly connected to the ciliary membrane. Distal Filaments (DFs) are visible at the plus ends of A-tubules and also connect with the membrane. The B-tubules do not present any capping structure and terminate proximally to the A-tubules forming the Singlet Zone. Because most of the microtubule associated proteins are not present in the singlet zone, the axoneme at the tip shows much lower complexity than the main part of cilium. We are now using a computational method called sub-tomogram averaging to reconstruct high-resolution models of the microtubule capping structures of the ciliary tip.

The primary cilium is a membrane-bound, microtubule based sensory organelle that plays essential roles in development and disease pathways. Cilia biogenesis requires coordination of a series of processes including, mother centriole to basal body transformation, recruitment of intraflagellar transport (IFT) and transition zone (TZ) proteins, and axoneme formation and association with a developing ciliary membrane. Membrane association with the distal appendages of the mother centriole is a critical step in ciliogenesis initiation. The membrane trafficking Rab GTPase Rab11-Rab8 cascade plays key roles in early ciliary membrane assembly, but the molecular details remain unclear. Here, we show that the membrane shaping proteins EHD1 and EHD3, in association with the Rab11-Rab8 ciliogenesis cascade, function in cilia assembly in zebrafish and mammalian cells. We discovered that EHD proteins localize to Rab11 pre-ciliary vesicles that dock to the distal appendages of the mother centriole, membranes we refer to as distal appendage vesicles (DAV). Using live and super-resolution imaging, as well as electron microscopy approaches, we established that EHD proteins are essential for the formation of the larger pre-axonemal ciliary vesicle (CV) from DAVs. Furthermore, we show that EHD1-dependent CV formation is critical for initiating mother centriole to basal body transformation and recruitment of IFT20 and transition zone proteins. Surprisingly, we found that Rab8 is recruited for ciliary membrane growth only after these steps, and in coordination with axonemal assembly. Investigations into the molecular mechanism of these early ciliogenesis initiation steps suggested that EHD proteins tubulate DAVs, bringing them in close proximity to allow fusion into the CV. This step is required for CP110 removal from the distal end of the mother centriole prior to recruitment of IFT20 and TZ proteins. Based on these findings we predicted that SNAREs, regulators of membrane fusion, would be important for CV assembly and ciliogenesis progression. We show that the SNARE SNAP29, an EHD1 interacting protein, is required for ciliogenesis and localizes with EHD1/3 on early ciliary membrane structures. Together, our studies provide new molecular mechanisms informing the classically described intracellular ciliogenesis pathway and uncover a previously uncharacterized step in ciliary assembly.

P994**Board Number: B320****Actin is required for IFT regulation in *Chlamydomonas reinhardtii*.**P. Avasthi¹, M. Onishi², J. Karpiak³, R. Yamamoto⁴, L. Mackinder⁵, M.C. Jonikas⁵, W.S. Sale⁴, B. Marshall⁶;¹Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA, ²Genetics, Stanford Univ Med Ctr, Stanford, CA, ³Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, ⁴Department of Cell Biology, Emory University School of Medicine, Atlanta, GA, ⁵Plant Biology, Carnegie Institution for Science, Stanford, CA, ⁶Biochemistry and Biophysics Dept., University of California, San Francisco, San Francisco, CA

Assembly of cilia/flagella require the bidirectional transport of motors and cargo, termed intraflagellar transport (IFT). Recruitment of IFT machinery to the base of flagella is increased in shorter, rapidly assembling flagella and is reduced at the base of longer, slowly assembling flagella that are approaching their final steady state length. Disruption of the actin network has been shown to affect ciliary formation, length and number but the mechanisms are unknown. We utilized the green alga *Chlamydomonas reinhardtii* to investigate potential mechanisms by which actin might regulate cilia/flagella formation. In *Chlamydomonas*, actin is found in the inner dynein complexes within flagella as well as in the cell body. While, previous attempts to localize filamentous actin in vegetative cells have failed, we have localized filaments to both perinuclear and anterior regions using expression of a tagged filament binding peptide, Lifeact-Venus. We also show that actin disruption using small molecule inhibitors and a null actin mutant results in impaired flagellar regeneration, IFT injection and recruitment of IFT material to the flagellar base, with recruitment lacking the normal dependence on flagellar length. Each phenotype is recapitulated when using a myosin II inhibitor and we have modeled the potential binding of this inhibitor to a *Chlamydomonas* myosin. Mid-cell localization of a tagged version of this myosin is disrupted when flagellar regeneration is induced. Our data suggest actin and myosin are involved in establishing the length dependence of flagellar assembly via IFT regulation.

P995**Board Number: B321****Rsg1 Is Required for Normal Cilia Number, Limb Patterning, and Heart Development in the Mouse Embryo.**S.O. Agbu¹, K.V. Anderson¹;¹Developmental Biology Program, Sloan-Kettering Institute, New York, NY

We use forward genetic screens to uncover novel regulators of murine embryonic development. From a recent screen, we identified the *pixiebob* (*pxb*) mutant line based on abnormal limb development. This line carries a recessive mutation that results in lethality at embryonic day 12.5 (e12.5). Recombination mapping and deep sequencing showed that the *pixiebob* mutation is a thymine-to-adenine transversion in the *Rsg1* gene, which results in a valine-to-aspartic acid substitution. *Rsg1* is a member of the

Rem2/Rab family of small GTPases that was identified based on its interaction with Fuzzy, a protein required for cilia formation in vertebrates. Analysis of *Rsg1* morphants showed that it plays a role in the formation of motile cilia in the multiciliated cells of the *Xenopus laevis* epithelium, where it appears to facilitate the trafficking of proteins required for ciliogenesis. In mouse embryonic fibroblasts derived from *pxb* embryos, the number of cells with primary cilia is reduced to about 20% of wild-type levels. At e11.5, *pxb* embryos exhibit preaxial polydactyly and edema, which implies that the *pxb* mutation interferes with limb and heart development. An increase in *Gremlin1* and *Fgf8* expression is observed in *pxb* limbs by RNA in-situ hybridization, suggesting that the *pxb* mutation affects signaling pathways that are essential for anterior-posterior limb patterning. Primary cilia are important for Hedgehog signaling, and we find that Gli3, which negatively regulates *Gremlin1* and *Fgf8*, is reduced upon Western blot analysis in *pxb* embryos, consistent with a disruption in cilia-dependent Hedgehog signaling. Hematoxylin and eosin (H&E) staining of *pxb* heart tissue reveals a cardiac septal defect, which may be responsible for the embryonic lethality observed. Our studies will define the function for *Rsg1* in primary cilia formation and in mammalian embryonic development.

Motile cilia are whip-like projections that generate hydrodynamic force. Motile cilia function within ciliary arrays that contain hundreds of cilia positioned with a high degree of spatial organization. Ciliary arrays are required for symmetry breaking during embryogenesis, fluid flow within complex tissues and the directed movement of unicellular organisms. Cilia are nucleated by basal bodies, which are microtubule scaffolds that are rotationally polarized due to the asymmetric attachment of auxiliary structures. Since basal body polarity dictates the direction of ciliary beating, basal body polarity must be aligned along a common axis of cellular polarity to generate coherent cilia-generated fluid flow. However, the structures and molecules that align basal body polarity remain ill-defined. Here, we investigate the mechanisms that establish and maintain basal body polarity in the multi-ciliated unicellular organism *Tetrahymena*. We accomplish this by analyzing the classical mutant *disorganizedA* (*disa1*) that exhibits defective basal body organization and rotational polarity. Using next-generation sequencing, we show that *disa1* results from a single nucleotide substitution that causes a loss-of-function of a novel 31 kDa coiled-coil protein that we name Disa1p. Disa1p localizes to the proximal

portion of the anterior face of the basal body at an asymmetric structure called the kinetodesmal fiber (KF). KFs are an evolutionarily conserved class of striated fibers that attach asymmetrically to basal bodies and project in a planar fashion directly opposite the ciliary power stroke. We show that KFs are dynamic structures that elongate in response to increased cilia-generated force. In the absence of functional *Disa1p*, KFs are unable to elongate, causing severe KF truncation. KFs structurally oppose the ciliary power stroke and terminate adjacent to neighboring basal bodies. It has been proposed that KFs provide a physical linkage that maintains basal body polarity by stabilizing basal bodies against ciliary forces. We test this hypothesis using a variety of manipulations to modulate ciliary force in *disa1* cells. We demonstrate that short KFs allow basal bodies to rotate at the cell cortex in response to increased ciliary forces, which randomizes KF orientation relative to cellular polarity. Conversely, randomization of basal body polarity is rescued by reducing ciliary force. Finally, we show that nascent basal bodies traverse the KF as they migrate towards their eventual position at the cell cortex. Therefore, the truncated and misoriented KFs that result from *Disa1p* mutation propagate basal body disorganization, demonstrating that *Disa1* is a genic input into the structural inheritance of basal body polarity and organization in *Tetrahymena*.

The uncovering of three new *Chlamydomonas* deflagellation genes and the identification of ADF1.

F. Meili¹, P. Buckoll¹, L. Hilton¹, J. Kirschner¹, J. Rodriguez¹, C. Choutka¹, L.M. Quarmby¹;

¹Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC

The two flagella of *Chlamydomonas reinhardtii* are shed upon exposure to cellular stresses, such as pH shock. In response to intracellular acidification, a Ca²⁺-influx occurs that ultimately activates severing of the axonemal microtubules at a site distal to the flagellar transition zone. Our previous screen for deflagellation-defective mutants produced multiple alleles of FA1 and FA2, which are defective in axonemal severing, and multiple alleles of ADF1, which are defective in acid-induced Ca²⁺-influx. Both FA1 and FA2 were successfully cloned and encode a scaffolding protein and a NIMA-related kinase, respectively, but the identity of ADF1 was elusive, until now. Additionally, several predicted players in the deflagellation pathway were not uncovered in the original screen. We expected, but did not find fa mutants defective in a Ca²⁺-sensor or in a microtubule severing protein. Armed with advances in whole genome sequencing (WGS) and strategies to rapidly identify point mutants, we undertook a new screen of UV-mutagenized cells. We recovered 29 new mutant strains, including two new alleles of FA1, four new alleles of FA2, fourteen new alleles of ADF1, and alleles of three new deflagellation genes, including two temperature-sensitive alleles of FA3, one (ts) allele of ADF2, one allele of ADF3 and one allele of ADF4, which exhibits a novel gamete-specific deflagellation-defective phenotype. We had previously mapped ADF1 to a 450 kb region of chromosome 9, and WGS of three new alleles and one of the original alleles of ADF1 revealed that all four mutant alleles carry mutations in a TRP channel that lies at the heart of our mapped region, consistent with our prediction of a calcium-permeant channel in the

acid deflagellation pathway. We have rescued the phenotype and identify TRP15 as the channel that mediates calcium influx in response to intracellular acidification.

A Genetic Screen for Molecules that Regulate Axoneme Stability in Response to Post-Translational Microtubule Glutamylation.

R. O'Hagan¹, S. Bellotti¹, M. Morash¹, W. Zhang¹, M.M. Barr²;

¹Genetics, Rutgers University, Piscataway, NJ, ²Rutgers University, Piscataway, NJ

When polymerized into microtubules (MTs), tubulins accumulate post-translational modifications (PTMs) such as polyglutamylation. PTMs have been proposed to act as signposts that regulate MT stability and the activities of other proteins that bind MTs, such as kinesin and dynein motors. The MTs that form ciliary axonemes are especially prone to post-translational modification, but the roles that MT PTMs play in cilia are largely unknown.

The enzymes that regulate post-translational glutamylation of tubulins profoundly affect cilia structure in *C. elegans* sensory neurons. Loss of CCPP-1, a homolog of murine Ccp1, which deglutamylates MTs, causes the progressive degeneration of amphid neuronal cilia. However, ciliary degeneration in *ccpp-1* mutants can be suppressed by deletion of *ttll-4*, *ttll-5*, or *ttll-11*, which encode glutamylases that add glutamylation to MTs. These data suggest that excess MT glutamylation destabilizes ciliary MTs, leading to ciliary degeneration.

To understand the mechanism by which MT glutamylation regulates ciliary MT stability, we performed a forward genetic screen for suppressors of *ccpp-1*-induced amphid degeneration. To visualize intact versus degenerate cilia, we soaked animals in a fluorescent dye that is absorbed through cilia and illuminates intact amphid cilia. In *ccpp-1* mutants, the ciliary degeneration of amphid neurons is usually complete by adulthood, such that adults fail to take up the dye and appear completely "dark." Therefore, we searched for suppressor mutations by dye-filling the adult F2 progeny of mutagenized *ccpp-1* animals and looking for animals with amphids that were illuminated by the dye.

We isolated fifteen suppressor mutants, including some that fail to complement *ttll-4*, *ttll-5*, and *ttll-11* mutations. We hope that our suppressor alleles will illuminate pathways by which post-translational glutamylation regulates MT structure and function.

P999**Board Number: B325****HDAC2 mediates loss of primary cilia in pancreatic ductal adenocarcinoma cells.**T. Kobayashi^{1,2}, K. Nakazono¹, M. Tokuda¹, B.D. Dynlacht², H. Itoh^{1,2};¹Nara Institute of Science and Technology, Ikoma, Japan, ²School of Medicine, New York University, New York, NY

Primary cilium functions as a cellular antenna to sense extracellular environment and transduces signals to the cell. Loss of primary cilia is frequently observed in tumor cells, including pancreatic ductal adenocarcinoma (PDAC) cells, suggesting that the absence of this organelle may promote tumorigenesis through aberrant signal transduction and the inability to exit the cell cycle. However, the molecular mechanisms that explain how PDAC cells lose primary cilia remain unknown. We found that treatment with several histone deacetylase (HDAC) inhibitors restores primary cilia in PDAC cells. We next performed knock-down experiments using siRNAs and observed that silencing of HDAC2, a known transcriptional regulator, induces primary cilia formation. On the other hand, inhibition or depletion of HDAC6, which was previously reported to be required for cilia resorption, had no effect on the number of primary cilia. These data suggest that HDAC2 specifically suppresses primary cilia formation in PDAC cells. The mechanistic and practical implications of these studies will be discussed.

Sensory and Signaling Functions of Cilia**P1000****Board Number: B326****Ciliary membrane protein trafficking in *Chlamydomonas* is uni-directional and depends on cytoplasmic retrograde IFT motor activity and shedding of ciliary ectosomes.**J. Ning¹, M. Cao¹, C. Hernandez-Lara¹, O. Belzile¹, Q. Wang¹, Y. Liu¹, W.J. Snell¹;¹Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX

The role of the primary cilium in key signaling pathways depends on dynamic regulation of ciliary membrane protein composition, yet we know little about the motors or membrane events that regulate ciliary membrane protein trafficking in fully formed organelles. Previously we showed that cilium-generated signaling during ciliary adhesion between plus and minus gametes of *Chlamydomonas* induced rapid, cytoplasmic microtubule-dependent redistribution of the membrane polypeptide, SAG1-C65, from the plasma membrane to the periciliary region and the ciliary membrane, and that protein redistribution depended on cytoplasmic microtubules. Here, we report that the retrograde IFT motor, cytoplasmic dynein 1b, is required in the cytoplasm for this rapid redistribution. Furthermore, we find that trafficking of SAG1-C65 into cilia is unidirectional. During adhesion and signaling, SAG1-C65-HA is depleted from cells and released into the medium as ciliary ectosomes. Shedding of SAG1-C65 is the

major fate of the protein and the entire complement of pre-existing cellular SAG1-C65 is shed during sustained adhesion/signaling in the form of a distinct ciliary ectosome membrane compartment that retains signal-inducing activity. Thus, during ciliary signaling, ciliary trafficking of a membrane protein is uni-directional and cells regulate ciliary membrane protein composition through cytoplasmic action of the retrograde IFT motor and shedding of ciliary ectosomes. Supported by NIH GM25661.

The Intraflagellar Transport Protein IFT27/RABL4 Promotes BBSome Exit from Cilia through the GTPase ARL6/BBS3.

G.M. Liew¹, F. Ye¹, A.R. Nager¹, J.P. Murphy², J.S. Lee¹, M. Aguiar², D.K. Breslow¹, S.P. Gygi², M.V. Nachury¹;

¹Dept. of Molecular and Cellular Physiology, Stanford University School of Medicine, Stanford, CA,

²Department of Cell Biology, Harvard Medical School, Boston, MA

The sorting of signaling receptors into and out of cilia relies on the BBSome, a complex of Bardet-Biedl syndrome (BBS) proteins, and on the intraflagellar transport (IFT) machinery. GTP loading onto the Arf-like GTPase ARL6/BBS3 drives assembly of a membrane-apposed BBSome coat that promotes cargo entry into cilia, yet how and where ARL6 is activated remains elusive. Here, we show that the Rab-like GTPase IFT27/RABL4, a known component of IFT complex B, promotes the exit of BBSome and associated cargoes from cilia. Unbiased proteomics and biochemical reconstitution assays show that, upon disengagement from the rest of IFT-B, IFT27 directly interacts with the nucleotide-free form of ARL6. Furthermore, IFT27 prevents aggregation of nucleotide-free ARL6 in solution. Thus, we propose that IFT27 separates from IFT-B inside cilia to promote ARL6 activation, BBSome coat assembly and subsequent ciliary exit, mirroring the process by which BBSome mediates cargo entry into cilia.

During the past decade, many studies shed light on cilia as sensory and motile organelles which play major roles in vertebrate development. Indeed, defects in cilia formation lead to a wide range of

structural birth defects. To build all mammalian cilia, the intraflagellar transport (IFT) machinery is required. Proteins of both retrograde and anterograde IFT complexes are highly conserved across ciliated species from *Chlamydomonas* to human. However, two proteins of the core IFT complex B - IFT25 and IFT27 - are absent from certain ciliated organisms like *Caenorhabditis* and *Drosophila* suggesting that they may have a unique role distinct from ciliogenesis. To get better insight in their role in mammal development, we generated *Ift25* and *Ift27* null mice. Mutant mice die at birth with major developmental defects indicative of Hedgehog signaling dysfunction. Since Hedgehog signaling occurs within cilia in mammals, we looked for cilia dysfunction at the cellular level and show that mutant cells are able to grow cilia. However, cilia lacking IFT25/27 have defects in the signal-dependent transport of multiple Hedgehog components resulting in the accumulation of patched-1 and smoothed. Similarly smoothed accumulates in cilia on cells mutated for BBSome components or the BBS binding protein/regulator *Lztf1*. Interestingly, the BBSome and *Lztf1* accumulate to high levels in *Ift27* mutant cilia as well. Since *Lztf1* mutant cells accumulate BBSome but not IFT27 it is likely that *Lztf1* functions downstream of IFT27 to couple the BBSome to the IFT particle for coordinated removal of patched-1 and smoothed from cilia during hedgehog signaling.

The signaling scaffold protein Parafusin localizes to both cilia and the nucleus.

B. Satir¹, E. Wyroba², L. Liu¹, M. Lethan¹, P. Satir¹, S. Christensen³;

¹Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ²Nencki Institute of Experimental Biology, Warsaw, Poland, ³Biology, Univ Copenhagen, Copenhagen, Denmark

Signaling scaffold proteins could play a role in eukaryotic cell evolution. One of these proteins is parafusin (PFUS), a component of dense core secretory vesicle (DSCV) scaffolds in apicomplexan exocytosis. PFUS, a 63 kDa cytoplasmic protein, first discovered in the unicellular eukaryote *Paramecium* is closely related to eubacterial rather than archeal phosphoglucomutases (PGM) but has no PGM activity. A PFUS specific peptide antibody was made to an amino acid sequence not present in PGM. Immunofluorescence microscopy with this antibody showed that PFUS was localized around the base of the primary cilia in a variety of mammalian cultured cells, including mouse embryonic (MEFs) and human foreskin fibroblasts (hFFs), human carcinoma stem cells (NT-2 cells), and human retinal pigment epithelial (RPE) cells. PFUS also localized to the nucleus of fibroblasts, and particularly to nucleoli of MEFs. Localization studies were confirmed by Western blot analysis, showing that the antibody specifically recognized PFUS in both MEF cytoplasmic and nuclear fractions and that the single 63kDa band in the blots disappeared when the fractions were treated with blocking peptide. Finally, immunofluorescence microscopy showed that PFUS localized to nuclei and cilia as well as DSCVs in *Paramecium*. These results support the possibility that PFUS could traffic between nucleus and cilia, as is true for many molecules involved in signaling pathways. It seems likely that the cilium and the nucleus both evolved around the time of eukaryotic emergence. We hypothesize that near the beginnings of eukaryotic cell evolution, scaffold proteins such as PFUS arose as peripheral membrane protein

identifiers and signaling molecules for cytoplasmic membrane trafficking and were employed similarly during the subsequent evolution of exocytic, nuclear transport, and ciliogenic mechanisms.

Superresolution Pattern Recognition Reveals an Architectural Map of the Ciliary Transition Zone.

T. Yang¹, J. Su², W. Wang³, A. Suresh¹, M. Tsou^{3,4}, J. Liao¹;

¹Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, Taiwan, ²Department of Biomedical Engineering, Johns Hopkins University, Baltimore, MD, ³Cell Biology Program, Memorial Sloan Kettering Cancer Center, New York, NY, ⁴Weill Cornell Graduate School of Medical Sciences, Cornell University, New York, NY

The ciliary transition zone (TZ), which is part of the gating apparatus at the ciliary base, is home to a large number of ciliopathy molecules. The architecture of the TZ, however, is poorly understood, hindering mechanistic understanding of its role as a diffusion barrier. Taking advantage of special patterns resulting from convolution of the slender point spread function (PSF) of stimulated emission depletion (STED) superresolution microscopy and ring-shaped protein distributions, we were able to reveal differential localization of TZ proteins. Using a series of these STED images mapped to electron microscopy (EM) images, we defined novel geometric distributions of TCTN2, TMEM67, MKS1, and RPGRIP1L from the ciliary membrane to the axoneme at the same axial level. CEP290 is surprisingly localized at a different axial level toward the proximal side of the TZ. Upon this molecular architecture, two reservoirs of intraflagellar transport (IFT) particles, correlating with phases of ciliary growth, are present: one colocalized with the transition fibers while the other situated beyond the distal edge of the TZ. Taken together, we have pushed the limit of subdiffraction imaging to localize multiple key proteins at the ciliary base, revealing an unprecedented structural framework and transport variations upon this framework.

Primary cilia's role in cellular gravitransduction.

M. Aydogan¹, J. Wetzsteon¹, D. Klaus², J. Marcus¹, A. Hoenger¹;

¹Department of Molecular, Cellular, and Developmental Biology, University of Colorado, Boulder, CO,

²Department of Aerospace Engineering Sciences, University of Colorado, Boulder, CO

Gravity is one of the most fundamental forces which organisms have to cope with on Earth, and inducing changes in the magnitude of this force leads to various cellular responses including cell proliferation, migration, and differentiation. Although little is known about how cells perceive gravitational acceleration and trigger biochemical alterations upon changes in gravity force, hypotheses include

primary cilia, non-motile cellular antennae, acting as gravity transducers due to their ability to sense various mechanical stimuli. However, strong empirical evidence to support this idea has not been established yet. In our study, we show that primary cilia in MC3T3-E1 osteoblast cells are required for the mechanotransduction of hyper-acceleration stimulus into proliferative responses. We also report that the translation of hyper-acceleration into cellular response, through primary cilia, involves regulating beta-catenin levels and contact inhibition of cell growth. Our results demonstrate that primary cilia in MC3T3-E1 cells have a role in mediating cellular gravitansduction. The existence of such cellular transduction element suggests that the gravity force, though nearly constant on Earth, might be a regulatory factor for cell fate determination. Furthermore, we expect our study to be a beginning for more sophisticated research investigating the mechanisms with which organisms perceive gravitational acceleration. This might lead to a better understanding of bone disorders, e.g. bone loss, particularly in the context of space research and medicine.

Tuning cellular mechanosensitivity: Mechanical and chemical modulation of primary cilia bending.

A.M. Nguyen¹, C.R. Jacobs¹;

¹Biomedical Engineering, Columbia University, New York, NY

The primary cilium is a solitary, nonmotile microtubule-based protrusion found on nearly every cell in the human body and has been established as a mechanosensor across several tissues. Several groups have reported cilia length adapts in response to mechanical stimuli while other groups have reported relatively small changes in length can affect cilia deflection and downstream load-induced changes in gene and protein expression. Collectively, this suggests cilia mechanosensitivity may be modulated. Our lab has shown that when a cilium is exposed to fluid flow and flow is stopped, the cilium often does not return to its original position. We hypothesized that exposure to flow increases the cilium's bending stiffness. Mouse inner medullary collecting duct cells transfected with somatostatin 3 receptor fused to GFP were exposed to a wall shear stress of 0.25 Pa for two periods of flow separated by a rest period. Cilia bending behavior was captured with a confocal microscope and modeled as a beam anchored by a torsional spring. We found a significant increase in bending stiffness along the ciliary axoneme and torsional stiffness at the base before and after the rest period, an increase of 2.2 ± 0.4 and 4.0 ± 0.8 fold ($n=12$), respectively. We hypothesized that this stiffening may be mimicked by altering tubulin. Acetylation and other post-translational modifications of tubulin have previously been shown to increase microtubule stiffness and interestingly, microtubule acetylation increases with load. To increase acetylation, we inhibited deacetylation with two different methods: tubacin, a chemical inhibitor of microtubule-associated histone deacetylase 6 (HDAC6), and HDAC6 siRNA. We found a similar stiffening effect in cilium bending, a 4.0 ± 1.3 fold increase with tubacin and a 2.7 ± 0.9 fold increase with HDAC6 knockdown ($n=5$ /group), and hypothesized that the stiffening of the cilium would lead to decreased mechanosensitivity. We exposed cells to oscillatory fluid flow (1 hr, 1 Pa peak shear

stress) and measured gene expression. We confirmed downregulation of HDAC6 (30.5±8.9% decrease in HDAC6/GAPDH expression, n=10/group) and increased acetylation (marked increase in acetylated α tubulin staining). This increase in acetylation inhibited flow-induced increases in cyclooxygenase-2/GAPDH expression by 55.9±16.3% (n=5/group). Using a transgenic mouse expressing GFP in primary cilia, allowing cilia to be easily visualized *in situ*, we measured *in vivo* primary cilia bending in the kidney proximal tubules of a live mouse and validated previous *in vitro* measurements made by our lab and others. Taken together, our data demonstrate that the cilia bending response may be modulated by both mechanical and chemical stimuli and is coupled to cellular mechanosensitivity.

Polycystins have discrete patterns of expression in Hydra and may regulate Hydra behaviors.

S. McLaughlin¹;

¹Biological Sciences and Geology, Queensborough Community Coll, Bayside, NY

The cnidarian *Hydra* is one of the most primitive metazoans with a nervous system, but nevertheless displays complex behaviors, including cnidocyte (stinging cell) release and a stereotypical set of movements during its feeding response. Chemical, mechanical and photo stimuli have been shown to affect these behaviors, but the molecular mechanisms regulating these activities are still poorly understood. The purpose of this study is to determine if TRP (transient receptor potential) channels are expressed in hydra, and if they play a role in hydra behaviors.

TRP channels are a diverse superfamily of nonselective cation channels that function as polymodal cell sensors. A search of the hydra genome revealed the presence of multiple TRP subclasses, including several members of the TRP polycystin 2 (PC2) subfamily. Several potential polycystin 1 (PC1) homologs were also identified in the hydra genome. PC1 proteins are not TRP channels, but are known to interact with PC2 proteins; it has been proposed that the PC1 protein responds to a signal (chemical or mechanical) through its extracellular N terminus, and in turn gates its associated PC2 protein.

Whole mount *in situ* hybridizations revealed that three polycystin genes exhibit specific patterns of expression in hydra. H6908 (PC2) and H5453 (PC1) are strongly expressed in the tentacles (where most mature cnidocytes are located) and the basal disc. H3133 (PC2) is expressed in cells immediately surrounding the mouth, as well as in discrete patches of cells in the hydra body. To assess the possible role of these hydra polycystins, non-specific chemical inhibitors of PC2 channels were used in prey capture and mouth opening assays. The inhibitors reduced the ability of hydra to capture prey and also reduced mouth opening in response to glutathione (a known mouth-opening stimulus).

Examining the role of polycystins in hydra will lead to a further understanding of how signal transduction in single cells can lead to the development and evolution of complex behaviors. In addition, studying

polycystins in hydra can further our understanding of the function of these proteins in more complex organisms.

The Biogenesis Of Lysosome-Related Organelles Complex-1 (BLOC-1) Subunit Pallidin And The Exocyst Subunit Exo70 Are Involved In Membrane Protein Trafficking To The Primary Cilium.

W.J. Monis¹, G.J. Pazour²;

¹Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA,

²Molecular Medicine, Univ Massachusetts Medical School, Worcester, MA

Most vertebrate cell types possess a single non-motile primary cilium on their cell surface. This organelle is thought to perceive the extracellular environment through the utilization of signaling receptors localized in the ciliary membrane and communicate these signals to the cell body. Currently, little is known on how these signaling receptors are targeted to this organelle. Primary cilia are assembled and maintained by the process of intraflagellar transport (IFT). This system is dependent on two protein complexes: IFT complex A and B. The complex B subunit IFT20 is the only IFT protein known to localize at both the primary cilium and Golgi apparatus. Previously we showed that IFT20 interacts with the golgin GMAP210. Furthermore, knockdown of IFT20 or knock out of GMAP210 results in reduced steady state levels of the membrane protein polycystin-2 in primary cilia. This has led to the proposal that both IFT20 and GMAP210 are important for sorting and/or transport of ciliary membrane proteins. However, the step(s) at which they function remains to be defined. Published large-scale yeast-two hybrid screens have identified new potential IFT20-interacting proteins. Two proteins of interest include the biogenesis of lysosome-related organelles complex-1 (BLOC-1) subunit pallidin and the exocyst subunit Exo70. We find that both pallidin and Exo70 co-immunoprecipitate with IFT20. Additionally, overexpression of either pallidin or Exo70 in IMCD cells displaces IFT20 from the Golgi apparatus. This evidence suggests that pallidin and Exo70 interact with IFT20. To further understand the role of IFT20 in trafficking ciliary membrane proteins, we developed a quantitative fluorescence-based pulse-chase assay to measure the time that it takes for membrane proteins to exit the Golgi apparatus and be delivered to the cilium. The shRNA knockdown of IFT20 or GMAP210 significantly decreases the rate of fibrocystin and polycystin-2 delivery to the cilium while the delivery rate of Smoothed is only modestly affected. The shRNA knockdown of Exo70 significantly decreases the rate of fibrocystin and polycystin-2 delivery to the cilium while the delivery rate of Smoothed is not affected. Lastly, the shRNA knockdown of pallidin significantly decreases the rate of polycystin-2 trafficking to the primary cilium. Ongoing research is focused on determining the mechanistic role of IFT20 and binding partners such as pallidin and Exo70 in ciliary membrane protein trafficking.

P1009**Board Number: B335****Role of the G-protein-coupled receptor, Gpr161, in vertebrate hedgehog signaling.**

K. Pal¹, S. Hwang¹, H. Badgandi¹, N.D. Somatilaka², P.K. Jackson³, K. De-Fea⁴, S. Mukhopadhyay¹;
¹Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX, ²University of Texas Southwestern Medical Center, Dallas, TX, ³Department Microbiology and Immunology, Stanford University School of Medicine, Stanford, CA, ⁴Cell Molecular Developmental Biology Program, UC Riverside, Riverside, CA

Long ignored as vestigial, primary cilia have now been established as sensory antennae in most vertebrate cells. Although, mechanisms driving formation of cilia have been extensively studied, the principles underlying signaling are largely unknown. The primary cilium is fundamentally important during developmental sonic hedgehog (Shh) signaling in vertebrates by acting as a compartment for dynamic localization of pathway components, and finally, regulating the bifunctional Gli transcription factors. The cAMP activated protein kinase A (PKA) triggers partial proteolytic processing that generates Gli repressors in a cilia-dependent manner; however, pathways that promote PKA activation, and the exact function of cilia is unclear. We previously showed that the tubby family proteins Tulp3 and Tubby, serve as an anchor between ciliary IFT-A complex and phosphatidylinositol 4,5-bisphosphate-rich membrane compartment in gating GPCRs to the cilia (Genes & Dev. 2010. 24: 2180-2193). We have recently identified an orphan ciliary GPCR, Gpr161 that acts as a negative regulator of Shh signaling during neural tube development by mediating the generation of Gli repressor via cAMP signaling. Active Shh signaling also results in removal of this receptor from the primary cilia (Cell 2013. 152: 210-223). Thus, Gpr161 is a candidate GPCR for activating PKA by generating a ciliary cAMP gradient, while also being regulated by Shh signaling in a positive feedback circuit. We are currently utilizing proteomic, cell biological and reverse genetic approaches to study distinct aspects of Gpr161 function, such as signaling, ciliary localization, and removal from cilia, and mechanistically investigating signaling in the context of intact cilia by uncoupling these functions. Dissecting mechanisms governing the regulation and signaling of Gpr161 in both cellular and organismal contexts, and extending these emerging principles to ciliary signaling, will reveal important insights into the role of cilia as signaling compartments.

P1010**Board Number: B336****EFHC1/Myoclonin regulates Wnt signaling, gene expression, cilia formation and neural plate and neural crest behavior in Xenopus.**

Y. Zhao¹, J. Shi¹, M. Klymkowsky*¹, M. Winey*¹;
¹MCDB, University of Colorado-Boulder, Boulder, CO

Eukaryotic cilia are complex cellular structures known to be involved in a range of functions including fluid flow generation, cellular organization and signaling transduction during development. EFHC1 is a conserved ciliary component, with three conserved "DM10" domains, of unknown function and two

adjacent EF-hand, putative Ca²⁺ binding motifs in its C-terminal domain. Homologs have been identified in *Chlamydomonas*, *Tetrahymena*, and throughout vertebrates. Mutations in *EFHC1/Myoclonin* cause a dominant form of Juvenile Myoclonic Epilepsy (JME) in humans. Despite some description of EFHC1 expression, localization, and interactions, the exact cellular functions of the EFHC1 protein and why when it is defective it gives rise to the JME phenotype remain obscure. Here we used the ciliate *Tetrahymena* and clawed frog *Xenopus laevis* to explore the cellular and developmental functions of EFHC1. Unlike *Tetrahymena* and mammals that have two EFHC-like proteins, there appears to be only one EFHC1 gene in *X. laevis*. *X.l.*EFHC1 RNA is supplied maternally and increases dramatically at the onset of gastrulation. *In situ* hybridization analysis reveals EFHC1 expression in the multiciliated cells of the epidermis and later in the developing central nervous system, the eye, the otic vesicle, and the neural crest. The morpholino-mediated down regulation of EFHC1 in *Xenopus* embryos produces defects in ciliated cell and cilia formation, the patterning of the neural plate and the formation and migration of the neural crest. These effects can be rescued by an EFHC1-GFP chimera that localizes to the axonemal region of cilia in multiciliated epidermal cells. The *Tetrahymena* proteins exhibit similar localization and deletion of either gene produces little phenotype. A double mutant strain is being constructed. Reduction of *Xenopus* EFHC1 leads to a Wnt-mediated feed forward loop that up-regulates Wnt8 RNA and down-regulations in *Tubb2b* (neuro-tubulin) RNA. Many but not all EFHC1 morphant phenotypes are rescued by blocking Wnt signaling using injection of SFRP2 RNA. Mutational studies indicate that the N-terminal domain and the first DM10 domain are required for full phenotypic rescue. The same domains of the *Tetrahymena* protein are required for axoneme and basal body localization. Finally, *X.l.*EFHC1 over-expression induces the ectopic expression of the bHLH transcription factor Twist1. Together, these observations identify a previously unsuspected role of EFHC1 in the regulation of Wnt signaling, and suggest that ciliary function and Wnt/Twist1 gene expression might be relevant to the etiology of JME.

Canonical Wnt signaling pathway regulates not only the odontoblast differentiation through primary cilia but also formation of primary cilia.

K. Kawata¹, K. Narita¹, S. Takeda¹;

¹Department of Anatomy and Cell Biology, Univ. of Yamanashi Interdisciplinary Graduate School of Medicine and Engineering, Yamanashi, Japan

Despite the facts that primary cilium appear ubiquitously in human body, very little is known about its physiological functions. Odontoblasts, which serve for dentin formation, also possess the primary cilia *in situ*. However, their physiological functions remain to be investigated.

To examine the roles of primary cilium in odontoblasts, we employed RNAi strategy to knockdown *Intraflagellar transport protein-88 (Ift88)*, which is required for the ciliogenesis in most of the quiescent cells, on cultured odontoblastic KN-3 cells. As a result, the ratio of cells positive for cilia has been decreased. Under this condition, KN-3 cells showed significantly retarded deposition of minerals on the

substrate of culture well. On the contrary, the production of dentin sialophosphoprotein (DSPP), a molecular marker of odontoblast differentiation, was promoted. Since *Ift88* knockdown resulted in increased accumulation of β -catenin, we considered that IFT88 modulates the odontoblastic differentiation through canonical Wnt signaling pathway. In order to test this hypothesis, we stimulate the canonical Wnt signaling pathway by recombinant Wnt3a, a representative agonist for canonical Wnt signaling pathway, or SB216763, glycogen synthase kinase-3 β inhibitor. Both treatments increased DSPP production and suppressed alkaline phosphatase (ALP) activity, the phenomena recapitulating the effects of IFT88 suppression on KN-3 cells. Moreover, ALP activity was gradually increased by progression of ciliogenesis in primary cultured dental pulp cells (DPCs), the results mimicking those observed in KN-3 cells treated with shRNA *Ift88*. Under this condition, the temporal pattern of DSPP expression took after that of IFT expression in DPCs. However, this result did not coincide with that of *Ift88* knockdown in KN-3 cells. In addition, inhibition of ciliogenesis was also observed through activation of canonical Wnt signaling pathway. Moreover, in DPCs, the accumulation of β -catenin gradually decreased with the progression of odontoblast differentiation. In contrast, the ratio of cilia-positive cells was increased.

These results collectively underscore the regulatory mechanism of canonical Wnt signaling pathway for the ALP activity through primary cilia, although it did not participate to DSPP expression level regulated through IFT88. Furthermore, our study also provides supportive evidence that canonical Wnt signaling pathway play an important role in ciliogenesis.

Single-molecule tracking of Smoothed reveals binding in the primary cilium that is altered by pathway agonists.

L.E. Weiss¹, L. Milenkovic², J. Yoon¹, S.J. Sahl¹, M.P. Scott², W.E. Moerner¹;

¹Chemistry, Stanford University, Stanford, CA, ²Developmental Biology, Stanford University, Stanford, CA

Hedgehog (Hh) signaling plays an essential role in cell division and differentiation in embryonic and adult stem cells. Disruption of the pathway can often lead to fatal defects in embryos, as well as a wide variety of cancer types later in life. The pathway is initially switched on by the binding of the Hh ligand to the transmembrane protein Patched. Shortly after, another transmembrane protein, Smoothed (Smo), is derepressed and relocates to a small microtubule-structured organelle that protrudes from the cell's surface called the primary cilium. Once there, it influences members of the Gli family of transcription factors that then upregulate target genes in the nucleus. Although the ciliary structure is known to be very complex, standard fluorescence microscopy measurements have been hindered by the small dimensions (~400 nanometers in diameter and 2-5 microns long) which are on the order of the diffraction limit. To overcome this barrier, we have used highly sensitive, single-molecule microscopy to obtain the trajectories of individual Smo proteins on the surface of cilia with high temporal and spatial resolution (10 millisecond and 30 nanometers, respectively). By analyzing their movements, we have

observed three distinctive modes of motion: diffusion, directed motion, and binding, the last of which is altered in the presence of natural and synthetic small-molecule agonists.

An olfactory cilia pattern in the mammalian nose ensures high sensitivity to odors.

R. Lewis¹, H. Tian¹, J. He¹, J. Jiang², X. Chen³, T. Connelly¹, L. Ma⁴, C. Yu⁴, J. Pluznick⁵, D. Storm³, L. Huang², K. Zhao^{2,6}, M. Ma¹;

¹Department of Neuroscience, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²Monell Chemical Senses Center, Philadelphia, PA, ³Department of Pharmacology, University of Washington School of Medicine, Seattle, WA, ⁴Stowers Institute for Medical Research, Kansas City, MO, ⁵Department of Physiology, Johns Hopkins University, Baltimore, MD, ⁶College of Life Sciences, Zhejiang University, Hangzhou, China

By converting environmental signals into intracellular responses, cilia are critical for many developmental and physiological processes, including olfaction. Cilia in different cell types exhibit distinct morphologies with specific numbers and lengths, but little is known about what factors shape cilia morphology and how morphology impacts function. We aim to address these questions using the mouse olfactory system as a model. We recently discovered that olfactory cilia vary drastically in length depending on the cell location in the olfactory epithelium. Using specific markers to label subsets of olfactory sensory neurons (OSNs) in the whole-mount epithelia of young adult mice, we found that cilia length increases from ~2 μm in the posterior nasal septum to ~14 μm in the anterior septum, with the longest cilia (up to ~50 μm) typically found in the dorsal recess and ventral septum. Remarkably, the cilia length pattern is positively correlated with odorant absorption, as determined by a 3D computational fluid dynamics model of the mouse nasal cavity. We also found that cilia length modifies OSN function, since cells with longer cilia show higher sensitivity to odorant stimulation compared to their short cilia counterparts. Surprisingly, neither sensory experience nor neuronal activity are required for the formation and maintenance of the cilia pattern, but type III adenylyl cyclase (ACIII), a key olfactory signaling molecule and ubiquitous marker for primary cilia, dramatically alters cilia length. Together, these findings reveal a previously unrecognized configuration in the nose to ensure high sensitivity to odors and a critical role of ACIII in shaping sensory cilia, independent of odor-induced activity.

P1014**Board Number: B340****Probing the function of environmentally released Extracellular Vesicles in *C.elegans*.**J.S. Akella¹, J. Wang¹, L. Haas¹, M.M. Barr¹;¹Genetics, Rutgers University, Piscataway, NJ

Extracellular vesicles (ECVs) are membrane-bound organelles that mediate intercellular communication by aiding the exchange of a variety of cargo including receptors, nucleic acids, and peptides. ECVs are released by most cell types and are abundantly found in bodily fluids such as urine, breast milk, and semen. Immune cell-derived ECVs are known to play important roles in the regulation of immune response including antigen presentation and mediating the exchange of peptides and nucleic acids (Robbins P.D. et al; Nature Reviews Immunology 14,195–208(2014)). We recently found that a subset of the ciliated neurons of the nematode *C.elegans* release ECVs into the environment (Wang J. et al; Current Biology 24, 1–7(2014)). We are studying the in vivo functions of environmentally released ECVs.

Transcriptional profiling of the ECV releasing neurons of *C.elegans* showed a significant enrichment of genes involved in the innate immune response including PMK-1 (a p38 MAP kinase), TRF-1 (a Tumor Necrosis Factor Receptor Associated Factor), lectins and anti-microbial peptide(Wang J.et al; to be submitted). Enrichment of genes involved in the innate immune response in the ECV releasing neurons could be explained by their exposure to the environment and thus, to pathogens. PMK-1, a member of the stress activated p38 MAP kinase pathway plays an important role in the innate immune response of *C.elegans* to various pathogens by upregulating the expression of anti-microbial genes (Troemel E. et al; PLoS Genet 2(11): e183(2006)). Furthermore, we have found that mutants of *pmk-1* are defective in ECV release into their environment, suggesting a role for PMK-1 in ECV biogenesis and or release.

Human urinary ECVs are packed with anti-microbial factors and our preliminary data suggests that *C.elegans* ECVs are anti-microbial in nature. This finding lets us ask many questions that could provide insights into the roles of environmentally released ECVs. Are the anti-microbial factors induced by PMK-1 upon infection or stress packed into ECVs and released into the environment? Do ECVs isolated from mutants of *pmk-1* have different bioactivity in immunological assays? Are mutants that have defects in ECV biogenesis or environmental release more susceptible to infections? If yes, can this be rescued by applying wild type derived ECVs? Together, our *C.elegans* model will allow us to address fundamental questions regarding the bioactive functions of ECVs in vivo.

P1015**Board Number: B341****Dzip1 regulates the ciliary translocalization of smoothed for activation of the hedgehog pathway.**G. Wang¹, B. Zhang¹, Q. Jiang¹, C. Zhang²;¹School of Life Sciences, Peking University, Beijing, China, ²Peking Univ Coll Life Scis, Beijing, China

The hedgehog pathway plays important roles in regulating cell proliferation and individual development, and its hyper-activation often leads to tumorigenesis in humans. In most vertebrate cells, the primary cilia transduce the hedgehog signaling through providing a unique space for the localization of smoothed (Smo) and other components of this pathway. It is shown that Smo interacts with the BBSome, a vesicle-associated protein complex that provides sorting signals for cargo proteins destined to the cilia, via its C-terminal. However, how BBSome assembly is linked with the translocation of Smo into the cilia and consequently the activation of the hedgehog pathway is poorly understood. Here we report that Dzip1, a centrosome protein which regulates cilia assembly, is required for the activation of the hedgehog pathway via regulating the ciliary translocation of Smo. Furthermore, Dzip1-knockdown leads to sequestration of Smo in Rab8-positive vesicles in cytoplasm when the pathway is activated. Mechanically, Dzip1 interacts with the BBSome, and Dzip1-depletion leads to the absence of Smo from the BBSome. Together, our data revealed an important role of Dzip1 in governing the interaction of Smo with the BBSome and the activity of the hedgehog pathway.

Centrosome Assembly and Functions 2**P1016****Board Number: B343****Stress promotes non-random spindle pole body inheritance through the Pkc1 cell wall integrity pathway in budding yeast.**J. Lengefeld¹, Y.P. Barral²;¹Swiss Fed Inst Technol, Zürich, Switzerland, ²Institute of Biochemistry, ETH Zurich, Zurich, Switzerland

Age-dependent centrosome/spindle pole body (SPB) segregation is observed across many asymmetrically dividing eukaryotic cells. In budding yeast, SPBs are mainly conservatively duplicated i.e. an 'old' SPB is inherited from the previous mitosis and drives the assembly of the second newly synthesized 'young' SPB. Remarkably, the old SPB is segregated into the bud whereas the young SPB is kept within the mother cell. In this process, the SPB component Nud1, a protein related to mammalian centriolin, plays a central role by specifying SPB identity via the mitotic exit network (MEN; mammalian Hippo signaling pathway). However, the biological relevance and the mechanism of non-random SPB inheritance still remain unclear.

We studied the effect of environmental stress on age-dependent SPB inheritance. We observed that the stress induced by (long-term) fluorescence microscopy improves non-random SPB inheritance in MEN mutant cells. We provide evidence that the protein kinase C (Pkc1) cell wall integrity pathway is involved in this process: An overactive Pkc1 mutant under non-stress conditions improves age-dependent SPB and the disruption of the kinase Bck1 (downstream factor of Pkc1) abolishes the improvement of age-dependent SPB segregation under high stress conditions.

Together, our results indicate under stress conditions the Pkc1 cell wall integrity pathway promotes non-random SPB inheritance. While under non-stress conditions the previously described MEN pathway ensures faithful SPB inheritance, under stress conditions non-random SPB inheritance cannot be fully achieved via the MEN pathway, but is compensated by the Pkc1 signaling pathway. This indicates that the biological relevance of non-random SPB inheritance may be of particular importance under stressful conditions.

Chemical genetic analysis of Polo-like kinase 4 activity.

T. Moyer¹, K. Clutario¹, A.J. Holland¹;

¹Molecular Biology and Genetics, Johns Hopkins University School of Medicine, Baltimore, MD

Centrioles are small tube-like structures that form the core of the centrosome, the major microtubule-organizing center of the cell that plays a central role in most microtubule-related functions, including cell motility, formation of cilia, intracellular transport and chromosome segregation in mitosis. For centrioles to coordinate these diverse cellular processes their biogenesis and copy number must be strictly controlled. Centrioles normally duplicate in a tightly coordinated process that ensures each centriole reproduces only once per cell cycle. Polo-like kinase 4 (Plk4) has emerged as a dose-dependent, master regulator of centriole biogenesis: excessive levels of Plk4 result in the production of supernumerary centrioles while loss of kinase activity causes a failure of centriole duplication. Studying Plk4 kinase activity in vivo has proven to be a challenge due to the incredibly low cellular abundance of the protein and a lack of rapid and specific molecular tools to modulate Plk4 activity in vivo. Here, we describe a system by which we use CRISPR genetic engineering technology to knock-in an analog-sensitive (AS) mutation into both alleles of Plk4. This mutation does not affect the kinase's normal function, but does allow it to be specifically inhibited by the bulky ATP-analog 3-MB-PP1. We show that this cell line allows for rapid and reversible control of Plk4 activity. Thus, the Plk4 AS cell line is a novel tool to examine the immediate effects of Plk4 inhibition.

P1018**Board Number: B345****Molecular basis of ordered Plk4 binding to two distinct scaffolds critical for centriole biogenesis.**J. Park¹, S. Park¹, T. Kim¹, J. Kim², M. Kwak³, B. Ku², L. Tian⁴, S. Kim², B. Oh³, W. Yang⁴, K. Lee¹;¹NIH/NCI, Bethesda, MD, ²Korea Research Institute of Bioscience and Biotechnology, Daejeon, Korea,³Korea Advanced Institute of Science and Technology and Biotechnology, Daejeon, Korea,⁴NIH/NIDDK, Bethesda, MD

Polo-like kinase 4 (Plk4) is a key regulator of centriole duplication, an event critical for the maintenance of genomic integrity. How Plk4 is regulated at subcentrosomal structures remains unknown. Human Plk4 binds two distinct centrosomal scaffold proteins, Cep192 and Cep152, which form concentric ring structures around a centriole. We observed that Plk4 colocalizes with Cep192 around a daughter centriole in early G1, and then relocates to the outer Cep152 ring, which assembles around the Cep192-encircled daughter centriole in late G1 as Cep152 is recruited to this site. Plk4 cryptic polo-box domain (CPB) interacted with Cep192 (201–258) or Cep152 (1–60) fragment with a K_d of 177 ± 23 nM or 32 ± 4 nM, respectively. Analyses of the X-ray crystal structures of apo-CPB or CPB in complex with Cep192 (201–258) or Cep152 (1–60) revealed that, unlike the previously reported *Drosophila* CPB proposed to form a pseudosymmetric “four-winged” homodimer with both PB1-PB1 and PB2-PB2 contacts, the CPB of human Plk4 formed a symmetrical “X-shaped” homodimer with a PB2-PB2 interface. Cep192 (201–258) and Cep152 (1–60) bound to the same concave surface of CPB along the $\alpha 1$ of PB1 in opposite orientations and in a mutually exclusive manner. Consistent with their incompatible binding nature and differential CPB-binding affinities, *in vitro* biochemical experiments showed that Cep152 (1–60) effectively snatches the CPB away from a preformed CPB-Cep192 (201–258) complex, but not vice versa. Notably, a cancer-associated Cep152 (V8A) or (E21K) mutation impaired in the Plk4 CPB interaction induced defects in procentriole assembly and chromosome segregation. Thus, Plk4 is intricately regulated in time and space through ordered interactions with two distinct scaffolds, Cep192 and Cep152, and this unidirectional scaffold switching from Cep192 to Cep152 is likely critical to promote Plk4-mediated centriole biogenesis and to prevent aneuploidy that leads to cancers in humans.

P1019**Board Number: B346****Characterizing centriole biogenesis with auxin-inducible destruction of endogenous Plk4.**B.G. Lambrus¹, A.J. Holland¹, K.M. Clutario¹;¹Molecular Biology and Genetics, Johns Hopkins University School of Medicine, Baltimore, MD

Centrioles are small, cylindrical structures that nucleate centrosomes and play a key role in orchestrating various microtubule-related processes, such as cell motility, cilia formation, and mitotic spindle

organization. In order to ensure the proper coordination of these diverse functions, centriole biogenesis and copy number must be tightly controlled. In cycling cells, centrioles are restricted to duplicate precisely once per cycle. Though the mechanism of this duplication remains poorly understood, Polo-like kinase 4 (Plk4) is recognized as a dose-dependent, master regulator of centriole copy number. Previous efforts to study how Plk4 acts to coordinate centriole duplication have been hindered due to the technical difficulty of manipulating Plk4 protein levels with temporal precision. We have developed a tool to overcome this challenge. Application of the *auxin-inducible degradation (AID) system* in RPE-1 cells allows induction of rapid and specific depletion of Plk4, degrading 90% of endogenous Plk4 levels within an hour of induction. Chronic depletion of Plk4 leads to a p53-dependent growth arrest. However, disruption of p53 enables continued proliferation, and the development of acentriolar cells. By washing out auxin and thereby allowing the re-accumulation of Plk4, we observe *de novo* centriole formation. We will describe how we use this assay to study the dynamics and molecular basis of *de novo* centriole formation.

Centriole maturation requires regulated Plk1 activity during two consecutive cell cycles.

D. Kong¹, V. Farmer¹, A.K. Shukla¹, J. Loncarek¹;

¹Laboratory of Protein Dynamics and Signaling, NIH/NCI-Frederick, Frederick, MD

Centrioles are conserved microtubule-based organelles that initiate the assembly of centrosomes and cilia. After initiation of their formation, young centrioles undergo a series of biochemical and structural modifications needed to acquire a competence for pericentriolar material organization, duplication, and cilia assembly. This ill-understood centriole maturation process is almost two cell cycles long and as a consequence, each cycling cell contains three generations of centrioles. Only one centriole per cell (the oldest one) is fully structurally mature and decorated with subdistal and distal appendages, which are needed for microtubule anchoring during interphase and for ciliogenesis, respectively. Appendages first form on the centriole by the end of its second mitosis, well after the centriole has already acquired its full length, organized a PCM, and undergone duplication in the previous cell cycle. Mechanisms that regulate appendage formation remain elusive. Previous work published by us and others indicated that Plk1 promotes centriole maturation. To better understand the effects of Plk1 on biochemical and structural centriole maturation we conducted a series of biochemical and correlative light and electron microscopy-based experiments. Our analysis revealed that controlled Plk1 activity during two consecutive cell cycles is required for gradual biochemical and structural maturation of the centrioles and timely appendage assembly. We found that inhibition of Plk1 impedes accumulation of appendage proteins and appendage formation on young centrioles. Exogenous expression of Plk1, either in cycling or interphase-arrested cells, stimulates premature accumulation of distal appendage proteins Cep164, Odf2/Cenexin, FBF1, SCLT1 and ccdc41, and assembly of appendages on younger centrioles, thus eliminating the age difference among the centrioles within one cell. These findings provide a new

understanding of how the centriole cycle is regulated and how proper cilia and centrosome number is maintained in the cells.

Loss of block-to-centriole reduplication without a loss of centriole orthogonal orientation in human cells.

A.K. Shukla¹, D. Kong¹, M. Sharma¹, J. Loncarek¹;

¹Laboratory of Protein Dynamics and Signaling, NIH/NCI-Frederick, Frederick, MD

Centrioles duplicate by formation of a daughter centriole in orthogonal orientation to the wall of a mother centriole. This configuration is preserved throughout interphase until mother and daughter centrioles separate at the end of mitosis. The orthogonal configuration between the two centrioles serves as an intrinsic block-to-centriole reduplication because the mother centriole cannot further duplicate unless this configuration is lost. The molecular mechanisms leading to the loss of block-to-centriole reduplication are not currently known. It has been proposed that disorientation between a mother and a daughter centriole at the end of mitosis requires APC/C-dependent proteolytic events. To better understand the role of centriole configuration in maintaining a block-to-centriole reduplication in human cells, we analyzed structural changes occurring at the centrosomes undergoing reduplication by a combination of live-, fixed-cell light microscopy and electron microscopy. Our results demonstrate that centrioles can reduplicate in cycling and S-phase arrested human cells before a loss of orthogonal orientation is detectable by live cell recordings or electron microscopy and, before global proteolytic events occur at the centrosome. We propose that a loss of orthogonal orientation is a facultative event following a removal of block-to-centriole reduplication. This data is consistent with the data obtained in insect cells (Vidwans et al, 2002; Gottardo et al, 2014) revealing new details in the process of the formation of a human centriole.

Asterless licenses daughter centrioles to duplicate for the first time in *Drosophila*.

Z.A. Novak¹, P.T. Conduit¹, A. Wainman¹, J.W. Raff¹;

¹Sir William Dunn School of Pathology, University of Oxford, Oxford, England

Centrioles form centrosomes and cilia, and defects in any of these three organelles are associated with human disease. Centrioles duplicate once per cell cycle when a mother centriole assembles an adjacent daughter during S-phase. Daughter centrioles cannot support the assembly of another daughter until they mature into mothers during the next cell cycle [1-4], however the molecular nature of this daughter-to-mother transition has remained mysterious. Using quantitative live imaging in *Drosophila*

embryos we show that the conserved centriole duplication protein Asterless (*Drosophila* Cep152) is not incorporated into daughter centrioles as they assemble during S-phase, but is only incorporated once mother and daughter separate at the end of mitosis. The initial incorporation of Asterless (Asl) is irreversible, requires DSas-4, and is essential for daughter centrioles to mature into mothers that can support centriole duplication. We therefore propose a “dual licensing” model where Asl incorporation provides a permanent primary license to allow new centrioles to duplicate for the first time, while centriole disengagement provides a reduplication license to allow mother centrioles to duplicate again. Our preliminary data suggests that the primary licensing of new centrioles through the incorporation of Asl is regulated by cell cycle-dependent phosphorylation, which alters the DSas-4 -Asl interaction.

The mechanism of maternal centriole elimination in starfish oocytes.

J. Pinto¹, J. König², T. Müller-Reichert³, P. Lenart⁴;

¹Cell Biology and Biophysics, EMBL, Heidelberg, Germany, ²TU Dresden, Dresden, Germany, ³Medical Faculty "Carl Gustav Carus", TU Dresden, Dresden, Germany, ⁴EMBL, Heidelberg, Germany

Centriole duplication and segregation is tightly coupled to the cell cycle in somatic cells to preserve centriole number over cell generations. However, at fertilization, upon gamete fusion, mechanisms have to exist to prevent the surplus of centrioles in the embryo that would lead to multipolar spindles and aneuploidy during early development. Therefore, centrioles are eliminated from the oocyte and only the sperm provides active centrioles to the zygote. Although this process is essential and common to animal species, the mechanisms underlying centriole elimination in female gametes are still poorly understood.

In most species, centrioles are eliminated during the long prophase of female meiosis that is difficult to access experimentally. In contrast, in starfish (*P. miniata*) oocytes, centriole elimination occurs during the rapid and synchronous meiotic divisions that can be easily followed by live-imaging. Therefore, to visualize centrioles *in vivo*, we established GFP markers and found that two pairs of centrioles are present at meiosis onset and contribute to spindle organization. Out of these two pairs, one is extruded into the first polar body at the end of the first meiotic division (MI). As no S-phase exists between MI and the second meiosis (MII), single centrioles form the poles of the MII spindle. Remarkably, by using the mother centriole specific marker Odf2-mEGFP, we found that the older, mother centriole always localizes to the spindle pole facing the plasma membrane. Consequently, the mother centriole is extruded into the second polar body, whereas a single daughter centriole remains in the mature egg. We additionally show, by tracking centrioles in live cells and by correlative electron microscopy, that the mother centriole is specifically transported to the plasma membrane at the end of MI, where it remains stably anchored. This likely occurs via the mother centriole specific appendages, in a mechanism that might be related to basal body formation. Additionally, the specific extrusion of mother centrioles is

functionally important, because if the centrioles are artificially retained in the egg (by inhibition of the polar body extrusion), only the mother centrioles remain active, recruit microtubules and cause multipolar spindles in the zygote.

Taken together, we propose the first comprehensive model for centriole elimination in animal oocytes that relies on the specific extrusion of the mother centrioles. We show that known and conserved features of the mother centrioles are employed in the oocyte for spindle positioning, membrane attachment and finally their own extrusion. Our observations suggest that the single daughter centriole remaining in the mature egg is not able to duplicate, leading to its elimination.

PLP forms novel centriole satellites and is critical for embryonic development.

D.A. Lerit¹, J.S. Poulton², H.A. Jordan¹, M. Peifer², N.M. Rusan¹;

¹Cell Biology and Physiology Center, NHLBI, NIH, Bethesda, MD, ²Department of Biology, University North Carolina, Chapel Hill, NC

Centrosomes serve as the microtubule-organizing centers (MTOC) of most eukaryotic cells. Functional changes in centrosome behavior and activity are linked to oscillations in pericentriolar material (PCM) levels during the cell cycle. Elucidating how PCM dynamics are regulated is critical to understanding centrosome function throughout the cell cycle and how centrosome dysfunction drives pathologies, such as microcephaly and cancer. Pericentrin is a key regulator of the PCM. Intriguingly, we have identified a novel, cell cycle-dependent structural reorganization of Pericentrin-like-protein (PLP) in the early *Drosophila* embryo. We find PLP localizes to radially extended “satellites” specifically during interphase that partially colocalize with Centrosomin (Cnn) flares. Unlike flares, however, PLP satellites are not ejected from the centrosome, suggesting they may serve as structural components of the interphase centrosome. Clonal mutant analysis confirms that PLP satellites function primarily to organize the interphase PCM structure. Moreover, we find the Pericentrin/AKAP-450 centriole-targeting (PACT) domain is dispensable for PLP targeting to satellites or centrioles, but is required to maintain proper PLP satellite and PCM organization. Further, we demonstrate that PLP is critical for efficient microtubule (MT) organization, genome stability, and embryo viability. Collectively, our data argue that proper organization of the interphase PCM by PLP is essential for normal cell division and early development.

P1025**Board Number: B352****Chemically-induced reversible organelle knockout of centrioles reveals an essential role in the proliferation of non-transformed cells.**Y. Wong¹, J. Anzola², R. Davis², M. Yoon², A. Motamedi², A. Kroll¹, C. Seo², T. Gahman², A. Desai³, A. Shiau², K. Oegema³;¹Department of Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, La Jolla, CA,²Small Molecule Discovery Program, Ludwig Institute for Cancer Research, La Jolla, CA, ³Ludwig Institute for Cancer Research, La Jolla, CA

Centrioles are microtubule-based organelles that direct the formation of centrosomes and cilia. Defects in centrosome structure and number are linked to aneuploidy and cancer, whereas ciliary dysfunction leads to a host of ciliopathies. Despite their broad impact on cell physiology, centriole function has been challenging to study in mammalian cells due to the lack of a facile methodology for specifically, persistently, and reversibly removing this organelle from cells. To facilitate analysis of centrioles, we developed centrinone – a specific small molecule inhibitor of PLK4, the kinase that initiates centriole assembly. Treatment with centrinone at sub-micromolar concentrations allows sustained depletion of centrioles from human and mouse cells, leading to loss of centrosomes and primary cilia. Depletion of centrioles from >30 human and mouse cell lines partitioned them into two distinct classes. Cell lines with a defective p53 pathway proliferated indefinitely in the absence of centrioles. G1+S and G2 durations were not altered, but spindle assembly was slowed and cells were more prone to mitotic defects that reduced population growth rate. Both centrioles and proliferation rate were restored upon centrinone washout. In cell lines with a wild-type p53 pathway, centriole removal triggered an irreversible p53-dependent G1 arrest within a few cell divisions. This arrest was not DNA damage signaling-dependent, and did not correlate with mitotic duration, indicating that the arrest triggered by centriole loss is distinct from the previously described prometaphase duration sensor. In transformed cell lines with different basal levels of centrosome amplification prior to centriole depletion, centrinone washout triggered a wave of de novo assembly and initial overduplication, followed by recovery to the level of amplification observed prior to centriole removal. Analysis of this recovery process indicated that overduplication is balanced by removal of cells with extra centrioles through multipolar mitosis and death. These results suggest that centriole number set points in cancer cell lines result from a dynamic equilibrium between centriole overduplication and removal of cells with extra centrioles, rather than being determined by historical overduplication events.

P1026**Board Number: B353****Cancer-wide survey of centrosomes reveals centriole fragmentation as a novel origin of supernumerary centrosomes.**G. Marteil¹, A. Guerrero², S. Godinho³, P. Machado^{1,4}, J. Loncarek⁵, S. Mendonça¹, I. Fonseca¹, D. Pellman⁶, M. Bettencourt-Dias¹;¹Instituto Gulbenkian de Ciência, Oeiras, Portugal, ²Instituto de Biotecnología Universidad Nacional Autónoma de México, Mexico, Mexico, ³Barts Cancer institute, London, United Kingdom, ⁴EMBL, Heidelberg, Germany, ⁵Laboratory of Protein Dynamics and Signaling, NIH/NCI-Frederick, Frederick, MD, ⁶Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA

A century ago, Theodor Boveri suggested that abnormalities in the major microtubule organising center of animal cells, the centrosome, lead to abnormal cell division and tumorigenesis. Those abnormalities have since been observed in cancer in vivo, but their incidence and causes remain poorly characterised. To address those important questions, we implemented a three-step screen and developed a state-of-the-art algorithm to score centriole number and length in 3D in the NCI-60 panel of cancer cell lines that represents cancer diversity. Importantly, we observed that the majority of these cell lines shows increase in both centriole number and length, and uncovered an important link between centrosome amplification and invasive capacity. Our work also suggests a novel origin of centriole amplification in cancer, which we subsequently validated with complementary approaches: as centriole length control is deregulated in cancer cells, centrioles can grow more than 3 fold and form an abnormal structure that fragments and generates smaller, functional centrioles. Centriole fragments then behave as microtubule organising centers leading to abnormal mitosis. The fact that centriole abnormalities are widespread in cancer, but not in normal cells, and the identification of novel causes of those abnormalities solidifies and suggests new avenues to the use of centrosomes in the clinic as diagnostic, prognostic and therapeutic tools.

P1027**Board Number: B354****A Novel Role for Primary Cilia in Centrosome Positioning and Division of Neural Progenitors.**T.J. Dantas¹, A. Baffet¹, A. Carabalona¹, R. Vallee¹;¹Department of Pathology and Cell Biology, Columbia University, New York, NY

Neural stem cells known as radial glial progenitors (RGPs) give rise to most of the neurons and glial cells in the developing mammalian cerebral cortex, as well as the stem cells of the adult. RGP cells are highly proliferative, and can divide symmetrically to increase the progenitor pool, or asymmetrically to produce neurons. The nucleus of the highly elongated RGP cell migrates basally during G1 and apically during G2, in a behavior known as interkinetic nuclear migration (INM). The RGP nucleus then enters mitosis and

divides exclusively at the apical terminus of the cell (Hu et al., 2013), located at the ventricular surface of the brain. The centrosome remains tethered at the apical terminus of the cell throughout the RGP cell cycle, and nucleates a primary cilium.

To determine the function of the primary cilium we first expressed ciliary markers in embryonic rat brain using in utero electroporation. We monitored primary cilia by high resolution light microscopic imaging of fixed and live brain tissue. In contrast to most cultured cell lines, we found primary cilia to project from the apical terminus of RGP cells throughout most of the cell cycle. To further test primary cilium function we interfered with ciliogenesis. Decreasing primary cilium assembly by disrupting IFT genes has been reported to alter hippocampal and cerebellar development via defects in sonic hedgehog signaling (Chizhikov et al., 2007; Han et al., 2008). However, we observe little effect of IFT inhibition on RGP cell behavior.

As a more definitive test of primary cilium function, we targeted earlier stages of ciliogenesis using RNAi or dominant negative cDNAs for centriolar distal appendage genes. In nonneuronal cells, this approach inhibits primary cilium assembly and also prevents the attachment of centrosomes to the plasma membrane (Tanos et al., 2013). In embryonic rat brain, disruption of some distal appendage genes resulted in a striking displacement of centrosomes from the apical terminus in a considerable fraction of RGP cells. This result suggests a completely novel role for ciliogenesis in restricting centrosome positioning to the apical terminus of RGP cells. A further consequence of interfering with distal appendage proteins was the appearance of ectopic mitotic events at substantial distances from the apical end of the cell at the ventricular surface.

These results strongly suggest that apical centrosome sequestration is triggered by the initial steps of ciliogenesis and maintained by the presence of the primary cilium throughout the cell cycle. In this manner, the primary cilium may be the responsible factor for restricting RGP mitosis to the ventricular surface of the brain and ensuring proper brain development.

Cyclin-dependent kinase control of centriole formation during differentiation of multiciliated epithelial cells.

E.K. Vladar¹, M. Stratton², J. Axelrod¹, T. Stearns^{3,4};

¹Stanford Univ Sch Med, Stanford, CA, ²Department of Biology, Stanford Univ, Stanford, CA,

³Department of Biology, Stanford University, Stanford, CA, ⁴Department of Genetics, Stanford School of Medicine, Stanford, CA

The centrosome is the microtubule-organizing center of animal cells, and at the core of each centrosome is a pair of centrioles. Centrioles are nine-fold symmetric microtubule structures that are required for formation of a cilium. The cilium is a critical signaling organelle and centriole and cilium dysfunction can lead to an array of diseases termed ciliopathies.

Along with chromosomal DNA, centrioles are the only structures that are duplicated once and only once per cell cycle. Centriole duplication and DNA replication are driven by the same cell cycle regulators, specifically the cell cycle kinase Cdk2 and its activators, cyclins E and A. In mammalian cells, Cdk2 in complex with cyclin E drives the G1-S transition, and in complex with cyclin A drives progression through S phase into G2-M. In a normal cell cycle centriole duplication and DNA replication are both initiated at the G1-S transition, and cannot occur again until after passage through mitosis. However, the two processes can be separated from each other in specialized cell types in which either centrioles or DNA are amplified. One example is multiciliated cells (MCCs) in which hundreds of centrioles form in the absence of DNA replication. We are interested in addressing the following question: how are two normally co-regulated cell cycle events separately regulated in differentiated cells?

MCCs exist in several locations of the mammalian body: the ventricles of the brain, fallopian tubes of the female reproductive tract, and respiratory tract. In cycling cells centrioles duplicate by forming adjacent to an existing centriole, whereas in MCCs most of the amplified centrioles form from granular structures termed deuterosomes. Molecular evidence indicates that despite the morphological differences, the same proteins and pathways are involved in centriole duplication and centriole amplification.

We show that Cyclin-dependent kinase2 (Cdk2), the major regulator of the S-phase events of DNA replication and centrosome duplication in cycling cells, is also required for centriole amplification without DNA replication in MCCs. We find that Cdk2 activity is required for centriole, but not deuterosome biogenesis. Interestingly, our results suggest that Cdk2 activity in these cells relies on the expression of a motile ciliogenesis-specific Cyclin activator.

Dissecting the role of PCNT in centriole engagement.

E. Rodenas¹, C. Chen¹, S. Doxsey²;

¹Molecular Medicine, University of Massachusetts Medical School, Worcester, MA, ²Univ Massachusetts Med Sch, Worcester, MA

Pericentrin (PCNT) is an integral component of the pericentriolar material (PCM) that serves as a scaffold for the anchoring of multiple proteins to the centrosome. Several human diseases are associated with PCNT mutations, one in particular is Majewski Osteodysplastic Primordial Dwarfism (MOPDII). The cause of MOPDII is biallelic loss-of-function mutations in PCNT, leading to loss of functional protein. To understand the molecular mechanism of MOPDII phenotypes, we engineered *Pcnt*^{-/-} mice and generated mouse embryonic fibroblasts (MEFs). Strikingly, *Pcnt*^{-/-} MEFs contained an increase in centrosome number compared to control, suggesting that *Pcnt* may be involved in centriole duplication. Concomitantly, we found that in *Pcnt*^{-/-} MEFs the centrioles lose 3 proteins out of 27 tested. Furthermore, these 3 proteins were immunoprecipitated with *Pcnt*. This subcomplex included two mother centriole appendage proteins, ninein and centriolin, and a protein previously reported to interact with *Pcnt*, Cep215. Centrosome duplication occurs once and only once per cell cycle. The first

step of centrosome duplication is the disengagement of the daughter centriole from the mother during the G1 phase of the cell cycle. If centrioles remain disengaged too long they will continuously form adjacent procentrioles, leading to centriole overduplication. The increase in overall centriole number in Pcnt^{-/-} MEFs suggests that Pcnt is involved in either centriole engagement or directly involved in duplication. We are currently investigating the molecular mechanism for Pcnt, and its newly identified interactions with centriolin, Cep215, and ninein, in the process of centriole engagement.

Seay Center for Musculoskeletal Research, Texas Scottish Rite Hospital for Children, Edinburgh, United Kingdom, ¹⁰Institute of Genetics and Molecular Medicine, Western General Hospital, Edinburgh, United Kingdom, ¹¹Department of Pediatrics, A.I. Dupont Hospital for Children, Wilmington, DE, ¹²Univ Pittsburgh, Pittsburgh, PA, ¹³PMM, Univ Massachusetts Med Sch, Worcester, MA

Majewski Osteodysplastic Primordial Dwarfism type II (MOPDII) is caused by mutations in the centrosome gene pericentrin (PCNT) and leads to severe pre- and post-natal growth retardation. As in MOPDII patients, disruption of pericentrin (Pcnt) in mice caused a number of abnormalities including microcephaly, aberrant hemodynamics analyzed by in utero echocardiography, and cardiovascular defects, which were associated with mortality as in the human condition. To identify the mechanisms underlying these defects, we tested for deficiencies in cell and molecular function. All Pcnt^{-/-} mouse tissues and cells examined showed spindle misorientation. This mouse phenotype was associated with misdirected ventricular septal growth in the heart, decreased proliferative symmetric divisions in brain neural progenitors and increased misoriented divisions in fibroblasts; the same phenotype was seen in fibroblasts from three MOPDII individuals. Misoriented spindles were associated with disrupted astral microtubules and near complete loss of a unique set of centrosome proteins from spindle poles (ninein, Cep215, centriolin). All these proteins interact with Pcnt, suggesting that Pcnt serves as a molecular scaffold for this functionally-linked set of spindle pole proteins. Importantly, Pcnt disruption had no detectable effect on localization of proteins involved in the canonical cortical polarity pathway (NuMA,

p150glued, aPKC). Not only do these data reveal a spindle-pole-localized complex for spindle orientation, but they identify key spindle symmetry proteins involved in the pathogenesis of MOPDII.

Protein phosphatase 1 regulates ZYG-1 levels to limit centrosome duplication.

N. Peel¹, J. IYER², A. Naik¹, K.F. O'Connell²;

¹Department of Biology, The College of New Jersey, Ewing, NJ, ²LBG, NIDDK/NIH, Bethesda, MD

In humans, perturbations of centrosome number are associated with tumorigenesis and microcephaly, therefore appropriate regulation of centrosome duplication is critical. Centrosome duplication involves building a single daughter centriole adjacent to each existing (mother) centriole and occurs once per cell cycle. The kinase Plk4 is essential for centriole biogenesis and its overexpression causes the formation of extra daughter centrioles in association with a single mother centriole. The *C. elegans* homolog of Plk4, ZYG-1, is required for centriole duplication, but our understanding of how ZYG-1 levels are regulated remains incomplete. We have identified the single PP1 β ortholog, GSP-1, and its regulators I-2^{SZY-2} and SDS-22 as controlling ZYG-1 levels. We find that down-regulation of PP1^{GSP-1} activity either directly, or by mutation of *szy-2* or *sds-22* can rescue the loss of centrosome duplication associated with the *zyg-1(it25)* mutation. This effect is a result of increased ZYG-1 levels, suggesting that PP1 normally antagonizes ZYG-1 proteins levels. Moreover we find that depleting PP1 activity in an otherwise wild-type embryo leads to centrosome amplification demonstrating the physiological relevance of PP1 action in modulating centrosome duplication.

SAS-6 Assembly Templated by the Lumen of Cartwheel-less Centrioles Precedes Centriole Duplication.

C. Fong¹, M. Kim^{1,2}, T. Yang³, J. Liao³, M. Tsou^{1,2};

¹Cell Biology Program, Memorial Sloan Kettering Cancer Center, New York, NY, ²Weill Cornell Graduate School of Medical Sciences, Cornell University, New York, NY, ³Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, Taiwan

Centrioles are 9-fold symmetric structures duplicating once per cell cycle. Duplication involves self-oligomerization of the centriolar protein SAS-6, but how the 9-fold symmetry is invariantly established remains unclear. Here, we found that SAS-6 assembly can be shaped by preexisting (or mother) centrioles. During S phase, SAS-6 molecules are first recruited to the proximal lumen of the mother centriole, adopting a cartwheel-like organization through interactions with the luminal wall, rather than via their self-oligomerization activity. The removal or release of luminal SAS-6 requires Plk4 and the cartwheel protein STIL. Abolishing either the recruitment or the removal of luminal SAS-6 hinders SAS-6

(or centriole) assembly at the outside wall of mother centrioles. After duplication, the lumen of engaged mother centrioles becomes inaccessible to SAS-6, correlating with a block for reduplication. These results lead to a proposed model that centrioles may duplicate via a template-based process to preserve their geometry and copy number.

Phosphorylation-driven Cnn scaffold assembly during centrosome maturation.

Z. Feng¹, P.T. Conduit², J.W. Raff²;

¹University of Oxford, Oxford, United Kingdom, ²Sir William Dunn School of Pathology, University of Oxford, Oxford, England

Centrosomes comprise two major components: a pair of centrioles surrounded by pericentriolar material (PCM). The PCM expands dramatically in the process of centrosome maturation, functioning to nucleate and anchor microtubules (MTs). However the mechanism underlying this process remains unknown. Recently we have identified a domain (Phospho-Regulated-Multimerization PReM domain) in the *Drosophila* Centrosomin (Cnn) protein, which is phosphorylated by Polo/Plk1 at the centrosome during mitosis and is essential for PCM scaffold formation. Mutations that block the phosphorylation of PReM domain strongly disrupt the assembly of Cnn scaffolds, whereas phospho-mimicking mutations allow Cnn to multimerize in vitro and forming the spontaneous cytoplasmic scaffolds in vivo that organize MTs independent of centrosomes. Here, we present the further biochemical characterizations of this PReM domain to provide structural insights into the phosphorylation-driven self-interaction of Cnn molecules during centrosome maturation.

Stabilization of Cartwheel-less Centrioles for Duplication Requires CEP295-Mediated Centriole-to-Centrosome Conversion.

D. Izquierdo^{1,2}, W. Wang³, K. Uryu⁴, M. Tsou^{3,5};

¹Weill Cornell Grad Sch Med Scis, New York, NY, ²Cell Biology, Memorial Sloan Kettering Cancer center, New York, NY, ³Cell Biology Program, Memorial Sloan Kettering Cancer Center, New York, NY, ⁴Electron Microscopy Resource Center, Rockefeller University, New York, NY, ⁵Weill Cornell Graduate School of Medical Sciences, Cornell University, New York, NY

Vertebrate centrioles lose their geometric scaffold, the cartwheel, during mitosis, concurrently with gaining the ability to recruit the pericentriolar material (PCM) and thereby function as the centrosome. Cartwheel removal has recently been implicated in centriole duplication, but whether "cartwheel-less" centrioles are intrinsically stable or must be maintained through other modifications remains unclear. Here, we identify a newborn centriole-enriched protein, KIAA1731/CEP295, specifically mediating

centriole-to-centrosome conversion but dispensable for cartwheel removal. In the absence of CEP295, centrioles form in the S/G2 phase and lose their associated cartwheel in mitosis but cannot be converted to centrosomes, uncoupling the two events. Strikingly, centrioles devoid of both the PCM and the cartwheel progressively lose centriolar components, whereas centrioles associating with either the cartwheel or PCM alone can exist stably. Thus, cartwheel removal can have grave repercussions to centriole stability, and centriole-to-centrosome conversion mediated by CEP295 must occur in parallel to maintain cartwheel-less centrioles for duplication.

Kinetochores Assembly and Functions 1

Board Number: B362

Tension-Based Elongation of *Drosophila* Kinetochores Protein CENP-C Promotes Stabilization of Kinetochores-Microtubule Attachments.

S. Cane¹, J. Sanghvi¹, T.J. Maresca¹;

¹Biology Department, Univ Massachusetts-Amherst, Amherst, MA

Formation of stable kinetochores-microtubule (kt-MT) attachments is accompanied by movement of the binding interface away from the inner region of the kinetochores. In *Drosophila*, the outer kinetochores is ~40 nm further from the inner kinetochores at bioriented attachments than it is at unattached kinetochores. We refer to this 40 nm displacement between the inner and outer kinetochores as intrakinetochores stretch. It has been proposed that intrakinetochores stretch spatially repositions the attachment factors in the outer kinetochores beyond the reach of the Aurora B kinase activity centered at the inner centromere, thereby contributing to the establishment of stable bioriented attachments. We initially set out to identify the particular proteins that underpin intrakinetochores stretch in *Drosophila*. The protein CENP-C forms a link between the inner and outer regions of the kinetochores, binding to DNA and to centromere-specific nucleosomes through its C terminus and to the outer kinetochores through its N terminus. The intervening region of *Drosophila* CENP-C is predicted to lack secondary structure and contains no known, conserved structural motifs, and we hypothesized that this intrinsically disordered segment of the protein stretches under tension. After fluorescently labeling CENP-C at either end we determined, using super-resolution microscopy, that the protein lengthens by ~20 nm at bioriented attachments during metaphase. We next sought to examine the effect of artificially reducing the protein's length. To do so, we engineered a shortened, non-stretchable "minimal CENP-C" by removing 907 amino acids from the disordered region of the native protein. We verified that the shortened protein, unlike the full-length (1411 amino acid) version, does not elongate in the presence of tension at metaphase. Compared to wild-type cells, cells with the non-stretchable minimal CENP-C formed unstable kt-MT attachments and aligned fewer of their chromosomes at the metaphase plate. We also fused the C-terminal region of CENP-C directly to the Mis12 complex component Nsl1, producing a "hyper-shortened" version of the inner-to-outer kinetochores linkage. Cells with hyper-shortened CENP-C also formed unstable attachments and displayed an even greater

alignment defect than that seen in cells with minimal CENP-C. The alignment defect seen in both CENP-C mutants could be partially rescued by chemical inhibition of Aurora B activity. Cells with either shortened or hyper-shortened kinetochores also exhibited chaotic chromosome movements within the spindle that are suggestive of an inability to form stable kt-MT attachments. Efforts are now under way to rescue the deleterious effects associated with non-stretchable kinetochores by replacing the deleted region of CENP-C with peptide linkers of various lengths and physical properties, including other intrinsically disordered protein domains. Our results are consistent with a model in which tension-derived CENP-C elongation enables dephosphorylated outer kinetochore attachment factors to form stable kt-MT attachments.

Centromere identity through cell cycles is maintained epigenetically by the presence of nucleosomes containing the histone H3 variant CENP-A. Consistent with a role as a stable epigenetic mark, we find that CENP-A nucleosomes are quantitatively retained at the centromere at which they are first assembled. The CENP-A nucleosome binding protein CENP-C is constitutively and directly bound to CENP-A nucleosomes at the centromere and is a prime candidate to stabilize CENP-A nucleosomes at the centromere. Indeed, using reconstituted centromere complexes, we find that CENP-C reshapes the histone core of the nucleosome, and rigidifies both surface and internal nucleosome structure. We find that depletion of CENP-C leads to the rapid removal of CENP-A from centromeres, indicating that CENP-C is necessary to retain CENP-A nucleosomes at the centromere. These data shed light on the molecular requirements of maintaining centromere identity, and lead to a model wherein CENP-A and CENP-C collaborate to maintain centromere identity.

P1037**Board Number: B364****Lateral to End-on Conversion of Chromosome-Microtubule Attachment Requires Kinesins CENP-E and MCAK.**R.L. Shrestha¹, V.M. Draviam¹;¹Department of Genetics, Univ Cambridge, Cambridge, England

Background: Proper attachment of chromosomes to microtubules is crucial for the accurate segregation of chromosomes. Human chromosomes attach initially to lateral walls of microtubules. Subsequently, attachments to lateral walls disappear and attachments to microtubule ends (end-on attachments) predominate. While it is known in yeasts that lateral to end-on conversion of attachments occurs through a multistep process, equivalent conversion steps in humans remain unknown.

Results: By developing a high-resolution imaging assay to visualize intermediary steps of the lateral to end-on conversion process, we show that the mechanisms that bring a laterally bound chromosome and its microtubule end closer to each other are indispensable for proper end-on attachment because laterally attached chromosomes seldom detach. We show that end-on conversion requires (1) the plus-end-directed motor CENP-E to tether the lateral kinetochore onto microtubule walls and (2) the microtubule depolymerizer MCAK to release laterally attached microtubules after a partial end-on attachment is formed.

Conclusions: By uncovering a CENP-E mediated wall-tethering event and a MCAK-mediated wall-removing event, we establish that human chromosome-microtubule attachment is achieved through a set of deterministic sequential events rather than stochastic direct capture of microtubule ends.

P1038**Board Number: B365****Centromere Protein-F Includes Two Sites that are Efficient Couplers to Depolymerizing Tubulin.**J. McIntosh¹, V. Volkov², W. Old¹, P. Grissom¹, V. Arzhanik², T. McClure-Begley¹;¹Univ Colorado, Boulder, CO, ²Ctr Theoretical Problems of Physical and Chemical Pharmacology, Moscow, Russia

The attachment of kinetochores to dynamic microtubules (MTs) is of central importance to accurate chromosome segregation at mitosis. Centromere Protein F (CENP-F) has been shown to include two MT binding domains, so it may participate in this key mitotic process. Here we show that a 558 amino acid fragment from the N-terminus of CENP-F forms dimers in solution that prefer binding to curled oligomers of tubulin relative to a MT wall by ~15-fold, suggesting that CENP-F may play a role in the firm bond that forms during prometaphase between a kinetochore and the plus ends of dynamic kinetochore MTs. This N-terminal fragment contains three coiled coils but studies using electron microscopy, cross-

linking, and mass spectrometry indicate that it folds to form a binding site that associates with β -tubulin at K392, a residue that lies near the inter-dimer boundary in a MT and close to the interface between adjacent protofilaments. A 522 amino acid fragment from CENP-F's C-terminus prefers taxol-stabilized MTs, but either of these CENP-F fragments can bind to and diffuse on the wall of a stable MT. Measurements of fluorescence brightness suggest that these fragments oligomerize when bound to a MT, and when they associate with dynamic tubulin polymers, they will follow the end of a shortening MT. When either of these binding domains is coupled to a microbead, the force it can transduce from a shortening MT averages ~ 5 pN but can exceed 13 pN, making CENP-F the most effective coupler to shortening MTs so far discovered outside the fungi.

Dissecting the Spatiotemporal Regulation of CENP-A Assembly.

B.T. French¹, A.F. Straight¹;

¹Biochemistry, Stanford School of Medicine, Stanford, CA

The proper segregation of chromosomes in mitosis requires the correct assembly of the kinetochore upon centromeric chromatin. Nucleosomes containing the centromere specific histone H3 variant, CENtromere Protein A (CENP-A), form the specialized chromatin of the centromere that specifically recruits proteins for centromere and kinetochore assembly. A central question in understanding centromere function is how new CENP-A is recruited and assembled to maintain centromeres through replication and division. This process must be carried out with spatial and temporal precision to protect against the formation of ectopic centromeres or the loss of centromeres, both of which can lead to chromosome missegregation and aneuploidy.

CENP-A assembly requires two protein complexes, the Mis18 complex and the CENP-A chaperone HJURP. These complexes are targeted to vertebrate centromeres in anaphase and G1 when new CENP-A assembly occurs. Mis18 complex recruitment is mediated in part through the direct binding of the Mis18 complex subunit M18BP1 to the conserved centromere protein CENP-C. Using an *in vitro* CENP-A assembly system in *Xenopus* frog egg extracts we showed that the interaction between CENP-C and M18BP1 occurs only in metaphase and that depletion of either CENP-C or M18BP1 inhibited new CENP-A assembly. Thus, the mitosis-specific interaction of CENP-C and M18BP1 may provide a mechanism to control the spatiotemporal regulation of CENP-A assembly.

Here we report the interaction domains for M18BP1 and CENP-C and demonstrate that the conserved SANTA domain of M18BP1 is required for its localization in both mitosis and interphase. In addition, we found that mutation of the SANTA domain disrupts the interaction between CENP-C and M18BP1 during mitosis, suggesting that regulation of this interaction is a key regulatory step in CENP-A assembly. We found that both the mitotic localization of M18BP1 and the interaction between CENP-C and M18BP1 are regulated by phosphorylation. To test whether the phosphoregulation of the interaction between CENP-C and M18BP1 is responsible for the cell cycle dependent localization of M18BP1 to centromeres,

we identified phosphorylation sites on M18BP1 in the interaction domain that binds CENP-C. We find that M18BP1 localization to centromeres and M18BP1 binding to CENP-C are controlled by different sets of phosphorylation sites. Taken together, our data supports a model where two distinct pathways control the localization of M18BP1 to metaphase centromeres, one through direct interaction with CENP-C and another through an as yet unidentified phosphorylation dependent mechanism.

Determinants of CENP-A for early steps in centromere establishment.

G.A. Logsdon¹, E.A. Bassett¹, J.E. DeNizio¹, E. Barrey², P. Heun², B.E. Black¹;

¹Department of Biochemistry and Biophysics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²University of Edinburgh, Edinburgh, United Kingdom

The centromere is the chromosomal locus required for the accurate segregation of chromosomes during cell division. In many eukaryotes, including vertebrates, the centromere is marked epigenetically by the histone H3 variant Centromere Protein A (CENP-A). CENP-A assembles into nucleosomes at the centromere and forms the chromatin that recruits centromere components at the foundation of mitotic kinetochores. To dissect the roles of CENP-A at the centromere, gain-of-function histone H3 chimeras containing various regions, unique to CENP-A, have been particularly helpful. Instead of examining the requirements at established centromeres, here we investigated the earliest events we could measure in centromere establishment. To do this, we targeted human CENP-A or histone H3 chimeras to Lac operator (LacO) sequences integrated into a site on a chromosome arm by fusing each of the chimeras to the Lac repressor (LacI). Using this approach, we found surprising CENP-A requirements for initial recruitment of two essential constitutive centromere proteins (CENP-C and CENP-T) that differ from the requirements observed in genetic replacement experiments using the same H3 chimeras (Fachinetti et al., 2013, Nat Cell Biol. 9:1056-66). In particular, we found that the C-terminal tail of CENP-A is required but not sufficient for recruiting any detectable CENP-C to LacO. We also found that the recruitment of CENP-T requires three distinct regions of CENP-A: 1) a short region within the N-terminal tail of CENP-A, 2) the CENP-A targeting domain (CATD), and 3) the C-terminal tail of CENP-A. Taken together, our results indicate that the regions of CENP-A required for new centromere formation differ from those required for centromere propagation. In this way, our centromere establishment experiments help to reveal the regions of CENP-A involved in recruiting centromere components required for centromere function at mitosis that could otherwise be obscured in traditional genetic approaches by the complex intermolecular interaction network of centromere proteins.

P1041**Board Number: B368****Identification of Cdk-dependent phosphorylation sites on the CENP-A chromatin assembly complex by quantitative phosphoproteomics.**L.Y. Guo¹, X. Cao¹, A. Stankovic², L.E. Jansen², B.A. Garcia¹, B.E. Black¹;¹Department of Biochemistry and Biophysics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²Instituto Gulbenkian de Ciência, Oieras, Portugal

Maintenance of genomic stability requires accurate propagation of centromere location with every cell division. Replication of centromeric DNA in S phase must be followed by loading of new CENP-A molecules into centromeric chromatin, to prevent loss of CENP-A nucleosomes from successive dilutions. But unlike canonical histones, CENP-A loading is not coupled to DNA replication, but rather occurs exclusively after mitotic exit. This unique timing is controlled by cyclin-dependent kinases 1 and 2 (Cdk1/2), whose activity prevents CENP-A loading until the decline of Cdk1/2 activity in telophase/G1, but the targets of Cdk regulation are unknown. By combining the powerful methods of stable isotope labeling by amino acids in cell culture (SILAC), affinity-purification of the CENP-A-containing chromatin assembly complex with HJURP and its partner histone H4, titanium dioxide enrichment of phosphopeptides, as well as high-resolution mass spectrometry, we quantitatively measured the changes of multiple phosphorylation sites on CENP-A-containing complexes upon Cdk inhibition. We will present the results of these experiments, including findings that putative Cdk sites on HJURP are heavily phosphorylated in early mitosis, and are rapidly dephosphorylated upon Cdk inhibition. In contrast, putative Cdk sites on the CENP-A N-terminal tail remain phosphorylated even after Cdk inhibition. All of these post-translational modifications are strong candidates to participate in the regulation of the CENP-A chromatin assembly pathway.

P1042**Board Number: B369****Localization and function of budding yeast CENP-A depends upon kinetochore protein interactions and is independent of canonical centromere DNA sequence.**K. Ho¹, D. Tsuchiya¹, A. Oliger¹, S. Lacefield¹;¹Indiana University Bloomington, Bloomington, IN

The assembly of kinetochore at the centromere is critical for accurate chromosome segregation in mitosis. Kinetochore assembly is initiated from the centromeric chromatin, which recruits the DNA-binding inner kinetochore and the microtubule-binding outer kinetochore subcomplexes to connect the chromosome to spindle microtubules. The kinetochore is structurally conserved in eukaryotic model organisms, but the underlying centromeric sequence is highly diverse without consensus sequence. Therefore, it has been proposed that the centromere is specified by epigenetic markers, such as the centromeric histone H3 variants, CENP-A. The only exception is in budding yeast, which has a small ~125

base pair point centromere that consists of three DNA sequence elements. Although the yeast centromeric DNA sequence is sufficient for de novo kinetochore assembly, tethering specific kinetochore proteins to a non-centromeric locus can induce the assembly of a functional synthetic kinetochore, suggesting that the centromeric DNA sequence is not necessary for kinetochore assembly. It has been shown that mutations of Cse4 (the yeast CENP-A) or centromeric DNA sequence abolish the localization of most kinetochore proteins at the centromere and lead to chromosome missegregation. However, it was not clear whether the DNA sequence and Cse4 only provide information to specify the locus for kinetochore assembly, or whether they are also involved in regulating kinetochore function. We used a synthetic kinetochore to address this question because it is assembled at an ectopic locus without the centromeric sequence. In combination with biochemical and genetic approaches, we found that Cse4 is localized to the ectopic kinetochore assembly site without centromeric sequence, and is required for the function of synthetic kinetochore. These results suggest that even in the point centromere in yeast, DNA sequence is not essential for Cse4 localization and the assembly of the kinetochore. Furthermore, our results indicate that Cse4 is part of a minimal functional kinetochore, and it is directly involved in regulating kinetochore function.

TRAMM is a moonlighting protein that functions in chromosome congression, kinetochore stability and CENP-E recruitment.

M. Sacher^{1,2}, M. Milev¹, B. Hasaj¹, D. Saint-Dic¹, S. Snounou¹;

¹Department of Biology, Concordia University, Montreal, PQ, ²Department of Anatomy and Cell Biology, McGill University, Montreal, PQ

Chromosome congression requires the stable attachment of microtubules to chromosomes mediated by the kinetochore, a large proteinaceous structure whose full complement of proteins is unknown. Here we present the unexpected finding that a protein we call TRAMM, that interacts with the TRAPP vesicle tethering complex, also plays a role in mitosis. Depletion of TRAMM results in non-congressed chromosomes and leads to arrest of cells in mitosis. TRAMM associates with chromosomes and its depletion affects a number of kinetochore proteins, the strongest effect being seen for CENP-E whose recruitment to the kinetochore is greatly reduced. TRAMM is phosphorylated early in mitosis and dephosphorylated during anaphase. Interestingly, this phosphorylation/dephosphorylation cycle correlates with its association/disassociation with CENP-E. Finally, we demonstrate that a phosphomimetic form of TRAMM recruits CENP-E to kinetochores more efficiently than does the non-phosphorylatable mutant. Our study identifies a moonlighting function for TRAMM during mitosis and adds a new component to kinetochores that regulates their stability. The migration from one large complex (TRAPP) during interphase to another large complex (kinetochore) during mitosis makes TRAMM unique amongst other moonlighting proteins.

P1044**Board Number: B371****A non-epigenetic component for maintenance of human centromere function dependent on the centromeric DNA binding protein CENP-B.**D. Fachinetti¹, J. Han², P. Ly², M. McMahon³, D.W. Cleveland⁴;¹Univ California-San Diego-LICR, La Jolla, CA, ²Ludwig Institute for Cancer Research, La Jolla, CA,³University of California, San Diego, San Diego, CA, ⁴Ludwig Institute for Cancer Research and Department of Cellular and Molecular Medicine, University of California, San Diego, CA

Human centromeres are specified by an epigenetic mark that identifies and maintains centromere function through a two-step mechanism relying on self-templating centromeric chromatin assembled with the histone H3 variant CENP-A, followed by CENP-A-dependent nucleation of kinetochore assembly. Nevertheless, natural human centromeres are positioned within specific megabase chromosomal regions containing α -satellite DNA repeats, a subset of which contains DNA sequence-specific binding sites for the centromere protein CENP-B. We now demonstrate the existence of a parallel, DNA sequence-dependent pathway for kinetochore assembly that is dependent on CENP-B. CENP-B is shown to bind both CENP-A's amino tail and CENP-C. These interactions are shown to reinforce epigenetically defined centromere function through maintaining CENP-C levels at centromeres and promoting CENP-A deposition if CENP-C levels are reduced. These data identify a non-epigenetic component for human centromere function mediated by DNA sequence-specific centromere binding of CENP-B.

P1045**Board Number: B372****Artificial dimerization of INCENP/Sli15 makes the essential biorientation function of Aurora B/Ipl1 independent of its localization to microtubules and to the inner centromere.**C. Campbell¹, A. Desai², K. Turnbull²;¹University of California, San Diego, La Jolla, CA, ²Ludwig Institute for Cancer Research, La Jolla, CA

Accurate segregation of the replicated genome requires biorientation of chromosomes on the metaphase spindle, which is ensured by the kinase Aurora B/Ipl1, a member of the 4-subunit chromosomal passenger complex (CPC). In prometaphase, Aurora B localizes between sister kinetochores at the inner centromere and this localization is dependent on the CPC subunit Survivin. We had previously shown in budding yeast that disrupting inner centromere CPC localization, by truncating the N-terminus of the INCENP/Sli15 scaffold of the CPC to eliminate association with Survivin/Bir1, did not affect chromosome segregation during mitosis and meiosis (Campbell & Desai. Nature 2013 497:118-21). As N-terminally truncated Sli15, in contrast to wildtype Sli15, concentrated prematurely on pre-anaphase spindles, we proposed that the microtubule-binding activity of Sli15 was necessary for

bioorientation in the absence of inner centromere localization. Consistent with this idea, we show here that further truncation of Sli15 into the central, microtubule-binding region is lethal. Expression of a fragment (Sli15CT) that contains only the C-terminal 199 amino acids of the 698 aa-long Sli15 results in chromosome missegregation equivalent to a null mutant. Surprisingly, Glutathione-S-Transferase (GST)-mediated dimerization of Sli15CT rescued the lethality observed with Sli15CT and resulted in only mild chromosome segregation defects. In addition, GST-Sli15CT no longer localized prematurely to pre-anaphase spindles, indicating that dimerization compensates for microtubule localization. Cumulatively, these results indicate that the CPC can sense tension and correct misattachments independently of its concentration on either chromatin or microtubules. These results are consistent with a model in which physical clustering activates Aurora B/Ipl1 and kinetochore-intrinsic sensing of tension is sufficient for chromosome bioorientation.

Celular, Universidade do Porto, Porto, Portugal, ⁵Cell Division Unit, Department of Experimental Biology,

Faculdade de Medicina, Universidade do Porto, Porto, Portugal

Kinetochore-localized kinesin-7, CENP-E, is a microtubule plus end-directed motor, which is responsible for the transport of pole-proximal chromosomes from the spindle poles to the spindle equator. The plus ends of astral microtubules nucleated from the spindle poles point toward the cell cortex. However, the pole-proximal chromosomes must be transported to the spindle equator, while avoiding moving along astral microtubules towards the cell cortex. Interestingly, spindle microtubules pointing to the equator, but not the astral microtubules, are enriched in alpha-tubulin lacking the C-terminal tyrosine residue, so-called detyrosinated tubulin. To test if microtubule detyrosination affects CENP-E motility, we performed a series of in vitro assays with purified CENP-E kinesin and fully detyrosinated or tyrosinated human tubulin. Using single molecule TIRF microscopy with microtubules polymerized from these two different tubulins, we show that CENP-E walks faster and for longer distances on detyrosinated microtubules. Our preliminary force measurements using an optical trap system suggest that the CENP-E kinesin can sustain higher forces on detyrosinated vs. tyrosinated microtubules, implying that microtubule detyrosination is an important regulatory event in the specification of microtubules within the mitotic spindle. We propose that the enhanced motility of CENP-E motor on detyrosinated microtubules is responsible for the preferential motion of polar chromosomes toward the spindle equator.

P1047**Board Number: B374****CENP-E and detyrosinated microtubules guide peripheral polar chromosomes towards the cell equator.**M. Barisic¹, P. Aguiar², S. Geley³, H. Maiato^{1,4};¹Chromosome Instability Dynamics Laboratory, Instituto de Biologia Molecular e Celular, Universidade do Porto, Porto, Portugal, ²INEB, Universidade do Porto, Porto, Portugal, ³Biocenter, Innsbruck Medical University, Innsbruck, Austria, ⁴Cell Division Unit, Department of Experimental Biology, Faculdade de Medicina, Universidade do Porto, Porto, Portugal

Accurate chromosome segregation during cell division in metazoans relies on proper chromosome congression at the equator. Chromosome congression is supported by the coordinated action of motor proteins that slide misaligned chromosomes along pre-existing spindle microtubules. These proteins include the minus end-directed kinetochore motor Dynein, and the plus end-directed motors CENP-E at kinetochores and chromokinesins on chromosome arms. However, how these opposite and spatially distinct activities are coordinated to drive chromosome congression remains unknown. Here we used RNAi, chemical inhibitions, kinetochore tracking and laser microsurgery to uncover the functional hierarchy between kinetochore and arm-associated motors, exclusively required for congression of peripheral polar chromosomes in human cells. We show that Dynein poleward force counteracts chromokinesins to prevent stabilization of immature/incorrect end-on kinetochore-microtubule attachments and random ejection of polar chromosomes. At the poles, CENP-E becomes dominant over Dynein and chromokinesins to bias chromosome ejection towards the equator. Finally, we show that experimental inhibition of tubulin detyrosination in living human cells dissociates CENP-E from microtubules and impairs congression of peripheral polar chromosomes, similarly to CENP-E depletion/inhibition. This bias for detyrosinated microtubules explains the dominant and selective role of CENP-E in sliding polar chromosomes exclusively towards the equator.

P1048**Board Number: B375****Kinetochore architecture encodes a mechanical toggle-switch to control the spindle assembly checkpoint.**P. Aravamudhan¹, A.A. Goldfarb², A.P. Joglekar^{1,2};¹Biophysics, University of Michigan, Ann Arbor, MI, ²Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

How microtubule attachment to the kinetochore silences the Spindle Assembly Checkpoint (SAC) has puzzled cell biologists for over two decades. It is clear that the architecture of kinetochore changes following microtubule attachment, and that this altered architecture disrupts SAC signaling. However,

the network of protein complexes that forms the kinetochore can change in innumerable ways following microtubule attachment, and one or more of these changes can disrupt any of the steps in SAC activation. Therefore, defining the molecular mechanism that enables this attachment sensitive signaling has been challenging. To overcome this challenge, we asked how the well-defined architecture of attached kinetochore disrupts SAC signaling. We show that microtubule attachment to the kinetochore changes the separation between two conserved kinetochore proteins, Ndc80 and Spc105 to disrupt phosphorylation of Spc105, an essential step in SAC activation.

We used a comprehensive analysis of the activity of SAC proteins artificially localized at specific kinetochore positions to find that the architecture of attached kinetochore prevents Mps1 kinase from phosphorylating Spc105. Furthermore, attachment could control the phosphorylation of Spc105 only when Mps1 was localized in the outer kinetochore, proximal to the microtubule-binding domain of Ndc80. Mps1 localized in the inner kinetochore constitutively activated the SAC, irrespective of the attachment state. This suggested that Mps1 must bind to the outer kinetochore to enable attachment-dependent SAC signaling. An engineered sensor for Mps1 activity revealed that this was the case. These observations, when combined with structural and biochemical properties of Ndc80 and Spc105 suggested a simple toggle-switch like mechanism that controls the SAC: In unattached kinetochores, the microtubule-binding domain of Ndc80 and the phosphodomain of Spc105 are in close proximity. This allows Mps1 bound to Ndc80 to phosphorylate Spc105 and turn the SAC on. Microtubule attachment to the kinetochore separates the two domains, and prevents phosphorylation of Spc105 to turn the SAC off. FRET between the microtubule-binding domain of Ndc80 and the phosphodomain of Spc105 confirmed that the two domains are in close proximity (less than 10 nm) in unattached kinetochores, and are separated by microtubule attachment. We further demonstrated the working of the toggle-switch by artificially reducing the separation between its terminals: moving the phosphodomain of Spc105 close to the microtubule binding domain of Ndc80 activated the SAC irrespective of the attachment state of the kinetochore. Our results demonstrate how a specific change in the architecture of the kinetochore disrupts SAC signaling.

Reconstitution of strong kinetochore attachments requires more than the microtubule binding components.

E.M. Kudalkar¹, N. Umbreit², D. Gestaut³, E.A. Scarborough^{1,4}, C. Asbury⁵, T. Davis¹;

¹Department of Biochemistry, University of Washington, Seattle, WA, ²Harvard Medical School, Boston, MA, ³Stanford, Palo Alto, CA, ⁴Department of Biochemistry and Biophysics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, ⁵Department of Physiology and Biophysics, University of Washington, Seattle, WA

The binding strength of a native kinetochore is greater than that provided by the sum of its components. The kinetochore must retain a grip on the ends of dynamic microtubules as they proceed through phases of assembly and disassembly while under tension. If the grip is too loose, kinetochores release; if

the grip is too tight, they detach with the disassembling tubulin subunits. Native kinetochore particles with no more than 20 copies of each mechanical arm bind to dynamic microtubules with a lifetime of 40 minutes at physiologically relevant forces. The Ndc80 complex (Ndc80c) is a key microtubule-binding component of the kinetochore that is essential for viability, but only weakly binds microtubules and cannot alone recapitulate the behavior of a kinetochore. Even ~100 copies of Ndc80c on a bead achieves an attachment lifetime of only 40 seconds with an average rupture force of 2.5 pN. Previous studies have shown that combining Ndc80c with another outer kinetochore complex, Dam1c, enhances its microtubule affinity, its ability to track with dynamic tips, and its capacity to remain tip-bound under load. Dam1c and Ndc80c together yield a rupture force of 7.5 pN, significantly weaker than purified kinetochore particles, which rupture at 9 pN on average. We found that the central kinetochore complex MIND, which does not directly bind microtubules, can also enhance the strength and affinity of Ndc80c for microtubules. Using total internal reflection fluorescence (TIRF) and optical trap microscopy we demonstrate that addition of MINDc increases the residence time of Ndc80c on microtubules by 6-fold and the strength of microtubule attachments nearly 2-fold. MINDc and Ndc80c bind with a 1:1 stoichiometry; therefore the mechanism of activation cannot be simply due to oligomerization of Ndc80c by MINDc. Intriguingly, the MIND complex binds Ndc80c far away from its microtubule-binding domain, suggesting that it allosterically enhances Ndc80c-microtubule interactions. Combining the Dam1 and MIND complexes with Ndc80c additively enhances its microtubule binding and strengthens the microtubule attachment to 9 pN, the level of purified native kinetochores. This correspondence suggests that the load-bearing capacity of the kinetochore can be recapitulated using only 3 of the 8 kinetochore complexes, highlighting the importance of these complexes in maintaining strong attachments. These results highlight the individual and combined contributions of kinetochore complexes at the molecular level, providing a better understanding of kinetochore function and regulation during cell division.

Board Number: B377

Manipulating mitotic kinases through chemical dimerization: increased Aurora B or Mps1 activity at metaphase kinetochores drives chromosomes out of alignment.

E.R. Ballister¹, A.M. Mayo¹, K.K. Chiou², M.A. Lampson¹;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA, ²Physics and Astronomy, University of Pennsylvania, Philadelphia, PA

The mitotic kinases Aurora B and Mps1 play critical, inter-related roles at kinetochores and are required for both chromosome alignment and mitotic checkpoint activity. Much of our knowledge of the functions of these kinases is built on loss-of-function experiments. As a complementary approach, we sought to test the effects of increasing their activity at kinetochores during metaphase, when the activity of both kinases is normally minimal. We used chemically-induced dimerization to artificially recruit either Aurora B or Mps1 to metaphase kinetochores with temporal precision. In both cases the

metaphase plate became progressively disordered as chromosomes migrated towards spindle poles. Both perturbations destabilized kinetochore-microtubule attachments, caused Mad2 to accumulate at kinetochores and prevented cells from entering anaphase. The disruptive effect of hyperactivating Aurora B at kinetochores is consistent with prevailing models of Aurora B function and with earlier results using constitutively kinetochore-tethered Aurora B. By contrast, the effects of Mps1 activity on kinetochore-microtubule interactions were unexpected. These results motivate future experiments investigate whether Mps1 acts through direct destabilization of kinetochore-microtubule interactions, by proxy through Aurora B activation, or some combination of both processes.

Molecular Mechanisms Regulating Localization and Proteolysis of Centromeric Histone H3 Variant Cse4.

M.A. Basrai¹;

¹Genetics Branch, NIH/NCI, Bethesda, MD

Cse4p is an essential centromeric histone H3 variant in *Saccharomyces cerevisiae* that defines centromere identity. Overexpression and mislocalization of CENP-A (human homolog of Cse4) has been observed in several colorectal cell lines (Tomonaga et al. 2003). Budding yeast is an ideal model system to identify genes/pathways that can be targeted for selective lethality in cancer cells that show overexpression and mis-localization of CENP-A. Mis-localization of Cse4 is observed in yeast *spt4Δ*, *cac1Δhir1Δ*, *snf2Δ* and *psh1Δ* mutants. Proteolysis of Cse4/Cid prevents mis-localization of these proteins in yeast and flies. Psh1, an E3 ligase, interacts with the C-terminus of Cse4 and regulates its ubiquitin-mediated proteolysis. Despite ubiquitination of Cse4 by Psh1, Cse4 is only partially stabilized in *psh1Δ* strains, and the interaction of Psh1 with the C-terminus of Cse4 is not sufficient for proteolysis suggesting that additional factors and domains within Cse4 regulate its proteolysis. Studies from our laboratory are aimed at: a) defining the region(s) of Cse4 that mediate its proteolysis to prevent mis-localization to non-centromeric regions and b) characterizing pathways for proteolysis of Cse4 for faithful chromosome segregation. We provided evidence for a direct relationship between mislocalization of Cse4, and chromosome loss in budding yeast (Au et al., 2008) and showed that the N-terminus of Cse4p regulates its ubiquitin-mediated proteolysis for faithful chromosome segregation (Au et al., 2013). We performed genome-wide synthetic lethal screens with GALCSE4 to identify and characterize pathways that regulate the cellular levels of Cse4. The results of the screen has yielded a 'gold mine' of data and provided a global genetic view into potential mechanisms to target cancers overexpressing CENP-A. Our results represent the first identification for essential genes that encode components of the evolutionarily conserved ubiquitin ligase (SCF) and replication dependent kinases (DDK) complexes in Cse4 proteolysis. For non-essential genes, we identified PSH1 as well as multiple components of multi-subunit complexes such as the replication-independent histone chaperone complex (HIR1, HIR2, HIR3 and HPC2) within the top ten most significant hits of the screen. We have used multiple approaches to validate the roles of SCF, DDK complexes and histone chaperones in Cse4

proteolysis. We will present a working model showing how multiple pathways regulate the ubiquitin-mediated proteolysis of Cse4 and localizatoin. Given the evolutionary conservation of the yeast genes we will pursue studies with the human homologs to identify pathways that when disrupted lead to selective killing of cancer cells overexpressing CENP-A.

Plk1-dependent timely delocalization of the PBIP1-CENP-Q complex from kinetochores is critical for proper chromosome segregation.

C. Park¹, J. Park², T. Kim², K. Lee²;

¹Korea Research Institute of Chemical Technology, Daejeon, Korea, ²NIH/NCI, Bethesda, MD

Mammalian polo-like kinase 1 (Plk1) is critically required for proper M-phase progression. In addition to centrosomes and midbody, Plk1 localizes to late interphase and early mitotic kinetochores in a manner that requires the function of its C-terminal polo-box domain (PBD). However, the underlying mechanism of how Plk1 is recruited to and delocalized from this site and the physiological significance of this dynamic cellular process remain largely uninvestigated. We have previously shown that Plk1 recruits itself to interphase centromeres by phosphorylating and binding to the T78 residue of a kinetochore scaffold protein, PBIP1 (also called MLF1IP and CENP-U/50) through its PBD. PBIP1 also tightly interacts with another centromere component, CENP-Q, and forms a stable complex. Here, we demonstrated that the PBIP1-CENP-Q complex becomes hyperphosphorylated and unstable at the late stage of the cell cycle, and rapidly delocalized from late stage kinetochores as cells enter mitosis. Plk1 phosphorylated the CENP-Q subunit of the PBIP1-CENP-Q complex at multiple sites, and mutation of 9 Plk1-dependent phosphorylation sites to Ala (9A) enhanced CENP-Q association with chromatin and prolonged CENP-Q localization to kinetochores. Conversely, mutation of the 9 sites to phospho-mimicking Asp/Glu (9D/E) residues dissociated CENP-Q from chromatin and untimely delocalized CENP-Q from kinetochores. Strikingly, however, both the 9A and 9D/E mutants induced a defect in mitotic progression and chromosome segregation, suggesting that either prolonged localization to or precocious delocalization from kinetochores can obliterate the CENP-Q function. Notably, cytosolic PBIP1-CENP-Q complex exhibited a greater sensitivity to proteasome-dependent degradation than chromatin-bound complex in a manner that does not require Plk1 activity, suggesting that Plk1-dependent delocalization itself can indirectly lead to the degradation of the complex in mitotic cytosol. Thus, we propose that timely phosphorylation of the PBIP1-CENP-Q complex by Plk1 is important for proper delocalization and ultimate destruction of the complex, and these processes are important not only to promote Plk1-dependent mitotic progression but also to reset the timing of Plk1 recruitment to kinetochores in the next cell cycle.

P1053**Board Number: B380****Mps1 is a critical sensor that coordinates microtubule attachment and spindle checkpoint activation.**Z. Ji¹, H. Gao¹, H. Yu^{1,2};¹Department of Pharmacology, University of Texas Southwestern Medical Center, Dallas, TX, ²Howard Hughes Medical Institute, Dallas, TX

The fidelity of mitotic chromosome segregation is ensured by a surveillance mechanism called the mitotic spindle checkpoint. Generally, it senses the microtubule-unattached kinetochore and generates “wait” signals to arrest cells in mitosis. In turn, proper kinetochore-microtubule (MT) attachment could turn off the checkpoint. However, it is still unclear how the spindle checkpoint is directly tuned by microtubule attachment. Mps1 is an essential checkpoint kinase, whose kinetochore recruitment is a critical step for checkpoint activation. In this study, we have discovered a direct interaction between Mps1 and the outer kinetochore Ndc80 complex (Ndc80C). This interaction is mediated by two independent motifs of Mps1, N-motif and M-motif. Surprisingly, of the two, only N-motif contributes to Mps1 kinetochore localization. M-motif of Mps1, although dispensable for localization, is crucial for substrate phosphorylation and downstream signaling. In addition, Ndc80C is also the kinetochore receptor for spindle microtubules. Strikingly, the Ndc80C-microtubule interaction can directly prevent both N- and M-motif from engaging with Ndc80C, which restricts Mps1-Ndc80C binding and subsequent checkpoint activation to microtubule-unattached kinetochores. Taken together, we conclude that Mps1 is an attachment sensor that is critical to coordinate checkpoint activation and microtubule attachment.

P1054**Board Number: B381****Centromeric Plk1 activity stabilizes the kinetochore to ensure high-fidelity chromosome segregation.**R. Lera¹, M.E. Burkard¹;¹University of Wisconsin-Madison, Madison, WI

Polo-like kinase 1 (Plk1) has a multitude of required functions which are executed during human cell division. In early mitosis, Plk1 localizes to kinetochores, amongst other sites. Over 20 substrates of Plk1 have been described at the kinetochore but their relative contributions to overall mitotic fidelity remain obscure. Here, we used allele-specific chemical probes to isolate Plk1 functions at the kinetochore. With modest reductions in overall Plk1 activity, most functions are preserved, but chromosomes missegregate on bipolar spindles in anaphase. Mechanistically, this occurs due to tension-sensitive kinetochore dysfunction wherein CENP-A and all other kinetochore proteins tested are lost from a single sister chromatid, which is silent to the mitotic checkpoint. Loss of histone-variant CENP-A is particularly surprising because Plk1 is not readily detected at the centromere. To evaluate whether the requisite

Plk1 activity arises indirectly from outer-kinetochore or occurs directly from centromeric activity, we tethered complementing Plk1 kinase domain to distinct locales from microtubule tips (Kif18, MCAK), to kinetochore (Hec1, BubR1, Bub1, Dsn1) to the centromere (MCAK, CENP-A, CENP-B), and to chromatin (H2B). We separately control activity of this complementing kinase using orthogonal chemical genetics (Burkard et al. ACS Chem Biol 7:978, 2012). After confirming localization and activity, we evaluated for ability to rescue the chromosome missegregation phenotype. Surprisingly, only inner-centromeric and chromatin-localized Plk1 activity rescue kinetochore dysfunction (MCAK- and H2B-tethered). Crucially, the rescue is lost with specific chemical inhibition of this localized activity. These two constructs co-localize only at the centromere, suggesting that this is the site of Plk1 action. To test this, we performed MCAK mutational analysis to independently enforce localization at microtubule tips or the centromere. Only Plk1 tethered to MCAK at the centromere was functional. Thus, our data provide convergent evidence of critical mitotic functions of Plk1 that occur at the inner centromere. Our results suggest that a small pool of active Plk1 exists at the centromere, where it is not readily detected. Alternatively, kinetochore-bound Plk1 may phosphorylate centromeric proteins until tension from the spindle effectively removes the possibility of Plk1-centromere overlap. In either case, only a limited pool of Plk1 is available to act at centromeres, explaining why the kinetochore –dysfunction phenotype is highly sensitive to modest losses of kinase activity. We are thus able to isolate and localize discrete Plk1 functions using chemical biology to obtain mechanistic insight into function of this pleotropic mitotic kinase.

Lateral and end-on kinetochore attachments are required for chromosome segregation in *Drosophila* oocytes.

S.J. Radford¹, K.S. McKim¹;

¹Waksman Institute, Piscataway, NJ

Proper chromosome segregation is achieved through the regulated interaction of chromosomes with a bipolar array of microtubules that constitute the spindle. The meiotic spindle in the oocytes of many organisms, including humans and *Drosophila*, is built in the absence of the classical microtubule-organizing centers known as centrosomes. In the presence of centrosomes, chromosome segregation depends on interactions between the kinetochore, a protein complex that assembles at the centromere, and microtubules that connect to the centrosomes. However, it has been suggested that kinetochore-microtubule interactions may not participate in chromosome congression or segregation in acentrosomal oocytes. To determine the role of kinetochores during spindle assembly and chromosome orientation in *Drosophila* oocytes, we used a technique in which RNAi knockdown of kinetochore components is confined to oocytes after meiotic entry. Our results suggest that the proportion of kinetochore-dependent microtubules in the spindle changes as oocytes progress from prometaphase to metaphase, such that kinetochores are essential for metaphase spindle stability. In addition, we found that both lateral and end-on kinetochore-microtubule interactions are required for the proper

orientation of centromeres toward spindle poles, although lateral interactions are sufficient for prometaphase chromosome movements. Surprisingly, we also found that the kinetochore may play a role in sister centromere co-orientation, perhaps by affecting sister chromatid cohesion. These results support a model in which oocyte chromosomes initially interact with microtubules laterally at kinetochores while orientation is established, then end-on kinetochore-microtubule interactions are required to direct chromosome segregation.

CLIP-170 is required to recruit PLK1 to kinetochores during early mitosis for chromosome alignment.

M.A. Amin^{1,2}, K. Tanaka³;

¹Tohoku Univ, Aoba-ku, Sendai, Japan, ²Biochemistry and Molecular Biology, University of Dhaka, Dhaka, Bangladesh, ³Tohoku Univ, Sendai, Japan

During cell division, faithful chromosome segregation is dependent on the efficient and correct formation of kinetochore–microtubule (KT–MT) attachments on the mitotic spindle, which facilitate the progress of chromosome alignment. Polo-like kinase 1 (PLK1) is a key regulator of mitotic division and required for the formation of stable KT–MT attachments and chromosome alignment. Cytoplasmic linker protein (CLIP)-170, a microtubule plus-end-tracking and outer kinetochore protein, also has a role in KT–MT attachment and chromosome alignment during mitosis. However, the mechanism of CLIP-170's role in chromosome alignment remains unknown. Here we report that CLIP-170 functions in chromosome alignment by recruiting PLK1 to kinetochores during early mitosis and, in turn, stabilizing K-fibers, both of which are mediated by phosphorylation of its CDK1-site T287. We show that CLIP-170 co-localizes with PLK1 at kinetochores during early mitosis. Depletion of CLIP-170 results in a significant reduction of PLK1 recruitment to kinetochores leading to reduction of kinetochore localization of CENP-E and CLASPs. The reduction of localization of kinetochore proteins causes kinetochore-fiber (K-fiber) instability and defects in chromosome alignment at the metaphase plate. These phenotypes are dependent on the phosphorylation of CLIP-170 at a CDK1-site, T287, as ectopic expression of wild-type CLIP-170, but not non-phosphorylatable mutant, CLIP-170–T287A, restores PLK1, CENP-E and CLASPs localization at kinetochores and rescues K-fiber stability and chromosome alignment. Immunoprecipitation experiments show that the interaction between CLIP-170 and PLK1 is dependent on CLIP-170 phosphorylation on the CDK1-site, T287, during early mitosis. These data suggest that CLIP-170 acts as a novel recruiter and spatial regulator of PLK1 at kinetochores during early mitosis, to promote K-fiber stability and chromosome alignment for error-free chromosome segregation. The relative contributions of different pathways for PLK1 recruitment to kinetochores to facilitate KT–MT attachment and chromosome alignment will be an important topic for future studies.

P1057**Board Number: B384****The novel mitotic factor CR1 governs PLK1 docking and function at kinetochores.**H. Lee¹, H. Cho¹;¹Ajou University, Suwon, Korea

Polo-like kinase1 (PLK1) at mitotic kinetochores plays an essential role for faithful chromosome alignment and segregation; however, it remains unknown how PLK1 is recruited to kinetochores. Here, we show that novel mitotic factor CR1 resides at mitotic kinetochores and directly binds PLK1. Kinetochores localization of PLK1 was disrupted by CR1 depletion, which was fully rescued by the C-terminal fragment of CR1. CR1 was phosphorylated by CDK1 at the Ser1375, which triggers PLK1 deposition and subsequent PLK1-mediated phosphorylation on CR1. CR1S1375A neither bound PLK1 nor accumulated PLK1 at kinetochores. Chromosome alignment was profoundly defective in CR1-depleted cells; these defects were rescued by phosphomimetic CR1S1375D. Together, the results indicate that CR1 is an essential centromeric component that recruits PLK1 to kinetochores and plays a crucial role for genomic integrity.

P1058**Board Number: B385****How the kinetochore harnesses microtubule force and centromere stretch to move chromosomes revealed by a FRET tension sensor within Ndc80 protein.**A. Suzuki¹, B.L. Badger¹, J. Haase¹, T. Ohashi², H.P. Erickson², E.D. Salmon¹, K.S. Bloom¹;¹Biology, University of North Carolina, Chapel Hill, NC, ²Department of Cell Biology, Duke University Medical Center, Durham, NC

The Ndc80 complex (Ndc80, Nuf2, Spc24, Spc25) is a highly conserved kinetochore protein essential for end-on anchorage of kinetochore microtubule (kMT) plus-ends and for force generation coupled to attached plus-end polymerization and depolymerization. Spc24/Spc25 at one end of the Ndc80 complex binds the kinetochore. The N-terminal tail and CH domains of Ndc80 at the other end bind microtubules (MTs). An internal loop domain of Ndc80 may be linked to microtubule-associated proteins (MAPs) such as the Dam1 complex. To determine how the MT and MAP binding domains of Ndc80 contribute to force production at kinetochores in budding yeast, we have inserted a characterized FRET tension sensor into Ndc80 protein about halfway between its CH and loop domains. During the cell cycle, the FRET sensor reported low tension from late anaphase through interphase and high tension at metaphase, when pericentromeric chromatin is maximally stretched between sister kinetochores. In addition, we found that both Stu2, which concentrates at MT plus ends during polymerization, and tension reported by the FRET sensor fluctuated over time indicating that tension at the MT binding domains of Ndc80 is different for the polymerization and depolymerization phases of kMT dynamic instability. Surprisingly, FRET sensor measurements showed that reducing MT dynamicity with low dose benomyl at metaphase caused a major drop in tension at the MT binding domains of Ndc80 without loss of normal centromere

stretch. In addition we found that tension at the MT binding domains of Ndc80 is abnormally low with a Dam1 mutation (DAM1-765, Shimogawa et al., 2006) that enhances Dam1 complex affinity for MTs and produces at metaphase hyper-centromere stretch. The above data suggest that Dam1 complex bound to Ndc80 complex at a site inside the FRET tension sensor has a dominant role, compared to the MT binding domains of Ndc80, for attachment to kMT plus ends at metaphase. Based on the above in vivo studies and in silico simulations, we propose a mechanical model for the Ndc80 force coupler at budding yeast kinetochores. During depolymerization, pushing forces from peeling protofilaments against the Dam1 complex pulls on the Ndc80 complex to stretch the centromere and drags the MT binding domains of Dam1 and Ndc80 poleward along their kMT at the velocity of depolymerization until a switch occurs to polymerization. Then, during polymerization, pulling force from centromere stretch on the Ndc80 complex drags the MT binding domains of Dam1 and Ndc80 complexes away from the pole along their kMTs until a switch occurs to depolymerization.

The Nucleoporin MEL-28/ELYS promotes chromosome segregation during meiosis I by recruiting Protein Phosphatase 1 (PP1).

N. Hattersley¹, M. Stefanutti², M. Moyle¹, J. Dumont², K. Oegema¹, A. Desai¹;

¹Ludwig Institute for Cancer Research, La Jolla, CA, ²Institut Jacques Monod, Paris, France

In many species that undergo open mitoses, a subset of nucleoporins (most prominently the Y-complex, also known as the Nup107/160 complex) localize to kinetochores following nuclear pore disassembly. Despite wide conservation of this dynamic localization pattern, the function of these nucleoporins in chromosome segregation remains poorly understood. We have been using *C. elegans* as a model to understand how the Y-complex functions in chromosome segregation. This effort has revealed a key role for one complex member MEL-28 (ELYS in vertebrates) in meiosis I anaphase. MEL-28 depletion prevents the segregation of chromosomes in oocyte meiosis I, although it does not perturb bipolar spindle formation, spindle positioning, chromosome alignment, or activation of the cohesin-cleaving enzyme separase. Meiotic chromosome segregation activity is intrinsic to MEL-28 and distinct from its role in nuclear pore assembly, as it does not require other Y-complex subunits. MEL-28 is 1784aa in length with the first half forming folded beta-propeller and alpha-solenoid domains and the second half being primarily unstructured. Truncation analysis of MEL-28 revealed a short 50aa region adjacent to the structured domains as being essential for meiotic chromosome segregation. Sequence analysis of this region revealed a potential PP1 (protein phosphatase 1) docking motif and biochemical and yeast 2-hybrid assays confirmed motif-dependent direct interaction of MEL-28 with GSP-1/2 (*C. elegans* PP1 catalytic subunit homologues). Importantly, mutation of the PP1 docking motif phenocopied the MEL-28 depletion phenotype in meiosis I anaphase chromosome segregation. However, in contrast to MEL-28 depletion, the PP1 docking motif mutant did not appear to disrupt nuclear pore assembly, which is enabling current efforts to investigate the function of the MEL-28-PP1 interaction during mitotic chromosome segregation. Notably, despite poor primary sequence conservation in the unstructured

region, the PP1 docking motif is conserved in vertebrate homologues of MEL-28. These results suggest that the MEL-28-PP1 interaction plays a conserved role in chromosome segregation, which has become functionally critical in the context of meiosis I anaphase in *C. elegans* oocytes.

Kn1-dependent Determinants of Human Mad1 Kinetochores Recruitment.

G.V. Caldas¹, T.M. Lynch¹, D. Varma², J.G. DeLuca¹;

¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, ²Biochemistry and Biophysics, UNC Chapel Hill, Chapel Hill, NC

Several lines of evidence point toward a central role for the protein KNL1 in kinetochore function. KNL1 is necessary for proper kinetochore targeting and function of proteins involved in several mitotic pathways, including checkpoint signaling and checkpoint silencing. In yeast, it has been recently determined that Bub1, recruited to kinetochores through KNL1, is the main receptor for Mad1 and Mad2, the key proteins that signal activation of the mitotic checkpoint. In human cells, however, it is not yet well established which kinetochore protein(s) function as the Mad1/Mad2 receptor. Previous work showed that Bub1 depletion from human cells results in decreased Mad1/Mad2 levels at kinetochores. Interestingly, it has also been proposed that Mad1 localization depends on proper kinetochore recruitment of the RZZ complex, required for checkpoint silencing and also dependent on KNL1, and Zwint-1. Because the ability of KNL1 to mediate Mad1/Mad2 and RZZ targeting to kinetochores sets the foundation for checkpoint signaling, we investigated the KNL1-dependent requirements for Bub1, Mad1, and RZZ complex kinetochore localization, and the dependencies among these proteins. Consistent with data from other organisms, we find that Mad1 localization to kinetochores follows the same KNL1-dependence pattern as that of Bub1 and is significantly decreased upon Bub1 depletion. We also find that depletion of Rod (a subunit of the RZZ complex) results in almost a complete loss of Mad1 from kinetochores. However, a KNL1 fragment that is able to recruit Rod is not sufficient for Mad1 kinetochore localization. Finally, depletion of Bub1 caused a significant decrease in the kinetochore localization of the RZZ complex. Our results provide evidence for a Kn1-dependent hierarchy for Mad1 recruitment to mitotic kinetochores.

P1061**Board Number: B388****Kif18a stabilizes kinetochore microtubule attachments.**H. Kim¹, A. Czechanski², C. Byers², I. Greenstein², C. Fonseca¹, L. Reinholdt², J.K. Stumpff¹;¹Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, ²Genetic Research Science, Jackson Laboratory, Bar Harbor, ME

During mitosis, duplicated genetic material is segregated to each daughter cell, mediated by the dynamic network of microtubules within spindle. A specialized protein complex known as the kinetochore provides the physical linkage between the chromosome and the spindle microtubules. The phosphorylation state of kinetochore proteins influences their affinity for the microtubule lattice. Stable, high-affinity attachments between microtubules and kinetochores maintain the structural integrity of the spindle, are required to silence the spindle assembly checkpoint, and facilitate chromosome segregation. The mitotic kinesin Kif18a (kinesin-8) has been shown to regulate kinetochore microtubule (k-fiber) length to promote chromosome alignment (Mayr et al, 2007, Stumpff et al, 2008). However, our data suggest that Kif18A also functions to stabilize kinetochore-microtubule attachments. Somatic human cells depleted of Kif18A display an increase in the number of kinetochores that are positive for MAD1, a key component of the spindle assembly checkpoint. In addition, depleting Kif18A from diploid human cells also leads to a modest increase in the time required for cells to progress from nuclear envelope breakdown to anaphase. Furthermore, we show that primordial germ cells, but not somatic cells, from Kif18A mutant mice arrest in mitosis and display a severe proliferation defect. These data indicate that Kif18A promotes connections between kinetochores and microtubules and that this function may be essential during mammalian development for the proliferation of germ line precursors.

P1062**Board Number: B389****A role for Aurora A kinase in kinetochore-microtubule attachment regulation.**K.F. DeLuca¹, J. Mick¹, J.G. DeLuca¹;¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

One of the most important regulatory aspects of chromosome segregation is the ability of kinetochores to precisely control their attachment strength to microtubules. During early mitosis, attachments are labile to prevent prematurely stabilized connections, whereas during late mitosis, attachments are stabilized so that forces can be generated for chromosome congression and to silence the spindle assembly checkpoint. Central to this regulation is Aurora B kinase, a mitotic kinase that phosphorylates kinetochore substrates to promote microtubule turnover. Arguably, one of the most critical Aurora B targets for this regulation is the Hec1 subunit of the NDC80 complex, which is the primary force-transducing link between kinetochores and microtubules. Phosphorylation of the unstructured N-terminal tail of Hec1 reduces NDC80-microtubule affinity in vitro and kinetochore-microtubule affinity in cells. Previous work using phospho-specific antibodies to multiple Hec1 tail target sites revealed high

levels of phosphorylation in early mitosis and low levels in late mitosis, consistent with the idea that high levels of Hec1 phosphorylation promote rapid kinetochore-microtubule turnover. Recently, we generated a phospho-specific antibody against Serine 69 of the Hec1 tail to determine whether this residue, positioned close to the Hec1 calponin homology domain (which directly binds the microtubule lattice), exhibits a similar phosphorylation pattern to that of other tail phospho-residues. Strikingly, the phosphorylation pattern for Ser69 is quite different from that of Ser8, Ser15, Ser44, and Ser55, as Ser69 phosphorylation is high during early mitosis and does not decrease during metaphase. In addition, unlike the other phospho-sites, the pSer69 signal is not significantly reduced following Aurora B kinase inhibition. Testing other mitotic kinase inhibitors led us to Aurora A kinase, whose inhibition in PtK1, HeLa, and RPE1 cells results in a significant decrease in the phosphorylation of Hec1-Ser69, but not of other Hec1 residues. Furthermore, we found that inhibition of Aurora A kinase prevents proper metaphase chromosome dynamics. These findings uncover an unexpected role for Aurora A kinase, as it is known to localize to spindle poles and is primarily implicated in spindle assembly.

Stable kinetochore-microtubule attachment satisfies the spindle assembly checkpoint in the absence of sister kinetochore biorientation.

J.G. DeLuca¹, E.C. Tauchman¹;

¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Accurate segregation of replicated chromosomes during mitosis is essential for the maintenance of genomic integrity. To ensure faithful chromosome segregation, eukaryotic cells have developed a surveillance network called the spindle assembly checkpoint (SAC) that delays anaphase onset until sister kinetochores of duplicated chromosomes are properly attached to microtubules emanating from opposite spindle poles. SAC proteins accumulate at kinetochores of mitotic chromosomes in the absence of stable microtubule attachments and transmit a signal that inhibits the Anaphase Promoting Complex/Cyclosome (APC/C). Once microtubules attach to kinetochores, SAC proteins are evicted, which leads to silencing of the SAC inhibitory signal, activation of the APC/C, and subsequent mitotic exit. Precisely how the inhibitory SAC signal is extinguished in response to microtubule attachment remains unresolved, although it is likely that both the physical attachment of microtubules to kinetochores and the ensuing pulling forces that result are important aspects of the signaling process. Here we investigate how hyper-stabilization of kinetochore-microtubule attachment affects progression through mitosis. To induce kinetochore-microtubule hyper-stabilization, we used a mutant version of the kinetochore-microtubule attachment factor Hec1 that is unable to be phosphorylated by Aurora B kinase: 9A-Hec1. Specifically, this is a mutant in which nine identified Aurora B target sites were mutated to alanine (9A). Cells depleted of endogenous Hec1 and rescued with 9A-Hec1-GFP harbor hyper-stable kinetochore-microtubules as evidenced by increased inter-kinetochore distances, increased kinetochore-fiber size, an accumulation of erroneous attachments including merotelic and syntelic, and defects in correcting such errors. We find that the hyper-stable kinetochore-microtubule attachments in cells expressing 9A-Hec1

GFP are sufficient to silence the SAC, even in the absence of chromosome bi-orientation or experimentally induced tension. Furthermore, we find that hyper-stable kinetochore-microtubules are sufficient to induce structural changes in kinetochores, as evidenced by development of intra-kinetochore stretch, even in the absence of amphitelic attachment. Our results suggest that the structural changes brought on by stable kinetochore-microtubule attachment are sufficient to silence the SAC, and furthermore, these changes are sensed autonomously by individual kinetochores.

The Missing Link in Kinetochore-Microtubule Error Correction: Detachment at Spindle Poles.

K. Yang¹, L. Chmatal¹, R. Schultz¹, M.A. Lampson¹;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA

Faithful DNA segregation between dividing cells requires chromosomes to attach to microtubules from opposite spindle poles (bi-orientation). This process is regulated by Aurora B kinase, which selectively destabilizes microtubule attachments until proper orientations are achieved. To correct syntelic attachments, in which sister kinetochores are attached to the same spindle pole, Aurora B drives the mal-oriented chromosome towards the pole without releasing its microtubule attachments. The chromosome then re-congresses and aligns the metaphase plate, but it is unclear how erroneous microtubules are detached before proper attachments are formed. Here we demonstrate that proximity to the spindle poles destabilizes kinetochore-microtubules. To study the pole effect without interference from other components of error correction, we used meiotic systems featuring asymmetrical chromosomes (i.e. trivalents, unbalanced bivalents) that are off-centered even when correctly attached. We show that kinetochores near the spindle poles are less likely to have stable microtubule attachments and that these attachments can be restored by inhibiting Aurora A kinase. We also show that MAD1 accumulation on kinetochores is directly linked to the poleward movement of chromosomes. Our results suggest that syntelic attachments can be destabilized by pole proximity, which is critical for ensuring chromosome bi-orientation and accurate segregation.

P1065**Board Number: B392****Generational conflict in mitosis: old centrosome retains non separated sister chromatids.**I. Gasic¹, J. Meadows², P. Nerurkar³, P. Meraldi¹;¹Cell Physiology and Metabolism, University of Geneva, Geneva, Switzerland, ²Biomedical Cell Biology, University of Warwick, Coventry, UK, ³Institute of Biochemistry, ETH Zürich, Zurich, Switzerland

The centrosomes of the two spindle poles contain centrioles of different age, one old and one young, creating an inherent asymmetry in the mitotic spindle. In the self-renewing asymmetric stem cell divisions, unequal old-young centrosome behaviour results in a bias in centrosome positioning and inheritance, which is critical for daughter cell fate determination. In contrast, it is assumed that in symmetric cell divisions the behaviours of the two centrosomes are indistinguishable. Here, we demonstrate that even in somatic symmetric cell divisions the old and the young centrosomes are functionally different during mitosis. Both in transformed and non-transformed human cells centrosomes display a difference in the stability of kinetochore-microtubules associated to them. This difference is reflected in the efficiency of chromosome alignment onto the metaphase plate, as we find that chromosomes bound to the old centrosome are delayed in their alignment. The unequal stability of kinetochore-microtubules persists in anaphase: merotelic sister chromatids that fail to separate have a 9-fold higher probability to mis-segregate to the cell that inherits the old centrosome. This bias in chromosome mis-segregation is conserved during evolution, as non-separated merotelic sister chromatids have the same 9-fold higher probability to end up in the cell with the old spindle pole body in the fission yeast *Schizosaccharomyces pombe*. We thus postulate that the inherent age difference of centrosomes favours stem cells to retain chromosomes in the event of sister chromatids non-separation.

P1066**Board Number: B393****Scaling and Evolutionary Dynamics of the Mitotic Spindle.**R. Farhadifar^{1,2}, C.F. Baer³, A. Valfort⁴, E. Andersen⁵, T. Müller-Reichert⁶, M. Delattre⁴, D.J. Needleman^{1,2,7};¹FAS Center for Systems Biology, Harvard University, Cambridge, United States, ²Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA, ³Dep. Biology, University of Florida, Gainesville, FL, ⁴CNRS, Lyon, France, ⁵Molecular Biosciences, Northwestern University, Evanston, IL, ⁶Medical Faculty "Carl Gustav Carus", TU Dresden, Dresden, Germany, ⁷School of Engineering and Applied Sciences, Harvard University, Cambridge, MA

Cellular structures such as the nucleus, the Golgi apparatus, centrioles, and the spindle show remarkable diversity across different species. The mechanisms that produce these variations in cell biology are not known. We study the mechanisms that contribute to variations in morphology and dynamics of the

mitotic spindle, the subcellular structure that segregates the chromosomes during cell division. We developed a high-throughput microscopy platform and automated image analysis software that allows us to obtain quantitative information on the structure and dynamics of spindles from thousands of embryos in hundreds *C. elegans* lines. We found extensive variations among wild isolates of *C. elegans* for all traits we studied including: cell size; the length, motion, and speed of elongation of the spindle; the size of centrosomes; the positioning of the cleavage plane. We demonstrate that the effects of spontaneous mutations on cell division in a single generation, combined with stabilizing selection on embryo size, are sufficient to quantitatively explain both the levels of within species variation in the spindle and the diversity in the spindle over ~100 million years of evolution. Our results argue that selection acts predominantly on embryo size, which is also the size of the cell for the first mitotic division in nematodes, and indirectly influences the spindle morphology and structure through the scaling of the spindle with cell size. Our finding of extensive within species variation for the spindle demonstrates that there is not just one “wild type” form, rather cellular structures can exhibit a surprisingly broad diversity of naturally occurring behaviors. Also, mapping the genetic basis of these within species differences opens a novel route for studying evolutionary and mechanistic aspects of cell biology.

Homology modeling and functional analysis of the mitotic checkpoint complex in budding yeast.

T. Van Eeuwen¹, J. Luginsland¹, P. Melloy¹, G. Anderle¹;

¹Fairleigh Dickinson Univ, Madison, NJ

The interactions of Cdc20p/Mad3p/Mad2p, members of the mitotic checkpoint complex (MCC) in budding yeast, were examined using computational chemistry and cellular biology. Computer analysis of target protein structure was compared with observational data from *in vivo* studies. The focus of computer modeling was to evaluate structure, conformation and functional domains, specifically the KEN box receptor and D box receptors, sites of Cdc20/Mad3 interaction. Furthermore, the effects of known point mutations in CDC20 on the complex were also studied. To facilitate computational analysis, models of wild type Cdc20p, Mad3p, and Mad2p were constructed through homology modeling. The crystal structures of the *Schizosaccharomyces pombe* (fission yeast) homologs were used as the templates to generate homology models. Sequence alignment and manual optimization was performed in SWISS-MODEL and homology modeling completed in Molecular Operating Environment (MOE). Homology models were analyzed for accuracy by comparing side chain positions to crystal structures and structurally validated via Molprobit. Molecular dynamics (MD) simulations were then carried out in Amber10 for gross protein minimization and data acquisition of protein behavior in solution. Visual Molecular Dynamics (VMD) was used for frame-by-frame analysis of the system for evaluation of intermolecular bonding, protein-solvent interactions and movements. PyRosetta was used to refine average MD structures through a series high- and low-resolution conformational sampling functions.

Docking of the three MCC proteins was also performed through PyRosetta.

Additional analysis was conducted to look at the effect of the *cdc20-1* mutation on functional domains in Cdc20, targeting KEN and D box receptors, and to evaluate potential interference with Mad3 binding. Homology models were studied at temperatures simulated to match the permissive and non-permissive temperature for the *cdc20-1* mutant.

To complement the computational studies of interactions within the MCC complex, the *in vivo* localization of MCC proteins such as Cdc20p and Mad3p was examined using GFP tagging and fluorescence microscopy. The version of the protein expressed in the *cdc20-1* mutant was also studied and compared to the wild type.

The main objective of the *in vivo* studies was to understand the difference between the normal MCC protein interactions and the *cdc20-1* mutant protein when it is a part of the MCC. Our goal was to better understand interactions among members of the MCC complex; information that could lead to an enhanced understanding of mitosis in other organisms including humans.

Isolation of the tension-mediated spindle assembly checkpoint response using a novel Taxol-sensitive yeast model.

K.G. Proudfoot¹, M.L. Gupta²;

¹Cell and Molecular Biology, Univeristy of Chicago, Chicago, IL, ²Univeristy of Chicago, Chicago, IL

The spindle assembly checkpoint (SAC) delays anaphase until all kinetochores bind microtubules, and there is tension between sister chromatids, which signifies bipolar attachment. Despite its critical role in maintaining genomic stability, mechanistic details of the tension-mediated SAC response remain unclear. One significant limitation of current model systems is the experimental intractability of the tension and the attachment status at kinetochores. In metazoan cells, Taxol stabilizes microtubules and reduces tension, but also causes a subset of kinetochore sites to remain unbound by microtubules. Budding yeast has been a preeminent system for investigating SAC function, but a major limitation is that microtubule stabilizers like Taxol have no effect on yeast cells. Conventionally, kinetochore tension is reduced by inhibiting chromosome replication or cohesion. However, these treatments stimulate kinetochore detachment and also disturb bipolar spindle organization. We developed a novel, Taxol-sensitive yeast system in which we can limit tension across sister chromatids independent of microtubule detachment. This allowed us to experimentally isolate a tension-specific SAC response in otherwise normal, bipolar spindles. By manipulating the cell cycle we allowed proper bipolar spindles to assemble in the absence of Taxol. We observed that, similar to metazoan cells, addition of Taxol decreased the distance between sister kinetochores. Significantly, yeast kinetochores bind only one microtubule, and the reduced tension did not disrupt bipolar attachment. Strikingly, Taxol induced a transient SAC-dependent delay in anaphase onset. Similarly, while deletion of all SAC proteins makes cells supersensitive to microtubule destabilizing drugs, a subset of deletions rendered cells supersensitive to Taxol, suggesting that attachment and tension sensing may have different signaling

requirements. In summary, we developed and leveraged a novel model system to demonstrate a distinct, tension-mediated SAC response.

Three-dimensional reconstructions of the first mitotic spindle reveals a novel mechanism for spindle assembly in *C. elegans*.

S. Redemann¹, A. Kratz², D. Needleman³, S. Prohaska², T. Müller-Reichert⁴;

¹TU Dresden/MTZ, Dresden, Germany, ²Zuse Institute, Berlin, Germany, ³Harvard School of Engineering and Applied Sciences, Cambridge, MA, ⁴Medical Faculty "Carl Gustav Carus", TU Dresden, Dresden, Germany

Upon entering mitosis, the microtubule cytoskeleton of any eukaryotic organism undergoes a fundamental reorganization to form a bipolar spindle, which first aligns the condensed chromosomes on the metaphase plate and then segregates them to the resulting daughter cells. Despite the fact, that bipolar spindles are composed of the same building blocks and conduct the same function, there is a huge variety in spindle size, assembly and architecture across eukaryotic species. In order to understand spindle architecture, it is essential to understand the detailed 3D ultrastructure of a mitotic spindle and to quantitatively study the key features. We generated full 3D reconstructions of the first mitotic spindle in *C. elegans* during metaphase and anaphase using serial-section electron tomography. We combined this detailed structural data with dynamic data from light microscopy. Using this approach we were able to detect individual microtubules attached to the holocentric kinetochores. This analysis provided us with detailed information on the number of microtubules attached per chromosome, as well as the position of attachment sites on the chromosomes. To our surprise the percentage of kinetochore microtubules within the spindle is very small, only about 5%. In contrast to our expectations, our results argue that kinetochore microtubules do not originate at the centrosomes, but polymerize from kinetochores, most likely with the minus ends of the microtubules facing towards the centrosome. This suggests a yet unknown mechanism in *C. elegans*, in which microtubules nucleated from centrosomes interact with microtubules originating from kinetochores to form the bipolar mitotic spindle.

Polar ejection forces are involved in Spindle Assembly Checkpoint satisfaction during mitosis of unreplicated genome.

D. Drpic¹;

¹IBMC, Porto, Portugal

Complete DNA replication during S phase and establishment of bipolar attachments during mitosis is from crucial importance for the life of the cell. In our work we are investigating the Spindle Assembly

Checkpoint (SAC) satisfaction in the absence of interkinetochore tension. For that propose, we used Dup (double parked) RNAi depletion, a protein involved in origin of replication and post-replication checkpoint response at the end of G2 phase, which allowed *Drosophila* S2 cells to enter mitosis without previous replication of the genome. This interesting phenomenon is known as mitosis of an unreplicated genome (MUG). S2 cells undergoing MUG have condensed single chromatids, unstably attached to spindle microtubules. By using live cell imaging and *Drosophila* S2 cells stably expressing fluorescently labeled proteins we were able to follow the dynamics of mitotic proteins during MUGs. *Drosophila* S2 cells undergoing MUG stayed longer time in mitosis compared with control cells, which was result of slower cyclin B degradation in RNAi treated cells. Nevertheless, after delay (2-3h) Dup depleted cells were able to exit mitosis with previous SAC satisfaction.

The correct mechanism how SAC can be satisfied in the absence of interkinetochore tension is unknown. Here we show the role of Polar Ejection Forces (PEFs) in establishment of intrakinetochore stretch, as a mechanism for SAC satisfaction in the absence of interkinetochore tension during mitosis of unreplicated genome.

Measurement of the force that centers the mitotic spindle in the early *C. elegans* embryo using magnetic tweezers.

C. Garzon-Coral¹, H. Fantana¹, J. Howard²;

¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ²Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

Because the plane of cell division bisects the mitotic spindle, the positioning of the spindle specifies the size and location of the two daughter cells. Little is known, however, about the mechanical processes underlying spindle positioning. To study this mechanism, we applied calibrated magnetic forces to the spindle via super-paramagnetic beads inserted into the cytoplasm of one- and two-cell *C. elegans* embryos.

At metaphase in the one-cell embryo, a 20 pN force displaced the mitotic spindle pole of one-cell embryos approximately 1 μm away from the anterior-posterior axis over 10-20 seconds. By tracking the bead displacement, we found that the spindle behaved roughly as a damped spring with a spring constant of 18 ± 12 pN/ μm and a drag coefficient of 127 ± 65 pN·s/ μm (mean \pm SD).

The centering stiffness was two-fold higher in the two-cell embryo, consistent with a centering mechanism that scales inversely with cell size. The stiffness increased when the number of microtubules reaching the cortex was increased two fold using RNAi against the depolymerizing kinesin klp-7, but remained roughly the same when the interaction time of microtubules with the cortex was increased using RNAi against efa-6, a cortical catastrophe factor and when cortical pulling forces were reduced by RNAi against gpr-1/2, an activator of the cortical force generators. Furthermore, the stiffness was five-

fold higher during anaphase in both the one- and two-cell stage embryos, indicating that the centering forces change during the cell cycle.

Taken together, our results constrain molecular models of centering. The *gpr-1/2* RNAi knockdown results rule out a role for cortical forces pulling on the spindle via astral microtubules and the scaling with cell argues against pulling by cytoplasmic factors. On the other hand, the results are consistent with centering being mediated by astral microtubules pushing against the cortex as the centering forces scales with the number of microtubules, the cell size and the pushing time of microtubules against the cortex.

Moreover, these results help us to understand how change in mechanical properties is linked to the function of the spindle in metaphase and anaphase.

Chromosome alignment in the middle of the bipolar spindle is a hallmark of metazoan cell division. When we force human cells to build asymmetric spindles by creating an asymmetric distribution of centrioles numbers at each spindle pole, we find that they always re-center the position of the metaphase plate before anaphase onset. This plate centering mechanism is made possible by delaying satisfaction of the spindle assembly checkpoint, to provide cells enough time to correct metaphase plate position before anaphase onset. Cells with only one centriole at each pole do not elicit a checkpoint response, indicating that the spindle assembly checkpoint response depends on the asymmetry of centriole distribution, and not on the change in centriole numbers per se. The checkpoint response in cells with an asymmetric centriole distribution is not elicited by unattached or tension free kinetochores, but by minor defects in the maturation of kinetochore-microtubule attachments, which arise as a consequence of an imbalance in microtubule stability between the two half-spindles. Stabilizing these attachments by depleting the microtubule depolymerases KIF2a and MCAK satisfies the checkpoint, and results in anaphase entry with asymmetric spindles that lead to asymmetric cell divisions. We thus postulate that the symmetric metaphase plate position plays an essential role for the control of cell division symmetry.

P1073**Board Number: B404****Theory of spindle assembly.**S. Fürthauer^{1,2}, M. Shelley³, D.J. Needleman^{4,5,6};¹Courant Institute of Mathematical Sciences, New York, NY, ²Harvard University, Cambridge, CT,³Courant Institute, New York University, New York, NY, ⁴FAS Center for Systems Biology, HarvardUniversity, Cambridge, United States, ⁵School of Engineering and Applied Sciences, Harvard University,Cambridge, MA, ⁶Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

We develop a comprehensive theoretical model for the *Xenopus* meiototic spindle based on the physics of active liquid crystals. Our model captures the interplay between motion caused by molecular scale force generators - such as dyneins and kinesins - and the dynamics of regulatory proteins - such as Ran and its binding partners - which are believed to spatially regulate microtubule nucleation. We recover much of the known phenomenology of spindle assembly and can reproduce its response to external perturbations, which provides insights into the mechanisms responsible for determining spindle shape.

P1074**Board Number: B405****Balanced Activity of Three Mitotic Motors Is Required for Bipolar Spindle Assembly and Chromosome Segregation.**R.G. van Heesbeen¹, M.E. Tanenbaum², R.H. Medema³;¹Division of Cell Biology, Netherlands Cancer Institute, Amsterdam, Netherlands, ²Department of Cellularand Molecular Pharmacology, University of California, San Francisco, San Francisco, CA, ³Division of Cell

Biology, the Netherlands Cancer Institute, Amsterdam, Netherlands

Bipolar spindle assembly requires force to organize the microtubule network. Here, we show that three motor proteins, namely Eg5, Kif15, and dynein, act together to produce the right force balance in the spindle. Excessive inward force results in monopolar spindle formation, while excessive outward force generation results in unstable spindles with splayed spindle poles. Blocking activity of all three motors prevents bipolar spindle formation, but established bipolar spindles are refractory to loss of all motor activity. Further analysis shows that although these preformed spindles remain bipolar, outward force generation is required to establish sufficient tension on kinetochores and to accomplish successful chromosome segregation. Together, these results show how Eg5, Kif15, and dynein work together to build a bipolar spindle and reveal an important role for antagonistic motors in chromosome segregation.

P1075**Board Number: B406****Biophysics of mitotic spindle positioning in *C. elegans* embryos.**H. Wu^{1,2}, C. Yu^{2,3}, R. Farhadifar^{2,4}, D.J. Needleman^{2,3,4};¹Physics, Harvard University, Cambridge, MA, ²FAS Center for Systems Biology, Harvard University, Cambridge, United States, ³School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, ⁴Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

During cell division, the spindle apparatus, which consists of microtubules, segregates chromosomes and determines the plane of cleavage furrow formation. The mitotic spindles in eukaryotic cells have to be positioned and orientated correctly in specific ways to help cells divide properly. Our goal is to explore the biophysics of mitotic spindle positioning. We choose the *Caenorhabditis elegans* early-stage embryo, which is a powerful tool for studying cell division, as an animal model. During the first mitosis of a *C. elegans* embryo, the spindle elongates and takes chromosomes apart. Meanwhile, the spindle moves off-center giving rise to two daughter cells with different sizes and fates later (called "asymmetric cell division"). We want to know what molecular forces are involved in the positioning and orientating process, and how those forces are coordinated. In vitro experiments have demonstrated the existence of several molecular forces, and different models have been proposed to explain this dynamic process, but it remains unclear which of these possible mechanisms contribute in vivo. In addition, the off-center positioning of the mitotic spindle is accompanied with transverse oscillating motion of two spindle poles. This oscillation effect further opens a window for testing different models. Many issues are still under dispute. First, is it cytoplasmic force or cortical force, or a combination of both, contributing to the positioning of the mitotic spindle? To answer the question, we want to analyze the relative motion of cytoplasmic fluid and microtubules. We use fluorescent nanodiamonds with non-targeting surface treatment as seeding particles. We microinject those nanoparticles into the syncytial gonads of the tubulin:GFP-expressing *C. elegans*, and those particles would be integrated into embryos later. Those fluorescent nanodiamonds can be imaged and tracked, while microtubules can be visualized by GFP-labeled tubulins at the same time during the first mitosis. Analysis of the relative motion helps find out the force sources of spindle positioning. Second, we want to investigate how different forces are coordinated to yield the spindle positioning and orientating behavior. We study the phenomena by perturbing the oscillating motion of spindle poles using laser ablation. For this purpose, we set up a microscopic system to ablate part of the spindle structure with high spatial and temporal precision, and analyze various perturbed motions quantitatively. Combining the above studies, we hope to understand this fascinating dynamic system.

P1076**Board Number: B407****Microtubule Polarity and Biophysics of Anaphase B.**C. Yu¹, H. Wu^{2,3}, R. Farhadifar^{3,4}, D. Needleman¹;¹School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, ²Physics, Harvard University, Cambridge, MA, ³FAS Center for Systems Biology, Harvard University, Cambridge, United States, ⁴Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

In anaphase B, the spindle elongates by a process that is thought to be driven by the recruitment of proteins to anti-parallel microtubules. However, it remains unclear how the interplay between anti-parallel microtubules and protein localization produces the changes in microtubule behaviors that drive spindle elongation. To study the mechanisms of anaphase B, we have developed a method to quantitatively measure the polarity of microtubules in spindles in real time using a combination of second harmonic generation and two-photon fluorescence microscopy of labeled microtubules. We are combining measurements of the dynamics of microtubule polarity in the spindle with measurements of protein localization and genetic, biochemical, and physical perturbation. We are interpreting our results with the aid of mathematical models and numerical simulations. This work will provide insight into the process by which proteins are recruited to anti-parallel microtubules, the manner in which these proteins modify microtubule behaviors, and the mechanism by which these changes in microtubule behaviors drive spindle elongation, allowing us to test proposed models of anaphase B.

P1077**Board Number: B408****Antiparallel microtubules bridge sister kinetochores and regulate the force balance in the mitotic spindle.**J. Kajtez¹, A. Solomatina¹, I. Šumanovac Šestak¹, M. Novak², N. Pavin², I.M. Tolic^{1,3};¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ²Department of Physics, Faculty of Science, University of Zagreb, Zagreb, Croatia, ³Dept. Molecular Biology, Ruder Boškovic Institute, Zagreb, Croatia

Accurate segregation of the genetic material in a cell relies on complex molecular machinery called mitotic spindle. Mitotic spindle is a dynamic self-assembled structure that maintains its architectural steady state through accurate balance of forces. Current model of the spindle architecture recognizes two distinct populations of microtubules (MTs) that do not interact with each other: k-fibers and interpolar MTs. According to this model, k-fibers attached to bioriented sister kinetochores interact only through the centromeric region of the chromosome that acts as a spring between the two k-fibers. Here we show that there exists subpopulation of antiparallel MTs named bridging MTs (bMT) that span the region under sister kinetochores and facilitate a lateral connection between corresponding k-fibers. We observed bMT fibers in live-cell fluorescence imaging of HeLa cells. To confirm bMT fiber attachment to k-fibers, we developed a laser ablation assay: the outermost k-fiber is severed to observe movement,

directed away from the spindle center, of the kinetochore pair along with the intact k-fiber and the severed k-fiber stub. Corresponding bMT fiber accompanied this motion verifying that it is laterally attached to opposing k-fibers of one chromosome. In order to test if the forces in the spindle can be explained including the bMT fiber, a theoretical model was constructed. The model accurately predicts the convex shape of the spindle and outer position of kinetochore pair with respect to the corresponding bMT fiber. The model also predicts that thicker bMT fibers generate higher compressive forces in the spindle. To confirm this prediction we created thicker bMT fiber by overexpressing tubulin and antiparallel MT crosslinking protein PRC1. This resulted in much faster movement after the ablation, confirming that compressive force in the spindle was increased. Finally, our results indicate that bMT fiber has an important role as a safety structure for the aberrant mitotic spindle. If the severed k-fiber stub does not reestablish connection with the spindle pole before the onset of anaphase, bMT fiber acts as a rail along which the sister chromatids are moved apart providing an alternative mechanism for chromosome segregation.

Force on spindle microtubule minus ends moves chromosomes.

M.W. Elting^{*1}, C. Hueschen^{*1}, D. Udy¹, S. Dumont¹;

¹University of California, San Francisco, San Francisco, CA

*These authors contributed equally to this work.

The spindle is a dynamic self-assembling machine that coordinates mitosis. The spindle's function depends on its ability to organize microtubules into poles and maintain pole structure despite mechanical challenges and component turnover. Although we know that dynein and NuMA mediate pole formation, our understanding of the forces dynamically maintaining poles is limited: we do not know where and how quickly they act or their strength and structural impact. Using laser ablation to cut spindle microtubules, we identify a force that rapidly and robustly pulls severed microtubules and attached chromosomes poleward, overpowering opposing forces and repairing spindle architecture. Molecular imaging and biophysical analysis suggest that transport is powered by dynein pulling on minus ends of severed microtubules. NuMA and dynein/dynactin are specifically enriched at new minus ends within seconds, re-anchoring minus ends to the spindle and delivering them to poles. This force on minus ends represents a newly-uncovered chromosome transport mechanism that is independent of plus end forces at kinetochores and is well-suited to robustly maintain spindle mechanical integrity.

P1079**Board Number: B410****Kinetochores-microtubule depolymerization opposes Eg5-mediated outward forces in the metaphase spindle.**A.S. Gayek¹, R. Ohi¹;¹Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

The mitotic spindle requires a balance of forces to maintain its bipolar geometry and proper steady state length. These two features are essential for the spindle to carry out its function of segregating duplicated chromosomes into two daughter cells. The nature of force-balance in the metaphase spindle is still poorly understood. It is well appreciated that kinesin-5/Eg5 slides apart antiparallel microtubules (MTs) from the two centrosomes to push the poles outward as the spindle forms, but the role of Eg5 and Eg5-opposing forces at metaphase is less clear. Eg5-opposing, inward force is thought to come chiefly from MT sliding by minus end-directed motors (dynein and HSET/Kinesin-14), but our data suggest an important role for MT dynamics in generating inward force. We have shown that the ability of spindles to maintain bipolarity without Eg5 depends on the stability of their kinetochore-MTs (K-MTs), a class of MTs that are bundled and attached to chromosomes at the kinetochore whose stability is generally higher in transformed cells than in nontransformed cells. In several transformed cell lines, inhibition of Eg5 at metaphase does not grossly disrupt force-balance, and spindles maintain bipolarity. This maintenance of bipolarity depends on the high stability of their K-MTs. In addition, we have shown that bipolar spindles of nontransformed cells tend to collapse following Eg5 inhibition, but that stabilizing their MTs (including K-MTs) allows them to maintain bipolarity. This demonstrates the importance of K-MT stability for metaphase force-balance. Moreover, expression of a mutated kinetochore protein that increases the strength of kinetochore-to-MT binding exacerbates spindle collapse. The results of this very specific, localized perturbation are consistent with the idea that increasing the strength of kinetochore binding to the MT increases the productive pulling force from each depolymerizing MT, and suggests that plus-end depolymerization of K-MTs provides a significant inward force in the mitotic spindle of nontransformed human cells. This represents a previously understudied mechanism to generate Eg5-opposing, inward forces. Work is ongoing to determine the relative contributions of K-MT depolymerization and minus end-directed motors to force-balance in the metaphase spindle of nontransformed cells.

P1080**Board Number: B411****Contractility of Microtubule Networks in *Xenopus* Egg Extracts.**P. Foster¹, D. Needleman^{1,2};¹School of Engineering and Applied Sciences and FAS Center for Systems Biology, Harvard University, Cambridge, MA, ²Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

Spindles are self-organized subcellular structures that segregate chromosomes during cell division. Microtubule nucleation, microtubule polymerization dynamics, and motor mediated interactions between microtubules are all crucial for spindle self-organization. We are studying stabilized microtubules in *Xenopus* egg extracts to gain insight into microtubule interactions decoupled from nucleation and polymerization. We have found that networks of stabilized microtubules in *xenopus* egg extracts undergo a dynein-dependent bulk contraction. We are investigating the mechanism of this contraction through quantitative experiments and molecular perturbations. Our finding that microtubule motor interactions are net contractile, not extensile, as is often assumed, has important implications for models of spindle assembly.

P1081**Board Number: B412****Follow the leader: necessity for a leading microtubule assembly pathway during spindle assembly.**T. Cavazza^{1,2}, P. Malgaretti³, N. Brouwers¹, I. Peset⁴, I. Vernos^{1,5};¹Centre for Genomic Regulation - CRG, Barcelona, Spain, ²Universitat Pompeu Fabra, Barcelona, Spain, ³Max Planck Institute for Intelligent Systems, Stuttgart, Germany, ⁴Cancer Research UK, Cambridge Institute, Cambridge, UK, ⁵ICREA, Barcelona, Spain

The mitotic spindle is made of microtubules originated by the centrosomes and by the chromatin pathway. The relative contribution of these different pathways varies depending on the organism, the cell type and the developmental stage. The two pathways differ in topology, timing and kinetics. How these differences are integrated and kept in balance to ensure efficient spindle assembly is currently unclear.

Combining experiments in *Xenopus laevis* egg extract and in tissue culture cells we have addressed this question by changing this balance and examining the consequences on bipolar spindle formation. Decreasing the efficiency of the centrosome in generating microtubules has two main consequences depending on the system: in egg extract, centrosome positioning and therefore inheritance is randomized but the bipolar spindle forms efficiently; in cells, bipolar spindle assembly is compromised. These data suggest that dominant centrosome microtubule activity in cells entering mitosis is essential to facilitate proper spindle assembly. Altogether our data suggest that the two pathways do not act in a cooperative manner, rather we propose that one pathway should lead spindle assembly.

Using mathematical models we show that the two pathways are connected and balanced through a competition for free tubulin. This is particularly relevant in somatic cells in which tubulin is a limiting factor. Our work suggests that tubulin availability acts as a rate-limiting factor that defines the relative contributions to spindle assembly of the centrosomal and of the chromosomal pathways. Depending on the tubulin availability one pathway or the other will lead spindle assembly.

Live-cell imaging of Spindle Assembly Checkpoint dynamics in Germline Stems Cells of intact *C. elegans* larvae and adults.

A.R. Gerhold¹, J. Ryan¹, J. Labbe¹, P.S. Maddox²;

¹Institute for Research in Immunology and Cancer, Department of Pathology and Cell Biology, University of Montreal, Montreal, QC, ²Department of Biology, University of North Carolina, Chapel Hill, NC

The spindle assembly checkpoint (SAC) system inhibits mitotic progression and anaphase onset until all kinetochores are under bi-lateral attachment to microtubules. To date, our understanding of the SAC stems from work in cell culture and in embryos. How the SAC functions *in vivo*, in the varying physiological context of a maturing tissue, is largely unknown. Proteins of the Mitotic Checkpoint Complex bind to the Anaphase Promoting Complex (APC) co-factor cdc20, blocking APC activity. Once the SAC is satisfied, APCcdc20 targets Cyclin-B and securin for proteasome-mediated degradation, allowing separate to cleave the cohesion complex and anaphase to progress. While the SAC was widely viewed as an all-or-none signal, several studies have recently shown that in cell culture, the SAC may function in a graded manner, rather than as a thresholded on-off system. Here, we have developed a live-cell imaging assay to monitor APC activity relative to mitotic progression in germline stem cells (GSCs) within the intact gonad of larval and adult *C. elegans*. We used H2B::mCherry fluorescence variance as a readout of mitotic progression and measure degradation of Cyclin-B::YFP as an indication of APC activity. We validated this assay by activating the SAC and by compromising the SAC and the APC, and observing the change in Cyclin-B degradation rate. We have found that the duration of mitosis is shorter in larval GSCs undergoing expansion of the stem cell pool as compared to older adult GSCs engaged in stem cell homeostasis. In all cases, we have found that the rate of Cyclin-B degradation correlates with the duration of mitosis in GSCs, suggesting that *in vivo*, as inferred from cell culture studies, the SAC also functions in a graded manner. Furthermore, larval GSCs can initiate anaphase with higher levels of non-degraded Cyclin-B as compared to adult cells, suggesting that anaphase entry efficiency declines in aging stem cell populations. In sum, we have developed an assay to monitor degradation of Cyclin-B by APC in the GSCs of an intact, maturing organism. Our results show that mitotic mechanisms are sensitive to the physiological changes of aging, and open the possibility of further studying these mechanisms in a maturing tissue.

P1083**Board Number: B414****3D Print Approaches to Capture Metaphase Cells.**M.R. Castroagudin¹, Y. Zhai², Z. Li², M.G. Marnell², J.S. Glavy³;¹Department of Chemistry, Chemical Biology and Biomedical Engineering, Stevens Institute of Technology, Hoboken, NJ, ²CCBBME, Stevens Institute of Technology, Hoboken, NJ, ³Stevens Inst Technology, Hoboken, NJ

Mitotic spindles form outside the Nuclear Envelope (NE) in higher eukaryotes and the entire NE must disintegrate to facilitate chromosome separation. Discrete units of nuclear pore subcomplexes are released during G2/M phase transition of open mitosis then re-assembled as the cell exits M phase into G1. To track these changes, we rely on the visualization of the NE throughout mitosis using NE rim staining antibodies. HeLa metaphase cells that are synchronized by nocodazole treatment hold condense chromosomes that tend to generate rounded semi-attached cells. Even HeLa Metaphase cells are easily dislodged and require cytopinning to remain attached. In our investigations, we studied several alternative methods to attach these cells and readily visualize the windows of NE breakdown and re-assembly. We found a 3D print alternative to standard cytopin devices to be most effective to retain metaphase cells and visualize the NE throughout the unabridged cell cycle.

P1084**Board Number: B415****Live-Cell Imaging of mES Cells Reveals Diverse Effects of Microtubule Polymerase and Depolymerases on Mitosis.**O. Demir¹, I. Poser¹, A. Hyman², J. Howard³;¹MPI-CBG, Dresden, Germany, ²Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ³Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

To capitalize on recent advances in stem cell biology, it is important to understand the physiological properties of stem cells, especially how they divide and multiply. Such studies require live-cell imaging of many cells over many cell cycles. One limitation on imaging embryonic stem (ES) cells is their propensity to form spheres and to undergo apoptosis, making it difficult to image single cells in culture over times comparable to the cell cycle time. Here we describe an imaging system for mouse ES (mES) cells that is suitable for long-term live-cell imaging. The system combines BAC-based gene expression with wide-field deconvolution microscopy for mES cells plated onto the laminin-511-coated-surfaces and kept in CO₂-independent culture conditions. mES cells labeled with TUBB-GFP or H2A-GFP show low rates of apoptosis and aberrant mitosis. We used RNAi in combination with live-cell imaging to analyze the effects of microtubule polymerase and depolymerases on mitosis in ES cells and we performed single and double knockdowns of chTOG, EB1, Kif18A and MCAK to find out their effects in spindle assembly and morphology and as well as mitotic timing and chromosome segregation. Our results show that EB1 and MCAK knock-downs do not influence spindle morphology whereas Kif18A and ch-TOG cause

changes in spindle length without affecting the spindle width and the aspect ratio. The shortening effect of chTOG on spindle length could be partially rescued by EB1 knock-down. In addition, Kif18A strongly affects the timing of mitosis while chTOG and EB1 do not change it. Finally the depletion of each MAP causes chromosome segregation errors in anaphase and they could not be rescued by co-depletions. In conclusion we have generated a pipeline for the use of mouse embryonic stem cells in time-lapse microscopy and we have analyzed the effects of MAPs on spindle and mitotic progression. This method can be easily combined with RNAi technique to further study the cell biology of these unique cells.

Evidence that human tissue culture cells use G2 to prepare for timely anaphase.

A. Moskaleva¹, J.E. Ferrell^{1,2};

¹Chemical and Systems Biology, Stanford University, Stanford, CA, ²Biochemistry, Stanford University, Stanford, CA

To pass on its genome, a cell must finish replicating DNA before dividing. In the early embryo of *Drosophila* or *Xenopus*, division begins immediately after the completion of DNA replication. In tissue culture, division begins after cells spend hours in G2-phase. What happens during G2 is largely a mystery. We used time-lapse microscopy of MCF10A cells that overexpressed fluorescent PCNA, a reporter of S-phase, and fluorescent histone H2B, a reporter of M-phase, to measure G2 duration. We caused premature mitosis with PD0166285, an inhibitor of Wee1 and Myt1, and found a delay in anaphase onset inversely proportional to G2 duration. Co-treatment with PD0166285 and reversine, an inhibitor of the spindle assembly checkpoint, mostly rescued the delay. Surprisingly, co-treatment with PD0166285 and cycloheximide, an inhibitor of protein synthesis, did not change the anaphase delay, even though treatment with cycloheximide alone largely prevented mitotic entry. We infer that the most important regulation in G2 is not translational, but post-translational or mediated by non-protein-coding RNA. We observed the mitotic spindle by overexpressing fluorescent α -tubulin and found only a slight delay in its formation after shortened G2. Therefore, we speculate that a normal G2 may promote timely attachment of kinetochores to the mitotic spindle.

Towards a filament-independent model of abscission in *C. elegans*.

J. König¹, A. Audhya², T. Müller-Reichert¹;

¹Medical Faculty "Carl Gustav Carus", TU Dresden, Dresden, Germany, ²Biomolecular Chemistry, University of Wisconsin-Madison, Madison, WI

The narrow intercellular bridge connecting the two post-mitotic daughter cells is severed during abscission. This final stage of cytokinesis involves a reorganization of the plasma membrane as well as a coordinated disassembly of the microtubules. It was previously shown that ESCRT-III (endosomal sorting complex required for transport-III) components are involved in abscission in cultured cells, as well as in other membrane scission events, including multivesicular endosome formation and the budding of several retroviruses. In this study, we sought to investigate the potential existence of an ESCRT-independent mechanism for abscission. Taking advantage of the early *C. elegans* embryo, we cryoimmobilized zygotes at various stages of cytokinesis (from furrow ingression up to internalization of the midbody remnant). In contrast to tissue culture cells, our careful time-resolved study did not reveal the accumulation of spiral filaments during the abscission process. In addition, depletion of the ESCRT-I component Tsg101 did not block abscission. To our surprise, we only visualized filamental structures during post-abscission events (membrane shedding). Moreover, we performed drug treatment experiments with Nocodazole, Brefeldin A and Latruncullin A to investigate the roles of vesicle transport and fusion, and the function of actin during abscission. Our data indicate that the drugs affected abscission in distinct ways and at unique stages. By light microscopy, we found that Nocodazole and Brefeldin A inhibit the accumulation of vesicles at the midbody. In addition, Brefeldin A prevents the internalization of the midbody remnant in late stages. This effect was also observed in Latruncullin A-treated embryos. Currently, we are performing electron tomography to study the ultrastructure of the intercellular bridge in such drug-treated embryos to develop a model for abscission in the early *C. elegans* embryo.

Cell polarity contributes to contractile ring assembly and constriction during cytokinesis.

S.N. Jordan¹, V. Chand¹, M. Shirasu-Hiza², J. Dumont³, J.C. Canman¹;

¹Department of Pathology and Cell Biology, Columbia University, New York, NY, ²Department of Genetics and Development, Columbia University, New York, NY, ³Institut Jacques Monod, Paris, France

The tight coordination of cell polarity with division plane specification during cytokinesis is critical for every asymmetric cell division from embryogenesis to the maintenance of adult stem cell niches. The cell polarity machinery was thought to promote division plane specification indirectly, by regulating the position of the mitotic spindle, which then positions the site of contractile ring assembly. Recently, however, studies of *Drosophila* neuroblasts revealed that in the absence of a mitotic spindle, an actomyosin contractile ring still formed at the base of the apical-basal polarity boundary (Cabernard *et al.*, Nature, 2010). A role for the cell polarity machinery in directly regulating cytokinesis was not examined. Here we study the role of cell polarity in directly promoting contractile ring assembly and constriction during cytokinesis in *Caenorhabditis elegans* zygotes. We found that spindle-independent contractile rings also form at the interface of cortical anterior and posterior polarity boundaries, even in the absence of spindle microtubules. In sensitized cytokinesis mutants, disruption of either anterior (PAR-3, PAR-6, CDC-42) or posterior (PAR-2) polarity components weakened actomyosin ring constriction, illustrating a positive role for both anterior and posterior cortical boundaries in cytokinesis. We also found that increasing or decreasing the activity levels of the anterior polarity Rho GTPase CDC-42 led to increased or decreased filamentous actin levels in the contractile ring, respectively. Furthermore, with high-resolution temporal analysis using the Terminator (our newly developed device to rapidly inactivate temperature-sensitive protein function (Davies *et al.* Developmental Cell, 2014)), we found that cell polarity is required for robust constriction of the contractile ring. Specifically, we found a critical window for polarity machinery function early in the cell cycle (during the polarity maintenance phase) that is required for robust contractile ring constriction. Taken together, our data suggest a new role for CDC-42 and the cortical polarity machinery in directly promoting actomyosin contractile ring constriction during cytokinesis in asymmetrically dividing cells.

Characterization of the assembly, regulation and structures of two types of interphase nodes that merge to form cytokinetic nodes in fission yeast.

M. Akamatsu¹, K. Pu², J. Berro³, Y. Lin⁴, J. Bewersdorf⁵, T.D. Pollard^{5,6,7};

¹Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, ²Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, ³Molecular Biophysics and Biochemistry, Yale University, West Haven, CT, ⁴Department of Biomedical Engineering, Yale University School of Medicine, New Haven, CT, ⁵Department of Cell Biology, Yale University School of Medicine, New Haven, CT, ⁶Department of Molecular, Cellular and Developmental Biology, Yale University School of Medicine, New Haven, CT, ⁷Department of Molecular Biophysics and Biochemistry, Yale University School of Medicine, New Haven, CT

Fission yeast assemble a cytokinetic contractile ring from discrete, membrane-bound, multiprotein complexes called nodes. Interactions of myosin-II with actin filaments pull nodes together into a contractile ring. Nodes originate during interphase, but their origins, physical movements and fates were unclear.

We discovered that cytokinesis nodes assemble from two types of interphase nodes composed of different proteins. Type 2 nodes containing protein Blt1p, GTP exchange factor Gef2p, accessory protein Nod1p and kinesin Klp8p exist throughout the cell cycle and emerge from the contractile ring as it disassembles. Type 1 nodes with kinase Cdr1p, kinase Cdr2p and anillin Mid1p follow the separating nuclei and disperse into the cytoplasm during mitosis and reappear in a medial band around each daughter nucleus after mitosis. Quantitative measurements and computer simulations showed that these two types of nodes come together by a diffuse-and-capture mechanism: type 2 nodes diffuse to the equator where they are captured by stationary type 1 nodes.

The Septation Initiation Network (SIN) triggers septation and constriction of the contractile ring in fission yeast. We used conditional mutations to turn the SIN on and off and established that SIN activity is sufficient and necessary to disperse the core type 1 node protein Cdr2p into the cytoplasm. This explains why type 1 nodes assemble only during interphase through early mitosis when SIN activity is low. Activating the SIN during interphase dispersed Cdr2p from type 1 nodes a few minutes after the SIN kinase Cdc7p-GFP accumulated at spindle pole bodies. If the SIN was then turned off in interphase cells, Cdr2p reappeared in nodes in parallel with the decline in SIN activity. Hyperactivating SIN during mitosis dispersed type 1 nodes earlier than normal, and prolonged SIN activation prevented nodes from reforming at the end of mitosis. Conversely, inactivating SIN during mitosis prevented Cdr2p nodes from dispersing into the cytoplasm.

We used live cell FPALM super resolution microscopy to document the structures and motions of interphase nodes at ~ 35 nm resolution. Type 1 and 2 node proteins Cdr2p and Blt1p tagged with mEOS3.2 appeared as discrete structures ~ 50 nm in diameter, similar to Mid1p and consistent with their roles as core structural proteins that scaffold interphase nodes. Imaging cells expressing Blt1p-mEOS3.2 at 200 frames per second revealed nondirectional movements of type 2 nodes in the cell cortex with a diffusion coefficient ~ 400 nm²/s, while type 1 and 2 nodes near the cell equator moved little over 60 s, both requirements for successful simulations of our diffuse-and-capture model.

Tension and constriction of the cytokinetic contractile ring depend on anchoring of ring components to the plasma membrane.

S. Wang¹, B. O'Shaughnessy²;

¹Department of Physics, Columbia University, New York, NY, ²Department of Chemical Engineering, Columbia University, New York, NY

Cytokinesis involves constriction of a tension-producing actomyosin contractile ring that divides the cell into two. How the ring generates tension remains intensely debated. A sliding filament mechanism where myosin pulls actin filaments was proposed long ago, similar to striated muscle which has sarcomeric organization. However, contractile rings are far more disordered, and it is thought that random actomyosin bundles cannot generate tension. Recently, we presented evidence that tension

originates in anchoring of actin filaments to the membrane (Stachowiak et al., Dev. Cell, 2014) Anchoring allows a disordered arrangement to create tension by providing tension-generating resistance to force. A mathematical model with anchored actin filaments predicted ring tensions close to experimental values ~ 390 pN measured in the same study.

Here we mathematically modeled the constricting ring to explain a recent study of permeabilized fission yeast protoplast that examined ring constriction in controlled environments (Mishra et al, Nature Cell Biol., 2013). The experiments directly tested the role of ring anchoring, as parts of the ring were anchored while others were not: following ATP addition, rings partially detached from the membrane and constricted at a constant rate independent of initial length. Detached portions shortened at ~ 13 $\mu\text{m}/\text{min}$, ~ 50 -fold faster than normal constriction, while anchored portions maintained fixed length.

We extended our molecularly explicit model (Stachowiak et al., Dev. Cell, 2014) to explain these findings and to test the role of anchoring. The model assumes barbed end actin filament anchoring and includes the key components in amounts and with biochemical properties highly constrained by prior experiment. In agreement with the experiments of Mishra et al., simulated detached ring segments had almost zero tension and shortened at a rate somewhat less than twice the load-free velocity of myosin-II, $v_{\text{myo}}^0 \sim 0.14$ $\mu\text{m}/\text{s}$. Our analysis explains why the shortening rate is independent of ring length: detached regions did not contract, but shortened by being reeled in at their end points, each end point contributing v_{myo}^0 . The shortening of a detached portion relies on an adjacent anchored region, into which the detached portion is reeled. Thus, unanchored ring segments have zero tension but nevertheless shorten because they are connected to anchored segments with tension. When all anchoring was abolished, tension and constriction were absent: completely detached simulated rings did not constrict. Simulations reproduced other observations by Mishra et al, including the dependence of constriction on myosin-II but not on actin turnover, and retarded constriction by increased actin crosslinkin

Experimental measurement and simulations of the cytokinetic ring tension in fission yeast.

H.F. Chin¹, M.R. Stachowiak¹, C.E. Laplante², E. Karatekin³, T.D. Pollard^{2,4,5}, B. O'Shaughnessy¹;

¹Department of Chemical Engineering, Columbia University, New York, NY, ²Department of Molecular, Cellular and Developmental Biology, Yale University School of Medicine, New Haven, CT, ³Yale University, New Haven, CT, ⁴Department of Molecular Biophysics and Biochemistry, Yale University School of Medicine, New Haven, CT, ⁵Department of Cell Biology, Yale University School of Medicine, New Haven, CT

Cytokinesis in animals and fungi requires the assembly and constriction of an actomyosin contractile ring at the site of cell division, but the ring tension, the ring's principal mechanical property, has rarely been measured. Consequently, it has not been possible to relate the organization of the ring to its principal

function, and the mechanism of ring constriction has been difficult to establish. We recently developed a method to measure the cytokinetic ring tension in fission yeast for the first time, using yeast protoplasts whose cell walls have been enzymatically digested (Stachowiak *et al.*, *Dev. Cell*, 2014). Using micropipette aspiration to measure the membrane tension, and imaging the geometry of the membrane furrow induced by the tense ring, we deduced the ring tension from a force balance at the furrow. The measured tensions were reproduced by a detailed computer simulation of the constricting ring incorporating key components that have been biochemically and genetically characterized.

The availability of a method to measure cytokinetic ring tension has opened the door to observing the effect of mutations and drug treatments on ring tension that were previously invisible. Even for a mutation with little or no effect on the rate of constriction, the ring tension could be affected since constriction rates are determined by many factors. Here we refined the ring tension measuring technique so that we could track ring tension in real time throughout the full course of constriction, and we measured ring tension in fission yeast mutants, and in wild type cells following drug treatments, where the activity and dynamics of myosin or actin are compromised. We used these results in combination with our mathematical model of the constricting ring to test the basic mechanisms of tension production and constriction.

Dynamic Network Morphology and Tension Buildup in 3D Model of Cytokinetic Ring Assembly.

T.C. Bidone¹, H. Tan², D. Vavylonis¹;

¹Department of Physics, Lehigh University, Bethlehem, PA, ²Lehigh University, Bethlehem, United States

During fission yeast cytokinesis, actin filaments nucleated by cortical formin Cdc12 are captured by myosin motors bound to a band of cortical nodes and bundled by crosslinking proteins. The myosin motors exert forces on the actin filaments, resulting in a net pulling of the nodes into a contractile ring, while cross-linking interactions help align actin filaments and nodes into a single bundle. We used these mechanisms in a 3D computational model of contractile ring assembly, with semiflexible actin filaments growing from formins at cortical nodes, capturing of filaments by neighboring nodes, and cross-linking among filaments through attractive interactions. The model was used to predict profiles of actin filament density at the cell cortex, morphologies of condensing node-filament networks, and regimes of cortical tension by varying the node pulling force and strength of crosslinking among actin filaments. Results show that cross-linking interactions can lead to confinement of actin filaments at the simulated cortical boundary. We show that the ring formation region in parameter space lies close to regions leading to clumps, meshworks or double rings, and stars/cables. Since boundaries between regions are not sharp, transient structures that resemble clumps, stars and meshworks can appear in the process of ring assembly. These results are consistent with prior experiments with mutations in actin filament turnover regulators, myosin motor activity and changes in the concentration of cross linkers that alter the morphology of the condensing network. Transient star shapes appear in some simulations, which

offer an explanation for star structures observed in prior experimental images. Finally, we quantify tension along actin filaments and forces on nodes during ring assembly and show that the mechanisms describing ring assembly can also drive ring constriction once the ring is formed.

Back-to-back mechanisms drive actomyosin ring contraction during *Drosophila* cellularization.

Z. Xue¹, A.M. Sokac¹;

¹Verna and Marrs McLean Department of Biochemistry and Molecular Biology, Baylor College of Medicine, Houston, TX

While Myosin-2 motor activity is required for actomyosin ring contraction during cytokinesis in some cell types, recent findings suggest that motor activity is dispensable in other cell types, including mammalian cultured cells and budding yeast. One simple possibility is that different cell types use different mechanisms of actomyosin contraction during cytokinesis. Another possibility is that Myosin-2 dependent and independent mechanisms act in the same cell type, but make different contributions to contraction. In this work, we address the contribution of Myosin-2 motor activity during the cytokinetic event of cellularization in early *Drosophila* embryos.

During cellularization, actomyosin rings contract to build the bottom of newly forming epithelial cells. By quantitative live cell imaging, we find that ring contraction proceeds in two morphologically and kinetically distinct phases. In Phase 1, hexagonal rings become circular, and the contraction rate is slow ($0.17 \pm 0.04 \mu\text{m}/\text{min}$, mean \pm S.E.M.). In Phase 2, rings get smaller, and ring contraction is fast ($0.66 \pm 0.03 \mu\text{m}/\text{min}$, mean \pm S.E.M.). F-actin and Myosin-2 levels increase or stay constant, respectively, during Phase 1, but both decrease during Phase 2, suggesting that the Phases are mechanistically distinct. Indeed, using genetic mutants and drug strategies to manipulate Myosin-2 motor activity and F-actin polymerization dynamics, we find that contraction during Phase 1 depends on Myosin-2 motor activity, while Phase 2 does not. Instead, Phase 2 contraction depends on F-actin depolymerization.

Taken together, our work shows that two back-to-back mechanisms drive distinct phases of actomyosin ring contraction during cellularization. Our data supports a model whereby Myosin-2 dependent and independent mechanisms conspire to drive ring contraction, within the same cell type, and even during the same cytokinetic event. Cellularization now provides a unique opportunity to compare distinct contraction mechanisms in the same cell type, and to understand what molecular components control the switch between Myosin-2 dependent and independent mechanisms.

P1093**Board Number: B424****Generating an Asymmetric Furrow: The Roles of Anillin and F-actin Alignment.**K. Rehai¹, J. Dorn², L. Zhang², B. Lacroix³, A.S. Maddox⁴;¹Genetics and Molecular Biology, University of North Carolina, Chapel Hill, NC, ²Pathology and Cell Biology, University of Montreal, Montreal, QC, ³Institut Jacques Monod, Paris, France, ⁴Department of Biology, University of North Carolina, Chapel Hill, NC

Cytokinesis, the physical division of a cell, is driven by the closure of a ring enriched for the actomyosin cytoskeleton. Despite the necessity of proper ring formation and function, the organization of ring components is still poorly understood.

In the *C. elegans* zygote the cytokinetic ring closes asymmetrically, a conserved feature of cytokinesis seen throughout Metazoa. In other systems, the asymmetry of ring closure can be explained by a pre-existing asymmetry such as an eccentric spindle, apical junctions, or substrate adhesions. However, the *C. elegans* zygote is a mechanically isolated cell, indicating that cell intrinsic processes can generate furrow asymmetry and that understanding asymmetry will reveal insight into general principles of cytokinesis. We propose that cell-intrinsic asymmetry is generated by differential organization of ring components on the faster versus slower ingressing side of the ring. This asymmetry of cytokinetic ring closure is dependent on the *C. elegans* protein ANI-1, a homologue of Anillin, which scaffolds structural and regulatory components of the ring. Importantly, the predicted actin binding domain of ANI-1 is sufficient to bundle F-actin *in vitro*. To assess the relationship between actin organization and asymmetry we developed a novel image analysis tool and found that F-actin is progressively circumferentially aligned at the cell equator just as cytokinesis initiates, and that this alignment is dependent on ANI-1.

These results demonstrate a positive correlation between F-actin alignment and asymmetry, supporting a model in which localized F-actin alignment activates a positive feedback loop causing further localized alignment, and ultimately generating asymmetry within the cytokinetic ring. To further test this model we generated a *C. elegans* strain expressing the isolated ANI-1 actin bundling domain tagged with GFP as well as a strain expressing ANI-1 lacking its actin bundling domain tagged with GFP. ANI-1 Δ actin-bundling-domain::GFP localizes to the cytokinetic ring, while the isolated ANI-1 actin-bundling-domain does not. In the presence of endogenous full length ANI-1, neither truncation has a clear dominant effect on cytokinesis. In ongoing work, we are testing the ability of these truncations to rescue depletion of endogenous ANI-1 by RNAi.

P1094**Board Number: B425****Cleavage-furrow ingression and F-actin dynamics in the green alga******Chlamydomonas reinhardtii****M. Onishi¹, L. Mackinder², M.C. Jonikas², J. Pringle¹;¹Genetics, Stanford Univ Med Ctr, Stanford, CA, ²Plant Biology, Carnegie Institution for Science, Stanford, CA

Cytokinesis in animals and fungi is achieved by ingression of the cleavage furrow, which involves a ring containing F-actin, type-II myosin, and functionally related proteins. This “contractile actomyosin ring” has long been thought to provide the force for ingression by a sliding interaction between actin and myosin filaments. However, the phylogenetic distribution of type-II myosin is confined to fungi, animals, and slime molds, whereas most other eukaryotes also divide by furrowing. To address this paradox, we are investigating the mechanisms of cleavage-furrow ingression in one such eukaryote, the green alga *Chlamydomonas reinhardtii*. Not only does *Chlamydomonas* have no type-II myosin, but the very existence of F-actin in vegetative cells has also been controversial. Although it has been reported that actin is enriched at the cleavage furrow, it was not labeled by phallotoxins, and a null mutation in the single conventional actin gene (*IDA5*) does not cause a significant growth defect. However, we have now demonstrated the existence of F-actin by developing a novel method to overexpress a Lifeact-Venus probe that should label only F-actin. In interphase cells, Lifeact-Venus localized to the mid-portion of the cell, forming a cage-like structure around the nucleus and to the flagellar-basal region as cortical dots; in dividing cells, it was found in the cleavage furrows. These signals were sensitive to the actin-depolymerizing latrunculins, confirming that they represent F-actin. In addition, the type-VIII myosin (the other two *Chlamydomonas* myosins are of type XI) has been successfully tagged with Venus and showed localization to the mid-cell cage and the flagellar-basal cortical dots, but not to the cleavage furrow. Latrunculin-treated cells continued to grow at a nearly normal rate with no apparent defect in cell division. However, these cells, like the *ida5* null mutant, had upregulated expression of a gene (*NAP*) encoding an unconventional actin (~65% identical to conventional actins), and the Nap filaments were resistant to the drug. These results show that *Chlamydomonas* has a surprising and robust mechanism to sense and react to the acute loss of F-actin structures, suggesting a requirement of F-actin for some important biological processes in this organism. However, the absence of a type-II myosin and the failure of the one myosin examined to date to localize to the cleavage furrow suggest that formation of a contractile actomyosin ring is not such a process. We will report on our ongoing genetic and molecular investigations of the F-actin-sensing mechanism and the mechanisms of cytokinesis in *Chlamydomonas*; these studies should illuminate both the roles of F-actin and the ancestral mechanisms of cleavage-furrow formation.

P1095**Board Number: B426****A chromatin microtubule-independent pathway driven by Ran-GTP helps define the division plane during cytokinesis.**T. Akhshi¹, A.J. Piekny¹;¹Department of Biology, Concordia University, Montreal, QC

Cytokinesis describes the physical separation of a mother cell into two daughter cells and is driven by the constriction of an actomyosin contractile ring. Formation and ingression of the contractile ring is regulated by the mitotic spindle; the central spindle recruits Ect2, a GEF that activates RhoA, to mediate ring assembly in the equatorial plane, while the astral microtubules restrict the localization of contractile proteins at polar cortices via a molecular mechanism that involves anillin. However, contractile proteins equatorially accumulate in the absence of microtubules, suggesting that redundant pathways regulate their localization. Here, using human Hela cells, we have provided evidence that a chromatin-based pathway involving Ran-GTP restricts the localization of contractile proteins. We found that there is a strong correlation between the boundary of equatorially accumulated anillin and chromatin position. We calculated the minimum distance from which cue(s) associated with chromatin could function in cells with intact spindles, and in cells lacking astral and/or central spindle microtubules and altered geometry. Furthermore, by targeting active Ran to the furrow or inactivating Ran in bipolar cells, we found that Ran-GTP negatively regulates the localization of contractile proteins. Our studies shed light on a chromatin-based pathway that likely functions to couple the division plane with the segregation of sister chromatids, which becomes essential when the mitotic spindle is perturbed or shifts too close to one pole.

P1096**Board Number: B427****Control and function of microtubule overlaps in the bipolar phragmoplast network.**J. de Keijzer¹, J. Verweij¹, T. Miki², G. Goshima², M. Janson¹;¹Laboratory of Cell Biology, Wageningen University, Wageningen, Netherlands, ²Division of Biological Science, Nagoya University, Nagoya, Japan

Constriction of the plasma membrane during cell division in animal cells is regulated by short regions of overlapping microtubules at the centre of the cell division apparatus. Similar regions of limited antiparallel microtubule overlap are found in the phragmoplast of plants, a bipolar microtubule network that constructs a cell plate to separate two daughter cells. We used the genetically tractable moss *Physcomitrella patens* to gain insight into the function and regulation of these overlaps. We found that overlaps act as recruitment sites for vesicles containing cell wall material. The short length of overlaps may thus be a prerequisite to precisely pattern the forming cell plate. To understand the control of

overlap length we investigated the balance between local rates of microtubule growth and microtubule sliding. The first activity extends overlaps whereas the second decreases overlap length and drives microtubule flux. By tracking growing microtubule ends and regions of photo-activated microtubule filaments we show that the bulk microtubule growth velocity is several times faster than the rate of relative sliding, implying that microtubule growth must be locally down regulated within overlaps. We therefore functionally analysed kinesin-4 proteins. In agreement with an established role in inhibiting microtubule growth, deletion of two kinesin-4 genes caused oscillations in overlap length. Moreover, the initial recruitment of vesicles to overlaps was more diffuse, cell plate construction was delayed, and completed cell plates were thicker and lacked structural integrity. Our results thus demonstrate the patterning of the cell plate by the phragmoplast involves kinesin-4 mediated length control of microtubule overlaps.

The kinesin-3 motor KIF14 exhibits distinct biochemical properties and structural features.

L. Talje¹, K. Arora², A.B. Asenjo³, P. Andersen⁴, K. Atchia⁴, M. Joshi², H. Sosa³, J.S. Allingham², B.H. Kwok¹; ¹Institute for Research in Immunology and Cancer, University of Montreal, Montréal, QC, ²Department of Biomedical and Molecular Sciences, Queen's University, Kingston, ON, ³Department of Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, NY, ⁴Institute for Research in Immunology and Cancer, University of Montreal, Montreal, QC

The mitotic kinesin-3 motor protein KIF14 is essential for cytokinesis during cell division. KIF14 has been found overexpressed in multiple cancers and its overexpression has been linked to poor prognosis in cancer patients. Therefore, KIF14 is sometimes referred to as the oncogenic kinesin. We characterized the motor domain of murine KIF14 biochemically and solved its crystal structure in the ADP-bound state. Our data show that KIF14 motor binds tightly to microtubules and does not display typical nucleotide-dependent changes in this affinity. It has robust ATPase activity but very slow motility. Interestingly, our ADP•KIF14 motor domain crystal structure reveals a drastically opened nucleotide-binding pocket, as if ready to exchange its bound ADP for Mg•ATP. In this state, the central β -sheet is twisted $\sim 10^\circ$ beyond the maximal amount observed in other kinesins. This configuration has only been previously observed in the nucleotide-free states of myosins-known as the "rigor-like" state. Fitting of this atomic model to electron density maps from cryo-electron microscopy indicates a distinct binding configuration of the motor domain to microtubules. We postulate that these properties of KIF14 are well suited for stabilizing microtubules at the midbody during cytokinesis.

P1098**Board Number: B429****Cdk1-dependent phosphorylation of leukemia-associated RhoGEF (LARG) during mitosis.**M.C. Helms¹, E. Grabocka¹, M.K. Martz¹, N. Suzuki², P.B. Wedegaertner¹;¹Department of Biochemistry and Molecular Biology, Thomas Jefferson University, Philadelphia, PA,²Department of Signal Dynamics, University of Tokyo, Meguro, Japan

Rho GTPases are crucial players in the regulation of actin cytoskeleton-dependent processes, including mitosis. Our laboratory has discovered a novel role and localization of the leukemia-associated Rho guanine-nucleotide exchange factor (LARG), a regulator of G protein signaling (RGS)-RhoGEF, during mitosis. Rho and LARG have been implicated in aberrant mitosis and embryonic development, as well as diseases such as hypertension and cancer, thus highlighting the importance for further research. The purpose of this study is to determine the molecular mechanism and role of mitotic-dependent phosphorylation of LARG. Our experiments are conducted in vitro, in HeLa cells, a human uterine cancer cell line, and human embryonic kidney (HEK293) cells, and experiments are conducted with cellular, molecular, and biochemical approaches. Using mitotic-shift assays and kinase inhibitors, we report that LARG undergoes a mitotic-dependent and Cyclin-dependent kinase 1 (Cdk1) inhibitor-sensitive phosphorylation. Cell synchronization followed by Western blot also identified the temporal feasibility of Cdk1 as a potential kinase. Furthermore, using in vitro kinase assays, we show that LARG can be directly phosphorylated by Cdk1. Using both N- and C-terminal deletion and multi-site phosphorylation mutants, we demonstrate that the mitotic-dependent shift of LARG relies on phosphorylation occurring in both termini. Using custom phosphospecific antibodies, we confirm that two sites are phosphorylated during mitosis and also in a Cdk1-dependent manner. Luciferase reporter assays for RhoA activity are being used to assess differences in RhoA activation depending on phosphorylation status of LARG. We conclude that Cdk1 phosphorylates LARG during mitosis, and phosphorylation of LARG may play a role in LARG activity and function. Since LARG has diverse signaling functions beyond mitosis such as in the heart and in embryonic development, it is important to understand the regulation of the protein.

P1099**Board Number: B430****Large tumor suppressors 1 and 2 regulate the centrosomal activation of LIM-kinase 1 by phosphorylating a motor protein CHO1.**A. Okamoto¹, N. Yabuta¹, S. Mukai¹, K. Torigata¹, H. Nojima¹;¹Osaka Univ, Suita, Osaka, Japan

Large tumor suppressor 1 and 2 (Lats1/2) are core Ser/Thr kinases of the Hippo signaling pathway that controls organ size by modulating cell proliferation and cell death. Lats1/2 also play important roles in mitosis by regulating centrosomal integrity, chromosome segregation and cytokinesis. As components of

the centralspindlin complex, the kinesin-like motor protein CHO1 and its splicing variant MKLP1 regulate the formation of the contractile ring and completion of cytokinesis by colocalizing with chromosome passenger proteins and GTPases. However, the regulatory mechanisms of CHO1 remain unclear. Here, we show that Lats1/2 regulate cytokinesis by directly phosphorylating Ser716 in the F-actin binding region of CHO1, which is absent in MKLP1. We found that CHO1-pS716 localizes to the centrosomes and midbody during mitosis and cytokinesis, respectively. Furthermore, we also found that LIM-kinase 1 (LIMK1), a modulator of actin dynamics, interacts with the Lats1/2-mediated S716-phosphorylated form of CHO1. Indirect immunofluorescence and immunoblotting analyses revealed that overexpression of phosphorylated and non-phosphorylated mutants of CHO1 altered the mitotic localization and activation of LIMK1 at the centrosomes in HeLa cells, leading to the cytokinesis failure through excessive phosphorylation of Cofilin, an actin depolymerization factor, and mislocalization of Ect2, a Rho guanine nucleotide exchange factor. These results suggest that Lats1/2 stringently regulate cytokinesis by phosphorylating CHO1, leading to interaction with and subsequent activation of LIMK1 on centrosomes during early mitosis. Therefore, we propose that the Lats1/2-CHO1-LIMK1 axis is a pivotal signaling pathway that links centrosome integrity and the fidelity of cytokinesis to prevent polyploidization.

Cdc42 Signaling Pathway Drives Onset of Actomyosin Ring Constriction During Cytokinesis.

B. Wei¹, M. Das¹;

¹University of Tennessee, Knoxville, TN

Cytokinesis, the last stage in cell division is a complex process involving multiple steps. During cytokinesis in fission yeast, first the precursor nodes localize to the cell middle which then recruit proteins that form the actomyosin ring. Next, the ring undergoes maturation followed by constriction (1). A leading question in the field is what triggers actin ring constriction. Here we show for the first time a potential role for the conserved GTPase Cdc42 in promoting the onset of actomyosin ring constriction during cytokinesis. Our results show that Cdc42 activation occurs during ring maturation and persists through ring constriction. Cdc42 is activated by Guanine nucleotide Exchange Factor (GEF), which promotes GTP binding (2). Loss of the Cdc42 GEF Gef1 does not show Cdc42 activation during ring maturation and constriction. Further, upon loss of gef1 the ring persists in the maturation phase longer and onset of ring constriction is delayed. Cells lacking gef1 also display fewer non-medial actin cables that are known to incorporate in to the ring. Non-medial actin cables are dependent in the actin polymerizing formin Cdc12. Here we show that loss of gef1 mutants display increased mobility of Cdc12 within the ring as determined by FRAP analysis. Taken together these observations suggest that Gef1 activates Cdc42 during actin ring maturation to promote stabilization of Cdc12. Stabilized Cdc12 possibly leads to increased actin polymerization and non-medial cable formation. Further we propose that incorporation of non-medial actin cables in to the ring during maturation is required for the onset of actin ring constriction. Current experiments are focused on studying the above hypothesis.

The identification of novel putative partners of USP22, oncoprotein and potential chemotherapeutic target.

L. Biswas¹, S.B. McMahon², T.J. Stanek²;

¹Biochemistry, Widener University, Chester, PA, ²Department of Cancer Biology, Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA

Cancer stem cells play a fundamental role in tumor development and metastasis in many forms of cancer, including chronic myelogenous leukemia, acute lymphoblastic leukemia, and breast cancer. The transformation of normal stem cells to cancer stem cells may be mediated through epigenetic mechanisms, some of which have been reported to involve Polycomb group proteins. Recently, an 11-gene signature, including Polycomb group genes, for aggressive cancers was identified; this signature includes USP22, which codes for a histone ubiquitin hydrolase. USP22 acts as part of the human SAGA complex in the nucleus to activate transcription of Myc via histone deubiquitination. However, USP22's role in the cytoplasm, beyond its association with SIRT1, is poorly characterized. In order to better understand USP22's cytoplasmic activity, we conducted tandem mass spectrometry of FLAG-tagged USP22 immunoprecipitates, identifying over twenty potential novel partners of USP22 in the cytoplasm. Subsequent purification of the USP22 core enzymatic complex, consisting of USP22, ATXN7L3, ATXN7, and ENY2, has allowed for screening of a small molecule library for inhibitors of USP22's enzymatic activity. Such inhibitory compounds represent potential chemotherapeutic agents and will harness current understanding of USP22's role in aggressive cancers.

The role of Par1b during *Helicobacter pylori* infection.

A. Zamperone¹, D. Cohen¹, D.M. Fernandez¹, A. Muesch¹;

¹Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY

Gastric carcinoma, the second leading cause of cancer-related deaths in the world, has been linked to infection with *Helicobacter pylori*, a bacterium that colonizes the gastric mucosa. *H. pylori* strains that express a gene called cytotoxin-associated gene A (CagA), present a much higher cancer risk for their host than strains that lack CagA and it has been shown to function as an oncogene in mice. CagA induces loss of cell polarity, increased cell migration and apoptosis of gastric epithelial cells and promotes aberrant growth signals by activating the Ras-MAP-cascade. Recently, studies from our group and others

have identified the serine/threonine kinase Par1 as a CagA-target. Here we utilized *H. pylori*-infected polarized human primary gastric epithelial cells (HGECs) and a human adenocarcinoma cell line (AGS) to demonstrate that Par1b inhibition contributes to a CagA-dependent activation of DNA double strand breaks and the initiation of DNA double strand repair (DDR) upon acute *H. pylori* infection as well as to the activation of the Jnk kinase. Ongoing work is aimed at identifying the Par1b substrates involved.

Canonical Wnt signaling pivotally regulates cell fate and proliferation during embryonic development and tumorigenesis. Nuclear accumulation of β -catenin is the central event of canonical Wnt signaling cascade. However, the molecular mechanisms that control β -catenin nuclear localization remain poorly understood. Here, we identify LisH2 as a critical downstream component of Wnt/ β -catenin signaling, which is required for Wnt induced β -catenin nuclear localization. Wnt increases LisH2 protein level and promotes LisH2 nuclear accumulation through the inactivation of the Axin complex. Either depletion of LisH2 or LisH2 mutation that disrupts LisH2- β -catenin interaction abolishes nuclear localization of β -catenin in response to Wnt signaling. Furthermore, LisH2-mediated β -catenin nuclear accumulation is essential for proper dorsoventral patterning of zebrafish embryos and colonic tumor progression. Thus, our data suggest a previously undescribed mechanism whereby LisH2 facilitates β -catenin nuclear localization in canonical Wnt signaling.

P1104**Board Number: B436****Wnt/ β -catenin signaling enhances RUNX1 expression in leukemia cells and hematopoietic progenitors.**G.D. Ugarte¹, M.A. Medina¹, M.F. Vargas¹, A.A. Elorza¹, A. Loyola², G.V. De Ferrari¹;¹Center for Biomedical Research, Universidad Andres Bello, Santiago, Chile, ²Fundación Ciencia Vida, Santiago, Chile

Canonical Wnt/ β -catenin signaling has a crucial role in proliferation and differentiation of haematopoietic lineages and its deregulation is thought to be involved in leukaemia. Similarly, the transcription factor RUNX1 is required for definitive haematopoiesis and is frequently rearranged in various types of leukaemia. Here we report that RUNX1 expression is readily induced in leukemia cell lines HL-60 and Jurkat and CD34+ primary human hematopoietic progenitors in response to induction with a purified Wnt3a protein or pharmacological treatments with lithium chloride. Serial deletion of a 1.7 Kbp of the P1-distal promoter fragment allowed us to identify a minimal β -catenin responsive region, which showed maximal response in gene-reporter assays, that includes a novel T-cell factor/lymphoid enhancer factor (TCF/LEF)-response element (TBE Site II), located upstream of the canonical RUNX1 transcription start site. This observation was further confirmed by site directed mutagenesis and chromatin immunoprecipitation (ChIP) assays. Our results link the transcription of the RUNX1 gene to Wnt/ β -catenin signaling and may open a novel window to understand the development or the deregulation of the hematopoietic process.

P1105**Board Number: B437****CDO, an Hh-coreceptor, mediates lung cancer cell proliferation and tumorigenicity through Hedgehog signaling.**J. Bae¹, Y. Leem¹, K. Baek¹, J. Kang²;¹School of Medicine, Sungkyunkwan University, Suwon, Korea, ²Sungkyunkwan Univ Sch Med, Suwon, Kyunggi-do, Korea

Hedgehog (Hh) signaling plays essential roles in various developmental processes, and its aberrant regulation results in genetic disorders or malignancies in various tissues. Hyperactivation of Hh signaling is associated with lung cancer development, and there have been extensive efforts to investigate how to control Hh signaling pathway and regulate cancer cell proliferation. In this study we investigated a role of CDO, an Hh co-receptor, in non-small cell lung cancer (NSCLC). Inhibition of Hh signaling by SANT-1 or siCDO in lung cancer cells reduced proliferation and tumorigenicity, along with the decrease in the expression of the Hh components. Histological analysis with NSCLC mouse tissue demonstrated that CDO was expressed in advanced grade of the cancer, and precisely co-localized with GLI1. These data

suggest that CDO, most likely via Hh signaling activation, is required for proliferation and survival of lung cancer cells via Hh signaling.

Regulation of Na,K-ATPase by Sonic hedgehog signaling in cerebellar granule precursor cells.

Z. Li¹, A. Litan¹, S. Lee¹, B. Graves¹, S. Lindsey¹, S.P. Barwe¹, S.A. Langhans¹;

¹A I duPont Hosp Children, Wilmington, DE

Na,K-ATPase is a membrane protein that maintains intracellular ion homeostasis, and is responsible for generating ion gradients across cell membranes. It consists of a catalytic alpha subunit, and a beta subunit that pumps sodium ions out and potassium ions into the cell using ATP. Studies from our laboratory and others have established additional roles for Na,K-ATPase as a signaling scaffold and a cell adhesion molecule. Some of the signaling pathways modulated by Na,K-ATPase have been linked to cancer progression including cell growth, cell adhesion, and cell motility. Changes in Na,K-ATPase function and expression have been reported in various cancers and may occur at very early stages of tumorigenesis, suggesting that altered Na,K-ATPase subunit expression and function may contribute to tumor development and progression.

The sonic hedgehog pathway (Shh) is an important signaling pathway involved in cerebellar development. Shh is secreted from the Purkinje cells, and acts as a mitogen for cerebellar granule precursor (CGP) cells located in the external granule layer of the cerebellum. Mutations leading to hyperactive Shh signaling have been associated with medulloblastoma, which is a common form of pediatric brain cancer thought to originate from improper migration and differentiation of CGP cells. The molecular targets contributing to Shh-mediated proliferation and differentiation of these cells are still poorly understood. We now found reduced Na,K-ATPase beta1-subunit expression in tumors of a transgenic medulloblastoma mouse model with aberrant activation of Shh signaling and activation of Shh signaling prevented upregulation of the beta1 subunit in primary CGP cultures from wild-type cerebella. In addition, shRNA-mediated beta1 knockdown increased cell proliferation, and subcutaneous xenografts of beta1 knockdown cells grew faster than control xenografts. We further show that the polycomb transcription factor Bmi1 that is induced upon activation of Shh signaling may suppress beta1-subunit expression, and we suggest that Bmi1-mediated repression of Na,K-ATPase beta1 subunit may contribute to tumor progression in Shh-mediated medulloblastoma.

P1107**Board Number: B439****CD44 intracytoplasmic domain (CD44-ICD)-mediated signaling pathway in breast cancer cells.**D.A. Grinnage¹, N. Gadde², K.E. Miletti-Gonzalez¹;¹Department of Biological Sciences, Delaware State University, Dover, DE, ²Department of Health Sciences, University Of Delaware, Newark, DE

The expression of CD44 in breast cancer cells has been associated with increased cell aggressiveness, which involves changes in cell migration, invasion, adhesion and multi-drug resistance. We have shown that CD44 is able to modulate the cancer cell phenotype in part by regulating the expression of key cancer-related genes through its intracytoplasmic domain (CD44-ICD), a product of the cleavage of its C-terminus by the gamma secretase complex. The CD44-ICD is commonly translocated to the nucleus where it can interact with its response element (CIRE) and/or with the transcription factor Runx2/AML3. Based on these previous findings, we hypothesize that CD44 has the ability to regulate multiple genes and potentially interact with additional transcription factors. Using transcription factor-specific profiling plate arrays to analyze nuclear extracts, we compared the expression of 96 transcription factors in MCF-7 (low invasive negative CD44) and MCF-7/CD44 (highly-invasive CD44 positive stable transfectant) cells. Preliminary data from this analysis indicates that the expression of CD44S correlates with the regulation of numerous genes encoding transcription factors relevant in cancer. We also analyzed the potential protein-protein interaction with other transcription factors using the same plate array methodology. We found that several transcription factors do interact with the CD44-ICD including some that its gene expression is regulated by CD44. Some of the TF/CD44-ICD protein-protein interactions will be validated by chromatin immunoprecipitation (ChIP) assays. Identification and validation of these interactions will provide mechanistic information of the interaction as well as the identity of the genes regulated by the CD44-ICD mediated signaling pathway.

P1108**Board Number: B440****The conserved aromatic loop of human RECQ1 helicase is required for catalytic strand separation vital for an intact replication stress response.**T. Banerjee¹, J.A. Sommers¹, J. Huang¹, M.M. Seidman¹, R.M. Brosh¹;¹National Institute on Aging (NIA/NIH, Baltimore, MD)

RECQ1, a RecQ helicase important for genomic stability, is highly expressed in a spectrum of cancers; however, its precise roles are poorly understood. We used genetic and biochemical assays to dissect RECQ1's role in DNA replication and chromosomal integrity. Two highly conserved residues in the aromatic loop of the RECQ1 helicase core domain were replaced by site-directed mutagenesis (F231A, W227A) and the mutant recombinant proteins purified. Both mutants bound DNA similar to RECQ1-WT;

however, unwinding of forked duplex DNA substrates was severely compromised and branch-migration of mobile D-loops or Holliday Junctions was completely abolished. In contrast, RECQ1-W227A or -F231A were modestly compromised in ATP hydrolysis and retained their ability to bind ATP, oligomerize, and catalyze efficient strand annealing. Therefore, the RECQ1 aromatic loop is critical for efficient coupling of ATPase to DNA unwinding or branch-migration. Genetic rescue experiments in RECQ1-depleted HeLa cells expressing either RECQ1 aromatic loop mutant revealed a markedly reduced replication rate and consequent random firing of dormant replication origins as demonstrated by single molecule DNA fiber assays. These cells displayed significantly elevated spontaneous double-strand breaks and sensitivity to the DNA damaging agents camptothecin (CPT) or H₂O₂. Moreover, expression of either mutant exerted a dominant negative effect on replication rate and sensitivity to exogenously induced DNA damage. CPT-treated RECQ1-depleted cells expressing either RECQ1 aromatic loop mutant revealed a defect in RPA foci formation. The damage induced RPA foci were restored in RECQ1-depleted cells overexpressing RPA, suggesting RECQ1 deficiency leads to random activation of dormant origins which recruit RPA to sites of nascent DNA synthesis, thereby exhausting the pool of RPA available to localize at DNA damage sites, resulting in elevated double strand breaks. MRE11 foci formation was also defective in CPT-treated RECQ1-depleted cells, suggesting a problem in much earlier events of DNA repair upstream of RPA recruitment. In addition, RECQ1-depleted cells expressing either catalytically defective aromatic loop mutant accumulated more CPT-induced DNA damage and bypassed the replication checkpoint, allowing faster growth potentially pushing the cells towards tumorigenesis. Taken together, our results demonstrate that catalytic inactivation of RECQ1 helicase disrupted normal replication and the DNA damage response. Furthermore, RECQ1 is critical to maintain normal replication rate and suppress dormant origin activation, thereby making RPA available to recruit to both endogenous and exogenous induced DNA damage sites. Our findings reveal a potential tumor suppressor role of RECQ1.

Coordinated Regulation of Exo1 in DNA End Resection.

X. Chen¹, I. Kim², Y. Honaker¹, S.C. Paudyal¹, W. Koh¹, H. Piwnicka-Worms³, T. Ellenberger², Z. You¹;

¹Department of Cell Biology and Physiology, Washington University School of Medicine, Saint Louis, MO,

²Biochemistry and Molecular Biophysics, Washington University School of Medicine, Saint Louis, MO,

³Cancer Biology, The University of Texas M.D. Anderson Cancer Center, Houston, TX

The cellular response to DNA double-strand break (DSB) damage is essential for the maintenance of genome stability and the prevention of an array of systemic human diseases such as cancer, premature ageing, neurological and developmental disorders. The DNA end resection process dictates the DSB damage response through activating DNA repair by homologous recombination and the ATR checkpoint response. Although a myriad of protein factors have been identified in the DNA end resection pathway, it is still not clear how the extent of end resection and its termination are regulated. Our studies in human cells and *Xenopus* egg extracts indicate that the major resection nuclease Exo1 is regulated both positively and negatively by multiple protein-protein interactions to ensure a proper level of DNA

resection. We find that poly(ADP-ribose) (PAR) binding to the N-terminal catalytic domain of Exo1 initiates Exo1 damage recruitment, while PCNA interaction with the C-terminal domain of Exo1 facilitates Exo1 retention at damaged chromatin and enhances its resection processivity. In contrast, association of 14-3-3 proteins with the central region of Exo1 negatively regulates the recruitment and DNA end resection of Exo1 by inhibiting Exo1 interaction with PAR and PCNA. Furthermore, our work suggests a feedback mechanism for resection termination: DNA end resection leads to activation of ATR and its downstream kinase Chk1, which, in turn, phosphorylates Exo1, creating high-affinity binding site(s) for 14-3-3 proteins. Binding of 14-3-3s then inhibits Exo1 damage association, leading to termination of DNA resection. Collectively, our results provide important mechanistic insights into the coordinated regulation of Exo1 and the DNA end resection process.

Colorectal cancer (CRC) is the second most common fatal cancer in the U.S. with ~ 30% familial cases. Genetic predispositions have only been defined for 25% of familial CRC (FCRC). For the undefined group (uFCRC), current screening methods lack a molecular diagnosis and understanding of the natural history of disease, resulting in under- and over-screening. The known deficits cause DNA repair abnormalities that result in base changes. We hypothesized that uFCRC would originate from a distinct form of genetic instability: defective suppression of DNA double-strand breaks (DSBs). We assayed primary T-lymphocytes from uFCRC patients for the presence of the DSB marker γ H2AX and compared them to age- and sex-matched controls. Elevated γ H2AX levels were observed in 12/21 patients vs. 1/10 controls (P = 0.008). Exome sequencing in the patients (N = 24) identified typically 1 to 3 rare, high quality gene variants that are predicted to damage protein function, are involved in pathways that suppress and/or repair DSBs to maintain normal cell cycle progression and have not been previously implicated in CRC. Variants were enriched in nucleotide excision repair (P = 0.0015), Fanconi's anemia (P = 0.015), and DNA polymerase (P = 0.03) proteins. Patients with polyposis had more variants (P = 0.01). These variants were enriched for genes related to mitosis (P = 0.005) and included novel cell proliferation/signaling

related variants in Adenomatous Polyposis Coli, BMP7, and CDKN3, suggesting features of potential importance for tumor initiation. In all, eight variants map at or near the 26 loci linked previously to CRC risk. Next, we studied one patient in detail. Metaphase spreads exhibited greater sporadic chromosomal gains (8%) than in controls (1.4 %). Flow cytometry showed a high G2/M fraction in the patient than controls. This patient harbored candidate disease-causing variants in 3 DNA DSB repair genes: ERCC6, WRN, and FAAP100. Both the WRN and ERCC6 variant proteins were dysfunctional in biochemical tests. We next established EBV transformed cell lines from this patient and controls. The patient-derived lines revealed, at baseline and in response to several DNA damaging agents, elevated levels of γ H2AX and larger nuclear comets, a second indicator of DSBs. This phenotype could be rescued by expression of wild type WRN or ERCC6. In contrast, expression of the WRN or ERCC6 variants failed to rescue the phenotype. Further, the phenotype could be induced by knockdown of WRN or ERCC6 in CRC cells. We propose that defects in a number of genes that suppress DSBs cause constitutional genomic instability that presents as uFCRC. Identifying novel genetic subsets of FCRC, would clarify the natural histories of disease in these groups and improve screening/diagnosis.

Exploring the Functional Relationship Between CDK6 and the EYA Proteins.

J. Blair¹, A. Guerrero¹, M. Gossel¹;

¹Department of Biology, Connecticut College, New London, CT

Cyclin-dependent kinase 6 is a member of a family of kinases that regulate DNA replication. CDK6 phosphorylates pRB, which releases E2F, which in turn goes on to activate the transcription of genes necessary for cell proliferation (Gossel, 2006). It has recently been proven that CDK6 also binds to and promotes the degradation of EYA2 protein, which may in turn allow the cell to proceed into the S phase of the cell cycle (Gossel, 2014). The purpose of our work was to see if CDK6 also interacted with family member protein, EYA3. This is important as the overexpression of EYA proteins has been known to lead to many different types of cancer. To begin, EYA3 protein was produced and detected, as shown in figure 4. Then, an IP was performed using cell lysates that overexpressed both EYA3 and CDK6. The CDK6-conjugated antibody was collected from the lysates and the bound proteins were run on a western blot. EYA3 was also detected on this blot as shown in figure 5. The results suggest that CDK6 does indeed bind EYA3 protein.

P1112**Board Number: B444****Exploring the Relationship between CDK6 and EYA Family Member Proteins.**A. Guerrero¹, J. Blair¹, M. Gossel¹;¹Department of Biology, Connecticut College, New London, CT

Studies have shown that cyclin-dependent kinase 6 plays an important role in cell proliferation by phosphorylating the protein pRB making it inactive. Inactivation of pRB releases it from the E2F protein. E2F can then go on to initiate transcription of genes needed for DNA replication in the S-phase of the cell cycle. (Gossel, 2006) CDK6 has been linked to cancer because overexpression of this protein blocks differentiation and promotes cell division. A recent discovery reveals that CDK6 is not only involved in cell proliferation and differentiation, but also binding to and mediating EYA2 degradation. (Gossel, 2014). The EYA proteins are a family of regulatory proteins that promote cell proliferation and are also essential for organogenesis. Overexpression of these proteins is associated with breast, ovarian, cervical, hematopoietic cancers, and lung adenocarcinoma. Further research was conducted to determine if CDK6 binds to and promotes the degradation of other EYA family member proteins. Our data suggest that CDK6 binds to and degrades EYA3.

P1113**Board Number: B445****MECHANISTIC INSIGHTS TO CDK6-MEDIATED EYA2 DEGRADATION.**D. Kohrt¹, L. Placek¹, P. Hinds², H. Ford³, M. Gossel¹;¹Department of Biology, Connecticut College, New London, CT, ²Developmental, Molecular and Chemical Biology, Tufts University School of Medicine, Boston, MA, ³Pharmacology, University of Colorado School of Medicine, Aurora, CO

The D-cyclin activated kinase, CDK6, may only be essential for proliferation of specialized cell types, perhaps suggesting that it plays a role in differentiation. Our lab has shown that Cdk6 binds to and promotes degradation of the EYA2 protein. Here we investigate mechanisms of Cdk6-mediated EYA2 degradation. EYA2 is a member of the EYA family of transcriptional regulatory proteins that activate genes essential for the development of multiple organs. Eya proteins regulate cell proliferation and are misregulated in cancer. Our findings suggest that Cdk6 directly regulates the activity of the EYA2 protein. We propose that the Cdk6/Eya2 interaction affects fundamental properties of the cancer cell and may also function in normal development of some cell types.

P1114**Board Number: B446****Characterization of nuclear cyclin D1 interactions with replication regulatory elements in human cancer cells.**

M.M. Martin¹, T. Shimura², C. Redmon³, H. . Fu⁴, Y. Zhang⁴, M. Ryan⁵, K. Kim⁵, E.M. Epner⁶, M.I. Aladjem⁴;
¹Grambling State University, Ruston, LA, ²Environmental Health, National Institute of Public Health, Wako, Saitama, Japan, ³University of Maryland of Baltimore County, Baltimore, MD, ⁴Laboratory of Molecular Pharmacology, National Cancer Institute/National Institutes of Health, Bethesda, MD, ⁵InSilico Solutions, Fairfax, VA, ⁶Hematology/Oncology, Penn State Hershey Medical Center, Hershey, PA

During normal cell cycle progression, cyclin D1 associates with CDK 4 and CDK 6 to regulate cells passage from G1 to S phase. In cancers cyclin D1 is either mutated, amplified or overexpressed altering cell cycle progression and may contribute to tumorigenesis. Cyclin D1 overproduction in the nucleus causes cancer cells to over-replicate portions of their genome and exhibit high levels of genomic instability. Here, we investigated mutant cyclin D1's role in the etiology of cancer. To that end, we characterized cyclin D1 expression patterns, cellular localization along with chromatin modifications, and replication profiles in cancer cells that exhibited cyclin D1 modifications. Our studies employed chromatin immunoprecipitation followed by whole-genome sequencing (ChIP-Seq), gene expression analyses, whole-genome replication profiling using asynchronous, and cell cycle fractionated cancer cells obtained by centrifugal elutriation. Since mutant cyclin D1 was shown to interact with members of the pre-replication complex in mice, we also asked whether replication patterns change in response to accumulation of nuclear cyclin D1. Cyclin D1 migrated to the nucleus in human hepatocellular carcinoma cells that were exposed to low doses of irradiation over a long time period (fractionated radiation). We also found that cyclin D1 was present in the nucleus of primary patient-derived leukemia cells. In those leukemia cells, the stabilized nuclear cyclin D1 associated with chromatin and exhibited sequence-specific interactions with activated promoters. These studies generated a whole-genome map of cyclin D1 chromatin binding patterns in cancer cells harboring mutated nuclear cyclin D1, allowing us to investigate if nuclear cyclin D1 binding sites co-localized with replication initiation sites and chromatin modifications. Future studies will probe possible alterations of replication patterns in cancer cells harboring mutated nuclear cyclin D1.

P1115**Board Number: B447****Investigating spindle checkpoint component expression levels in nasopharyngeal carcinoma tissue culture cells.**Y. Chu¹, S.C. Schuyler¹;¹Biomedical Sciences, Chang Gung University, Taoyuan, Taiwan

The spindle checkpoint is a mechanism contributing to the prevention of chromosome mis-segregation. De-regulation of the spindle checkpoint is thought to drive aneuploidy, potentially increasing the risk of tumorigenesis. A number of reports demonstrated alterations in the levels of spindle checkpoint components in cancer cells. Here, we focus on nasopharyngeal carcinoma (NPC), a cancer that remains a challenge to diagnose early. Our long-term goal is to characterize spindle checkpoint function in NPC cells. Our first objective was to investigate the expression levels of specific spindle checkpoint components, MAD1 and MAD2, and two other regulators of mitotic exit in NPC tumor cell lines TW-02 and TW-06 as compared to a normal nasopharynx epithelial cell line NP-69. We have measured the relative expression of MAD1, MAD2, p31comet and CUEDC2 mRNA by real-time quantitative PCR. We have observed that MAD2 expression levels appear to be aberrant. Our next goal is to perform similar analyses on mRNA isolated from NPC tumor biopsy samples.

P1116**Board Number: B448****Apical mistrafficking of epiregulin can be a driver event in epithelial cancers.**B. Singh¹, G. Bogatcheva¹, R.J. Coffey¹;¹Medicine (GI), Vanderbilt University Medical Center, Nashville, TN

The EGF receptor (EGFR) ligand epiregulin (EREG) is delivered preferentially to the basolateral cell surface of polarized MDCK cells. Recently, we showed that EREG basolateral trafficking is regulated by a conserved tyrosine residue within a YXXΦ motif (Y₁₅₆ERV) in its cytoplasmic domain. Interestingly, a Y156A substitution led to apical mistrafficking of EREG and transformation of polarized MDCK cells (PNAS 110: 8960-5, 2013). We have identified EREG mutations (R147stop) in human tumors that is predicted to disrupt the basolateral sorting motif of EREG; we now report that EREG mistrafficks to the apical surface in MDCK cells expressing the this mutation. To test the hypothesis that apical mistrafficking of EREG can be a driver event in epithelial cancers rather than a mere passenger, we have generated MDCK cells stably expressing, inducible (Tet-ON) wild-type and Y156A mutant EREG. Uninduced clones form normal appearing cysts in 3D Matrigel cultures, regardless of EREG status. Upon induction, however, only (Y156A)EREG-expressing cells form abnormal cysts with ectopic lumens and inward growth that correlates with transformation in Matrigel cultures, providing support for our hypothesis. Furthermore, we show that EGFR activity is required for EREG mistrafficking-induced ectopic lumen formation as preincubation with the irreversible EGFR kinase inhibitor, EKI-785 abrogates formation of lateral lumens. Using EREG cytoplasmic domain as a bait in a yeast-2-hybrid screen, we

have identified interacting proteins that could modulate polarized sorting of EREG. We have subsequently confirmed these interactions by co-immunoprecipitation. Under a separate inducible control (Cumate switch), we have now expressed these interacting proteins simultaneously with Tet-inducible EREG constructs, to test if their interaction alters EREG localization and subsequent ectopic lumen formation. Results from these experiments will be presented at the meeting. In summary, dynamic regulation of EREG localization (by interacting proteins) can mediate transformation induced by apical mistrafficking of EREG.

EGF promotes cell migration in 2D and 3D non-small cell lung cancer cultures mediated by Akt and Erk pathways.

C. Lauand¹, E.L. Niero¹, G. . Machado-Santelli¹;

¹Department of Cell and Developmental Biology, University of Sao Paulo, Sao Paulo, Brazil

Lung cancer commonly exhibits ErbB1 gene mutation and amplification. ErbB1 encodes EGFR and its high expression in non-small cell lung cancer (NSCLC) has been associated with more aggressive disease and low response to therapy. Our group showed that HK2 cells have more ErbB1 gene copy number compared to A549 but lower EGFR expression. We also showed that EGF stimulus in NSCLC cells (A549 and HK2) grown in monolayer caused cell migration but not proliferation, independently of ErbB1 gene copy number or EGFR expression. The aims of this study are to investigate if Erk or Akt pathways are involved with regulation of EGFR-mediated motility and to establish a three dimensional culture (3D) to verify the effects of EGF, since 3D cultures is closer to *in vivo* conditions. 3D cultures were obtained by using cell suspensions in medium free of extracellular matrix elements submitted to rotation (20 rpm – alternating rotation to right/left) in non-adherent dishes at 37°C. A549 and HK2 cells formed spheroids. Western blotting analysis showed p-Akt and p-Erk expression, without EGF stimulation, in 2D and 3D cultures. The expression of these proteins increased after EGF stimulus. Exposure to AG1478, inhibitor of EGFR phosphorylation, decreased p-Akt levels only in 2D culture, but decreased p-Erk in monolayer and spheroids. We found p-EGFR expression without EGF stimulus in 3D. On the other hand, we did not observe EGFR phosphorylation in 2D culture without EGF stimulus, an important difference when we compare both systems of cell culture. Cell proliferation in spheroids was evaluated by cell cycle analysis and BrdU labeling by flow cytometry. Spheroids were stimulated with EGF or inhibited with AG1478 and no differences were detected in cell proliferation compared to control group. To investigate cell migration in monolayer we used wound healing assay, while sphere migration assay was performed in 3D cultures (spheroids were transferred individually to 24-well plates, treated with EGF or AG1478 and allowed to migrate; the diameter of migrating cells was measure). UO126 and LY294002 were added to inhibit, respectively, Erk and Akt pathways. Erk and Akt were involved in cell migration signaling in both cell lines cultured in monolayer. In 3D, cells exhibited higher rates of distant migration after EGF stimulation that was inhibited by AG1478. We could conclude that EGF did not induce cell proliferation but promoted cell migration in cells grown in 2D or 3D model. The migration of NSCLC cells induced by

EGF was mediated by Erk and Akt pathways. These results also provide new insights to culture NSCLC in a 3D model. Financial Support: FAPESP, CAPES and CNPq.

Chromosomal copy number changes contribute to multidrug resistance in human cancer cells.

L. Kabeche^{1,2}, S. Gerber^{1,2}, A. Grassetti^{1,2};

¹Department of Biochemistry, Geisel School of Medicine at Dartmouth College, Hanover, NH, ²Norris Cotton Cancer Center, Lebanon, NH

Aneuploidy is an important and common feature of cancer, present in over 90% of solid human tumors. Many cancer cells become chromosomally unstable (CIN) - a state in which cells lose chromosome segregation fidelity - which can lead to persistent changes in karyotype and tumor heterogeneity. Importantly, CIN is associated with drug resistance and poor patient prognosis in most cancers. Acquired drug resistance is a serious contributing factor to the ineffectiveness of current therapies. However, it still remains unclear how CIN correlates with drug resistance. There are two competing models of how CIN relates to increased acquired drug resistance: (i) the selective karyotype model, which suggests that upon treatment, resistant karyotype(s) of the heterogeneous tumor will continue to proliferate and repopulate the tumor, while non-resistant karyotype(s) will die, and (ii) the intrinsic karyotype model, which suggests that CIN cells uniquely exhibit more dynamic cell signaling pathways, which make them more fit to survive chemotherapy treatments. Based on our findings, we hypothesize that CIN promotes multidrug resistance through the selective karyotype model. Our preliminary results support this hypothesis, as we see marked karyotype changes in multidrug resistant HeLa (R-HeLa) cells compared to parental HeLa cells. R-HeLa cells have increased mRNA and protein expression of the Multidrug resistant 1 (MDR1) ATP dependent efflux pump and exhibit high rates of lagging chromosomes. Through fluorescence in-situ hybridization and NanoString nCounter karyotyping, we discovered that R-HeLa cells exhibit stable karyotype changes with a gain of chromosomes 1 and 7, and a loss of chromosome 5. Interestingly, MDR1 is localized on chromosome 7. To investigate whether a single gene (MDR1) on a chromosome is sufficient for the selection of whole chromosome gain/loss, we have used targeted genome editing to insert MDR1 into the AAVS1 locus on chromosome 19 in HeLa cells. Confounding evidence for the selective karyotype model emanates from multiple karyotypes seen in resistant cell lines. However, the extent to which these chromosome changes lead to downstream protein changes or contribute to drug resistance is not understood. Therefore, we have begun to quantitatively analyze the proteomes and phosphorylation and ubiquitylation events of R-HeLa cell clones compared to non-resistant HeLa cells. This will allow us to better understand the downstream effects of karyotype changes in the context of CIN and multidrug resistance. These studies are crucial in understanding the cellular and molecular mechanisms of multidrug resistance.

P1119**Board Number: B451****Crosslink of cell cycle and cell migration.**H. Huang¹;¹Inst Molec/Cellular Biol-National Taiwan Univ, Taipei, Taiwan

Metastasis is the cause of 90% death from cancer, yet little is known about how it relates to other cellular processes. A recent dynamic investigation revealed that the metastasis promoter, Slug, is under temporal regulations during the course of cell cycle. This inspired the question of whether cell migration or invasion, and ultimately cancer metastasis, could also display a cell-cycle dependent pattern. With FUCCI (two-colored Fluorescent Ubiquitination-based Cell Cycle Indicator) and single-cell fluorescent microscopy, we were able to monitor cell cycle progression in individual cells while they migrate. We found that cells appeared to travel with highest speed in G1, as compared to the rest of the cell cycle. More specifically, cells tend to jump apart after cytokinesis. We hypothesize that the cortical pulling forces from the previous cell division could aid in cell migration. When we blocked spindle bipolarity with Kinesin-5 inhibitor (an antimetastatic drug), leaving cells with monopolar spindles, the high speed that peaked right after cell division was lost. Our results suggest that even if cancer cells resist killing from Kinesin-5 inhibitor, failed mitosis induced by the drug still have the benefit of preventing them to metastasize.

P1120**Board Number: B452****Probing and interrogating cell cycle control in MultiCellular Tumour Spheroids.**O. Mondésert¹, C. Frongia¹, C. Lorenzo¹, V. Lobjois¹, B. Ducommun¹;¹CNRS USR3505 ITAV, Toulouse, France

Major recent advances have recently been made in the understanding of the molecular pathways regulating the cell cycle machinery and their deregulations in cancer. These results open new avenues for the development of innovative antitumor pharmacological strategies targeting the cell cycle and its checkpoints.

MultiCellular Tumor Spheroid (MCTS) are now considered as invaluable models to study cancer cell biology and for the preclinical development of new antiproliferative drugs. To fully exploit the features of MCTS, it is essential to preserve the 3D regionalization level of analysis when investigating the effect of a drug. We will report here a breakthrough in the use of MCTS with new technological developments that can be used to explore the regionalization and the live dynamics of the effects of anticancer drugs in 3D. Spheroids expressing fluorescent cell cycle reporters (i.e. Fucci) and biosensors were engineered and used to monitor cell cycle arrest and DNA damage Response (DDR) pathway activation induced by chemotherapeutic agents. The kinetics and regionalized aspects of the response were investigated on genetically modified spheroids using innovative 3D imaging strategy (based on 3D light sheet microscopy). We will present our latest results on the characterization of the effects of several

anticancer drugs including DNA damaging agents alone or in association with checkpoint abrogating compounds.

This study opens new perspectives for original 3D assays dedicated to the identification of new original targets and compounds and for the investigation of the dynamics of the 3D response to novel antiproliferative agents.

Identification of evolutionarily conserved DNA Damage Response (DDR) genes that regulate response to cisplatin.

A.V. Gaponova¹, I.G. Serebriiskii¹, T.N. Beck¹, H. Liu¹, E.A. Golemis²;

¹Fox Chase Cancer Center, Philadelphia, PA, ²Developmental Therapeutics Program, Fox Chase Cancer Center, Philadelphia, PA

Cancer treatment commonly involves the use of cytotoxic agents that damage DNA. Although these agents provide clinical benefit, tumors often develop resistance. The molecular mechanisms of resistance to one of the most common DNA-damaging agents, cisplatin, are not fully understood, although many known resistance mechanisms involve proteins functioning in the DNA Damage Response (DDR) pathways. A better understanding of the cellular response to DNA damage will probably give us possibility of identifying new therapeutic targets, providing new avenues for disease management.

To identify new regulators of DDR, we considered the fact that DDR involves multiple protein complexes and signaling pathways, some of which are evolutionarily ancient and conserved from yeast to humans. This is evidenced by the existence of yeast-human orthologs involved in certain DDR pathways. Based on this functional conservation, we hypothesized that thorough identification of genes regulating sensitivity to cisplatin and/or ionizing radiation in yeast may help to uncover human genes previously unknown to be involved in DDR. We first performed an extensive bioinformatics analysis, combining analysis of functional screens, gene expression response to DNA damage, protein interaction analysis, and other metrics. We then evaluated which genes shown to regulate resistance to DNA damage in *Saccharomyces cerevisiae* have human orthologs, identifying 122 candidates.

Squamous-cell carcinomas of the head and neck (SCCHN) are a heterogeneous group of cancers with a global incidence of 550,000 patients per year worldwide, and an annual mortality rate of 271,000. A major problem in treatment of SCCHN is an emergence of resistance to radio- and chemotherapy, which are frontline agents for the disease. We used siRNA knockdown of genes selected from the candidate gene set in a panel of SCCHN cell lines to identify those which regulate sensitivity to cisplatin. We have identified 20 genes that influence cisplatin resistance, and further explored their biological functions, analyzing their regulation of foci formation by phosphorylated histone protein γ H2AX (a sensitive marker for DSBs), cell cycle progression in presence and absence of cisplatin, and the activation and

expression of known DDR-associated signaling proteins. These results demonstrate the value of evolutionary modeling in generating new insight into therapeutic response.

Board Number: B454

In vitro and In vivo Efficacy of Diaminotiazoles is p53 Independent.

R. Thamkachy¹, R. Kumar¹, K.N. Rajasekharan², S. Sengupta¹;

¹Cancer Research Program-3, Rajiv Gandhi Centre for Biotechnology, Thiruvananthapuram, India,

²Department of Chemistry, University of Kerala, Trivandrum, Kerala, India

Diaminotiazoles are a novel class of potential anticancer agents that show antimitotic and antiangiogenic properties. Earlier studies have shown that a lead diaminotiazole DAT1 (4-amino-5-benzoyl-2-(4-methoxy phenyl amino) thiazole) induced strong apoptotic response mostly due to triggering of Death Receptor 5 (DR5) mediated extrinsic pathway. We have studied the role of p53 and the upstream regulators of DAT1 action. We have also checked the toxicity and efficacy of DAT1 *in vivo* and confirmed the signaling pathway in xenograft tumours. p53 mutated and knocked out cell lines were used and signaling pathway was checked by western blotting. Acute and sub-acute toxicity studies were performed in Swiss Albino mice. Xenograft tumours were developed in SCID/NOD mice with subcutaneous injection of wild type colon cancer HCT116 cells and HCT116 cells with knocked out p53 gene.

Here, we found that DAT1 is cytotoxic to cell lines having dysfunctional p53 status through p53 independent upregulation of the death receptor DR5 followed by activation of caspase 8. It has also been found that DAT1 causes nuclear translocation and activation of ERK but not of p38 and JNK/SAPK. Acute toxicity study of DAT1 showed that there was no adverse effect of this compound up to 50 mg/kg. Further, in a sub-acute toxicity study, the serum ALP, ALT, AST, creatinine and BUN levels did not differ much from the control values which indicated that the drug is non-toxic to liver and kidney tissues. It was found that DAT1 was effective in causing reduction in both types of xenograft tumour growth in mice starting from a concentration of 10 mg/kg.

Tunnel assay and immunohistochemistry results clearly showed more apoptosis in tumour tissue that received DAT1 as compared to the tissue which received vehicle alone. The immunohistochemical results also revealed that DR5 and pERK expression were more in DAT1 treated tumour tissue as compared to the vehicle treated tissue while p38 and pJNK/SAPK levels were similar showing consistency with the *in vitro* results. Further, western blot studies of the tissue lysates also confirmed the immunohistochemistry results. Our findings thus show that the diaminotiazole DAT1 has minimal toxicity in mice and is highly effective in xenograft tumour models. Both *in vitro* and *in vivo* investigations show that ERK acts as an upstream regulator of DAT1 mediated apoptosis with p53 having little role. This study places diaminotiazoles as a highly promising anticancer agent even in tumours with inactivated p53.

P1123**Board Number: B455****Epigenetic repression of c-Myc P2 promoter by Sendai F-virosome mediated delivery of tumor specific shRNA in Hepatoma cells.**M.K. Zakaria^{1,2}, I. Khan¹, P. Mani³, D.P. Sarkar³, P. Chattopadhyay¹, S. Sinha²;¹Dept. of Biochemistry, All India Institute of Medical Sciences, New Delhi 110029, India, ²National Brain Research Centre, Manesar, Haryana 122050, India, ³Dept of Biochemistry, South Campus, University of Delhi, New Delhi 110021, India

Combinatorial association of a liver specific vehicular system with a therapeutic entity active only under neoplastic condition could make an ideal system for targeting hepatocellular carcinoma (HCC). Sendai virus home to hepatocytes based on the liver specific expression of asialoglycoprotein receptors (ASGPRs), which are recognized by viral fusion (F) protein's terminal galactose moiety. Sendai F-virosomes, derived from Sendai virus, are reconstituted viral envelopes with surface F-proteins. Removal of viral RNA genome and surface hemagglutinin neuraminidase (HN) proteins prevent their independent replication and non-specific/systemic interaction respectively. Transcriptional gene silencing (TGS) is a recent approach of RNAi involving dsRNAs. Unlike Post-transcriptional gene silencing (PTGS), TGS induces epigenetic silent state chromatin and DNA marks, leading to heritable and long term transcriptional repression of the target gene. Furthermore, it does not require continuous si/shRNA supply. ME1a1 binding site is required for maintaining active transcriptional state of the proto-oncogene c-Myc P2 promoter. Around 90% of the c-Myc transcripts are driven by its P2 promoter, making it a suitable candidate for targeted cancer therapy. Using such Sendai F-virosomal delivery, HCC activated alpha-fetoprotein (AFP) promoter was utilized, in combination with various tumor specific enhancers, to drive the expression of shRNA encompassing ME1a1 binding site, in order to induce TGS in hepatocarcinoma cells. The dual specificity of liver specific delivery with AFP promoter/enhancer driven expression of shRNA ensured that the TGS was activated only in transformed liver cells leading to apoptosis and decreased survival. The mechanistic study revealed that the extensive cancer cell death was as a result of specific histone modifications (H3K9 Di-methylated, H3K27 Tri-methylated and decreased H3 acetylation) and DNA methylation (CpG 8, 9 and 10) around the shRNA target locus, ultimately repressing the c-Myc P2 promoter. This was possibly due to the recruitment of histone deacetylases (HDACs) and DNA methyl transferases (DNMTs), by the shRNA, at the target site, since the shRNA failed to induce such epigenetic changes in the presence of DNMT/HDAC inhibitors. c-Myc down-regulation, by TGS, also led to the decrease of other pro-proliferative genes such as cyclin D3 and hTERT, suggesting a shift from neoplastic potential towards normal. This therapeutic system is potentially safe, since no interferon (IFN) response was generated by Sendai virosome/AFP promoter-enhancer – c-Myc shRNA expression system. Moreover, this could serve as an added advantage over other gene therapeutic approaches, since persistent c-Myc inactivation is required for HCC suppression. Additionally, this system could also be used to introduce genes specifically in embryonic liver and to tackle recalcitrant cancer cells with de-regulated c-Myc.

P1124**Board Number: B456****Characterization of an Inhibitor of the NF- κ B Signaling Protein NEMO.**S. Penix^{1,2}, T. Gilmore², A. Yeo²;¹Massbay Community College, Wellesley, MA, ²Molecular Biology, Boston University, Boston, MA

The Nuclear Factor kappa beta (NF- κ B) is a member of a family of eukaryotic transcription factors that are involved in inflammatory response, developmental processes, cellular growth, and apoptosis. It is persistently active in a number of disease states such as cancer, chronic inflammation, asthma, and neurodegenerative diseases and has been heavily implicated in their onset. Activation of NF- κ B requires the cytoplasmic phosphorylation and later degradation of interferon kappa-beta alpha (IKBA), these events release of NF- κ B for entry into the nucleus where it would finally serve its role as a transcription factor. Because of its possible role in chronic and acute inflammation as well as the onset of cancer, NF- κ B modulation has often been considered as a likely candidate for therapeutic agents. Therefore, many groups have sought to identify compounds that can inhibit NF- κ B and/or its pathway for diverse therapeutic and regulatory purposes. In this project, we characterized a recently synthesized compound (identified as 9644) that has been shown to inhibit NF- κ B signaling by disrupting the NF- κ B essential modulator (NEMO) and interferon kappa kinase (IKK) protein-to-protein interaction. The NEMO/IKK protein complex is required for activation of the I κ B kinase complex in canonical NF- κ B signaling and is directly responsible for the phosphorylation and degradation of I κ BA. It is important to note that the activation of the NEMO/IKK complex itself is product of the activation of a tumor necrosis factor (TNF) receptor, a protein also entangled in the networks of cancer cell biology and inflammation. Previous analysis of the compound 9644 through crystallography have hinted that the mechanism of action of compound 9644 does entails a direct interaction with a cysteine residues located within and around the CC1 and CC2 domains of NEMO. For our analysis we have induced point mutations within clones of NEMO cDNA to induce point mutations and subsequent substitutions of the cysteine residues for alanine residues within the CC1 and CC2 domains to confirm the specific residue that 9644 binds. After confirmation of the mutations through use of restriction enzymes and PCR, the different NEMO mutants were added to plasmid backbones to for transfection into human embryonic kidney cells (A293T) culture, expression and analysis of the effects that the 9644 compound would have in them, the formation of the NEMO/IKK complex and activation of NF- κ B. Analysis of protein extracts with Western Blotting showed that replacing all the cysteine residues in the indicated region (7xALA NEMO construct) does reduce the action of 9644 while still permits the formation of the NEMO/IKK complex. We hope to expand our analysis in the future to pinpoint the specific residue responsible for the action of the compound 9644.

P1125**Board Number: B457****Lung cancer cells after irradiation indicate viability and malignancy dependent on activating transcription factor 5.**S. Ishihara^{1,2}, M. Yasuda³, A. Ishizu⁴, H. Haga^{1,2};

¹Faculty of Advanced Life Science, Hokkaido University, Sapporo, Japan, ²Research Center for Cooperative Projects, Graduate School of Medicine, Hokkaido University, Sapporo, Japan, ³Department of Oral Pathobiology, Graduate School of Dental Medicine, Hokkaido University, Sapporo, Japan, ⁴Division of Medical Laboratory Science, Faculty of Health Sciences, Hokkaido University, Sapporo, Japan

Radiotherapy is a major therapeutic way for treating malignant tumors. However, a part of cancer cells after irradiation survives and repopulates tumors that indicate malignant phenotypes correlated with poor prognosis. It is not exactly known how cancer cells survive and regenerate malignant tumors after irradiation. We here show that activating transcription factor 5 (ATF5) enhances viability and malignant phenotype, such as tumorigenesis, cell growth, and invasiveness, in lung cancer cells after irradiation. We established a transgenic A549 human lung adenocarcinoma cell line overexpressing ATF5 (A549-ATF5). A549-ATF5 cells indicated high viability comparing with control A549 cells after 10 Gy irradiation. Next, we examined the relationship between the expression of ATF5 and the cell cycle. ATF5 was highly expressed during the late G1 phase to S phase in A549 cells. Furthermore, at the late G1 phase, the cells indicated higher viability after irradiation than the M phase. In addition to the viability after irradiation, A549-ATF5 cells also displayed high ability of cell growth and invasiveness comparing with control A549 cells in vitro. A549-ATF5 cells also showed higher ability of tumorigenesis and invasiveness than control cells in vivo. Moreover, A549 cells that survived after irradiation indicated greater expression of ATF5 than control A549 cells and showed high invasiveness dependent on ATF5 expression. We also revealed that ATF5 enhances the invasiveness in A549 cells by promoting the expression of integrin beta1, which contributes to cell-matrix adhesion, and dephosphorylation of myosin regulatory light chain, which regulates cellular contractile force. These results suggest that lung cancer cells which highly express ATF5 dependent on cell cycle survive after irradiation, and as a result, regenerate more malignant tumors than non-irradiated lung cancer cells.

P1126**Board Number: B458****Elucidating the Role of Centrosome Amplification in Tumorigenesis.**M.S. Levine¹, A.J. Holland¹;

¹Molecular Biology and Genetics, Johns Hopkins University School of Medicine, Baltimore, MD

Centrosomes are the major microtubule organizing centers of animal cells and play an important role during mitosis where they organize the poles of the bipolar microtubule spindle apparatus upon which chromosomes are segregated. Extra copies of centrosomes frequently result in errors in spindle assembly that give rise to chromosome missegregation and the production of aneuploid daughter cells

with an abnormal chromosome content. Almost one hundred years ago, Theodor Boveri proposed that centrosome amplification could contribute to tumorigenesis. Since then, supernumerary centrosomes have been identified as a consistent feature of aneuploid tumors. Moreover, centrosome amplification is found early in the development of some hematological cancers and solid tumors and has been shown to correlate with tumor grade, proliferative index and the level of genomic instability. However, despite the large body of circumstantial evidence linking extra centrosomes to the development of cancer, it remains unclear whether supernumerary centrosomes actively contribute to tumorigenesis or arise as a byproduct of cellular transformation.

The serine/threonine kinase Polo-like kinase 4 (Plk4) is a master regulator of centrosome copy number, and its overexpression leads to the production of supernumerary centrosomes. To test the in vivo consequence of centrosome amplification in the absence of other defects, we have developed a novel mouse model in which Plk4 can be reversibly overexpressed using a doxycycline-inducible promoter. Using this animal model, we show robust centrosome amplification can be induced in multiple primary cell types in vitro and in vivo. We have observed that overexpression of Plk4 leads to supernumerary centrosomes in 25%, 50%, and 80% of bone marrow cells, mammary epithelial cells, and mouse ear fibroblasts, respectively. Moreover, we observed that centrosome amplification is lethal early in life, but well tolerated in young adult animals. We will describe our ongoing efforts using this model to analyze the consequence of centrosome amplification in tumor development.

The Effect of Nuclear Import Inhibition on Ovarian Cancer Cells.

A. Chi¹, W. Wei², M. Birrer², V. Leaner¹;

¹Clinical Laboratory Sciences, University of Cape Town, Cape Town, South Africa, ²Harvard Medical School, Harvard University, Boston, MA

BACKGROUND Karyopherins are a family of protein receptors responsible for transporting cargo molecules across the nuclear membrane. Previous studies have shown that KPNA2, a member of this protein family promotes cell proliferation and tumorigenicity, and that its over-expression significantly correlates with poor prognosis in ovarian cancer (OvCa). KPNA2 acts in concert with KPNB1 and together they import proteins carrying the nuclear localization signal. KPNB1 has also been shown to be expressed in other cancers such as cervical and esophageal, and its inhibition using both siRNA and a small molecule inhibitor of nuclear import, C43 result in cancer cell death. C43 is a small molecule identified in silico as a potential KPNB1 inhibitor and showed inhibitory effects on KPNB1 associated nuclear import. The aim of this study is to investigate KPNB1 expression and nuclear import inhibition using C43 in OvCa. **METHODS** Western blot analysis and qRT-PCR were used to measure KPNB1 protein and mRNA expression in ten OvCa cell lines. The effect of inhibiting nuclear import using a small molecule C43 on OvCa cell biology was investigated, including cell survival; and KPNB1 cellular distribution using immunofluorescence and nuclear-cytoplasmic separation. KPNB1 expression was examined in response to platinum-induced cellular stress, and a combination treatment of cisplatin with

the nuclear import inhibitor was explored. **RESULTS** KPNB1 was found to be highly expressed in all the OvCa cell lines examined at both the mRNA and protein levels. Treatment of OvCa cells with the nuclear import inhibitor C43 induced OvCa cell death. Immunofluorescence and nuclear/cytoplasmic fractionation showed C43 was able to decrease nuclear localization of KPNB1 in OVCAR4 and OVCAR8 cell lines. Furthermore, sub-lethal doses of cisplatin treatment resulted in increased KPNB1 expression within one hour of treatment, suggesting that KPNB1 may be involved in platinum-induced early stress-response. Pre-treating OvCa cells with C43 to inhibit nuclear import via KPNB1 increased the sensitivity to cisplatin treatment. **CONCLUSION** Our data shows that the nuclear receptor KPNB1 is highly expressed in OvCa cells and that inhibiting nuclear import results in OvCa cell death. In addition, KPNB1 appear to have a role in the platinum induced early stress response in OvCa. As drug resistance and toxicity is a major problem in treating OvCa, our data suggest that a combination treatment of nuclear import inhibition via KPNB1 and cisplatin may increase the sensitivity of OvCa cells to cisplatin.

Mediator Kinase Module is a transducer of Oncogenic Wnt/Beta-catenin signaling.

A.D. Clark*¹, M. Oldenbroek*¹, J.M. Spaeth¹, F. Gao¹, T.G. Boyer¹;

¹Department of Molecular Medicine, UT Health Science Center - San Antonio, San Antonio, TX

*Co-presenting authors

CDK8 is a colorectal cancer (CRC) oncoprotein whose amplification-dependent overexpression identifies a significant subset of colorectal cancer patients with poor prognosis. Mechanistically, Cyclin C (CycC)-dependent CDK8 kinase activity drives tumorigenesis by regulating beta-catenin transcriptional activity. Accordingly, inhibition of CDK8 kinase function offers a promising therapeutic approach for CDK8-overexpressing colorectal cancers. Cyc-CDK8, along MED12 and MED13, comprise a discrete 4-subunit "kinase" module within Mediator, a conserved multiprotein interface between gene-specific transcription factors and RNA Polymerase II. Here, we identify a network of physical and functional interactions within the Mediator kinase module critical for oncogenic Wnt/beta-catenin signaling. We show that beta-catenin binds directly to MED12 in Mediator, which in turn activates CycC-dependent CDK8 kinase activity and beta-catenin target gene induction. MED12-dependent CDK8 activation occurs through a direct interaction involving the MED12 N-terminus and a phylogenetically conserved surface groove on CycC. Mutagenic disruption of the MED12/CycC interface inhibits CDK8 kinase activity and beta-catenin target gene expression, and concomitantly impairs CRC cell proliferation and clonogenicity. These findings identify the MED12/CycC interface as a critical transducer of oncogenic Wnt/beta-catenin signaling and a potential therapeutic target in colorectal and other CDK8-driven malignancies.

P1129**Board Number: B461****A snapshot of pan-cellular PTM in response to Sorafenib mediated multi-kinase inhibition.**M. Bell¹, C. Loch¹;¹Research and Development, AVMBioMed, Malvern, PA

More fundamentally than regulating specific functions or cascades, PTM affords proteins the mechanical complexity necessary to make human cells function. We believe that specifically modified forms of proteins are what conduct the cells business, and that by monitoring these “proteoforms” we can gain unique insight into cellular physiology. To test this, we treated HepG2 hepatocellular carcinoma cells with the multi-kinase inhibitor Sorafenib, and observed pharmacodynamic changes to PTM across the cellular proteome. Our novel approach, referred to as Snapshot Proteomics, revealed changes in phosphorylation to known targets of this drug. Intriguingly, we also observed changes to proteins whose roles make them strong candidates for mediating the clinical side effects of Sorafenib treatment. We also observed that the changes mediating the therapeutic response were far from the most dramatic ones observed, suggesting other, unexpected proteins as better putative pharmacodynamic biomarkers. Finally, we found that manipulating cellular phosphorylation pharmacologically had dramatic and interesting effects on other PTM pathways as well, ubiquitin in particular. This confirmed the already established crosstalk between these pathways, and supports our contention that no PTM occurs in a vacuum.

P1130**Board Number: B462****K20E, an Oxidative-coupling Compound of Methyl Caffeate, Exhibits Anti-angiogenesis Activities through Down-Regulations of VEGF and VEGF Receptor-2.**C. Wu¹, C. Pan^{1,2}, . Lin³;¹Pharmacy, Taipei Medical University, Taipei, Taiwan, ²Pharmacy, Taipei Medical University, Taipei, Taiwan, ³Pharmacy, China Medical University, Taichung, Taiwan

Anti-angiogenesis is one of the most popular clinical interventions for applying on cancer chemotherapy. A new synthesized derivative of methyl caffeate, named as K20E, was used to investigate its anti-angiogenesis activity and possible pharmacological mechanisms. Anti-angiogenesis effects of K20E were evaluated in the experiments of murine allograft tumor model and Matrigel plug assay as well as cell models in the human umbilical vascular endothelial cells (HUVECs) and the LLC1 lung cancer cells. Our results suggested that K20E suppressed tumor growth in the allograft tumor model and exhibited anti-angiogenesis activity in Matrigel plug assay. Besides, HUVEC viability can be significantly reduced through inducing cell cycle arrest at G2/M phase and apoptosis. Cell migration, invasion, and tube

formation of the HUVECs were also markedly suppressed by K20E treatment. K20E largely down-regulated the protein expression of vascular endothelial growth factor (VEGF) in the LLC1 cancer cells. Besides, the expression levels of VEGF receptor-2 (VEGFR-2) and its downstream signaling cascades (PI3K-AKT-mTOR and MEK1/2-ERK1/2) as well as the expression and activity of gelatinases were also evidently reduced in the HUVECs treated with K20E. Inversely, K20E can up-regulate the expression levels of p53 and p21 proteins in the HUVECs. Based on these results, our study suggested that K20E possessed antitumor effect by anti-angiogenesis which is associated with reducing VEGF expression in the cancer cells as well as decreasing the expression and activation levels of VEGFR-2 and its downstream signaling cascades in the vascular endothelial cells (VECs).

Carcinoma-specific inhibition of cell proliferation by down-regulating farnesoid x receptor expression.

T. Fujino¹, R. Yokokawa¹, A. Iijima¹, R. Sakurai¹, M. Hayakawa¹;

¹Tokyo Univ Pharmacy/Life Scis, Hachioji, Japan

Farnesoid X receptor (FXR) is a pivotal factor maintaining bile acid homeostasis and highly expressed in the liver, kidney, intestine, and adrenal gland. We have previously revealed that FXR controls the proliferation of hepatocellular carcinoma cells: FXR stimulates cell proliferation by suppressing the p16/INK4a expression whereas downregulation of the FXR stimulates the expression of CDK inhibitors p16/INK4a and p21/Cip1, resulting in the suppressed cell proliferation (Fujino T, et al. J.Biochem. 2012). In the present study, we investigate whether or not FXR exerts carcinoma-specific cytotoxicity toward hepatocellular carcinoma cells and renal adenocarcinoma cells.

Hepatic cells: The treatment of HepG2, human hepatocarcinoma cell line, with FXR siRNA transcriptionally elevated the level of p16/INK4a and p21/Cip1 expression resulting in the inhibition of cell proliferation. By contrast, in human hepatocyte-derived cell line Fa2N-4, FXR knockdown post-transcriptionally reduced p16/INK4a and p21/Cip1 expression resulting in the stimulation of cell proliferation. Proteasome inhibitor treatment restored FXR knockdown-caused down-regulation of p16/INK4a and p21/Cip1 in Fa2N-4 cells, indicating the down-regulation of p16/INK4a and p21/Cip1 is proteasome-dependent.

Renal cells: The treatment of ACHN, human renal adenocarcinoma cell line, with FXR siRNA transcriptionally elevated the level of p21/Cip1 expression resulting in the inhibition of cell proliferation. By contrast, in human renal cell line HK-2, FXR knockdown transcriptionally reduced p21/Cip1 expression resulting in the stimulation of cell proliferation.

In conclusion, FXR negatively regulates the cell proliferation of hepatocellular carcinoma cells and renal adenocarcinoma cells, while it stimulates that of normal hepatic and renal cells. Our study may contribute the development of anti-cancer medicine with minimal side-effects.

P1132**Board Number: B464****Using Targeted Molecular Imaging Agents (TMIA) to Evaluate Differences between Two- and Three-Dimensional Cell Culture Cancer Models.**H.D. Ophardt¹, A.M. Butera¹, H.F. Schmitthenner², I.M. Evans¹;¹GSOLS, Rochester Institute of Technology, Rochester, NY, ²SOCAMS/ Center for Imaging Science, Rochester Institute of Technology, Rochester, NY

The goal of this research is to recreate and understand the three dimensional (3D) organoid which constitutes cancer, the King of the Maladies in order to develop better targeted molecular imaging agents (TMIA). To create a 3D cancer model, cancer cells are embedded in a matrix whose signaling contributes to malignant progression of the cancer cells. To further understanding of cancer cells and metastases, the human lung adenocarcinoma cell line A549 and the murine brain endothelial cell line, bEnd3, were cultured using traditional two-dimensional methods as well as several three-dimensional matrices including, Matrigel, Geltrex, and Collagen type I. An ever increasing body of literature indicates significant differences in cell morphology, gene expression, proliferation, migration and many other cellular properties between 2D and 3D cultured cells, with 3D culture more accurately representing that which is observed within live animal models in vivo. Fluorescent microscopy on a Leica TCS SP5 confocal microscope was used in conjunction with multiple fluorescent dyes including NucBlue, Tubulin Tracker Oregon Green, and Mitotracker Red, targeting the nucleus, microtubules, and mitochondria respectively. In addition, the targeted molecular imaging agent (TMIA) Cy5.5-RGDyk conjugate, synthesized at RIT, which specifically targets $\alpha\beta3$ integrins and has been shown to be over expressed on the surface of some cancer cell strains, was also employed. Our results show differences between the properties of 2D and 3D cell culture systems which may be important in the way cancer cells metastasize and spread throughout the body of a cancer patient. We also observed that the TMIA agents utilized penetrated 3D cancer models and stained cells buried inside the spheroid tumor model. We conclude that the use of 3D cellular models which mimic more closely in vivo tumors should facilitate development of Targeted Molecular Imaging Agents (TMIA) and result in molecules which target to metastatic tumors illuminating their presence, size, and structure thus allowing better treatment and enhanced cancer survival.

P1133**Board Number: B465****Novel and facile fluorescence microscopy method for detection of intracellular galectin-3 inhibition by small molecules in vitro.**G. Sharma¹, J. Stegmayr^{1,2}, M. Carlsson^{1,3}, U.J. Nilsson⁴, S. Oredsson², H. Leffler¹;¹Department of Laboratory Medicine, Lund University, Lund, Sweden, ²Department of Biology, Lund University, Lund, Sweden, ³Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark, ⁴Department of Chemistry, Lund University, Lund, Sweden

Galectins are intra- and extracellular proteins that bind to β -galactosides and are implicated in a broad range of cellular functions such as cell proliferation, cell adhesion, and apoptosis with consequences in cancer and inflammation. As possible treatments of such diseases, we have developed high affinity inhibitors of galectin-3, the most studied galectin. However, there is no method till date to determine whether a therapeutic agent (galectin inhibitor) will reach and bind to intracellular galectin. Taking this into account, there was an unmet need to develop highly specific method capable of detecting intracellular inhibitor effects on galectin-3. Hence, we analysed the effects of a galectin-3 inhibitor (bis-{3,3'-deoxy-3,3'-[4-(3-fluorophenyl)-1*H*-1,2,3-triazol-1-yl]}-1,1'-sulfanediyl-di- β -D-galactopyranoside) on an intracellular effect directly shown to depend on galectin-3 carbohydrate interaction – the accumulation of galectin-3 around disrupted intracellular vesicles. Treatment of cells with Glycylphenylalanine-2-naphthylamide (GPN), or Leucine-Leucine-Omethyl (L-L-OMe), or amitriptyline was used to induce disruption of lysosomes and accumulation of galectin-3 around them, observed by immunofluorescence microscopy as puncta. Pretreatment of the cells with the inhibitor inhibited this accumulation of galectin-3, recorded as decreased formation of puncta in a dose and time dependent manner.

P1134**Board Number: B466****Fluorescence-based co-culture of normal and cancerous cells as an indicator of cancer therapeutic effects.**H. Matsui¹, M. Tamura¹, J.K. Tanaka¹, Y. Miwa¹;¹Faculty of Med, Univ Tsukuba, Tsukuba, Japan

Comprehensive evaluation of cancer therapeutic effects is difficult in vitro because of the need to distinguish the main effects from the side effects with in data. This difficulty cannot be overcome by comprehensive evaluation involving monoculture. For a solution of this problem, we established two cell lines which are the GFP-expressing rat gastric mucosal cell (RGM-GFP) and the Kusabira orange-expressing cancerous RGM cell (RGK-KO), and use of these, we tried fluorescence-based co-culture with both of RGM-GFP and RGK-KO. An origin of RGK-KO was established from RGM by an exposure of chemical carcinogen, therefore, the native gene background was same among both of cells. RGM-GFP

and RGK-KO should be an ideal pair of cells for comprehensive evaluation in some cancer fields. We evaluated major cancer therapy such as chemotherapy and X-ray treatment using this co-culture. These results clearly distinguished the cancer-selective toxicity. While Adriamycin induced a cell death against both of cells, 5-FU induced it against RGK-KO mainly. X-ray treatment also showed a cancer-selective toxicity under our experimental condition. We also tried a three-dimensional co-culture with both of cells. RGM-GFP was spread and created the monolayer on a matrigel, while, RGK-KO invaded into matrigel. Furthermore RGK-KO on the monolayer of RGM-GFP also invaded into matrigel through the layer. As a conclusion, we developed the fluorescent co-culture of normal cells and cancer cells for evaluation of cancer therapeutic effect, especially cancer-selective toxicity. We could distinguish main effects from side effects in anti-cancer drug and X-ray treatment using the co-culture system. The three-dimensional co-culture with matrigel showed potential as a promising method for use in biological and pharmaceutical science fields.

Double edge sword: Atmospheric gas plasma as a source of protection against tumor development for normal cells and as a killer for tumor cells.

M. Ishaq¹;

¹Manufacturing Flagship, CSIRO, North Ryde, Australia

Background: Atmospheric gas plasmas (AGP), which is source of reactive oxygen and nitrogen species is able to activate anti-oxidant system in normal cells. Furthermore AGP can selectively induce apoptosis in cancer cells, offers a promising alternative approach to conventional therapies which have unwanted side effects such as drug resistance and toxicity. However, the mechanism of AGP-induced anti-oxidant system activation in normal cells and cancer cell death is unknown. **Purpose of the study:** The aim of this study was to explore the intracellular mechanism, how AGP induced anti-oxidant system in normal non-transformed cells and apoptosis in cancer cells without effecting normal cells. **Experimental procedures:** Mice (BALB/c-Fox1nuAusb) were used in this study. AGP treated solution was injected I/V into mice. Melanoma cancer cell lines were injected S/C into AGP treated or untreated mice to develop tumor. Tumor tissues and normal melanocytes were used to study the effect of AGP by measuring the apoptosis, intracellular ROS/GSH/NO production, intracellular gene expression by RNA Microarray and qPCR, immunoblotting and ELISA and enzymatic activity of kinases.

Results: In this study, mice injected with AGP-treated solution were resistant to develop tumor compared to untreated mice which develop melanoma tumor in 2 weeks. Gene expression array study showed that antioxidant genes like Srx, NQO1 and AKR1C1 were up-regulated in AGP treated mice normal melanocytes cells compared to untreated mice. Knockout of anti-oxidant activator Nrf2 in mice blocked the AGP ability to activate antioxidant enzymes like Srx in mice and revert mice ability for tumor development. On the other hand, mice without AGP treatment developed melanoma. AGP treatment of tumors reduced the volume of tumors. Gene expression array studies show that genes from TNF (tumor-necrosis factor) pathway were mostly differentially up-regulated. Further studies showed AGP activated

ASK1 kinases downstream of TNF pathway were involved to induce apoptosis in tumor cells. This data show, activation of anti-oxidant system in mice can prevent tumor development and also AGP can kill tumor cells by inducing apoptosis without effecting normal cells. Future study will focus to attain long-term activation of anti-oxidant system in the animals to resist tumor development. Further experiments will be conducted to explore the exact mechanism involved in AGP-induced antioxidant system defence mechanism against tumor development.

Conclusion: The evidence for Nrf2 dependent anti-oxidant system activation and resistance against tumor development after AGP-treatment can be used as a new tool for cancer preventive therapy.

Development of (+)-negamycin-derived ester-type prodrugs promoting premature termination codon-readthrough and its application for suppressing cancer cell growth.

K. Takayama¹, A. Taguchi¹, K. Hamada¹, M. Kotake¹, M. Shiozuka², F. Yakushiji¹, R. Matsuda², T. Usui³, Y. Hayashi¹;

¹ Department of Medicinal Chemistry, Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan, ² Univ Tokyo, Tokyo, Japan, ³ Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan

Duchenne muscular dystrophy (DMD) is the most severe form of dystrophinopathy caused by a mutation in the dystrophin gene, which codes an important structural protein dystrophin within muscle tissue. About 10-20% of this congenital disease is caused by nonsense mutations possessing the premature termination codons (PTCs). One promising approach against this mutation is a readthrough drug strategy, which is comprised of drugs that allow the translational machinery to skip PTCs, resulting in the production of full-length functional dystrophin. (+)-Negamycin **1**, which was a dipeptidic antibiotic containing a hydrazide structure, was reported that (+)-**1** restored dystrophin expression in the muscles of mdx mice, an animal model of DMD (Arakawa, M. *et al.*, *J. Biochem.*, 2003). Hence, the potent derivatives of (+)-**1** would be a promising therapeutic candidate for diseases caused by nonsense mutations. In our structure-activity relationship study through the reporter assay, we discovered more potent derivatives 3-*epi*-deoxynegamycin (Taguchi, A, *et al.*, *ChemMedChem*, in press) and TCP-112 without significant anti-microbial activities. These derivatives were particularly effective in the readthrough of a TGA-type nonsense mutation. Moreover, we synthesized derivatives of TCP112 focused on its C-terminal part (N-methyl *hydrazinoglycine* part) and found that C-terminal ester derivatives (TCP-169) exhibited a more potent readthrough activity. TCP-169 significantly suppressed the proliferation of cancer cells caused by nonsense mutation. These results suggested that (+)-negamycin derivatives were promising platform for the development of readthrough drug toward nonsense mutation-mediated genetic diseases.

P1137**Board Number: B469****Effect of Let-7a on Human Malignant Melanoma Cells.**G. Yang¹, J. Jiang¹, L. Wang¹, Y. Ma¹, Y. Yang¹;¹Emporia State University, Emporia, KS

Objective: The goal of this study is to examine the effect of Let-7a on the proliferation and invasiveness of human malignant melanoma cells and identify the gene(s) that Let-7a targets to affect the growth and metastasis of melanoma cells. **Methods:** The effect of Let-7a on proliferation, migration and invasion was measured by cell viability assay and Wounding healing assays, and Transwell migration assay, respectively. The expressions of MITF, and MAP4K3 genes at protein level were measured by Western blot. Cell cycle progression was determined by flow cytometer. **Results:** Let-7a displayed a significant ($p < 0.05$) inhibitory effect on the proliferation, migration and invasion on SKMEL-28 and WM1552C human melanoma cell lines. In addition, Let-7a induced cell cycle arrest at G1 phase. MITF gene was down-regulated by Let-7a in melanoma cells. **Conclusion:** Let-7a inhibited the growth, migration and invasion, also induced cell cycle arrest at G1 phase in human malignant melanoma cells. The expression of MITF was suppressed by Let-7a in SKMEL-28 and WM1552C melanoma cell lines. Taken together, these data suggests Let-7a act as tumor suppressors in melanoma cells and have the potential to function as a novel therapeutic small molecule against human malignant melanoma.

P1138**Board Number: B470****Investigating the effects of tellurium compounds on melanoma cell lines.**A.A. Martens¹, S.C. dos Santos¹, R.L. Cunha², G.M. Machado-Santelli¹;¹Departamento de Biologia Celular e do Desenvolvimento, Universidade de São Paulo, Sao Paulo, Brazil,²Centro de Ciências Naturais e Humanas, Universidade Federal do ABC, Santo André, Brazil

Melanoma genetic background is very heterogeneous, with mutations that compromise different signalling pathways in each case, which poses great difficulty to obtain a wide spectrum drug that would be reliable for these different mutations. Tellurium compounds have shown to act as anticancer drugs in a still unclear manner – they possess a marked redox potential, which appears to react with thiols inactivating proteins important to the survival of cancer cells. In this work, we evaluated the action of two enantiomeric organotelluranes on a melanoma panel, comprised of 4 human melanoma cell lines (HT-144, SK-Mel-19, SK-Mel-28, SK-Mel-147), murine melanoma cell line B16F10, and NGM (human nevus cell line) as a control. Previous experiments with these compounds showed inhibition of melanoma lung metastases in vivo, which seems to be associated with decreased migration and invasion capability in a concentration-dependent manner. Hence, it is important to study the cellular effects of these compounds. We decided to investigate their effects on cytoskeleton and cell cycle alterations, as well the induction of nuclear abnormalities. Cytoskeleton alterations varied, going from mild microfilaments hyperstabilisation to heavy disarray, with cell roundness and cortical distribution of

microfilaments and microtubules. Cell cycle disturbances seemed to be related to increased frequency of G2/M cells. Deeper analyses still have to be done to understand which signalling pathways intermediates are influenced by the action of these organotelluranes.

Prevention of the development of GST-dependent cisplatin resistance in a model of human H526 small cell lung cancer (SCLC) by ethacrynic acid and selenite.

P.B. Caffrey¹, K.L. McAndrew¹, K. Marks¹;

¹Biological Sciences, California Univ Pennsylvania, California, PA

Tumor cell resistance to the chemotherapy drug cisplatin (CP) has been associated with many mechanisms, including increased activity of glutathione-s-transferase (GST). While many studies have focused on reversing CP resistance, we are exploring its prevention, using models to mimic its development and to screen preventative agents. We previously designed an in vivo model of CP resistant small cell lung cancer (SCLC) using human H526 cells growing as xenografts in mice. We have now initiated cell cultures from two of these tumors: from an untreated control tumor (designated C-H526), and from a tumor (designated R-H526) pretreated with the dose of CP (1.5 mg/kg) that resulted in resistance to subsequent treatments. Tumors were homogenized, cells suspended and cultures maintained in RPMI with 15% FBS. Replicate dishes were exposed to either PBS or CP concentrations, counted before and after exposure and cell counts expressed as mean % of pre-dose counts. Following 36 hr exposure to 10 uM CP, 86.3% of R-H526 cells survived, compared to 45.7% survival of C-H526 cells. Thus cells retained the relative resistance of the tumors from which they were derived. We then measured GST activity as a function of GS-DNB conjugate production: it was nearly twice as high (1.04 activity units) in the resistant R-H526 cells as in the C-H526 cells (0.53 activity units). This suggests that inhibitors of GST activity, such as ethacrynic acid (EA) or selenite (which prevents GST-associated drug resistance in ovarian cancer cells) might prevent CP resistance in SCLC. To screen these potential preventative agents, we designed an in vitro model in which CP resistance was induced by pretreating H-526 cells with low, subtoxic concentrations of CP. After 36 hr, these cells were exposed for 24 hr to a high, toxic (15 uM) dose of CP. In response to this high dose CP, control cells pretreated with PBS decreased by 58.7%, whereas cells pretreated with low dose (7 uM) CP actually increased by 25.12%, indicating the development of resistance. To determine their prevention activity, subtoxic doses of EA or selenite were added to cultures 6-24 hrs prior to CP-pretreatment. Replicate cultures were pretreated with test agent alone or with PBS. Co-pretreatment with 40 uM EA caused a cell count decrease of 48.13% in response to high CP dose. The efficacy of EA confirms that this resistance is dependent on increased GST. Co-pretreatment with 1.5 uM selenite also prevented CP resistance, resulting in a 49.06% decrease in cells in response to high dose CP. This study suggests that increased GST activity is the mechanism of cisplatin resistance in our SCLC models, and that co-pretreatment with either EA or selenite prevents the development of this resistance.

P1140**Board Number: B472****Promising activity of Diaminotiazoles in overcoming multidrug resistance in cancer cells and xenograft tumor models.**S. Vasudevan¹, S.A. Thomas¹, K.N. Rajasekharan², S. Sengupta¹;¹Cancer Research Program-3, Rajiv Gandhi Centre for Biotechnology, Trivandrum, Kerala, India,²Department of Chemistry, University of Kerala, Trivandrum, Kerala, India

Antimitotic drugs are powerful chemotherapeutic agents, but their potentials are limited by neurotoxicity and development of resistance. Overexpression of drug efflux pumps along with target specific modulations and improper apoptotic machinery are found in tumors. Many small antimitotic agents are effective in multidrug resistant tumors, mainly because they elude the efflux pumps. However, eventually they also evoke resistance. It is important to find out agents that are potent in resistant tumors and to understand the resistance mechanisms against small molecules so that judicious combinations can be devised. We have investigated the efficacy of diaminotiazoles, a novel class of small, antimitotic, potential anticancer compounds, in multidrug resistant cancer cells. Also, our work compares the resistance mechanisms aroused in cells against small and large molecules.

Model resistant cell lines were raised against the clinically used antimitotic drug Taxol and a lead diaminotiazole, 4-amino-5-benzoyl-2-(4-methoxy phenyl amino) thiazole (DAT1). Xenograft tumors were derived from them in SCID mice. *In vivo* antitumor activity of DAT1 was tested in these multidrug resistant tumor models. Apoptosis was measured by chromatin condensation, caspase 3 and PARP cleavage. Cell cycle analysis was done by flow cytometry. Immunoblotting was conducted to analyze the expression of various resistance associated proteins: P-glycoprotein, beta tubulin isotypes, apoptotic and checkpoint proteins. Primary cells were derived from these xenograft tumor models and cytotoxicity studies were conducted.

Diaminotiazoles induced mitotic arrest leading to perturbation in checkpoint proteins like AuroraA, AuroraB, Mad2 and Bub1; eventually triggering resistant cells to undergo apoptosis. They could overcome the overexpression of P-glycoprotein, beta II and III tubulin isotypes and imbalance in the pro and apoptotic protein ratio. These proteins were also studied in xenograft tumors developed in SCID mice. P-glycoprotein overexpression was found to be the prominent resistance mechanism in SCID mice bearing Taxol resistant cells. Cytotoxicity studies with the primary cells derived from SCID mice bearing DAT1 resistant cells showed that their resistance against DAT1 diminished, and was lost quickly with passaging; indicating the transient as well as specific nature of DAT1 resistance.

Thus, diaminotiazoles showed promising antitumor activity in multidrug resistant cancers both *in vitro* and *in vivo*. We have also found that resistance against antimitotic drugs with higher size is broad-spectrum and multifactorial. On the contrary, resistance against small molecules is transient and target specific.

P1141**Board Number: B473****Proteomic profiling identified multiple short-lived members of the central proteome as the direct targets of the addicted oncogenes in cancer cells.**T. Qi¹, W. Zhang², Y. Luan¹, F. Kong¹, D. Xu¹, G. Cheng¹, Y. Wang³;¹Central Research Laboratory, The Second Hospital of Shandong University, Ji Nan, China, ²Department of Medical Imaging, The Second Hospital of Shandong University, Ji Nan, China, ³Central Research Laboratory, Jinan Central Hospital Affiliated to Shandong University, Ji Nan, China

Oncogene addiction is an unexplained phenomenon in the area of cancer targeted therapy. In this study, we have tested a hypothesis that rapid apoptotic response of cancer cells following acute inhibition of the addicted oncogenes is because of loss of multiple short-lived proteins whose activity normally maintain cell survival by blocking caspase activation directly or indirectly. It was shown that rapid apoptotic response or acute apoptosis could be induced in both A431 and MiaPaCa-2 cells, and quick down-regulation of 17 proteins, which were all members of the central proteome of human cells, was found to be associated with the onset of acute apoptosis. Knockdown of PSMD11 could partially promote the occurrence of acute apoptosis in both MiaPaCa-2 and PANC-1 pancreatic cancer cells. These findings indicate that maintaining the stability of central proteome may be a primary mechanism for addicted oncogenes to maintain the survival of cancer cells through various signaling pathways, and quick loss of some of the short-lived members of the central proteome may be the direct reason for the rapid apoptotic response or acute apoptosis following acute inhibition of the addicted oncogenes in cancer cells. These findings we have presented can help us better understand the phenomenon of oncogene-addiction and may have important implications for the targeted therapy of cancer

P1142**Board Number: B474****Ultrasonication as a Means to Degrade Chitosan.**C. Carnegie¹, C.D. Johnson¹, F. Akindoju¹, E. Williams¹, J.M. Stone¹, A. Oki², E.C. Regisford³, L.E. Carson¹;¹Cooperative Agricultural Research Center, Prairie View AM University, Prairie View, TX, ²Chemistry Department, Prairie View AM University, Praire View, TX, ³Department of Biology, Prairie View AM University, Prairie View, TX

Many drug delivery studies have been performed using polymeric material like poly(ethylene glycol) and poly(ethyleneimine). However, there is a need to study polymers that are less toxic to the body. In recent years, chitosan, a naturally occurring, biodegradable, linear cationic polysaccharide that is composed of β -(1-4) linked glucosamine and N-acetyl-D-glucosamine have been studied. Over time different methodologies are being used to successfully break apart the long chains of chitosan, one such method is ultra sonication. This study identifies the effect of ultrasound technology on natural sonication condition, chitosan dissolved in acetic acid. The ultrasonic frequencies used lead to

the process being known as ultra sonication or ultra-sonication. Fourier Transform Infrared Spectroscopy (FTIR) indicated no change in the characteristics of Chitosan, showing that between the 10 minutes, 20 minutes and 30 minutes timed ultra sonication experiments Chitosan showed no significant change in its chemical and physical properties. Thermo gravimetric Analysis (TGA) showed that 20% weight loss temperature of chitosan derivatives' was maintained between all the samples listed above and reiterated th.at there was no change in the physical and chemical properties of Chitosan.

Cytotoxicity on human breast cancer cells caused by a vanadium salt.

D. Vejselova¹, H.M. Kutlu¹;

¹Biology, Anadolu Univ, Eskisehir, Turkey

Vanadium and its compounds have been investigated for anti-cancer effects for a long time. The effects of vanadium on tumour growth inhibition have been investigated in T-cell leukaemia and B-cell lymphoma, as well as in cancers of the testis, the uterus, the kidney, the lung, the throat and the oesophagus [1]. Vanadium compounds are stated to have pharmaceutical effects on different types of cancer cells [2]. Vanadyl sulphate is found to cause single and double-strand breaks in the DNA in HeLa cells and prostate adenocarcinoma [3], also growth inhibition of rat hepatoma cell line [4]. At the present study we aimed to investigate the cytotoxic effects of vanadyl sulphate on human breast cancer cells. A stock solution of the agent (in distilled water) was prepared and for further dilutions fresh culture medium was used. In order to detect cytotoxicity for 24 hours, MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2H tetrazolium bromide) colorimetric assay was applied with the 50, 60, 70, 80, 90, 100, 110, 120 μ M concentrations of vanadyl sulphate. The viability percentages of the treated cells 68.2, 62.0, 59.01, 50.36, 47.89, 47.82, 38.2 and 29.0, respectively. IC50 concentration for 24 hours was determined as 85 μ M. According to our results vanadyl sulphate is found to be highly cytotoxic on human breast cancer cells. This result may show the anticarcinogenic potential of the agent and may be encouraging for further investigations in drug designing systems for cancer treatment.

An antibody that inhibits Wnt signaling in colorectal cancer cell lines.

K. Saito-Diaz¹, E. Lee¹;

¹Department of Cell and Developmental Biology, Vanderbilt University, Nashville, TN

The Wnt pathway is a highly conserved pathway that controls many developmental processes. In the absence of Wnt ligand, cytoplasmic b-catenin is degraded by a destruction complex assembled by the protein Axin and the tumor suppressor adenomatous polyposis coli (APC). Within this complex b-catenin is phosphorylated by glycogen synthase kinase 3 (GSK3) and targeted for ubiquitin-mediated

degradation. Activation of the Wnt pathway occurs upon binding of Wnt ligand to the seven-pass transmembrane protein Frizzled (Fz) and the low-density lipoprotein receptor-related protein 6 (LRP6). The formation of a Wnt-Fz-LRP6 complex promotes LRP6 phosphorylation, which binds to the b-catenin degradation complex. Binding of phosphorylated LRP6 to the b-catenin degradation complex leads to inhibition of both b-catenin phosphorylation and degradation. b-catenin subsequently accumulates in the cytoplasm, enters the nucleus, and activates a Wnt-transcription program. Mutations in the APC or b-catenin genes leading to constitutive activation of the Wnt pathway occur in over 80% of human colorectal cancers. Our lab has developed a monoclonal antibody (mabLRP6) that targets the coreceptor LRP6. Preliminary studies have shown the effectiveness of this antibody in inhibiting Wnt signaling *in vivo*, decreasing the expression of Wnt target genes in mice. Also, mabLRP6 blocks ligand-dependent Wnt activation in mammalian cells. Furthermore, mabLRP6 inhibits Wnt signaling in the colorectal cancer cell lines SW480 and DLD1, which are mutant for APC and exhibit constitutive Wnt signaling. This evidence suggests that mabLRP6 acts as a specific Wnt inhibitor and is a potential treatment for Wnt-driven tumors.

⁶Linkoping University, Linkoping, Sweden

Cancer is a leading cause of death. In fact, cancer killed over 8 million people around the world in 2012. Over 90% of these cancer deaths are due to metastasis, which results from tumor cell migration and invasion. Specific cancer biomarkers need to be identified in order to effectively target these motile cells. The transmembrane glycoprotein receptor podoplanin (PDPN) promotes tumor cell motility and metastasis in many aggressive cancers. Indeed, PDPN has emerged as a prime cancer biomarker and chemotherapeutic target. Here, we describe how PDPN can be targeted to inhibit the growth and motility of melanoma and oral cancer cells. PDPN has a short intracellular domain of 9 amino acids which include two conserved serine residues. PDPN also has a large extracellular domain that is extensively O-glycosylated with α 2,3-sialic acid linked to galactose. We are developing novel methods to target the intracellular and extracellular domains of PDPN to combat cancer progression. For example, we have found that some activators of protein kinase A can induce phosphorylation of the intracellular serine residues of PDPN to inhibit tumor cell migration. In addition, we have found that Maackia amurensis seed lectin (MASL) can target the extracellular domain of PDPN to inhibit tumor cell growth, migration, and tumor progression in cell culture and animal models. Furthermore, we utilized live cell

imaging to find that PDPN expression can be modulated in cancer associated fibroblasts to inhibit neighboring tumor cell migration and survival. Thus, reagents can be used to target PDPN from inside of the cell and outside of the cell to inhibit tumor cell migration and combat cancer progression. This work illuminates novel strategies designed to exploit PDPN as a functionally relevant biomarker and chemotherapeutic target.

ABCC3 expression is up-regulated in prostate gland after androgen deprivation.

R. Rosa-Ribeiro¹, H.F. Carvalho²;

¹Structural and Functional Biology Department, State University of Campinas, Campinas, Brazil,

²Structural and Functional Biology Department, State University of Campinas, Campinas SP, Brazil

Nowadays, prostate cancer is one of most important disease in males. Different treatments have been used to stop cell proliferation and to reduce cell survival of prostate cancer cells using as target the androgen receptor (AR) inhibition. However, after androgen blockade, many prostate cancers keep growing and developing under in the androgen-deprived environment. Our laboratory has tried to figure out new molecules and phenomena present in prostate gland after androgen deprivation in an attempt to find new therapeutic targets. In this work, comparing ventral prostate gland of Wistar rat (90 days old) from control group (CT) with those from surgically castrated rats (Cas) for 3 days, we figured out by DNA microarray (n=3) that the gene *Abcc3* was up regulated in Cas (eight-fold increase). The ABCC3 protein is a pump, member of family that promotes multidrug resistance. In cancer, this pump is responsible for drug efflux, rendering the cells resistant to chemotherapy. Therefore, the ABCC3 protein is an interesting target, because it might contribute for the resistance of prostate cancer to the treatments. The validation of microarray data was done by qRT-PCR, which showed a 35-fold increase in Cas as compared to the CT group (n=3). Using immunofluorescence, ABCC3 was found in the baso-lateral plasma membrane. To check if the ABCC3 is modulated by androgens, the functional experiment was done using RWPE-1, a normal prostate cell line, which expresses ABCC3 protein in the plasma membrane. The RWPE-1 cells were grown on matrigel layer without cypionate of testosterone (CT); with 10 nM of androgen for 96h (T); 48h with androgen and 48h without it (T48). When the cells were 90% confluent, it was added 100 uM in their media of two different substrates: one group as a negative control with rhodamine (cationic - not pumped by ABCC3) and another group with calcein (anionic - pumped by ABCC3). Loading was allowed for 1 hour. Afterwards, the media was changed and left for 20 minutes at 37°C and then collected. The media was changed and collected every 20 minutes up to 100 minutes. The collected media was read in a fluorimeter to quantify how much of substrate was pumped by RWPE-1 cells under testosterone conditions. After the quantification, we observed no rhodamine was pumped while calcein was better pumped by cells from T48 group than T and CT. Using *in silico* analysis of the ABCC3 proximal promoter region, revealed two putative AR binding site, suggesting there is a mechanism of *Abcc3* regulation in the prostate gland under androgen modulation. This study points to

the fact that androgens might regulate the expression of protein pumps to promote drug-resistance in the absence of androgens and also points to a molecular relationship between *Abcc3* and AR.

Biological Testing of Novel Telomerase Inhibitors.

K.L. Uhl^{1,2}, S. Sridhar¹, R. Smart², W. Schroeder²;

¹Biomedical Sciences, Grand Valley State University, Allendale, MI, ²Chemistry, Grand Valley State University, Allendale, MI

Normal cells are limited in the number of times they can divide by the caps on the ends of their chromosomes, called telomeres. These caps are supposed to become degraded over time, eventually signaling the cell to die when they become too short. During the summer of 2013, three novel compounds were made via synthesis of cinnamoyl chloride derivatives. These three compounds all contain active sites that are identical to those identified on BIBR 1532, a known telomerase inhibitor, with one key difference in the element attached to the aromatic ring. These three compounds were tested for anticancer properties on metastatic prostate cancer cell lines. Their efficacy will be compared against that of BIBR 1532 to determine if this novel compound would prove to be an adequate cancer treatment. If these compounds prove to be telomerase inhibitors, it would be a breakthrough as to how BIBR 1532 functions, and could potentially lead to a more effective cancer treatment. While the compounds were tested using metastatic prostate cancer cells, these potential treatments have applications in both breast and pancreatic cancers as well.

ANALYSIS OF N-GLYCOME OF INDUCED HEPATOCELLULAR CARCINOMA: A PRE-CLINICAL STUDY.

A.A. Amin¹, N. Zaki², D. McCarthy³, S. Ahmed⁴, A. Bashir¹, M. Lofty¹;

¹Biology Department, UAE University, Al-Ain, UAE, ²Intelligent systems, UAE University, Al-Ain, United Arab Emirates, ³Ezose Sciences Inc., Pine Brook, NJ, ⁴Eastern Biotech and Life Sciences, Dubai, United Arab Emirates

Hepatocellular carcinoma (HCC) is one of the most common types of cancer worldwide. Adequate markers are not present for the diagnosis of HCC. Glycans are emerging sensitive and simple potential biomarkers for various diseases including cancer. The aim of the present study is to evaluate qualitative and quantitative changes in N-linked glycosylation of proteins that occur in response to HCC in animal model of liver cancer. Liver tissue samples of 2 groups of rats- 1) normal (non-tumor-bearing) rats; 2) tumor-bearing rats; were collected and the liver lysates were used for biochemical and GlycanMap[®] analyses. Briefly, GlycanMap[®] analysis is high-throughput assay that provides a structural and

quantitative readout of protein-associated glycans using a unique, automated 96-well assay technology coupled to matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) and custom bioinformatics. Histopathology studies were also done to ensure the development of HCC in rat models. The glycomics analysis revealed 5 novel glycans that showed statistically significant differences between the normal and tumor rats. There was increase in high mannose structures in HCC rats compared to normal. Importantly, HCC rats showed increase in tumor-associated carbohydrates. The branched glycans were also increased in association with HCC. Those fluctuations in glycans correlated well with mutations of enzymes involved in glycan biosynthetic pathway, hence making altered glycans potential and reliable biomarker for HCC. Further study is needed to validate these findings in HCC cancer patients.

Molecular basis underlying resistance against Mps1/TTK inhibitors.

A. Koch¹, R.H. Medema²;

¹Division of Cell Biology, Netherlands Cancer Institute, Amsterdam, Netherlands, ²Division of Cell Biology, the Netherlands Cancer Institute, Amsterdam, Netherlands

Mps1/TTK is an essential dual specificity kinase, with an essential role in mitotic checkpoint signaling and proper alignment of the chromosomes. Mps1/TTK kinase has emerged as a potential target in cancer therapy and several Mps1 small molecule inhibitors have been described to date that exhibit promising anti-proliferative activity in human cancer cells. Among these compounds, NMS-P715, MPI-0479605, Mps-BAY1, Mps-BAY2a, Mps-BAY2b, and Mps1-IN-3 showed promising results in pre-clinical studies with rodent xenograft models. Phase I clinical trials for one of the Mps-BAY compounds in breast cancer treatment have been initiated recently. The emerging application of Mps1/TTK inhibitors in cancer therapy raises the question whether cancer cells can develop resistance to these drugs. Here, we identified and characterized a new potent and selective ATP-competitive Mps1/TTK kinase inhibitor. In addition, we identified four point mutations in the catalytic domain of Mps1/TTK that gave rise to inhibitor resistance but retained wild-type catalytic activity. Interestingly the single mutations confer resistance to only a subset of inhibitors, which seems non-specific for inhibitor scaffolds. Our studies predict that drug-resistant Mps1/TTK cells are likely to arise through the acquisition of mutations in the ATP pocket of the kinase that prevent the stable binding of the inhibitors. In addition, our results provide insight for future drug design to evict possible resistance mutations during clinical treatment.

P1150**Board Number: B482****In-Vitro Rescue and Recovery Studies of Human Melanoma (BLM) Cell Growth, Adhesion and Migration Functions after Treatment with Mifepristone (RU-486).**D.C. Leder¹, P. Ramaraj²;¹Biochemistry, A.T.Still University, Kirksville, MO, ²Biochemistry, A.T.Still University, Kirksville, MO

Our previous work with progesterone and its receptor antagonist RU-486 showed a significant inhibition on human melanoma (BLM) cell growth *in-vitro* (1,2,3). The mechanism of inhibition of cell growth by RU-486 was due to apoptosis (4). Inhibition of apoptosis by pan-caspase inhibitor (CI) showed a partial rescue in cell growth. This observation prompted us to check the effect of CI on other in-vitro functions such as adhesion and migration, as there were lot of cells floating in the medium. Partial rescue in cell growth also prompted us to investigate recovery of those in-vitro functions on their own after removing Ru-486 and CI. Hence, the aim of the study was to compare in-vitro functions of **RU-486 treated, CI rescued** and **recovered** human melanoma cells. Human melanoma (BLM) cells were treated with RU-486 or RU-486 + CI (20 μ M). After 24 hrs of treatment, cell growth was quantitated by MTT assay, adhesion was quantitated by crystal violet binding assay and migration by drill assay.

Twenty-four hrs of RU-486 (50 μ M) treatment resulted in 50% cell growth compared to untreated control cell growth (100%). But, addition of 20 μ M of CI to the cells, partially rescued cell growth to 67%. After 48 hours of recovery, treated cells recovered cell growth to 70%, whereas rescued cell recovered cell growth to 95%. When both cells were allowed to recover for a second 48 hrs, treated cells showed a cell growth of 82% and rescued cell 97%. CI rescued cells showed complete recovery of cell growth, whereas treated cells showed significant recovery. RU-486 (50 μ M) also resulted in 60% adhesion compared to control cell adhesion (100%). But CI rescued adhesion to 75%. When treated and rescued cells were allowed to recover for first 48 hrs, treated cells adhesion rose to 85%, whereas CI rescued cells adhesion rose to 97%. When the two group of cells were allowed to recover for a second 48 hrs, treated cells adhesion was 90% and CI rescued cells adhesion was 98%. Both treated and rescued cells recovered close to control level of adhesion. Migration drill assay showed that RU-486 (50 μ M) decreased migration to 26% compared to untreated control (100%). But CI rescued migration partially to 38%.

In conclusion, Ru-486 treatment decreased in-vitro cell growth, adhesion and migration functions of human melanoma (BLM) cells. So, Ru-486 has the potential to be an anticancer agent for melanoma. When apoptosis was blocked by CI, there were partial rescue in cell growth, adhesion and migration functions. But when the cells were allowed to recover, rescued cells recovered completely back to control level, whereas treated cells recovered significantly close to control level as reported in the recovery study of other metastatic cancer cell lines (5).

P1151**Board Number: B483****Inhibition of OV2008 Ovarian Cancer Cell Proliferation in the presence of Oleoyl Ethanolamide and Chlorpyrifos-Oxon.**J. Ricker¹, C. Kramer², P. Bagavandoss²;¹Integrative Health Studies, Kent State University @ Stark, North Canton, OH, ²Biological Sciences, Kent State University @ Stark, North Canton, OH

We have previously shown that both the acylethanolamide oleoylethanolamide (OEA) and its metabolically stable analog AM3102 (N-[(1R)-2-hydroxy-1-methylethyl-9Z-octadecenamide) induce apoptosis in OV2008 ovarian adenocarcinoma cells independent of PPAR- α receptor signaling pathway. This cytotoxicity was reversed in the presence of α -tocopherol, indicative of reactive oxygen species (ROS) involvement in cell death. We have also shown that palmitoyl trifluoromethyl ketone (PTK), independent of its inhibitory effect on phospholipase A2, enhanced the toxicity of OEA (ASCB 2012, Abstract #888). The enzyme neutral cholesterol ester hydrolase 1 (NCEH1) has also been shown to be a target of trifluoromethylketones (Nat Biotechnol 21:687, 2003). Furthermore, inhibition of NCEH1 leads to reduced migration of SKOV3 ovarian cancer cells in vitro and their tumor growth in vivo (Chem Biol 13: 1041, 2006). Therefore, in this study, using chlorpyrifos-oxon (CPO), a potent inhibitor of the enzyme NCEH1 (Toxicol Sci 91:166, 2006), we explored the relationship between OEA and NCEH1 in the OV2008 ovarian cancer cell line. Cytotoxicity was observed in response to both OEA (IC₅₀: 14-21 μ M) and CPO (IC₅₀: 48-50 μ M). When the cells were incubated with both compounds together, cytotoxicity was enhanced (OEA IC₅₀: 8-9 μ M; CPO IC₅₀: 15-19 μ M) with evidence of weak synergism. However, Western blot analysis of OEA and CPO treated cells indicated, when compared with control, no decrease in the expression of NCEH1. Live cell labeling with dihydroethidium showed an increase in superoxide by about 10% in the presence of OEA. CPO itself did not cause an increase in ROS. Live cell fluorescence microscopy using MitoSOX Red also revealed an increase in superoxide anion in mitochondria in the presence of OEA. The results of our study suggest that one mechanism by which OEA induces cytotoxicity in OV2008 cells is via superoxide generation. However, how additional toxicity is induced in the presence of both OEA and CPO needs further exploration (This undergraduate student research was supported by funds from the University Research Council).

Regulatory and Noncoding RNAs

Dependence of stress granule formation on microtubules supports the idea of stress granule specific “glue” arising in stress conditions.

A. Shpilman^{1,2}, E. Chudinova³, P. Ivanov¹, E. Nadezhdina³;

¹Lomonosov Moscow State University, Moscow, Russia, ²Moscow Institute of Physics and Technology, Moscow, Russia, ³Institute of Protein Research, Russian Academy of Science, Puschino, Russia

Stress granules are RNP-containing aggregates arising in cells under stress conditions and accumulating small ribosomal subunits, mRNPs and translation initiation factors. Previously, microtubules were shown to be involved in stress granule formation, although their role remained obscure. In this study, we found that stress granules' formation did depend on microtubules at low concentration of a stressing agent (arsenite) but did not depend on them at high arsenite concentration. However, at any arsenite concentration stress granules formed slower in cells with disrupted microtubules and were smaller. We found also that stress granules' formation was not directly coupled with protein synthesis inhibition, e.g. at low arsenite concentration protein synthesis was inhibited though stress granules did not form. We built a numerical model based on the suggestion that stress granules and their progenitors (presumably, 48S pre-initiation complexes) diffuse in cytoplasm and merge on contact. They could also move along microtubules by either linear diffusion or active transport. In such a model, if we proposed that each stress granules' and/or progenitors' contact resulted in their merging, the stress granules' formation did not depend on microtubules. Decreased probability of merging upon contact made the system dependent on microtubules, and microtubules served as assembly scaffolds since they had 100% probability to bind stress granules and/or their progenitors. In our model the contribution of active transport along microtubules to stress granule formation was variable and also dependent on overall merging probability rate. This model also suggests that there is an apparent optimum of microtubules for assembly of stress granules, which can explain the phenomenon of stress granules forming a ring in cytoplasm. The data support the concept of “glue” arising in stressed cells that binds stress granule components together.

P1153**Board Number: B486****Slicing activity of the *C. elegans* Argonaute CSR-1 tunes the expression of germline genes to control embryonic divisions.**A. Gerson-Gurwitz¹, S. Wang¹, K. Oegema¹, A. Desai¹;¹Ludwig Institute for Cancer Research, La Jolla, CA

The *C. elegans* Argonaute CSR-1 interacts with 22G small RNAs that are antisense to germline-expressed transcripts. Inhibition of CSR-1 leads to defects in spindle assembly and chromosome segregation in early embryos, resulting in penetrant embryonic lethality. Despite its robust mRNA slicing activity *in vitro*, a role for CSR-1 in restricting target expression has been disfavored. Here, we show that the CSR-1 depletion phenotype in early embryos closely resembles phenotypes associated with reduced microtubule assembly. Replacing CSR-1 with an engineered mutant lacking slicing activity further revealed that all early embryonic phenotypes associated with CSR-1 inhibition are directly related to its slicing function. Inspection of prior gene expression data indicated that the message encoding the microtubule depolymerase MCAK/KLP-7 is elevated 1.6 fold when CSR-1 is inhibited, suggesting that increased MCAK/KLP-7 activity could be responsible for the microtubule assembly defect. Immunoblotting indicated that MCAK/KLP-7 protein levels were elevated ~3.5-fold compared to controls, and reducing MCAK/KLP-7 levels restored microtubule and spindle assembly in CSR-1-inhibited embryos. Thus, MCAK/KLP-7 levels need to be precisely controlled by CSR-1 because even modest overexpression of this potent microtubule depolymerase leads to a dramatic phenotype. This result suggested that CSR-1, which binds 22G-small RNAs derived from essentially all germline transcripts, also tunes the expression levels of other germline proteins. To test this, we performed quantitative immunoblotting to measure the levels for 44 germline proteins for which antibodies are available. The majority of the tested targets were elevated between 1.5-3.5 fold in the presence of the CSR-1 slicing activity mutant, and the extent of elevation correlated with the abundance of CSR-1-bound 22G RNAs. We conclude that the CSR-1/22G-small RNA system functions to tune the expression of a large number of germline-expressed genes and that this control is essential for embryonic divisions. We speculate that evolution and/or organismal physiology employs this system to precisely control protein levels by adjusting 22G RNA levels for particular transcripts.

P1154**Board Number: B487****Expression levels of miR-454-3p and miR-33b in low birth weight and high birth weight neonates*.**S.P. Rodil-García¹, L.A. Salazar-Olivo¹;¹División de Biología Molecular, Instituto Potosino de Investigación Científica y Tecnológica, San Luis Potosí, Mexico

Recent advances in understanding the etiology of metabolic disorders have focused attention on the mechanisms related to its developmental origins, in which birth weight has long been used as an indicator [1–3]. MicroRNAs (miRNAs) are non-coding RNA molecules that act as post-transcriptional regulators. They have been proposed as early biomarkers since they are involved in the regulation pathways of several diseases [4,5]. To determine whether differences exist in miRNAs expression levels from neonates with different birth weight, we recovered miRNAs from neonatal screening Guthrie cards obtained from normal, low and high birth weight Mexican neonates and quantified their expression using an LNA-probe based stem-loop RT-qPCR. MiR-454-3p was over-expressed in low birth weight infants (p

P1155**Board Number: B488****The expression and the intracellular localization of $\Delta E2$ which is novel splice variant of Disrupted-In-Schizophrenia 1 (DISC1).**Y. Miyatake¹, M. Taniguchi², S. Matsuzaki^{1,2}, M. Tohyama^{1,3,4}, T. Manabe⁵, T. Katayama¹;¹Division of Molecular Brain Science, United Graduated School of Child Development, Osaka University, Suita City, Osaka Pref., Japan, ²Graduated School of Medicine, Osaka University, Suita City, Osaka Pref., Japan, ³Osaka Prefectural Hospital Organization, Osaka City, Osaka Pref., Japan, ⁴Research Institute of Traditional Asian Medicine, Kindai University, Osakasayama City, Osaka Pref., Japan, ⁵Institute for Comprehensive Medical Science, Fujita Health University, Toyoake City, Aichi Pref., Japan

Alternative splicing (AS) events contribute to generate distinct mRNAs from same primary transcript. Recently, it has been reported that some causes of diseases are abnormal AS events. On the other hand, disrupted in schizophrenia 1 (DISC1), is neural development related factor, acts on several pathways of brain development such as migration, proliferation, and neurite outgrowth of neurons. Moreover, it has been indicated that the DISC1 AS variants and its mRNA expression of patients with schizophrenia (SZ) differ from those of controls.

In this study, we identified the novel Disc1 variant that lacks exon 2 ($\Delta E2$) in mice brains by using RT-PCR assay. Northern blot analysis using Locked Nucleic Acid (LNA) probe showed the expression of $\Delta E2$ mRNA, clearly different from full length Disc1 (FL). LNA probe is an artificial nucleic acid probe which is bridged RNA and has features which are the capable of single nucleotide discrimination, the increased

target specificity, and the increased the thermal stability of duplexes. It thought suitable LNA probe was utilized for the detection of AS variants. As the result of northern blot assay, the expression of $\Delta E2$ in cortex and hippocampus increased in the developmental stage dependent manner, whereas the expression of FL at the developmental stage from embryonic day 15 to postnatal 8 weeks. Moreover, immunocytochemical analyses of ectopic- $\Delta E2$ -Flag and -FL-Flag in SK-N-SH cells were performed to reveal the subcellular localization of epitopic- $\Delta E2$ and -FL-Flag in cultured cell lines. The ectopic- $\Delta E2$ -Flag protein distributed in nucleus and in cytoplasm with fiber shape, and these cytoplasmic immunoreactivities were co-localized with F-actin. On the other hand, the ectopic-FL-Flag protein localized predominantly in cytoplasmic granule in cultured SK-N-SH cells.

These data show differences of the expression and localization patterns between the $\Delta E2$ and FL. Hereafter, conducting further performance analysis of $\Delta E2$ may solve the new role of Disc1, and it may be useful for the elucidation of the mechanisms of SZ development.

Investigation of dysregulated pathways involving long non-coding RNA (lncRNA) and gene expression of NR4A1 in myelodysplastic syndromes and acute leukemia.

F.A. Corrocher¹, B. Palodetto¹, F.M. Roversi¹, M.O. Baratti¹, P. de Melo Campos², F.S. Niemann¹, J.A. Machado-Neto², S.T. Saad³;

¹Hematology and Hemotherapy Center, University of Campinas-Unicamp, Campinas/SP, Brazil,

²Hematology and Hemotherapy Center, University of Campinas (UNICAMP), Campinas, Brazil,

³Hematology and Hemotherapy Center, University of Campinas, UNICAMP, Campinas, Brazil

The advent of whole transcriptome sequencing technologies revealed that most of the human genome is transcribed, producing a large repertoire of non-coding RNAs (ncRNAs). Among the different types of non-coding RNAs, long non-coding RNAs (lncRNAs) are arbitrarily defined as transcripts composed of more than 200 nucleotides. Recently, the number of studies describing the functionality and diversity long non-coding transcripts mapped in intronic and intergenic regions has increased dramatically. Whole transcriptome analysis shows that up to 70% of coding genes have antisense counterparts, and several examples of local regulation have been described in the literature. They are known to participate in epigenetic regulation at different levels and alter mRNA stability of coding genes. In this context it is not surprising that long non-coding RNAs are emerging as key players in carcinogenesis. We hypothesized that lncRNAs encoded in locus previously associated with hematopoietic malignancy may regulate hematopoiesis and development of malignancy. In this study, we identified an antisense non-coding transcript in the NR4A1 gene locus. The tumor suppressor NR4A1 has been associated with the regulation of apoptosis and proliferation pathways in various tumors and shows a reduced expression in AML. Additionally, the abrogation of this locus in murine models caused the development of myelodysplastic syndrome. The expression of NR4A1 and the antisense non-coding was evaluated by qRT-PCR and we observed a reduction of NR4A1 gene expression in AML and MDS patients with P

P1157**Board Number: B490****A novel multiplex assay for miRNA detection and profiling using barcoded hydrogel particles.**M.A. Santos¹, M. Bader¹, M.H. Hsu¹;¹Cell Biology, EMD Millipore, Temecula, CA

miRNAs play key roles in regulating gene expression. Abnormal miRNA expression has been observed in many human diseases, making miRNAs a new class of diagnostic biomarkers. Traditionally, miRNAs are studied using applications such as real-time PCR, microarrays, and by northern blot analysis. All of these applications do have their benefits; however, each platform also carries a few disadvantages.

Here we present a unique miRNA multiplex detection assay using barcoded hydrogel particles that can be detected on any existing flow cytometer. By using this porous, bio-inert, fluorescently encoded hydrogel particles, we can achieve up to 70 plex detection using the combination of two different concentrations of the barcode dye Cy3 at each ends of the bar-shaped particle; a 2nd dye is used for detection of miRNA target that hybridizes to the capture probe, hybridization of the specific target miRNA to capture probe will enable the templated ligation of the target to a universal biotinylated adapter, which will fluoresce upon binding to streptavidin PE-Cy5.

In this study, we validated the performance of this novel multiplex miRNA profiling assay using a variety of miRNA samples. We tested for miRNA target specificity and sensitivity by profiling the let-7 family of miRNA targets, which differs by only one nucleotide. Additionally, we have established the dynamic range and sensitivity of the assay to achieve 3-4 log dynamic ranges as well as sub-attomole sensitivity for detection. As a cross validation study, we performed RT-PCR to confirm our results, indicating that this novel microRNA detection system is a valid model for miRNA profiling and screening across a variety of testing samples.

P1158**Board Number: B491****miRNA-148/152 family members concordantly target genes important for tumor progression and chemoresistance.**D.J. Oliver¹, H. Ji¹, S. Lee², M. Karthikeyan³, H. Valafar⁴, M. Shtutman¹;¹Drug Discovery and Biomedical Sciences, University of South Carolina, Columbia, SC, ²Biology, University of South Carolina, Columbia, SC, ³Chemistry and Biochemistry, University of South Carolina, Columbia, SC, ⁴Computer Science and Engineering, University of South Carolina, Columbia, SC

To date, over 1800 human miRNAs have been identified (miRBase 21) targeting virtually every mRNA. The means by which miRNAs exert their effect on protein translation is usually through (i) inhibition of

translation, (ii) mRNA de-adenylation, or (iii) direct mRNA degradation. Which mechanism of translational repression occurs depends on miRNA/mRNA specific interactions. In addition, it is well known that each miRNA can target multiple mRNAs and conversely, many mRNAs are regulated by multiple miRNAs. The complexity and sensitivity of regulatory networks that these interactions can produce is astounding and require genomic scale experiments to tease out. Here we present our work using RNA sequencing (RNA-seq) to identify networks of genes regulated by the miRNA-148/152 family. RNA-seq provides several advantages for studying miRNA regulation networks including whole genome scale and identification of de-adenylation targets, direct degradation targets, and genes downstream of direct miRNA targets. The miRNA-148/152 family is a highly conserved miRNA family made up of three miRNAs - miR-148a, miR-148b, and miR-152. miRs-148b and 152 are encoded in the COPZ1 and COPZ2 genes, respectively while miR-148a is transcribed independently. The sequence of these miRNAs differ in only 2 base pairs (both outside of the classic seed region) making target prediction difficult. In addition, the miRNA-148/152 family members are differentially regulated during cancer progression. Specifically, miRs-148a and 148b are often maintained or upregulated while miR-152 becomes silenced in many cancers. Interestingly, analysis of RNA-seq data from 2 different prostate cancer cell lines over-expressing each of the three miRNA-148/152 members (8 cell lines total) shows that the majority of regulated genes are concordantly regulated rather than differentially regulated as expected from cancer progression data. These results suggest that the miR-148/152 family may behave in a rheostat model to regulate target mRNAs. Our RNA-seq data suggests that the miR-148/152 family of miRNAs are regulating genes and pathways involved in cancer development and progression, including EMT markers, EGFR family receptor signaling and DNA repair. Direct targets of miRNAs, identified through HITS-CLIP experiment and an analysis of miRNA dependent pathways, based on combined HITS-CLIP and RNA-seq results will be presented.

Differential expression of miR9, miR21 and miR34a in women with breast cancer.

P. Cortes-Reynosa¹, C. Rodriguez-Monterrosas², M. Sierra-Martinez³, S. Chavez-Ocaña³, E.P. Salazar²;

¹Biologia Celular, CINVESTAV, Mexico Distrito Federal, Mexico, ²Biologia Celular, CINVESTAV, Mexico

City, Mexico, ³Unidad de Investigacion. Servicio de Oncologia., Hospital Juarez de Mexico, Mexico City, Mexico

The discoveries of sensitive and specific minimally invasive biomarkers that can be used to detect early breast cancer are necessary. MicroRNAs (miRs) are involved in many cellular functions, and changes on their expression have been associated with cancer development and progression. Our aim was to determine the expression of miR9, miR21 and miR34 in sera of healthy women and patients with breast cancer at different stages. MicroRNAs were isolated from 200 µl of serum by using a miRNeasy serum/plasma kit (Quiagen). The MicroRNAs expression was analyzed by real-time PCR using the miRCURY LNA Universal RT microRNA PCR kit (Exiqon). Synthesis of cDNA was performed using specific primers for miR9, miR21 and miR34a. MiR16 was used as endogenous control. Expression was analyzed

using the ΔC_t method. Our findings demonstrate a differential expression of miR9 with respect to different stages and women without breast cancer; whereas miR21 and miR34a do not show different expression. These data suggest that miR9 might be used as marker to prognostic on late stages. This work is supported by a grant from ICYTDF(224/2012).

Sub-cellular localization of novel long non-coding RNAs in mouse early B cell differentiation.

M. Heydarian¹, J. Cutler¹, B. Sollner-Webb², K.L. Reddy¹;

¹Biological Chemistry and Center for Epigenetics, Johns Hopkins University School of Medicine, Baltimore, MD, ²Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD

Long non-coding RNA (lncRNA) transcripts are longer than 200 nucleotides (nt) and have no apparent protein-coding open reading frame longer than 100 amino acids. Long suspected to be products of pervasive, accidental, or unregulated transcription, lncRNAs have recently been implicated in regulation of differentiation (mESC, cardiogenesis, adipogenesis), cellular pathways (immune response, X chromosome inactivation, senescence), and nuclear architecture (paraspeckles, splicing speckles, X chromosome architecture). With the exception of a few noted examples, very little is known about the functions of lncRNAs, particularly in primary models or developmental systems. Therefore, we sought to identify novel lncRNAs in early B cell development in mouse and functionally characterize their potential role in B cell development. To enable these studies, we conducted RNA-sequencing on ribosomal RNA depleted, polyA neutral total (and nuclear extracted) RNA from two primary cell lines genetically arrested at distinct stages of early B cell development. We developed a user/biologist friendly workflow (that accepts standard RNA-seq output data) that identifies high confidence lncRNAs from the thousands of annotated as well as unannotated transcripts identified by RNA-seq. This 'TRUElncRNA' workflow identified ~190 novel lncRNAs from the ~38,000, 10% of which are highly (FPKM > 5) and differentially expressed. In efforts to ensure we are truly investigating lncRNAs that do not code for proteins shorter than 100 amino acids, we have restricted our functional assays to nuclear retained lncRNAs. To this end, we have employed cytological and molecular based analyses to determine the sub-cellular distribution of our highly expressed high confidence lncRNAs. Here we show the sub-cellular distribution patterns of our panel of high confidence lncRNAs in their native cellular states.

P1161**Board Number: B494****Cell-Free Packaging of MicroRNA into Exosomes Reveals Y-box Protein I as a Critical Sorting Factor.**M.J. Shurtleff¹, K.V. Karfilis², R.W. Schekman³;¹Department of Plant and Microbial Biology, University of California at Berkeley, Berkeley, CA, ²Institute of Molecular Biology, University of Oregon, Eugene, OR, ³Department of Molecular and Cellular Biology, University of California at Berkeley, Berkeley, CA

Exosomes are 30-100 nm vesicles that are released to the cell exterior. While numerous studies report the enrichment of select microRNAs (miRNA) in exosomes, little is known about how exosomal miRNAs are selectively packaged. Mechanistic studies in exosome biology are typically conducted with cells in culture, usually involving knockdown and over-expression of putative sorting or targeting proteins. Unfortunately, this approach suffers from possible indirect effects on exosome biogenesis or packaging. In this study, we sought to identify and functionally validate exosomal microRNA sorting components by investigating miRNA packaging into exosomes directly in a cell-free biochemical reaction.

To identify selectively packaged miRNAs, we purified exosomes from HEK293T conditioned media using a three-step purification strategy. Illumina-based small RNA sequencing revealed several miRNAs that are highly enriched in exosomes compared to cells. Next, we developed a cell-free reaction to detect the selective incorporation of an exosomal microRNA. Cytosol and crude membranes prepared from HEK293T cells were mixed with synthetic miRNA (miR-223) and ATP and incubated at 30°C. MiR-223, but not a cellular miRNA (miR-190), was incorporated into an RNase-protected membrane in a detergent sensitive manner. Protection was dependent on cytosolic proteins, membranes, ATP and incubation at physiologic temperature. To identify proteins that are directly involved in packaging miR-223, we combined *in vitro* packaging with proteomics. Y-box protein I (YBX1) co-precipitated with biotinylated miR-223 pulled-down from a complete cell-free reaction. We next generated a YBX1 knockout cell line (Δ YBX1) by CRISPR/Cas9 genome editing and found that cytosol from Δ YBX1 cells did not support miR-223 packaging *in vitro* but that packaging was restored with cytosol from Δ YBX1 cells transfected with YBX1. Δ YBX1 cells were only partially defective in miR-223 secretion due to compensatory overexpression of a germ-line restricted YBX1 paralog (YBX2). However, secretion of miR-223 was further diminished when YBX2 was depleted in Δ YBX1 cells. Our results show that efficient packaging of exosomal miRNA *in vitro* and *in vivo* requires Y-box proteins with YBX1 as the dominant sorting factor in HEK293T cells.

P1162**Board Number: B495****Generation of in vivo circular and snRNA reporters.**C.A. Schmidt¹, A.G. Matera^{1,2};¹Curriculum in Genetics and Molecular Biology, University of North Carolina, Chapel Hill, NC,²Departments of Biology and Genetics, Integrative Program for Biological and Genome Sciences, Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC

Previous attempts to study RNA in the cell have been dependent upon fluorescently tagged RNA binding proteins. The problem with this approach is that nonspecific binding can occur, and binding does not enhance the fluorescence of the protein. An alternative strategy is to utilize RNA aptamers that specifically enhance the fluorescence of a small molecule, such as the Spinach2-DFHBI system.

We have used Spinach2 to generate specific RNA reporters. First, we have created a series of snRNA reporters by replacing the majority of the coding sequence of Sm-class snRNAs with Spinach2 while retaining the Sm site and 3' stem loop. We plan to make transgenic flies so that we can answer fundamental questions about snRNA transport in *Drosophila melanogaster* development.

Second, we aim to study the biogenesis of tRNA intronic circular (tric)RNAs, which are a class of abundant non-coding RNAs that arise from the circularization of tRNA introns. We discovered tricRNAs using bioinformatic analysis of chimeric RNA-seq reads. Strikingly, we see a high degree of tricRNA conservation among Drosophilids, suggesting a potential function. To investigate the biogenesis of tricRNAs, we have utilized the Spinach2 fluorescent RNA system by replacing a tRNA intron with the Spinach2 gene. Circularized Spinach2 is fluorescent, and we can detect the difference in linear vs circular Spinach2 by a polyacrylamide gel assay. Experiments aimed at testing factors necessary for circularization using *Drosophila melanogaster* mutants will be presented.

P1163**Board Number: B500****Investigating the role of Npl3 in maintaining yeast telomeres.**J.Y. Lee-Soety¹, J.K. Jones¹, A. Ito¹, S. Spencer¹, M. Tremoglie¹;¹Biology, Saint Joseph's University, Philadelphia, PA

Linear chromosomes in eukaryotic cells end with telomere structures. In addition to safeguarding the integrity of the genome, the telomeres serve to protect the cell from perceiving the chromosome end as DNA damage and prevent cell cycle arrest. A variety of proteins have been shown to maintain the telomere. Telomerase, in particular, elongates the chromosome end and counteracts the end replication problem. Human somatic cells or mutant yeast cells that no longer express telomerase have progressively shortened telomeres which eventually leads to cell cycle arrest, also known as replicative senescence. Recently, several studies have shown that non-coding RNA is synthesized from the long-

thought transcriptionally silent telomeric region. These telomeric noncoding RNA (TERRA) molecules have roles in coordinating telomere-binding proteins. Our lab has found that yeast Npl3, an hnRNP-related protein that processes RNA, is involved in telomere maintenance since cells with mutations in both telomerase and Npl3 (*tlc1 npl3*) senesced much faster than cells with only the telomerase mutation (*tlc1*). In *tlc1 npl3* mutants, the levels of TERRA are also significantly increased compared to *tlc1* cells. This prompted us to investigate whether Npl3 participates in regulating chromatin structure at the telomeres to facilitate TERRA transcription or in promoting efficient TERRA elongation. It does not appear that deleting *HST1* (encodes NAD⁺-dependent histone deacetylase and involved in telomere maintenance) accelerates the senescence of *tlc1* or *tlc1 npl3* cells; this suggests that Npl3 may not work such histone modification molecule to maintain the “closed” chromatin at the telomeres. However, it is possible that Npl3 functions with Tho2 (required for transcription elongation) since *npl3 tho2* double mutants are non-viable. It will be very interesting to study this interaction at the telomeric region. Understanding the maintenance of telomeres has significant applications in cell aging and cancer.

Direct RNA binding stabilizes the histone methyltransferase SUV39H1 at pericentric heterochromatin.

W.L. Johnson¹, W.T. Yewdell¹, A.F. Straight¹;

¹Biochemistry, Stanford School of Medicine, Stanford, CA

Histone modifying enzymes regulate eukaryotic chromatin compaction and transcription, but how their interactions with chromatin are established and maintained is poorly understood. The conserved histone H3 methyltransferase Clr4/Su(var)3-9/SUV39H1 creates a platform for heterochromatin assembly by methylating histone H3 on lysine 9, providing a specific binding site for chromodomain-containing proteins including SUV39H1 itself and the essential Heterochromatin Protein 1 (HP1). In humans, constitutive heterochromatin formed by SUV39H1 is important for silencing transcription from the repetitive DNA sequences surrounding centromeres. This pericentric heterochromatin is the site for sister chromatid cohesion in mitosis, which is necessary for proper chromosome alignment and segregation. Defective pericentric heterochromatin and aberrant transcription of pericentric repeats is associated with genomic instability and cancer. In fission yeast, some transcription of pericentric RNA is necessary for recruiting heterochromatin proteins to pericentric chromatin, but it is unclear how human cells recruit and maintain heterochromatin proteins at pericentric regions. Using a method to specifically label RNA in human cells, we find that RNA is stably associated with the pericentric heterochromatin of human mitotic chromosomes, and colocalizes with SUV39H1. Purified SUV39H1 directly binds RNA in vitro through its chromodomain, in a manner that is not sequence specific but dependent on RNA length. Immunoprecipitation of tagged SUV39H1 from crosslinked cells reveals an in vivo interaction between SUV39H1 and repetitive centromeric RNA, which can be disrupted by a point mutation in SUV39H1 that reduces its direct binding to RNA. This mutation in SUV39H1 that disrupts RNA binding, or specific digestion of RNA by RNase, leads to loss of SUV39H1 localization from mitotic chromosomes.

We propose a model in which RNA associated with pericentric heterochromatin directly binds to SUV39H1, ensuring its stable association with chromatin and robust silencing of this heterochromatin domain.

Bovine microRNAs are bioavailable and affect gene expression in humans and mice.

J. Zempleni¹, S.R. Baier¹, J. Cui², T. Wolf¹;

¹Nutrition and Health Sciences, Univ Nebraska-Lincoln, Lincoln, NE, ²Computer Science and Engineering, University of Nebraska-Lincoln, Lincoln, NE

Claims that mammals absorb biologically effective amounts of plant microRNAs are highly controversial and have largely been dismissed by the scientific community. Here, we tested the hypotheses that (1) humans absorb biologically meaningful microRNAs from nutritionally relevant doses of milk, (2) milk-borne microRNAs regulate human gene expression, and (3) mammals cannot compensate for dietary microRNAs depletion by endogenous microRNA synthesis. Studies in colon carcinoma caco-2 cells suggest that human intestinal cells transport fluorophore-labeled bovine milk exosomes using a carrier-mediated process that exhibits saturation kinetics and depends on surface proteins in exosomes and cells. When healthy adults consumed nutritionally relevant doses of cow's milk, postprandial concentration time curves suggest that meaningful amounts of microRNA-29b (miR-29b) and microRNA-200c (miR-200c) were absorbed; plasma concentrations of miR-1 did not change (negative control). The expression of RUNX2, a known target of miR-29b, increased by 31% in blood mononuclear cells following milk consumption compared with baseline. When milk exosomes were added to cell culture media, mimicking postprandial concentrations of miR-29b and miR200c, reporter gene activities significantly decreased by 44% and 17%, respectively, compared with vehicle controls in HEK-293 human kidney cells. Our bioinformatics analyses predict that 175 microRNAs in bovine milk target about 10,000 human genes. When C57BL/6J mice were fed a milk microRNA-depleted diet for four weeks, plasma miR-29b levels were significantly decreased by 61% compared with microRNA-sufficient controls, i.e., endogenous synthesis did not compensate for dietary depletion. When humans consumed a broccoli sprout meal, no postprandial increases were observed for plant-specific miR-167a and brassica-specific miR-824 in plasma. We conclude that exosomes from bovine milk are bioavailable and elicit changes in gene expression in humans. [Supported by the National Institute of Food and Agriculture (multistate grant W3002) and the NIH (R01 DK063945, R01 DK077816, and 1P20GM104320)].

The Nuclear Envelope and Nuclear Pore Complexes

Nuclear displacement by centrifugal force reveals distinct LINC complexes engage microtubules and actin filaments to actively maintain nuclear position.

R. Zhu¹, G.G. Gundersen¹;

¹Department of Pathology and Cell Biology, Columbia University, New York, NY

Nuclei reside at specific sites that are characteristic of cell type. Except in cases where nuclei are actively moved, it is unclear whether nuclear positioning is an active process and whether the specific position is important for cell function. To address these issues, we developed a novel technique to displace nuclei by subjecting adherent cells to centrifugal force. Nuclear displacement was proportional to force from 1,000-20,000 x g and the centrosome, Golgi, ER or mitochondria were not displaced. If wounded fibroblast monolayers were placed orthogonal to the centrifugal force, nuclei in cells at the wound edge were displaced to the rear on one side, but towards the front on the other. After centrifugation, nuclei returned to the center from both positions, but at different rates and by different cytoskeletal mechanisms: front-to-center movement was inhibited by actin and myosin II inhibitors, whereas rear-to-center movement was inhibited by microtubule and dynein inhibitors and dynein heavy chain knockdown. Using siRNA to deplete LINC complex components revealed that nesprin-2G was required for both movements, SUN1 for the microtubule-dependent re-centering and SUN2 for actin-dependent re-centering. Using small fragments of nesprin-2G to rescue nesprin-2G depleted cells showed that distinct regions of nesprin-2G rescued the microtubule and actin-dependent movements. Our results show positioning of apparently stationary nuclei is an active process and suggest that a single nesprin can form different LINC complexes to engage different cytoskeletal elements to maintain nuclear position.

A novel nuclear re-sizing activity: cPKC is a regulator of nuclear size in Xenopus development.

L. Edens¹, D. Levy²;

¹Univ Wyoming, Laramie, WY, ²Department of Molecular Biology, University of Wyoming, Laramie, WY

Cell and nuclear sizes are tightly regulated amongst species, cell types, developmental stages and disease states. From fertilization of the *Xenopus laevis* egg to the post-gastrulation embryo there is an 8-fold reduction in nuclear surface area. These drastic nuclear size changes occur without changes in DNA content per cell, suggesting nuclear size is regulated by yet unknown cytoplasmic factors. In order to discover developmentally regulated proteins that control nuclear size during *X. laevis* embryogenesis,

we developed an assay whereby large nuclei assembled in egg extract shrink in the presence of late embryo extract (stage 11.5-12). Selective inhibition of protein kinase C (PKC) with chelerythrine blocked shrinking. Furthermore, by depleting calcium and diacylglycerol and by cPKC-specific antibody inhibition, we identified conventional PKC isozymes as being responsible for this activity. Importantly, we find that this PKC-dependent nuclear shrinking is conserved *in vivo*. Treating live embryos with chelerythrine or PMA (a PKC activator) led to increased and decreased nuclear size, respectively during interphase. Interestingly, while PKC protein levels do significantly change during early development, increased PKC activation and translocation to the nucleus were observed in late embryos, concomitant with reduced association of nuclear lamins with the nuclear envelope. Moreover, preliminary studies indicate that the cPKC-dependent nuclear re-sizing activity is conserved outside of development in *X. laevis* somatic cells and mammalian tissue culture cells. We propose a model of steady-state nuclear size regulation whereby nuclear expansion is balanced by an active cPKC-dependent mechanism that reduces nuclear size. Future mapping of PKC phosphorylation sites on nuclear lamins and subsequent phospho-mutant identification of the site that contributes to reducing nuclear size during developmental progression will allow us to directly alter nuclear size and characterize the functional impacts of nuclear size.

LINC Complexes Support Hair Follicle Integrity and Intercellular Adhesion.

R.M. Stewart¹, A.E. Zubek², K.A. Rosowski³, S.M. Schreiner¹, V.J. Horsley³, M.C. King¹;

¹Department of Cell Biology, Yale University, New Haven, CT, ²Dermatology, Yale University, New Haven, CT, ³Cell and Developmental Biology, Yale University, New Haven, CT

Keratinocytes of the mammalian epidermis and its appendages, including the hair follicle, require robust cell-cell and cell-extracellular matrix adhesions to withstand external mechanical stress. Interestingly, cadherin-based cell-cell adhesion between epithelial cells can alter nuclear positioning, suggesting a link between intercellular junctions and the nucleus. An interconnected cytoskeletal network linking cell-cell adhesions to cell-extracellular matrix adhesions may be integrated at the nucleus through nuclear envelope-spanning LINC complexes. The LINC complex mechanically couples the nuclear interior to the cytoplasmic cytoskeleton to support nuclear migration, positioning, and anchorage in various mammalian tissues, but these functions have not been extensively studied in the epidermis to date. Here, we have identified an unappreciated role for the LINC complex component SUN2 in the maintenance of intercellular adhesion between mammalian epidermal keratinocytes in the murine hair follicle. Mice deficient for SUN2 display defects in follicle structure and integrity during the first hair cycle, including excessive follicular bending and hair shaft breakage, leading to transient alopecia that resolves by the second hair cycle. Ultrastructural analysis revealed alterations in desmosome density between *Sun2*^{-/-} follicular keratinocytes, as well as irregular desmosome morphology and drastic intercellular gaps between cells. While primary keratinocytes derived from *Sun2*^{-/-} mice formed apparently normal desmosomal and cadherin-based adhesions *in vitro*, adhesive monolayers of *Sun2*^{-/-} keratinocytes fragmented significantly more than WT cells when mechanically challenged, indicating

that the resulting adhesions were functionally defective. Further, *Sun2*^{-/-} cells exhibited defective nuclear positioning in response to adhesion induction, with excessive nuclear movement toward intercellular adhesions. A compensatory increase in SUN1 expression in the epidermis of *Sun2*^{-/-} mice may account for the restoration of hair follicle structure during the second hair cycle by reestablishing LINC complex function. Overall, our results support a requirement for SUN2-based connections between the nucleus and cytoskeleton in the formation, maturation, or maintenance of intercellular adhesions both *in vivo* and *in vitro*. These results implicate LINC complexes, and therefore nuclear-cytoskeletal interactions, in the maintenance of cell-cell adhesion integrity, and the overall mechanical integrity of the epidermis.

Quality control of inner nuclear membrane proteins by the Asi complex.

O. Foresti¹, V. Rodriguez Vaello¹, C. Funaya², P. Carvalho¹;

¹Cell and Developmental Biology Programme, Center for Genomic Regulation (CRG), Barcelona, Spain,

²Electron Microscopy Core Facility, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

Misfolded proteins in the endoplasmic reticulum (ER) are eliminated by a quality control system called ER-associated protein degradation (or ERAD). This pathway also mediates the turnover of some folded ER proteins, thereby affecting other ER-related functions such as sterol homeostasis. However, how misfolded membrane proteins in the inner nuclear membrane (INM), a specialized ER subdomain with restricted access, are degraded is not known. Here, a quantitative proteomics approach led to the identification of a novel ERAD branch required for protein quality control in the INM. We show that this branch is defined by the integral membrane proteins Asi1, Asi2 and Asi3 (which assemble into the Asi complex at the INM) and requires the Cdc48 ATPase. Among the substrates of the Asi complex are both misfolded proteins and functional regulators of sterol biosynthesis, a feature common to all ERAD branches. Our findings highlight that the quality control of membrane proteins is spatially segregated between INM and the rest of the ER membrane.

Investigating repair of DNA double-strand breaks in live *S. pombe* cells using a lacO/lacI-GFP system to monitor DSB resection, position, and dynamics.

B.A. Leland¹, M.C. King¹;

¹Department of Cell Biology, Yale University, New Haven, CT

A cell must accurately correct DNA damage to maintain its genome. One pathway used to repair DNA double-strand breaks (DSBs) is homologous recombination (HR). In HR, the broken strand of DNA is

paired with a homologous donor strand (usually the sister chromatid in G2) that is then used as a template for repair. A key, early step in HR is nucleolytic degradation of the 5' ends flanking the DSB, a process termed resection. Resection commits a DSB to repair by the HR pathway and facilitates pairing with the homologous donor. Much is known about the molecular details of HR, including its regulation throughout the cell cycle and many of the enzymes that mediate the various steps of repair. However, less is understood about how HR (and more broadly, all types of DNA repair) is influenced by its cellular context: the densely packed and dynamically organized nucleus.

To investigate the role of sub-nuclear compartmentalization in DSB repair by HR, we developed a microscopy-based assay to observe the initial steps of repair in live *S. pombe* cells. Our assay uses a rapid induction system to generate a single, site-specific DSB that is directly adjacent to a lac operator (lacO) array. Binding of lacI-GFP to the lacO array allows us to track the position of the DSB during the course of repair. After DSB induction, loss of dsDNA sequence at the lacO array flanking the DSB due to resection provides a means to monitor various properties that influence the resection rate.

Unexpectedly, our data have revealed that the rate of resection is quite variable within a population of live cells in a manner independent from the cell cycle. We are currently addressing the molecular basis for this heterogeneity by visualizing repair proteins (such as Rad52-mCherry) and assaying strains deficient in various repair proteins. We are also investigating the role of DSB position, especially tethering at the nuclear periphery, in regulating resection.

Surveillance of nuclear pore complex assembly by the ESCRT machinery.

B.M. Webster¹, P. Colombi¹, J. Jager¹, P. Lusk¹;

¹Department of Cell Biology, Yale University School of Medicine, New Haven, CT

The assembly of Nuclear Pore Complexes (NPCs) during interphase is thought to occur through the stepwise recruitment of the ~30 nucleoporins (nups) to the nuclear envelope, which occurs concomitantly with the fusion of the inner and outer nuclear membranes. Given that a single defective NPC could compromise the barrier function of the nuclear envelope, it is essential to understand how NPC quality is ensured. Working in budding yeast, we will show evidence for a surveillance mechanism that oversees NPC assembly. Our data are consistent with a model in which surveillance is achieved through the recognition of early NPC assembly intermediates by integral inner nuclear membrane proteins of the Lap2, emerin, MAN1 family, Heh1 and Heh2. When NPC assembly is compromised, Heh2 recruits the Endosomal Sorting Required for Transport (ESCRT) –III subunit, which, along with the AAA-ATPase Vps4, acts to potentially clear and target the degradation of misassembled nups. Under conditions in which surveillance is compromised, defective NPCs accumulate in a compartment that we term the SINC for Storage of Improperly assembled Nuclear pore Complexes. Consistent with the idea that the SINC is a repository for malfunctioning NPCs, it is most prevalent in 'old' mother cells and is almost never transmitted to daughter cells through mitotic divisions. Thus, there are several mechanisms that ensure NPC quality to support proper nuclear compartmentalization. Moreover, our

data highlight an exciting functional relationship between two ancient membrane-bending/associated machineries.

Board Number: B510

Three-dimensional Super-resolution Mapping the Selective FG-Barrier in Nuclear Pore Complex.

J. Ma¹, A. Goryaynov¹, W. Yang¹;

¹Biology, Temple University, Philadelphia, PA

The nuclear pore complexes (NPCs) selectively mediate the bidirectional trafficking of macromolecules between the cytoplasm and the nucleus in eukaryotic cells. The selective barrier formed by natively unfolded phenylalanine-glycine (FG) nucleoporins (Nups) inside the NPC allows for passive and facilitated transport through the NPC. However, the mechanism of formation and spatial distribution of FG-barrier in the NPC remains unresolved. By single-point edge-excitation sub-diffraction (SPEED) microscopy, we have used various fluorescent transport receptors (TRs) and FG segments as probes to determine the structure of FG-barrier in three dimensions in the native NPC. The three-dimensional spatial locations of probe-based FG repeats for the first time provide the native status of FG barrier in the NPC. Moreover, the competitions among various TRs and between TR and FG segments while binding FG Nups were systematically explored. Two major transport receptors Imp β 1 and CRM1, possessing dominant binding FG Nups over the other transport receptors, surprisingly have distinct transport routes without competition through the native NPC.

SINC, a secreted effector of *Chlamydia psittaci*, targets emerlin and the nuclear lamina of infected cells and uninfected neighbors.

S. Mojica¹, K. Hovis¹, F. Matthew², J. Ravel³, K.L. Wilson⁴, P. Bavoil¹;

¹Department of Microbial Pathogenesis, University of Maryland School of Dentistry, Baltimore, MD,

²Department of Microbiology and Immunology, University of Maryland School of Medicine, Baltimore, MD, ³Institute for Genome Science, University of Maryland School of Medicine, Baltimore, MD,

⁴Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

The chlamydial type III secretion system injects effector proteins into the host cell cytosol to facilitate bacterial growth and pathogenesis. We characterized SINC, a new effector produced by the avian and human pathogen, *Chlamydia psittaci*. SINC is syntenic with CT694 of *Chlamydia trachomatis* and likewise expressed late in development. However SINC uniquely targets the nuclear envelope (NE) of both *C. psittaci*-infected and uninfected neighboring cells. Digitonin-permeabilization studies of infected or SINC-GFP-transfected HeLa cells suggest SINC targets the inner nuclear membrane (INM). Candidate

partners were identified by proximity to biotin ligase-fused SINC (BirA-SINC) in HeLa cells and mass spectrometry (BioID). Among the most abundant peptides were fragments of INM proteins MAN1 and emerin, and of the nuclear pore complex protein, ELYS, suggesting candidate interacting partners at the NE. SINC-GFP association with the native LEM-domain protein emerin of the nuclear lamina was confirmed by GFP pull-down. SINC localization at the NE was blocked by importazole, confirming SINC import into the nucleus. Our findings identify SINC as a novel effector that is transported to the NE of infected and neighboring uninfected cells where it targets LEM domain proteins of the nuclear lamina. This association suggests that *C. psittaci*, an aggressive pathogen, has the capacity to modulate host cell nuclear functions, from chromatin organization to signaling and cytoskeletal regulation, both endogenously and exogenously.

P1174

Board Number: B512

Probing transmembrane protein distribution along the nuclear envelope using super-resolution microscopy.

K.C. Mudumbi¹, W. Yang²;

¹Biology Department, Temple University, Philadelphia, PA, ²Biology, Temple University, Philadelphia, PA

The double membrane nuclear envelope (NE) serves as a physical barrier between the cytoplasm and the nucleoplasm in eukaryotic cells. Transmembrane (TM) proteins are synthesized outside the nucleus on the endoplasmic reticulum (ER) and are then transported from the outer nuclear membrane (ONM) to the inner nuclear membrane (INM). Electron microscopy has been the most common approach to determine the distribution of TM proteins along the NE. However, this *in vitro* method requires the time consuming process of either chemical-fixation or frozen cells. Here, we exploit the super-resolution capabilities of the recently developed single-point edge-excitation sub-diffraction (SPEED) microscopy technique to study the distribution of TM proteins on the ONM and INM of the NE *in vivo*. This method allows us to quickly obtain distribution data of TM proteins along the NE in living cells.

P1175

Board Number: B513

Crystal structure of Nup62·58·54 nucleoporin complex.

H. Chug¹, S. Trakhanov¹, B.B. Hulsmann¹, D. Görlich¹;

¹Cellular Logistics, Max Planck Institute for Biophysical Chemistry, Göttingen, Germany

Nucleoporins (Nups) are the building blocks of a highly sophisticated translocation machinery in the cell called the Nuclear Pore Complex (NPC), which allows the controlled exchange of macromolecules across the nuclear envelope (NE). Many Nups interact tightly to form subcomplexes that arrange in octahedral symmetry to impart a rigid NPC scaffold. The Nup62·58·54 subcomplex is located near the central NPC translocation channel. It comprises three subunits, Nup62, Nup58 and Nup54, all predicted to contain

coiled coil (CC) domains. The complex is essential, highly conserved in evolution, a major anchor site for NPC barrier-forming FG domains and attached to the NPC via Nup93 (Nic96 in *S.cerevisiae*). The molecular structure of Nup62·58·54 subcomplex is hotly debated, because attempts to crystallize a complete complex have so far failed and only fragments with apparently non-physiological oligomerization propensity and stoichiometry have been crystallized instead (see Science 2007, 315: 1729; Cell 2011, 147:590; PNAS 2013, 110: 5858 and MBoC 2014, 25:1484 for an opposing perspective). On the basis of the fragment structures, it had been proposed that the subunits of Nup62·58·54 complex would slide against each and thereby dilate or narrow the central NPC channel. In order to crystallize a complete xNup62·58·54 complex, we mapped its domain boundaries and reached a stable, hetero-trimeric complex that can also incorporate efficiently into the NEs of *in vitro* assembled nuclei, suggesting a biologically relevant complex. In order stabilize the flexible parts and hinge regions of the complex that interfered with its crystallization, we screened many single-domain antibodies (Nanobodies, Nbs), and found a few that bound the trimeric state and a single one that conferred crystallizability. We also identified the Nup93 binding sites on Nup62·58·54 complex. Crystals obtained from the Nb-bound Nup62·58·54 complex diffracted to 3.2Å. The Nup62·58·54 complex structure revealed a very extensive hetero-trimerisation interface including two hetero-trimeric coiled coil regions that are connected by a sharp kink and pack against each other through another extensive hydrophobic interface. This structure of the biologically relevant Nup62·58·54 complex rules out any sliding between the subunits. The structure includes a number of striking features, whose functional significance is currently being tested.

P1176

Board Number: B514

Determination of the three-dimensional organization of chromatin by modelling-supported selective chromosomal interaction capture (T2C).

T.A. Knoch¹, M. Wachsmuth²;

¹Biophysical Genomics, Dept. Cell Biology and Genetics, Erasmus MC, Rotterdam, Netherlands,

²European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

The dynamic three-dimensional chromatin architecture of genomes and the obvious co-evolutionary connection to its function – the storage and expression of genetic information – is still, after ~170 years, a central question of current research. With a systems genomics approach using a novel selective high-throughput chromosomal interaction capture (T2C) technique together with quantitative polymer simulations and scaling analysis of genomic structures and the DNA sequence, we determined the architecture of genomes with unprecedented molecular resolution and dynamic range from single base pair entire chromosomes: for several genetic loci of different species, cell type, and functional states we find a chromatin quasi-fibre exists with 5 ± 1 nucleosome per 11 nm, which folds into 40-100 kbp loops forming aggregates/rosettes which are connected by a ~50 kbp chromatin linker. Polymer simulations using Monte Carlo and Brownian dynamics approaches confirm T2C results and allow to predict and explain additional experimental findings. This agrees also with novel dynamics information from

fluorescence correlation spectroscopy (FCS) analysis of chromatin relaxations *in vivo* (see abstract M. Wachsmuth & T. A. Knoch, Dynamic and structural properties of interphase chromatin mapped *in vivo* with fluorescence correlation spectroscopy and quantitative modelling). Beyond, we find a fine-structured multi-scaling behaviour of both the architecture and the DNA sequence which shows for the first time, that genome architecture and DNA sequence organization are directly linked – again in detail on the base pair level. Hence, we determined the three-dimensional organization and dynamics for the first time in a consistent system genomics manner from several angles which are all in agreement as well as additionally also with the heuristics of the research of the last 170 years. Consequently, T2C allows to reach an optimal combination of resolution, interaction frequency range, multi-plexing, and an unseen signal-to-noise ratio at molecular resolution and hence at the level of the “genomic” uncertainty principle and statistical mechanics, this opens the door to architectural sequencing of genomes and thus a detailed understanding of the genome with fundamental new insights with perspectives for diagnosis and treatment.

ES cell dependence on NUP133 for normal nuclear pore number and density.

E. Freed¹, B. Souquet², A.J. North³, V. Doye², E.H. Lacy¹;

¹Developmental Biology, Memorial Sloan Kettering Cancer Center, New York, NY, ²Inst Jacques Monod-UMR 7592 CNRS-Univ Paris Diderot, Paris Cedex 13, France, ³Bio-Imaging Resource Center, Rockefeller University, New York, NY

Our previous studies on the mouse mutant, *mermaid* (*merm*), found that a null allele of *Nup133* disrupts differentiation of neural and likely other embryonic lineages (Lupu *et al.*, 2008). *During neural differentiation, NUP133-deficient embryonic stem cells (ESCs) recapitulate aspects of the merm embryo phenotype, including impairment in production of terminally differentiated neurons.*

Immunofluorescence to nucleoporins (NUPs) in *merm* ESCs and neural tubes demonstrated that, despite the absence of NUP133, nuclear pore complexes (NPCs) assemble in the nuclear envelope.

NUP133 is a component of the NUP107-160 (or Y) complex, a conserved structural unit of the NPC. Analyses implicate the Y complex as a participant in multiple cellular processes, including NPC assembly, macromolecular transport, and cell cycle regulation. How the *merm* phenotype results from disruption of these functions remains unknown. To elucidate the requisite roles of NUP133, we have examined nuclear pore number and density in wild type and *merm* ESCs.

To quantify NPC number and density we applied structured illumination super-resolution microscopy (Delta Vision OMX) to acquire images of WT, *Nup133*^{+/-} (Het), and *Nup133*^{-/-} (*merm*) ESC nuclei stained with antibodies to TPR, a nuclear basket component. Using Imaris software (Bitplane) we measured total NPC number and nuclear surface area, enabling an estimate of NPC density. We found comparable numbers in WT vs. Het ESCs but a reduction of number and density of TPR-labeled NPCs in 3 independent *merm* ESC lines.

To determine whether these data reflect a general deficiency in NPC assembly, we examined WT, Het and *merm* ESCs using mAb414, which recognizes a group of FG-repeat-containing NUPs. On WT cells, both antibodies yield similar estimates of NPC number. However, mAb414 detects more pores than anti-TPR in *merm* ESCs, suggesting the presence of incomplete NPCs in the mutant cells. To further evaluate these results, we are quantifying NPCs using antibodies to additional NUPs.

According to current models, two distinct mechanisms direct NPC assembly. One acts post-mitotically, the other during interphase, and each posits different requirements for NUP133. Preliminary evaluation of WT and *merm* ES cells, in G1 vs. G2, suggests that loss of NUP133 affects both pathways.

In addition, we are using *merm* ESCs stably expressing WT or mutant forms of GFP-mNUP133, and will present rescue experiments to assess the extent to which neural differentiation depends on NPC number and density in the nuclear envelope of a progenitor cell.

The role of SUN proteins in nuclear envelope spacing of force-bearing cells.

N. Cain¹, E.C. Tapley¹, K. McDonald², B. Cain³, D.A. Starr¹;

¹MCB, University of California Davis, Davis, CA, ²EML, University of California Berkeley, Berkeley, CA,

³Physics, University of California Davis, Davis, CA

The nuclear envelope is made up of two membranes, the inner and outer nuclear membranes, separated by a uniform distance of 40-50 nm, known as the perinuclear space. The mechanism by which even spacing of the two nuclear membranes is maintained has been poorly understood. Sad1p-UNC-84 (SUN) proteins, which interact with Klarsicht, ANC-1, and SYNE homology (KASH) proteins to connect the nucleoskeleton to the cytoskeleton, have been implicated as molecular rulers that set the nuclear envelope space. This hypothesis was based on the observation that HeLa cells depleted of SUN proteins show blebbing of the outer nuclear membrane away from the inner nuclear membrane. To test the hypothesis that the *C. elegans* SUN protein UNC-84 spans and regulates the perinuclear space, we examined the morphology of the nuclear envelope by electron microscopy in *unc-84(null)* mutant animals. In most *unc-84(null)* mutant tissues, nuclear envelope morphology was normal. Therefore, SUN proteins are not necessary to regulate nuclear envelope spacing. However, we did observe extreme separation of the outer nuclear membrane from the inner nuclear membrane in *unc-84(null)* L1 body wall muscle nuclei. These mutant animals also displayed irregular locomotion in liquid and perhaps serve as a model for human laminopathies due to defects in LINC complex proteins that have reduced muscle function. Our data suggest a correlation between nuclear envelope morphology and muscle function. Surprisingly, UNC-84 protein with a 300 amino acid deletion in the luminal domain was able to form functional nuclear envelope bridges, but did not have a noticeable effect on nuclear envelope spacing. We propose that SUN proteins are only required to maintain the nuclear envelope space in cells that are under strain. Rather than dictating the perinuclear space, SUN proteins have appeared to evolve to reach across it.

P1179**Board Number: B517****Karyopherin-centric control of nuclear pores based on multivalent binding with FG Nucleoporins.**L.E. Kapinos¹, R.L. Schoch¹, K.D. Schleicher¹, R.S. Wagner¹, R.Y. Lim¹;¹Biozentrum, University of Basel, Basel, Switzerland

Intrinsically disordered Phe-Gly nucleoporins (FG Nups) within nuclear pore complexes (NPCs) exert multivalent interactions with transport receptors (Karyopherins or Kaps) that orchestrate nucleocytoplasmic transport. Current FG-centric views reason that selective Kap translocation is promoted by alterations in the barrier-like FG Nup conformations. However, the strong binding of Kaps with the FG Nups due to avidity contradicts rapid Kap translocation *in vivo*, thereby underscoring how mechanistic and kinetic views of NPC functionality remain at odds. Here, I will discuss our recent efforts to understand how multivalent Kap-FG Nup binding impacts on transport selectivity and speed. This includes (i) studying the crosstalk between equilibrium affinity and kinetic rates of Karyopherin β 1 (Kap β 1) binding with conformational changes in the FG Nups *in situ*; and, (ii) assaying Kap-facilitated transport when binding FG Nups *in vitro*. A characteristic feature of the FG Nups is their ability to accommodate large numbers of Kap β 1 molecules at physiological concentrations by conformational changes. However, whereas most bound Kap β 1 molecules become long-lived constituents inside a FG Nup layer due to strong binding avidity, Kap β 1 molecules located at the layer periphery are weakly bound and dominate fast transport kinetics due to limited binding with the pre-occupied FG Nups. Hence, the number of free FG-repeats in a FG Nup layer, and the strength of Kap β 1 binding are directly correlated to the amount of Kap β 1 in solution. As proof-of-principle, we find that varying Kap β 1 concentration can control Kap β 1-facilitated motion on a FG Nup layer. This evokes differential behavior ranging from highly constrained to two-dimensional diffusion (i.e., Reduction of dimensionality) at physiological Kap β 1 concentrations. In contrast to FG-centric views, I will discuss how our findings show support for an emergent Kap-centric mechanism that may underlie barrier functionality and selective transport control in NPCs.

P1180**Board Number: B518****A genetic screen reveals the requirement for mRNA processing genes and the topoisomerase TOP2 in nuclear morphology.**R.A. Meseroll¹, O. Cohen-Fix¹;¹National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), National Institutes of Health, Bethesda, MD

The mechanisms dictating the size and shape of the nucleus in any cell type are poorly understood. The nucleus of the budding yeast *Saccharomyces cerevisiae* is round during interphase, with a crescent-shaped nucleolus located at the nuclear periphery. Previous work from our lab has demonstrated that nuclei in cells with upregulated phospholipid biosynthesis or that have been delayed in mitosis form a single extension or “flare” specifically at the nuclear envelope adjacent to the nucleolus. What are the mechanisms that contribute to nuclear morphology and confine expansion to the nucleolar region? To test this, we conducted a screen of randomly-generated conditional temperature-sensitive mutants to identify mutants that have multiple extensions or other abnormalities that form at sites away from the nucleolus. The screen yielded four mutants with the desired phenotype, encoding for single point mutations in three mRNA processing or splicing genes (*CEG1*, *PRP9*, and *PRP22*) and the topoisomerase *TOP2*. All four genes are essential and at least half of the nuclei in the mutants at the restrictive temperature have multiple extensions at sites other than the nucleolus. In addition to the nuclear morphology defects, some of these mutants also have nucleolar defects, such as collapsed nucleoli or nucleoli that appear detached from the nuclear periphery. It remains unclear whether the phenotypes in the mRNA processing and splicing mutants are due to a response to a global defect in mRNA processing or if improper capping or splicing of a particular message or subset of messages is responsible for the abnormal nuclear shape. Presently, we have focused our efforts on determining the role of *TOP2* in nuclear morphology. Topoisomerases are highly conserved proteins responsible for disentangling topological problems that result from DNA double helix unwinding. We hypothesize that nuclear morphology depends on chromatin structure and that aberrant chromatin conformation in the *top2* mutant leads to the nuclear shape defects we observe. We are currently characterizing nuclear and nucleolar defects, testing topoisomerase activity, and examining chromatin organization in the *top2* mutant to determine *TOP2* function in nuclear morphology.

P1181**Board Number: B519****Quantifying Nucleoporin Stoichiometry Inside Single Nuclear Pore Complexes In Vivo.**L. Mi¹, A. Goryaynov², M. Rexach³, A. Lindquist³, W. Yang⁴;¹Department of Optical Science and Engineering, Fudan University, Shanghai, China, ²Department of Cell Biology, Yale University School of Medicine, New Haven, CT, ³Department of Cell and Developmental Biology, University of California, Santa Cruz, Santa Cruz, CA, ⁴Biology, Temple University, Philadelphia, PA

The nuclear pore complex (NPC) is one of the largest supramolecular structures in eukaryotic cells. Its octagonal ring-scaffold perforates the nuclear envelope and houses a molecular sortase that regulates nucleocytoplasmic transport. It is composed of ~30 different nucleoporins (Nups), estimated at 8, 16 or 32 copies per NPC, although this has not been confirmed due to the inherent difficulty of counting proteins within supramolecular complexes. Here we used single-molecule SPEED microscopy to directly count the copy-number of twenty-four different Nups within the NPC of live yeast, and found significant deviations from previous estimates. Each NPC contained a maximum of 16 copies of Nsp1 and Nic96, rather than 32 as previously estimated; 16 copies of thirteen additional Nups; 8 copies of four Nups; and 10-15 copies of five Nups. This in situ molecular-counting technology can help resolve the architecture of NPCs and other supramolecular structures in living cells.

P1182**Board Number: B520****Nuclear size scaling during *Xenopus* early development contributes to the regulation of midblastula transition timing.**P. Jevtic¹, D. Levy¹;¹Department of Molecular Biology, University of Wyoming, Laramie, WY

Early *Xenopus laevis* embryogenesis is a robust system for investigating mechanisms of developmental timing. The first major developmental transition is the midblastula transition (MBT), when zygotic transcription begins and cell cycles elongate. Fertilization is followed by a series of rapid cell divisions with concomitant reductions in cell size and it has long been recognized that the nuclear-to-cytoplasmic (N/C) volume ratio changes dramatically during early *Xenopus* development. We quantified blastomere and nuclear sizes in *X. laevis* embryos and demonstrate that the N/C volume ratio increases rapidly prior to the MBT. Rather than examining the role of DNA amount in MBT timing, we investigated if MBT timing is regulated by nuclear size and developmental changes in the N/C volume ratio. We manipulated nuclear volume in embryos by microinjecting different nuclear scaling factors, including import proteins, lamins, and reticulons. Using this approach, we first monitored the onset of zygotic gene expression by performing whole-mount in situ hybridization to detect the GS17 transcript. We found that increasing the N/C volume ratio in pre-MBT embryos leads to premature activation of GS17 gene transcription, and

decreasing the N/C volume ratio delays GS17 transcription in MBT embryos. To corroborate our in situ hybridization data, we quantified additional zygotic transcripts (*xnr5-13*, *xnr3*, and *bix1.1*) by qPCR. Stage 6.5 embryos with increased nuclear size showed increased expression of MBT transcripts compared to GFP control-injected embryos, up to seven times greater in some cases. In late stage 8 embryos with decreased nuclear size, we observed less expression of zygotic transcripts compared to controls. Next, we analyzed time-lapse movies of microinjected embryos to test if altering nuclear size in early embryos affects the timing of cellular hallmarks of the MBT. Generally, control GFP-injected embryos cleaved synchronously until the 12th cleavage (the normal MBT), at which time cell cycles lengthened. Embryos with decreased nuclear size cleaved rapidly until, on average, the 14th cell cycle, while embryos with increased nuclear size exhibited longer cell cycles after only the 10th cleavage. Taken together, our data show that nuclear size scaling and changes in the N/C volume ratio that occur during early *Xenopus* embryogenesis act as an additional mechanism in the regulation of MBT timing, demonstrating the functional significance of nuclear size during development.

DNA zip codes induce relocalization to the nuclear periphery and mediate interchromosomal clustering of GAL genes.

D.G. Brickner¹, J. Brickner¹, V. Sood¹, R. Coukos¹, A. D'Urso¹;

¹Molecular Biosciences, Northwestern University, Evanston, IL

To allow growth in galactose, yeast cells induce a number of genes. Active *GAL* genes in yeast are targeted to the nuclear periphery/nuclear pore complex by cis-acting “DNA zip codes” in their promoters. Genes with identical zip codes cluster together and insertion of zip codes at an ectopic site induces clustering with endogenous *GAL* genes having the same zip code. Clustering of genes is specific; pairs of *GAL* genes that are targeted to the nuclear periphery by different zip codes do not cluster together. The molecular mechanism controlling targeting to the NPC is distinct from the molecular mechanism controlling interchromosomal clustering. Targeting to the nuclear periphery and interaction with functional nuclear pores is a pre-requisite for gene clustering. However, clustering can be maintained in the nucleoplasm and is regulated differently through the cell cycle. Also, although targeting of genes to the NPC is independent of transcription, interchromosomal clustering requires transcription. Finally, although targeting to the NPC promotes stronger expression, removal of a single gene from interchromosomal clusters does not affect the expression of the remaining genes in the cluster. These results suggest that genomes encode elaborate signals that mediate temporally dynamic spatial organization of the genome.

P1184**Board Number: B522****PLK1 functions in nuclear pore complex disassembly.**M.I. Mayr¹, C. Wandke¹, U. Kutay¹;¹Institute of Biochemistry, ETH Zürich, Zürich, Switzerland

Disintegration of the nuclear envelope (NE) is a prerequisite for mitotic spindle assembly in higher eukaryotes. Phosphorylation of nuclear pore complex (NPC) constituents and nuclear membrane proteins is key in initiating diverse steps of nuclear envelope breakdown (NEBD). We have previously shown that cyclin-dependent kinase 1 (CDK1) and NIMA-related kinases (Nek-6 and -7) are crucial for timely nuclear permeabilization in HeLa cells (Laurell et al., Cell, 2011). Reportedly, several nucleoporins (Nups) are phosphorylated on sites matching the consensus for polo-like kinase 1 (PLK1), raising the possibility that PLK1 directly contributes to NE permeabilization during NEBD. In support of this notion, we have observed that PLK1 localizes at the NE during prophase. Specifically, the noncatalytic carboxy terminus of the kinase, the polo-box domain (PBD) is sufficient for targeting to the NE, indicating that NE localization depends on priming phosphorylation. To explore a function of PLK1 in NPC disassembly, we applied a previously developed in vitro system that recapitulates nuclear disassembly on nuclei of semipermeabilized HeLa cells upon addition of mitotic extracts. Chemical inhibition of PLK1 activity as well as immunodepletion of PLK1 significantly delayed the kinetics of NPC disassembly in vitro without affecting CDK1 activity. Add-back of purified wild-type kinase restored timely NE permeabilization. To examine whether PLK1 function during NPC disassembly depends on the PBD we added GST-PBDWT or GST-PBDAA to mitotic extracts to compete with endogenous kinase activity. The addition of GST-PBDWT but not GST-PBDAA significantly delayed NPC disassembly kinetics. To understand the molecular mechanism of how Plk1 phosphorylation affects NPC disassembly, we are currently studying how PLK1-mediated phosphorylation of several candidate nucleoporins affects mitotic NPC disassembly.

P1185**Board Number: B523****Characterization of the interactions between Mps3, Elg1, and Cdc5.**L.M. Antoniaci¹, C. Brown²;¹Science, Marywood Univ, Scranton, PA, ²Science, Marywood University, Scranton, PA

Cdc5 is a polo-like kinase identified in *Saccharomyces cerevisiae*. Cdc5 functions in regulation of many essential cell pathways including Meiosis, Mitosis, and Cytokinesis. A genome wide screen for physical interactors of Cdc5 identified Mps3 as a potential candidate. Our lab has confirmed this interaction using GST pull down and Co-Immunoprecipitation. Mps3 is a nuclear envelope protein involved in several chromosome functions such as sister chromatid cohesion, DNA damage repair, and telomere clustering. Mps3 is hypothesized to be involved in many of these processes through its association with many chromatin associated proteins. One of these chromosome associated proteins is Elg1, which functions in many of the same processes of Mps3. Here we present data that Cdc5 and Elg1 also

physically interact. In addition we investigate the possibility that both Elg1 and Mps3 are substrates of Cdc5.

Characterization of the unique KASH domain protein *Lrmp*.

H. Werner¹, C.L. Stewart¹;

¹Institute for Medical Biology, Singapore, Singapore

KASH domain proteins are key components of the LINC complex (linker of nucleoskeleton and cytoskeleton). The LINC complex is formed by the interaction of SUN (Sad1, Unc-84) domain proteins and KASH (Klarsicht, ANC-1, Syne Homology) domain proteins. The interaction of both protein families builds the bridge between the nuclear lamina and the microtubule and actin network in the cytoplasm. Proteins of the KASH domain family are localized at the outer nuclear membrane, and interact via their C-terminal KASH domain with SUN (Sad1, Unc-84) domain proteins in the perinuclear space. Their cytosolic N-terminus connects with components of the cytoskeleton. In human and mouse, six members of the KASH domain protein family have been described, encompassing Nesprin1-4, KASH5, and the recently identified lymphoid-restricted membrane protein (*Lrmp*). *Lrmp* is localized to the ER, but it can be recruited via its conserved KASH domain to the nuclear envelope by SUN domain proteins. To investigate the physiological function of *Lrmp*, we created a *Lrmp*-deficient mouse strain (*Lrmp*^{-/-}) expressing a *LacZ* reporter gene. Performing a β-galactosidase staining on various tissues derived from *Lrmp*^{WT/-} and *Lrmp*^{-/-} mice, we can trace the expression of *Lrmp* in taste buds of the lingual papillae. Furthermore, we show that *Lrmp* is exclusively expressed in type II taste receptor cells which perceive sweet, umami and bitter flavours. This leads us to the question if *Lrmp* has a pivotal role in taste perception. We compared the taste preference of wild-type and *Lrmp*^{-/-} mice during a two-bottle preference test. However, taste perception in mice lacking *Lrmp* is indistinguishable from the wild-type littermates. We conclude that *Lrmp* is not essential for taste transduction and signalling. In this study, we can show a new expression pattern of *Lrmp*, a unique KASH domain protein, in the taste buds of mice. In future work, we will further investigate the physiological function of *Lrmp* and the LINC complex in taste receptor in conjunction with other putative proteins with which *Lrmp* interacts.

RecQL DNA Helicase Impact on the Nuclear Pore Complex in Aging Cells.

Y. Zhai¹, Z. Li¹, K. Nevola¹, J.S. Glavy²;

¹CCBBME, Stevens Institute of Technology, Hoboken, NJ, ²Stevens Inst Technology, Hoboken, NJ

From the surrounding shell to the inner machinery, nuclear proteins provide the functional plasticity of the nucleus. This study first highlights the association of nuclear pore NDC1 and Werner protein (WRN),

a RecQL helicase responsible for the DNA instability in some Progeria disorders. RecQL helicases are the caretaker of the genome acting to preserve genetic coding and therefore protect cells against aging. Likewise, Nuclear Pore Complexes (NPCs) maintain proper nuclear functionality through the transport of protein and mRNA. In established WRN knockout cell lines, we further demonstrate the interdependence of WRN, LaminB1 and nuclear pore complex nucleoporins. These changes do not completely change the barrier of the nuclear envelope, but do affect the distribution of transport FG Nups and the RAN gradient. Evidence from WRN knockout cell lines demonstrates changes in the processing and nucleolar localization of lamin B1. Furthermore we have found that other RecQL helicases effect the distributions and levels of Nups. We are gaining further proof of this NPC, RecQL helicases and lamin B1 triad.

On The Stoichiometry Of Channel Nucleoporins Nup62, Nup54 And Nup58: A Critical Appraisal.

S.R. Solmaz^{1,2}, A. Sharma³, G. Blobel³, I. Melcak³;

¹Department of Chemistry, Binghamton University-SUNY, Binghamton, NY, ²Laboratory of Cell Biology, HHMI at the Rockefeller University, New York, NY, ³Laboratory of Cell Biology, HHMI at the Rockefeller University, New York, NY

Of the 30 nucleoporins (nups) that make up the nuclear pore complex (NPC), three are centrally located: Nup62, Nup54 and Nup58. We recently pieced together the molecular architecture of the NPC transport channel from crystal structures of the binary complexes of Nup62•Nup54 and Nup54•Nup58 (3) and proposed a novel mechanism for how the central channel of the NPC opens and closes by dilation and constriction of mid-plane rings ('ring cycle') (2). Collectively, our crystal structures indicated a stoichiometry of 4:2:1 for Nup62, Nup54 and Nup58, respectively. However, solution studies of the three-protein complex had pointed towards its dynamic nature. In marked contrast, recent solution studies of structured regions of these three proteins suggested that they form a 1:1:1 'triple' complex. To address this ambiguity, we carried out additional solution studies. We found that Nup62, Nup54 and Nup58 do not form a 1:1:1 complex, but instead associate with each other in unstable mixtures of various stoichiometric ratios (1). The polydisperse nature of the ternary complex was demonstrated either by multi-dimensional electrophoretic analysis or by size-exclusion chromatography coupled to multi-angle light scattering. Moreover, probing the ternary complex with wild-type or mutant Nup54 'protomers' yielded data that strongly support the interaction domains of the three channel nups that were established previously by crystallographic methods. Specifically, we show that Nup58 interacts transiently with Nup54 in the assembled ternary complex, which is the basis for its observed heterogeneity. Our data support the 'ring cycle' model of nuclear transport, in which transient interactions between Nup58 and Nup54 would lead to transitions between dilated and constricted states of the transport channel. Specifically the transport of large cargo such as viruses, mRNPs and ribosomal subunits remains poorly understood, even though these processes impact crucial cellular

functions, such as RNA metabolism. To this end, the ring cycle provides a molecular basis for how the NPC can facilitate selective transport of cargo with a size range of 10-50 nm. Besides providing support for the ring cycle model, this study also addresses the widely discussed issue of the stoichiometry of the channel nups, providing a rationale for the different observations reported in the literature.

Quantitative 4D visualization of clathrin-coated vesicle formation in mammalian cells by correlated light and electron microscopy.

O. Avinoam¹, M. Schorb¹, J. Briggs¹, M. Kaksonen²;

¹The European Molecular Biology Laboratory (EMBL), Heidelberg, Germany, ²European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

Clathrin-mediated endocytosis (CME) is a conserved form of selective plasma membrane internalization in eukaryotic cells that plays a fundamental role in numerous physiological and pathological processes. Many components of the multi-protein machinery driving endocytosis have been identified in mammals. However, a comprehensive view of membrane shape transitions during coated vesicle formation is still missing. Clathrin coated vesicle (CCV) budding may occur either through increase in curvature of a pre-assembled coat, or through coat growth, with the curvature of the emerging bud remaining constant. These two models predict different membrane intermediates. Furthermore, for a coated membrane area to change in curvature, the overlying coat must constantly restructure. To distinguish between these models we visualized clathrin-coated pits (CCPs) by correlating fluorescence microscopy and electron tomography in genome-edited mammalian cells expressing fluorescently tagged clathrin and dynamin at physiological levels. We correlated clathrin fluorescence to endocytic sites ranging from flat to highly curved membrane patches and to coated vesicles. We focused on productive endocytic events by analyzing sites on the non-adherent surface of the plasma membrane that were able to recruit cargo. We quantified the curvature and coated surface area of over 200 CCPs and CCVs and found that the curvature of the membrane at the tip of the invagination increases during endocytosis while the area of coated membrane remains constant. These results imply that endocytosis occurs predominantly by inward deformation of flat clathrin lattices. In addition, the population labeled by both clathrin and

dynamin consisted exclusively of deep invaginations that showed membrane constriction at their base, consistent with the known role of dynamin in membrane scission at late stages of CME. To test whether the clathrin coat is remodeled during CME we performed dual color FRAP analysis of single endocytic sites containing clathrin-RFP and dynamin-GFP. Our preliminary results show that clathrin fluorescence largely recovers even in the presence of dynamin suggesting that clathrin is exchanged even at late stages of CME. Taken together, these results suggest that the coat is a dynamic structure that reshapes during endocytosis. Our quantitative 4D description of membrane shape transitions during CME in vivo provides strong evidence for budding via continuous increase in membrane curvature of a constant pre-coated membrane area.

Ultrastructure of the actin cytoskeleton associated with sites of clathrin-mediated endocytosis in dynamin2-depleted HeLa cells.

C. Yang¹, T. Svitkina¹;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA

Clathrin-mediated endocytosis (CME) plays an essential role in selective uptake of extracellular molecules and plasma membrane components in eukaryotic cells. The formation of an endocytic vesicle is a complex process operated by multiple proteins and the actin cytoskeleton is an important component of the molecular machinery driving endocytic vesicle internalization. Actin cytoskeleton transiently assembles at clathrin-coated pits toward the end of the endocytic cycle, shortly before the clathrin-coated vesicle is pinched off from the plasma membrane by dynamin2. Our understanding of specific roles of the actin cytoskeleton remains incomplete due to lack of detailed ultrastructural information. To get detailed insights into actin cytoskeleton architecture at the endocytic sites, we depleted dynamin2 in HeLa cells by lentiviral shRNA in order to block CME before the vesicle scission step. Platinum replica electron microscopy of unroofed cells revealed a dramatic increase in the fraction of clathrin-coated structures associated with the actin cytoskeleton in most dynamin2-depleted cells, as compared with control cells containing endogenous dynamin2. Actin filaments associated with clathrin-coated structures in dynamin2-depleted cells were organized into branched networks with the shape of long comet tails, in which barbed ends were oriented toward the clathrin-coated structure. These data support the idea that branched actin networks promote invagination of the endocytic bud and elongation of the bud neck by pushing onto the clathrin-coated structure with their barbed ends. This study sets the stage for better understanding of actin-dependent mechanisms of vesicle internalization during CME.

P1191**Board Number: B530****Chemical labelling of primary endocytic vesicles quantifies flux through clathrin coated pits, caveolae, and alternate endocytic pathways.**E. Shvets¹, V. Bitsikas¹, I. Correa², G. Howard¹, C. Hansen³, B. Nichols¹;¹MRC-LMB, Cambridge, England, ²New England Biolabs, Ipswich, MA, ³UCSD, La Jolla, CA

Several different endocytic pathways have been proposed to function in mammalian cells. Clathrin-coated pits are well characterised, but the identity, mechanism and function of alternative pathways have been less clear.

We applied chemical labelling of plasma membrane proteins to simultaneously define the origin and cargo composition of all primary endocytic vesicles. This was complemented by labelling of specific proteins with a reducible SNAP-tag substrate. These approaches provide high temporal resolution and stringent discrimination between surface-connected and intracellular membranes. Our data generate a complete and quantitative inventory of the different types of endocytic vesicle acting in unperturbed mammalian cells. Experiments employing mutated clathrin adaptors and loss of adaptor function allow analysis of the cargo load of endocytic vesicles when sorting of high affinity cargoes into clathrin coated pits is perturbed. These experiments reveal remarkably different effects on different classes of endocytic cargo.

Around 2% of endocytic vesicles arise from budding of caveolae from the plasma membrane, and these vesicles deliver cargo to endosomal compartments. Caveolae have a unique role in endocytosis, as both light and electron microscopy show that the caveolar bulb dynamically sorts plasma membrane components. The caveolar bulb acts as a molecular device that presents a different paradigm for sorting to the clathrin coated pit. These data provide new insight into the activity and diversity of endocytic pathways in mammalian cells.

P1192**Board Number: B531****A nanometer-scale survey of the structure and organization of clathrin-mediated endocytosis among mammalian cell lines.**K.A. Sochacki¹, J.W. Taraska¹;¹NHLBI/NIH, Bethesda, MD

Platinum replica electron micrographs (PREM) of unroofed mammalian cells provide an abundance of architectural detail about important cellular processes such as exocytosis, endocytosis, cytoskeletal organization, and adhesion. The topography of the cellular cortex and its spatial organization inform how the cell interacts and communicates with its surroundings. Structures like clathrin, non-clathrin vesicles, and actin are organized differently in different cell types reflecting their different functional

behavior. Here, we evaluate the size, shape, and spatial organization of these structures among 12 cell lines: PC-12 (rat adrenal gland), CHO-K1 (hamster ovary), HEK293 (human embryonic kidney), NIH/3T3 (mouse embryo), Cos7 (monkey kidney), HeLa (human cervix), INS-1 (rat pancreas), MCF7 (human breast), A549 (human lung), BS-C-1 (monkey kidney), U87 MG (human brain), and U2OS (human bone). High throughput image analysis using neural networks allows statistical analysis of cortex structures in several cells in each cell line. These data provide a systematic view of the plasma membrane molecular architecture in mammalian cells.

Internalization and Recycling of RET Receptor Tyrosine Kinase Isoforms.

M.J. Crupi¹, L.M. Mulligan¹, D.S. Richardson^{1,2};

¹Pathology and Molecular Medicine, Queen's University, Kingston, ON, ²Center for Biological Imaging, Harvard University, Cambridge, MA

The RET (REarranged in Transfection) receptor tyrosine kinase is crucial for the normal development of the kidneys and enteric nervous system, as well as the regulation of neural-crest cell behaviours, including proliferation, migration, differentiation and survival. RET is also a potent contributor to clinically challenging cancers. Activating mutations in RET can lead to multiple endocrine neoplasia type 2, a cancer syndrome characterized by medullary thyroid carcinoma. Increased activation of wildtype RET receptors has been linked to aggressive breast cancers, and enhanced invasion and perineural spread in pancreatic carcinoma. Two distinct isoforms of the growth factor receptor arise through alternative splicing of the 3' exons, and are termed RET9 and RET51 to denote the number of amino acids in each C-terminal tail. These isoforms induce unique phosphorylation patterns on intracellular tyrosine residues, differentially bind downstream signalling proteins, and possess different intrinsic abilities to cause cellular transformation. Here, we explore the differential subcellular localization and trafficking of the two isoforms in human cell line models to better understand RET-mediated cancers.

We have found that RET51 is efficiently matured and localized to the cell membrane, while immature RET9 matures more slowly, leading to lower relative expression on the plasma membrane. Upon RET activation, both isoforms at the cell surface are internalized to endosomes via AP2-adaptor interactions and the clathrin coated-pit pathway. Although RET51 is internalized more rapidly than RET9, a portion of RET51 molecules recycle back to the plasma membrane, maintaining high protein levels at the cell surface. We have shown that RET51 interacts with the sorting protein GGA3, which may promote localization to recycling compartments. Recycling of RET51 leads to a longer residency time in an endosomal compartment, where sustained Erk1/2 can occur. Differences in signaling potential may in part explain the greater transforming potential of RET51. Together, our data suggest that differences in RET isoform subcellular localization and trafficking would lead to differences in signal transduction and may in part explain the functional differences observed between RET isoforms.

Intracellular sorting and trafficking pathways require a complex orchestration of events for proper distribution of internalized cargo proteins. Retromer is necessary for the successful sorting and trafficking of cellular cargoes to both the plasma membrane and the Golgi. An important regulator of receptor trafficking by the retromer is the Wiskott-Aldrich Syndrome Protein and SCAR Homolog (WASH) complex, an Arp2/3 Type 1 nucleation promoting factor which induces branched F-actin networks at the endosome surface (Gomez and Billadeau 2009). The WASH complex is composed of five subunits: SWIP, Strumpellin, FAM21, WASH1, and CCDC53, interacts with the retromer via FAM21, and plays a role in both retrograde receptor trafficking to the TGN as well as plasma membrane transport of receptors. Herein, we characterize a novel protein complex containing COMMD proteins, CCDC22, CCDC93 and C16orf62 (referred to as the CCC complex) that localizes to endosomes in a WASH complex-dependent manner. Significantly, depletion of any CCC complex component impairs recycling and intracellular trafficking of receptors regulated by the WASH and retromer complexes, including α -5 integrin, CI-M6PR, and the copper transporter ATP7A.

P1195**Board Number: B534****Role of plasma membrane-bound sialidase NEU3 in clathrin-mediated endocytosis.**M. Rodríguez-Walker¹, A.A. Vilcaes¹, J.L. Daniotti¹;¹Univ Nacional de Cordoba-CIQUIBIC (CONICET-UNC), Fac. Ciencias Quimicas, Cordoba, Argentina

Gangliosides (GS) are sialic acid-containing glycolipids expressed on plasma membranes from nearly all vertebrate cells. They have been implicated in many physiological and pathological processes, e.g. in cell growth, cell adhesion and endocytosis; including its capacity to function as receptors for several toxins, viruses and antibodies. GS are synthesized at the Golgi complex, but recently a number of enzymes of GS anabolism and catabolism have been shown to be associated with the plasma membrane. NEU3, a key plasma membrane-bound sialidase for GS hydrolysis, has been implicated in similar cellular processes as GS, and its up-regulation has been observed in various human cancer cells. In the case of clathrin-mediated endocytosis, although this has been widely studied, the specific role of GS and NEU3 in this cellular process has not yet been well established. Using biochemical assays and confocal microscopy imaging, we studied the role of GS and NEU3 in different endocytic processes. Initially, we observed an increase in the internalization of transferrin (Tf), the archetypical cargo for internalization through clathrin-mediated endocytosis, in cell lines expressing GS with high level of sialylation. The ectopic expression of NEU3 led to a drastic decrease in Tf endocytosis, suggesting a participation of GS in this process. However, expression of NEU3 in GS-depleted cells only slightly affected its inhibition on Tf endocytosis, indicating that NEU3 modifies the internalization of Tf independently of its action on GS. Additionally, the internalization of low-density lipoprotein, another typical ligand in clathrin-mediated endocytosis, was also decreased in NEU3-overexpressing cells. In contrast, internalization of cholera toxin β -subunit, which is endocytosed by both clathrin-dependent and clathrin-independent mechanisms, remained unaltered. Kinetic assays carried out on NEU3 expressing cells revealed a significant reduction in the sorting of Tf to early and recycling endosomes, without significant changes recorded in the expression level of the Tf receptor. We found that NEU3 expression altered the subcellular distribution of clathrin adaptor AP-2 σ_2 subunit, but did not reveal any changes in the membrane distribution of clathrin or phosphatidylinositol (4, 5)-biphosphate. Finally, NEU3 did not alter the distribution of caveolin-1. Overall, these results suggest a specific and novel role of NEU3 in clathrin-mediated endocytosis.

P1196**Board Number: B535****Palmitoylation is required to recruit retromer to endosomes.**G. Modica¹, F. Jules¹, A. Simoneau¹, H. Wurtele¹, S. Lefrançois¹;¹Hopital Maisonneuve-Rosemont, Montreal, QC

Palmitoylation is a reversible enzyme-mediated post-translational modification consisting of the covalent attachment of palmitic acid to a cysteine residue of a target protein. Within the last 10 years, a group of enzymes that contain a conserved catalytic DHHC domain have been shown to have palmitoyltransferase (PAT) activity. So far, 24 PATs have been identified in humans while the yeast *S. Cerevisiae* genome has 7. The deletion of two yeast PATs, Swf1 and Akr1, results in the abnormal extracellular secretion of the vacuolar protein Carboxypeptidase Y (CPY), suggesting a defect in the vacuolar sorting machinery. The correct sorting of CPY requires the efficient recycling of its vacuolar protein sorting receptor Vps10 from the endosome to the trans-Golgi network (TGN). This intracellular trafficking pathway is mediated by retromer, a pentameric protein complex consisting of a trimer composed of Vps26, Vps29 and Vps35 and a dimer made by Vps5 and Vps17. We found that Vps10 is degraded in Swf1-deleted cells as it cannot recycle to the TGN. Furthermore, we demonstrated that the deletion of Swf1 leads to a mislocalization of retromer subunits from the membrane fraction to a cytosolic fraction, supporting a role for this PAT in sorting at the endosome. Subsequently, using Acyl-RAC (Resin-Assisted Capture), we found that Vps29 is palmitoylated, suggesting an association between palmitoylation and retromer recruitment and function. Interestingly, Ypt7, the Rab protein mediating the recruitment of retromer to endosomal membranes, is also palmitoylated, but in a Swf1-independent manner. We found that the enzyme responsible for Ypt7 palmitoylation is the vacuole associated PAT Pfa3. While the deletion of Swf1 leads to the mislocalization of retromer and to the secretion of CPY, the deletion of Pfa3 does not. This may suggest that Ypt7 palmitoylation per se is not required for correct retromer function. Altogether our data indicates that palmitoylation plays a complex role in the recruitment of retromer to endosomes and is required for the efficient endosome-to-Golgi trafficking of Vps10.

P1197**Board Number: B536****Role of the clathrin independent, CLIC/GEEC (CG) endocytic pathway in membrane homeostasis.**J.J. Thottacherry¹, A. Kosmalska^{2,3}, A. Elosegui-Artola^{2,3}, R. Vishwakarma⁴, P. Roca-Cusachs^{2,3}, S. Mayor¹;¹National Centre for Biological Sciences (NCBS), TIFR, Bangalore, India, ²Institute for Bioengineering of Catalonia (IBEC), Barcelona, Spain, ³University of Barcelona, Barcelona, Spain, ⁴Indian Institute of Integrative Medicine, bangalore, India

Eukaryotic cells have multiple endocytic pathways that help internalize nutrients, ligands, receptors and extracellular fluid. Endocytic pathways and subsequent recycling are also important for rapid membrane

redistribution during processes such as cell spreading, mitosis and cell migration¹. Cells need to tightly coordinate membrane exchange through these endo-exocytic processes for the maintenance of its plasma membrane area and cell shape. Membrane tension has been thought to play a role in coordinating the exo-endocytic delivery of membrane to and from the cell surface. However, the nature of the endocytic pathway(s), molecules or mechanism(s) behind these regulated processes remains largely unknown.

Unlike the extensively studied clathrin mediated endocytic pathway, clathrin independent endocytic (CIE) pathways in particular the CLIC/GEEC (CG) pathway could serve as a central player in the homeostasis of membrane tension or area. The CG pathway is a high capacity CIE pathway that internalize the equivalent of entire PM area in 12 minutes². The CG pathway also rapidly regurgitates a major fraction of endocytosed contents within 5 minutes of internalization³. These properties give it the potential to be a core regulator of membrane dynamics that could also respond to membrane tension.

Here we have explored the role of multiple endocytic pathways in mammalian cells using fluorescent microscopy during de-adhering or upon changing tension using a custom built stretching device. We find that CG endocytic pathway is specifically up regulated during de-adhering while caveolar or clathrin mediated endocytic pathways are not involved. Changing membrane tension by stretching or via other means triggers similar response from CG pathway. Modulating the CG pathway via perturbation of key genes that regulate this pathway appear to modify the membrane tension, indicating the pathway could help set the resting membrane tension or maintain area homeostasis of a cell.

Defining the endocytic function of Pan1 in *Saccharomyces cerevisiae*.

M.K. Bradford¹, K. Whitworth¹, B. Wendland¹;

¹Department of Biology, Johns Hopkins University, Baltimore, MD

Endocytosis is a well-conserved process by which cells invaginate small portions of the plasma membrane to create vesicles containing extracellular and transmembrane cargo proteins. Dozens of proteins and hundreds of specific binding interactions coordinate and regulate these events.

Saccharomyces cerevisiae is a powerful model system to study clathrin-mediated endocytosis (CME). Pan1 is thought to act as a scaffolding protein due to its interactions with several proteins that act throughout the endocytic process. Previous research on Pan1 has characterized some of Pan1's binding interactions, but due to Pan1's essential nature, the exact mechanisms of Pan1's function in endocytosis have been difficult to define. To clarify Pan1's roles, I have developed a conditional PAN1 auxin-inducible degron allele (Pan1-AID) using the methods of Nishimura et al. (2009). In Pan1-AID, Pan1 is specifically and acutely degraded upon the switch to nonpermissive conditions. Cell growth and endocytosis are arrested within minutes after Pan1 depletion and the cells begin to die after one to two hours. We can learn more about Pan1's endocytic and essential functions by studying the phenotypes of the arrested cells immediately after growth arrest has been achieved and before cell death. Using Pan1-AID, I have more clearly defined Pan1's mechanistic role in CME as a critical regulator of the transition from the early endocytic coat to the late coat. Additionally, I determined a key role for Pan1's central region in endocytosis and viability. I have identified three overlapping essential regions of Pan1, all of which contain a portion of the central region. All three regions are able to localize to endocytic patches, but only one is able to partially restore endocytosis, suggesting Pan1 has an alternative essential role in the cell. Lastly, I will use Pan1-AID to identify Pan1's essential function.

A ROLE OF OCRL IN CLATHRIN-COATED PIT DYNAMICS AND UNCOATING REVEALED BY STUDIES OF LOWE SYNDROME CELLS.

R.L. Nandez¹, D.M. Balkin¹, M. Messa¹, L. Liang², S. Paradise³, H. Czapl¹, M.Y. Hein⁴, J. Duncan², M. Mann⁴, P. De Camilli⁵;

¹Cell Biology, Yale University School of Medicine/HHMI, New Haven, CT, ²Radiology, Yale University School of Medicine, New Haven, CT, ³Department of Cell Biology, Yale University, New Haven, CT, ⁴Proteomics and Signal Transduction, Max Planck Institute of Biochemistry, Martinsried, Germany, ⁵Department of Cell Biology, Howard Hughes Medical Institute, Program in Cellular Neuroscience, Neurodegeneration and Repair, Yale University School of Medicine, New Haven, CT

Loss of function mutations in OCRL, an inositol 5-phosphatase, are responsible for Lowe syndrome and type 2 Dent disease. OCRL has a widespread localization within cells, primarily in the endocytic pathway, including very late-stage clathrin-coated pits. However, the precise function of OCRL in the dynamics of endocytic clathrin coats remains unclear. Mass spectrometry proteomics of OCRL immunoprecipitates strongly emphasized a link of the OCRL interactome to clathrin-dependent membrane traffic. Endocytic clathrin coat components revealed by this approach included SNX9, which we have found to be a novel direct interactor of OCRL. SNX9, which also interacts with clathrin and other endocytic factors, is implicated in the late stages of endocytosis. In Lowe Syndrome fibroblasts, which completely lack OCRL, we observed an increase in the number of endocytic clathrin-coated pits and a significant delay in their turnover. We also found that many components of endocytic clathrin coats, including SNX9, clathrin and AP-2, accumulated on intracellular vesicles nucleating actin tails, which have been previously described

as a hallmark cellular phenotype of Lowe syndrome fibroblasts. Expression of GFP-OCRL in patient cells reversed these phenotypes, while a catalytically inactive GFP-OCRL accumulated at both endocytic clathrin-coated pits and at the head of actin tails, indicating the dependence of tails on abnormal and ectopic PI(4,5)P₂ accumulation. We established that at least a fraction of vesicles driving tail nucleation originated from the plasma membrane, suggesting that they are clathrin-coated vesicles that failed to shed the clathrin coat. We had previously shown that the PI(4,5)P₂ phosphatase synaptojanin, the major inositol 5-phosphatase at the synapse, plays a major role in the uncoating of clathrin coated vesicles at synapses. The present study suggests that OCRL may participate in clathrin uncoating during endocytosis in non-neuronal cells. Defects in clathrin-mediated endocytosis may contribute to the clinical manifestations of Lowe Syndrome.

PtdIns(4,5)P₂ homeostasis in endosomal trafficking is controlled by the Rab35 GTPase and the Lowe syndrome phosphatase OCRL.

A. Echard¹;

¹Institut Pasteur, Paris, France

The membrane phospholipid phosphatidylinositol 4,5-bisphosphate [PtdIns(4,5)P₂] is major regulator of actin dynamics and activates complexes involved in actin polymerization. Our laboratory has recently shown that the Rab35 GTPase recruits and directly interacts with the PtdIns(4,5)P₂ 5-phosphatase OCRL in late cytokinesis bridges during cytokinesis. This is essential for a normal abscission by preventing local PtdIns(4,5)P₂ and actin accumulation in the intercellular bridge connecting the daughter cells (1,2,3). Mutations in OCRL are responsible for the Oculo-Cerebro-Renal Syndrome of Lowe, a rare genetic disease characterized by renal proximal tubular dysfunction, which likely results from defects in the endosomal pathway (4). How OCRL is localized to endosomes remains a key question. Since the Rab35 GTPase is located on the endosomal system (1) we hypothesized that Rab35 may recruit OCRL on endosomes to prevent actin accumulation at their surface, by analogy with our results during cytokinesis. Remarkably, the levels of lysosomal enzymes in the plasma and urine are increased in Lowe patients, suggesting defects in the intracellular trafficking of the cation-independent mannose 6-phosphate receptor (CI-MPR) (4,5,6). Our study suggests that Rab35 critically controls the timing of OCRL recruitment on clathrin-coated endosomes, and is essential for PtdIns(4,5)P₂ hydrolysis and consequently normal trafficking in the endosomal system.

P1201**Board Number: B540****Cross-talk between clathrin-mediated and clathrin-independent endosomal membrane systems coordinated by Rab35 and Arf6.**D. Dutta¹, J.G. Donaldson¹;¹Cell Biology and Physiology Center, NIH/NLHBI, Bethesda, MD

Clathrin-mediated endocytosis (CME) and clathrin-independent endocytosis (CIE) occur in most cells raising questions as to whether the two processes are coordinately regulated. In HeLa cells, we have identified an elaborate endosomal sorting system that sorts CIE cargo proteins on endosomes that also contain CME cargo proteins. This led us to investigate whether trafficking of CIE cargo proteins would be affected when CME is blocked. Using different approaches of inhibiting CME, we found that when CME is blocked, endocytosis by CIE continues but the intracellular trafficking of CIE cargo proteins is altered. CIE cargo proteins that normally traffic directly into Arf6-associated tubules after internalization and avoid degradation (CD44, CD98 and CD147), now traffic to lysosomes and are degraded. The endosomal tubules are also absent and the cargo proteins now visit endosomes associated with EEA1 on their way to the lysosomes. The altered trafficking and loss of the tubular endosomal network caused by inhibition of CME was rescued by expression of Rab35, a Rab associated with clathrin-coated vesicles, or by expression of the Rab35 effector ACAP2, an Arf6 GAP that inactivates Arf6. Indeed, Arf6-GTP levels were elevated in cells where CME was inhibited but were subsequently lowered in cells expressing Rab35. The other Rab protein associated with tubular endosome formation, Rab22, or other effectors of Rab35 and Arf6, MICAL-L1 failed to prevent the mis-sorting of CIE cargo proteins in the absence of CME. These observations indicate that Rab35 and Arf6 activities must be carefully regulated on endosomes and this regulation may be mediated by the mutual antagonism of Rab35 and Arf6 in that they each recruit GAPs that inactivate the other. With Rab35 marking CME input, loss of CME and thus Rab35 leads to elevated Arf6-GTP and shifts the sorting of CIE cargo proteins to lysosomes and degradation.

P1202**Board Number: B541****FCHo2 regulates protein assembly and efficiency of clathrin-mediated endocytosis.**E. Evergren¹, H. McMahon¹;¹Medical Research Council Laboratory of Molecular Biology, Cambridge, England

Clathrin-mediated endocytosis is important for receptor uptake, synaptic vesicle recycling, virus internalisation and tissue morphogenesis. Many of the proteins interactions involved in clathrin coated vesicle formation are mediated by short linear interaction motifs (SLiMs). The presence of multiple motifs within intrinsically disordered regions (IDRs) and the self-polymerization of clathrin in turn provide an ability to build large complexes necessary for vesicle formation. This implies a dynamic

process involving the assembly but also exchange of interacting partners with a functional efficiency, as assessed by uptake of ligands and receptors, based on the stoichiometry of components within the network. Whilst this is an established principle underpinning signal transduction it is so far unexplored in understanding clathrin coat formation. We hypothesize that endocytosis can be altered either by effects on recruitment or on the stability of recruited complexes. In this study we focus on FCHo2 and comprehensively define the motifs regulating its association with interacting proteins, discovering three novel motifs which mediate the binding of clathrin, AP2, Eps15R, Eps15, epsin1, CALM and intersectin-1. We then study the impact of disrupting these interactions on important subcomplexes en route to functional endocytic uptake of transferrin. Disruption has two important phenotypic outcomes: separation of protein subcomplexes from each other, or coalescing subcomplexes into larger complexes that do not mature. Adaptor proteins AP2 and FCHo2 bind to overlapping motifs in Eps15 via weak affinity interactions, and interactions between Eps15-Eps15R-FCHo2-AP2 function cooperatively to strengthen the complex in network modules. By changing their concentration a significant impact was found both in complex formation, colocalisation in cells, and the efficiency of ligand uptake. On the basis of our findings, we propose a model where colocalisation and protein complex formation of high-avidity low-affinity interactions between clathrin, FCHo2, AP2, Eps15 and Eps15R are fundamental to establishing efficient maturation of clathrin-coated pits. These cooperative interactions are sensitive to protein concentration. In cell-lines with different endogenous expression levels this was reflected in efficiency of transferrin uptake. Our study highlights the importance of assessing the impact of targeting a single endocytic adaptor protein on network organisation and protein complex formation rather than a single endpoint phenotype. It is well known in cell signalling that construction of higher order complexes is instrumental in building dynamic and yet robust processes. Here we show that similar principles also apply to the efficient assembly of clathrin coats.

Identifying Small Molecule Inhibitors of Epsin-Mediated Cargo Internalization.

W. Hsieh¹, R. Aguilar¹;

¹Department of Biological Sciences, Purdue University, West Lafayette, IN

The Notch Signaling Pathway is involved in several essential functions, such as tissue development and renewal. Misregulation of the pathway leads to a variety of diseases, including developmental syndromes and Cancer. Epsin (Epn), an endocytic adaptor, mediates the internalization of notch ligands, (e.g., Delta: DLL1), which is the crucial step to trigger the activation of the notch signaling pathway. Therefore, epn-mediated cargo internalization is a suitable target for therapeutic development. The goal of this project is to identify compounds that interfere the internalization of notch ligand by epn. We have recently identified a motif responsible for Epn-specific recognition of the yeast Na-transporter ENa1. This motif is bound by Epn via conserved determinants, and homologous motifs were found in known human Epn cargoes such as DLL1. Importantly, the DLL1 motif was able to mediate the epn-dependent internalization of ENa1 when inserted in the transporter sequence. Therefore, we developed

a highly efficient and low cost FACs based compound screening system in *Saccharomyces cerevisiae*. Briefly, since the vesicles containing internalized ENa1-GFP fuse with the lysosome/vacuole and the cargo is degraded, decrease of cell-associated GFP fluorescence under promoter repression conditions reports the levels of cargo internalization. Using cell sorting we compared the proportion of cells with low-mid-high fluorescence intensity in samples exposed to vehicle and compounds from a library of pharmacologically active compound (LOPAC). This strategy led to identify 44 compounds with negligible toxicity and potential activity against ENa1-DLL1 internalization (interestingly, we also found 33 candidates capable of enhancing cargo internalization). We are currently elucidating the mechanism by which the candidate compounds inhibit Ena1 internalization. We anticipate that these results will allow us to establish the foundations for developing therapies against diseases caused by misregulation of the Notch signaling pathway.

Loss of adaptor protein-3 complex leads to defective Vangl2 trafficking and disruption of planar cell polarity and convergent extension.

C.D. Tower-Gilchrist¹, S. Zlatic², Q. Chang³, V. Faundez⁴, E. Lin⁵, P. Chen²;

¹Department of Cell Biology, Emory University School of Medicine, Atlanta, GA, ²Department of Cell Biology, Emory University, Atlanta, GA, ³Otolaryngology, Emory University School of Medicine, Atlanta, GA, ⁴Emory University, Atlanta, GA, ⁵Otolaryngology and Cell Biology, Emory University, Atlanta, GA

Planar cell polarity (PCP) regulates coordinated orientation of cells along an axis parallel to the plane of the epithelium. It is critical in development and tissue function. Defects in PCP result in a range of developmental anomalies and diseases including disorganization of auditory hair cells in the sensory epithelium of the cochlea, deafness, neural tube closure defects, and cancer. PCP proteins are asymmetrically sorted across the planar polarity axis in the mammalian inner ear which plays a crucial role to regulate coordinated hair cell polarity and cochlear duct extension. However, the molecular mechanisms that regulate the asymmetric localization of several essential PCP transmembrane proteins remain largely unknown. To elucidate the underlying mechanisms for Vangl2 asymmetric membrane partition and dissect its role in PCP signaling, a 2-hybrid screen was performed to identify novel Vangl2-interacting proteins. From this screen, an adaptor protein (AP) component, u2 was identified as an interacting protein with Vangl2. Co-immunoprecipitation and co-localization experiments were performed and confirmed a biochemical interaction between Vangl2 with AP-2, as well as with AP-3. These adaptor proteins complexes are known to be associated with vesicles along the endocytic route. The biochemical association of Vangl2 with AP-2 and AP-3 suggest that Vangl2 may be an AP cargo that traffics through the endosomal pathways. Live imaging revealed that Vangl2 is indeed associated with early and recycling endosomes as evident by co-localization with Rab5 and Rab21, as well as Rab11 and Rab4, respectively. Furthermore, Vangl2 membrane targeting is inhibited in cells treated with inhibitors that block early and recycling endosomal pathways. In AP-3 depleted cells, Vangl2 localization is disrupted and Vangl2 is no longer enriched at cell membrane. We examined the distribution of a core

PCP protein, Fz3 and discovered reduced membrane localization of Fz3 in mocha mice, which are AP-3 deficient. We observed the presence of additional rows of hair cells in the basal turn and length of the cochlea suggesting convergent extension deficits. Vestibular analysis of mocha animals revealed a disruption in polarity in hair cell orientation in the posterior cristae. Mocha mice are deaf and balance deficient which is consistent with the morphological abnormalities. These findings strongly suggest that AP-3 mediated endosomal pathways are essential for the membrane targeting of core PCP proteins. In vivo studies will be further employed to determine whether the asymmetric localization of Vangl2 is dependent upon AP-2 and/or AP-3 mediated endosomal pathways.

Acute regulation of blood-brain barrier glucose permeability.

O. Ojelabi¹, A. Carruthers¹;

¹Department of Biochemistry and Molecular Pharmacology, UMass Medical School, Worcester, MA

The human brain uses glucose as its major energy source, consuming up to 75% of total daily glucose intake. The blood-brain barrier (BBB), however, forms a permeability barrier that prevents simple diffusion of substrates from blood circulation into the brain. Thus, glucose must be transported across the BBB endothelial cells (ECs) by the glucose transporter, GLUT1. Misregulation of BBB GLUT1 expression or function results in severe cognitive and developmental disorders. Until recently, BBB ECs were viewed as a passive conduit for the uptake of glucose into the brain, with GLUT1 expressed predominantly at luminal and abluminal cell surfaces to facilitate trans-cellular glucose transport. Our lab has recently shown that AMP-activated protein kinase (AMPK) mediates the acute regulation of GLUT1-dependent sugar transport in brain microvascular ECs. Acute AMPK activation increases cell surface localization of GLUT1, and glucose transport, without increasing total GLUT1 mRNA or protein expression. This suggests that AMPK controls GLUT1 trafficking between intracellular and cell surface membranes. We want to understand how AMPK regulates GLUT1-mediated glucose transport in BBB ECs. To accomplish this, we are using a reversible cell surface biotinylation technique to study the kinetics of GLUT1 trafficking in the presence or absence of AMPK activation. This will reveal whether GLUT1 endocytosis or exocytosis is controlled by AMPK and will aid in the identification of downstream signaling partners mediating AMPK regulation of GLUT1 trafficking. Our preliminary data in basal, murine brain endothelial (bEnd.3) cells show that approximately 3% of plasma membrane GLUT1 and transferrin receptor (TfR) is internalized over 20 minutes at 37°C, whereas cell surface Na-K ATPase is not internalized. Conversely, we observe up to 70% net internalization of TfR in HEK-293 cells after a 20-minute incubation at 37°C. GLUT1 expression in HEK-293 cells is very low, so we plan to investigate GLUT1 trafficking using HEK-293 cells stably expressing human GLUT1. Future studies will address whether the low net internalization of GLUT1 and TfR in control bEnd.3 cells reflects low unidirectional internalization or rapid re-externalization of internalized GLUT1 and TfR. We will also determine how AMPK activation affects the rate constants for GLUT1 and TfR endocytosis and exocytosis, and the signaling pathway involved in this process. Findings from this study will provide fundamental insights

into cerebral glucose transporter misregulation in diseases and may reveal mechanisms for pharmacologic manipulation of the BBB permeability.

¹Neurobiology and Anatomy, University of Texas Health Science Center at Houston, Houston, TX,

²University of Texas Graduate School of Biomedical Sciences at Houston, Houston, TX, ³Department of Pediatrics, Section of Hematology-Oncology, Baylor College of Medicine, Houston, TX, ⁴Cancer and Hematology Centers, Texas Children's Hospital, Houston, TX, ⁵Pediatrics, M.D. Anderson Cancer Center, Houston, TX

The function of plasma membrane proteins may be tuned by altering their residence time on the plasma membrane and their transit time in the endocytic pathway prior to lysosomal degradation. Ubiquitin modification ensures recognition and association of membrane proteins with endosomal protein complexes that mediate the sorting of proteins to be degraded from those to be recycled. The precise nature of coordination between the cellular machineries that govern ubiquitination and endosomal sorting is not well understood. Lack of a ubiquitin tag precludes epidermal growth factor receptor (EGFR) from being sorted into MVB internal vesicles, and therefore from lysosomal targeting and degradation. While ubiquitination of EGFR may occur early in the endocytic pathway at or near the plasma membrane, it is not sufficient to promote MVB sorting that leads to receptor degradation. We observed that an E3 ubiquitin ligase, UBE4B, associated with endosomes by binding directly to the ESCRT-0 component Hrs. We analyzed the mechanism by which UBE4B regulates the multivesicular body sorting, and ultimately degradation, of EGFR. However, UBE4B is not the only E3 ligase that is associated with endosomes and the ESCRT complexes, nor is it the only E3 ligase that affects the degradation of EGFR. Here we show that coordinated, sequential action of endosomally-associated E3 ligases contribute to the sorting and degradation of plasma membrane proteins that travel through the endocytic pathway.

RNF167 ubiquitinates Arl8b to control cargo trafficking to lysosomes.

S. Moon¹, J.B. Yoon¹;

¹Yonsei University, Seoul, Korea

Ubiquitination regulates a broad range of cellular processes, including endocytosis and endosome trafficking. A group of transmembrane RING finger proteins are localized to the endomembrane system

and are presumed to function as E3 ubiquitin ligases. To understand the function of these ubiquitin ligases, the identification of the substrates is of critical importance. Using proximity-directed biotin labeling technology, we devised an approach to identify substrates of a ubiquitin ligase. We applied this method to RNF167 and identified Arl8B as a potential substrate. We demonstrated that RNF167 ubiquitinates Arl8B at the lysine residue K141 and downregulates its expression. Overexpression of RNF167 caused delayed trafficking of EGF and dextran to lysosomes, indicating that RNF167 affected both receptor-mediated endocytosis and fluid phase pinocytosis. Coexpression of K141R mutant Arl8B abrogated inhibitory effects of RNF167 on cargo delivery to lysosomes, suggesting that RNF167 affected endosome trafficking by ubiquitination and subsequent degradation of Arl8B.

Towards Understanding Cell-Scale Spatiotemporal Dynamics of Intracellular Transport.

H. Lee¹, Q. Ba¹, G. Yang¹;

¹Carnegie Mellon University, Pittsburgh, PA

Intracellular transport is the process of distributing cargoes to specific destinations to meet the local metabolic and functional needs inside a cell. Given the dynamic and heterogeneous intracellular environment, a fundamental question regarding intracellular transport is how it is regulated to deliver the right cargo to the right place at the right time. So far, related studies have focused primarily on identifying and understanding the molecular machinery for transport of individual cargoes. However, the spatial and temporal control mechanism of intracellular transport, especially at the whole cell scale, remains poorly understood. To a great extent, this is due to the lack of methods for quantitative analysis of cell-scale spatiotemporal dynamics of intracellular transport. We propose an image based computational framework and related computational methods to characterize and analyze the cell-scale spatiotemporal dynamics of intracellular transport. We first developed an image processing technique to visualize the spatiotemporal dynamics of intracellular transport in an projected image. On top of that, machine learning techniques are used to identify patterns of the intracellular transport on the whole-cell scale. Specifically, we utilized the transport of fluorescently labeled lysosomes in BSC-1 cells as our model system. To mitigate the heterogeneity of cell shapes, micro-pattern contact printing technique were adapted to normalize cells into comparable conditions for systematic analysis. Our analysis revealed a few spatial patterns of lysosomal transport, suggesting the plausibility of global control mechanism on spatiotemporal distribution of lysosomes.

P1209**Board Number: B548****Mechanisms of membrane repair in polarized epithelia.**L. Tan^{1,2}, K.A. Toops^{1,3}, A. Lakkaraju^{1,2,3};¹Ophthalmology and Visual Sciences, University Wisconsin-Madison, Madison, WI, ²Pharmaceutical Sciences, University Wisconsin-Madison, Madison, WI, ³McPherson Eye Research Institute, Madison, WI

Maintenance of membrane integrity is critical for cell survival. Pore-forming toxins or the terminal complement complex C5b-9 create microlesions in membranes, leading to prolonged calcium influx and aberrant activation of signaling pathways that compromise cell function. Assembly of sub-lytic C5b-9 membrane attack complexes (MAC) on the plasma membrane of retinal pigment epithelial (RPE) cells contributes to the pathogenesis of age-related macular degeneration (AMD), the most common cause of irreversible blindness among older adults. Nucleated cells have multiple protective mechanisms to deal with sub-lytic MAC assembly including (i) expression of complement regulatory proteins such as CD59 to inhibit specific steps of MAC formation; (ii) elimination of assembled MAC by membrane shedding or by lysosomal degradation after endocytosis; and (iii) rapid resealing of membrane pores by the exocytosis of late endosomes and lysosomes. Here, we investigated which of these mechanisms operate in polarized monolayers of primary RPE using high-speed spinning disk and TIRF microscopy. Our data show that membrane integrity after sub-lytic MAC attack is maintained by the concerted actions of complement regulatory proteins and vesicle trafficking in the exocytic and endocytic routes. TIRF imaging using pHluorin-tagged constructs showed that synaptotagmin 7 participates in lysosome exocytosis after complement-mediated damage. We have previously demonstrated that lysosome exocytosis is predominantly basolateral in MDCK cells, due to the basolateral localization of syntaxin 4. In the RPE, syntaxin 4 is non-polar and as a result, lysosome exocytosis occurs both at the apical and basolateral domains. In RPE with lipofuscin bisretinoids or excess cholesterol, both of which are implicated in AMD pathogenesis, exocytic protective mechanisms are selectively impaired whereas endocytic mechanisms function efficiently. Cholesterol-mediated activation of acid sphingomyelinase in cells with bisretinoids induces microtubule acetylation, which interferes with the delivery of the GPI-anchored CD59 to the plasma membrane and inhibits lysosome exocytosis. Pharmacological inhibition of acid sphingomyelinase restores the protective mechanisms in cells with bisretinoids or excess cholesterol. Our studies provide insight into how membrane integrity can be compromised and restored in the face of multiple pathological insults in the RPE and suggest that precise organelle trafficking is critical for preventing chronic inflammation in the RPE and the retina.

P1210**Board Number: B549****Control of nutrient signaling and proteostasis by PI3K-C2-mediated PI(3,4)P2 synthesis.**A.L. Marat¹, W. Lo¹, V. Haucke¹;¹Leibniz Institut Fuer Molekulare Pharmakologie, Berlin, Germany

Eukaryotic cell function depends on a tight balance between biosynthetic growth promoting and degradative pathways. The mTOR pathway integrates signals elicited by growth and differentiation factors with the sensing of amino acids to promote protein synthesis and cell growth, while inhibiting lysosomal protein turnover and autophagy. Activation of mTOR signaling among other factors involves stimulation of class I phosphatidylinositol 3-kinase to synthesize phosphatidylinositol 3,4,5-trisphosphate [PI(3,4,5)P₃], which activates Akt to promote S6 kinase-mediated regulation of translation and shutdown of autophagy by phosphorylation of ULK1, as well as the nutrient stimulated generation of PI3P via the class III PI 3-kinase mVps34. How mTOR signaling is inactivated following nutrient and growth factor deprivation and whether and how this process is regulated by phosphoinositides is unknown. Here we identify class II phosphatidylinositol 3-kinase C2 (PI3K-C2) as a novel negative regulator of mTORC1 signaling. Depletion of PI3K-C2, an enzyme that specifically synthesizes phosphatidylinositol-3,4-bisphosphate [PI(3,4)P₂], promotes mTORC1 signaling and causes the dispersion and functional inactivation of LAMP1-positive late endosomes and lysosomes. This phenotype is rescued by co-depletion of the GTPase Arl8 or its effector SKIP, factors that crucially regulate lysosomal transport. Furthermore, there is a functional association of PI3K-C2 with the raptor subunit of mTORC1. Together, these data identify PI3K-C2-mediated PI(3,4)P₂ synthesis as a critical switch between growth promoting nutrient signals and lysosomal proteostasis, by negatively regulating mTORC1 signaling.

P1211**Board Number: B550****Ankyrin-B is required for directed cell migration and targeted recycling of β 1-integrin.**F. Qu¹, D.N. Lorenzo^{2,3}, V. Bennett^{4,5};¹Departments of Cell Biology and Biochemistry, Duke University, Durham, NC, ²Department of Biochemistry, Duke University Medical Center, Durham, NC, ³Howard Hughes Medical Institute, Durham, NC, ⁴Department of Biochemistry, Duke University, Durham, NC, ⁵Howard Hughes Medical Institute, Duke University, Durham, NC

Directed intracellular organelle transport is essential for many cellular processes, including cell migration. In migrating cells, the continuous recycling of β 1-integrin between plasma membrane and intracellular compartments facilitates cell adhesion and cell motility events. Ankyrin-B was recently

shown to promote microtubule-based multi-organelle transport by coupling dynactin to intracellular organelles through PIP3P. Here we report that ankyrin-B regulates the dynamic transport of β 1-integrin in mouse embryonic fibroblasts (MEF). We found that ankyrin-B null (AnkB^{-/-}) fibroblasts exhibited a ~50% delay in wound closure and deficits in directional cell migration on fibronectin substrates that were independent of alterations in the organization of the actin and microtubule-based cytoskeleton. Interestingly, loss of ankyrin-B resulted in disruption of β 1-integrin recycling to the plasma membrane and in accumulation of large intracellular β 1-integrin aggregates. To get a mechanistic insight into the role of ankyrin-B in promoting β 1-integrin recycling, we performed a series of structure-function studies by expressing ankyrin-B proteins lacking key residues or domains in ankyrin-B null MEFs. We show that the deficits in β 1-integrin recycling were fully rescued by expression of wild-type 220-kDa ankyrin-B or DAR975AAA ankyrin-B lacking β 2-spectrin-binding activity, and only partially restored by DD1320AA ankyrin-B lacking dynactin-binding activity. Surprisingly ankyrin-B proteins lacking the death domain completely lost their ability to localize to β 1-integrin positive compartments and failed to rescue β 1-integrin recycling. The death domain is highly conserved among members of the ankyrin family in different species but its function remains unknown. We demonstrate that ankyrin-B regulates the targeted trafficking of β 1-integrin and potentially other cargoes through a dynactin-dependent step working in concert with the heretofore uncharacterized death domain.

Polymerization of Clathrin by Ent5 Regulates the Timing of Maturation of Clathrin Coated Vesicles.

C. Hung¹, M. Duncan²;

¹biology, University of North Carolina, Chapel Hill, NC, ²Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

Membrane traffic is an essential cellular process that delivers proteins and lipids to the right cellular compartments. Many protein cargos are delivered by clathrin coated vesicles (CCVs). The recruitment of clathrin to membranes is regulated by clathrin adaptors, which bind to lipids and cargo. Recruitment of clathrin by adaptors is thought to be sufficient for clathrin assembly. At the TGN and endosomes, two adaptors Gga2 and Ent5 bind directly to clathrin and also one another. These adaptors undergo stereotypical recruitment dynamics, where Gga2 always precedes Ent5. It is unclear why, if clathrin assembly only requires clathrin recruitment, Gga2 structures never form and mature in the absence of Ent5. Here we report that Ent5 clathrin binding is important for the maturation of Gga2 containing clathrin coats, thus preventing coats from maturing without Ent5. We find that Gga2 binds cooperatively to Ent5 and to clathrin. Clathrin binding stabilizes the interaction between Ent5 and Gga2. However, the interaction of Ent5 with clathrin but not with Gga2 is important to stabilize Ent5 at membranes. This finding suggests that direct interaction between Gga2 and Ent5 is not important for Ent5 recruitment. Similarly, Ent5 fails to co-purify with clathrin vesicles when Ent5 cannot bind to clathrin, suggesting that the interaction with clathrin is required for Ent5 to be incorporated into vesicles. Using time-lapse

microscopy, we demonstrate that when Ent5 is unable to bind to clathrin, the lifespans of Gga2 containing structures are prolonged and the recruitment of Ent5 is delayed significantly. This mutation causes a defect in the traffic of Chs3 at TGN and endosomes, indicating the delay is functionally important. Our findings suggest that the interaction between Ent5 and clathrin is the key for clathrin to polymerize into coated structures. We propose that the interaction between Ent5 and clathrin is an important check point for vesicle formation at TGN and endosomes. This interaction ensures that CCVs form in timely manner.

Macropinosome-lysosome fusion is a clathrin dependent process in bone marrow derived macrophages.

N.W. Thiex¹, L. Huang², J. Lou², H. Abdeljalil¹, G.P. Thompson¹, A.D. Hoppe²;

¹Biology and Microbiology, South Dakota State Univ, Brookings, SD, ²Chemistry and Biochemistry, South Dakota State Univ, Brookings, SD

Macrophages nonspecificly take up extracellular fluids, solutes and macromolecules by macropinocytosis. Understanding the mechanisms of macropinosome maturation will inform the study of lipid uptake, viral entry, antigen processing and presentation, as well as regulation of cell growth. Recently, we demonstrated that colony stimulating factor-1 receptor (CSF-1R) is internalized by small vesicle endocytosis, trafficked to nascent macropinosomes and degraded. These CSF-1R positive macropinosomes mature through a sequence similar to endosomes, progressing from EEA1 and Rab5 to Rab 7 positive vesicles before fusing with lysosomes. Here we report the assembly of large clathrin rings on internalized macropinosomes shown both by live-cell microscopy of clathrin light chain-yellow fluorescent protein (CLTA-YFP) overexpression and by immunostaining of endogenous clathrin heavy chain (CHC). Partial depletion of the clathrin heavy chain by siRNA prevented macropinosome-lysosome fusion and impaired degradation of the CSF-1R, with only minimal effects on the delivery of the CSF-1R to the macropinosome. Immunofluorescence staining of endogenous proteins demonstrates that clathrin assembled on macropinosomes co-localizes with the CSF-1R as well as ESCRT-0 member HRS, and homotypic fusion and protein sorting (HOPS) complex member VPS 39. These data indicate a novel role for clathrin in mediating macropinosome maturation and macropinosome lysosome fusion in macrophages.

P1214**Board Number: B553****Transport of the Macrophage Colony Stimulating Factor 1-Receptor into the Lumen of Macropinosomes.**L. Huang¹, N.W. Thiex², A.D. Hoppe¹, J. Lou¹;¹Chemistry and Biochemistry, South Dakota State Univ, Brookings, SD, ²Biology and Microbiology, South Dakota State Univ, Brookings, SD

The colony stimulating factor-1 receptor (CSF-1R) is a single pass type 1 membrane receptor. Upon ligand binding, it is internalized via small vesicles that are subsequently transported to macropinosomes in macrophages and is rapidly degraded. Using immunostaining against the both the N-epitope and C-epitope of CSF-1R, we demonstrate that upon arrival at the macropinosomes, CSF-1R is transported to the lumen of macropinosomes via a processes consistent with intraluminal budding. Hrs, a key member of the Endosomal Sorting Complex Required for Transport (ESCRT), co-localized with the CSF-1R on macropinosomes during this time. Furthermore, the ubiquitin ligases Cbl and Cbl-b were required for efficient transport of the CSF-1R to the macropinosomes and rapid co-localization with Hrs. Surprisingly, Cbl and Cbl-b are not required for CSF-1R degradation. In primary bone marrow macrophages derived from Cbl/Cbl-b double knock out animals, CSF-1R degradation takes place in a non-macropinosome derived compartment. In conclusion, targeting of the CSF-1R to macropinosomes via ubiquitination by Cbl and Cbl-b followed by Hrs assembly on macropinosomes leads to the rapid degradation of activated CSF-1R and mediates an important deactivation step in CSF-1R signal transduction.

P1215**Board Number: B554****The Legionella pneumophila effector protein LegC7 alters yeast endosomal trafficking.**K. O'Brien¹;¹Microbiology, University of Georgia, Athens, GA

Legionella pneumophila are obligate intracellular pathogens that invade environmental amoebae as well as human alveolar macrophages resulting in the severe form of pneumonia known as Legionnaires' disease. In order to avoid lysosomal degradation, Legionella secretes a large number of effector proteins via a Type IVb secretion system into the host; some of these proteins manipulate a myriad of host membrane trafficking events to create the membrane-bound replicative niche, termed the Legionella-containing vacuole (LCV). Using the model system, Saccharomyces cerevisiae, we seek to define the effects and targets of one such effector protein, LegC7, previously shown to be toxic when expressed in yeast and causing an apparent Class E vacuolar protein sorting phenotype. In this work, we identify a point mutant in the second coiled coil domain of LegC7 that results in greatly decreased toxicity, indicating that the second coiled coil domain of LegC7 is crucial for either target binding or

proper protein folding. We also show that LegC7 disrupts vacuolar delivery of both biosynthetic and endocytic cargo yet does not disrupt endosome-independent pathways to the yeast vacuole. Furthermore, we demonstrate that a deletion of the ESCRT-0 complex member VPS27 causes a partial reversal of LegC7 toxicity; no other mutations of ESCRT pathway components display a similar phenotype. Taken together, we hypothesize that LegC7 functions to directly manipulate endosomal maturation in host cells, which could be exploited by the bacterium to help prevent phagosome-lysosome fusion during infection.

Inducible expression of MCOLN2 in immune cells.

L. Sun¹, s. vergarajauregui¹, r. Puertollano¹;

¹NHLBI, National Institutes of Health, Bethesda, MD

Mucolipins (or TRPMLs) constitute a family of endosomal cation channels with homology to the transient receptor potential superfamily. In mammals, the mucolipin family includes three members, mucolipin-1, -2, and -3 (MCOLN1-3). MCOLN1 and -3 have been well characterized. However, the cellular function of MCOLN2 remains elusive. Consistent with the proposed role of MCOLNs in Ca²⁺-dependent membrane trafficking, we have previously described that recombinant MCOLN2 enhances recycling of internalized GPI proteins back to the cell surface in HeLa cells. To further corroborate MCOLN2 function in a more physiologically relevant cell type, we analyzed MCOLN2 expression in a series of mouse tissues and organs by RT-PCR. We found that MCOLN2 was expressed predominantly in lymphoid and kidney organs. Notably, expression of MCOLN2 was tightly regulated at the transcriptional level. While MCOLN2 was present at low levels in resting RAW 264.7 macrophages, its expression was induced over 10 fold in response to Toll-like Receptors (TLRs) activation. In contrast, the levels of MCOLN1 and MCOLN3 did not change upon TLR activation. To confirm the upregulation of MCOLN2 in response to TLR activation in primary cells we isolated bone marrow macrophages, alveolar macrophages, and microglia from mice and treated them with a panel of TLR activators, including Zymosan (TLR2 ligand), PolyIC (TLR3 ligand), LPS (TLR4 ligand), R-848 (TLR7/8 ligand), and Imiquimod (TLR7 ligand). In all cases, we observed a significant increase in the levels of MCOLN2 upon TLR activation as assessed by RT-PCR, western-blot, and immunofluorescence. Endogenous MCOLN2 co-localized to perinuclear vesicles that also contain transferrin receptor and likely correspond to recycling endosomes. This is in clear contrast with MCOLN1 and MCOLN3 that mainly localize to the late and early endosomal pathway, respectively. Overall, our data reveal interesting differences in the regulation and distribution of the members of the MCOLN family and suggest a possible role of MCOLN2 in innate immune response.

P1217**Board Number: B556****Distinct Intracellular Trafficking Patterns of Host IgG by Herpes Virus Fc-Receptors.**B. Ndjamen¹, S.E. Fraser², P.J. Bjorkman^{1,3};¹Biology and Biological Engineering, California Institute of Technology, Pasadena, CA, ²Translational Imaging Center, University of Southern California, Los Angeles, CA, ³Investigator, Howard Hughes Medical Institute, Pasadena, CA

Members of both alpha and beta herpes viruses affects 50–98% of people around the world. They cause severe symptoms in congenitally infected newborns, a lifelong latent infection that is lethal in immunocompromised individuals, and are associated with several types of cancer. Human cytomegalovirus (HCMV) and herpes simplex virus type 1 (HSV-1) viruses express proteins (HCMV gp68 and gp34; HSV-1 gE-gI) that function as Fc receptors (FcRs) by binding to the Fc regions of human IgG. In addition to binding free IgG, these viral FcRs can bind to IgG complexed with an antigen to form an antibody bipolar bridged (ABB) complex. Although HCMV gp68 and HSV-1 gE-gI have an overlapping binding site on Fc, the finding that the gp68/Fc interaction is stable at pH values between 5.6 and 8.1 but that gE-gI binds only at neutral or basic pH suggests distinct pH-based downstream events after IgG is internalized via receptor-mediated endocytosis into intracellular compartments. Here we developed a cell-based in vitro model system to define the fates of ABB complexes formed by the two types of viral FcRs. We found that alpha (HSV-1) and beta (HCMV) herpes virus FcRs displayed distinct intracellular trafficking patterns to target internalized ligands: HSV-1 gE-gI dissociates from its IgG-antigen ligand in acidic endosomal compartments and recycles back to the cell surface, whereas HCMV FcRs (gp68) are transported together with IgG-antigen complexes to lysosomes for degradation. In both cases, anti-viral IgGs and their viral targets are selectively degraded, a potential immune evasion strategy allowing herpes viruses to escape from IgG-mediated immune responses.

P1218**Board Number: B557****Differential regulation of organelle dynamics by tubulin acetylation in polarized epithelia.**K.A. Toops^{1,2}, L. Tan^{1,3}, A. Lakkaraju^{1,2,3};¹Ophthalmology and Visual Sciences, University Wisconsin-Madison, Madison, WI, ²McPherson Eye Research Institute, Madison, WI, ³Pharmaceutical Sciences, University Wisconsin-Madison, Madison, WI

Intracellular trafficking is coordinated by the actin and microtubule cytoskeletons and associated motor proteins. Organelle-specific recruitment of motor proteins is accomplished in part by post-translational modifications of α -tubulin such as acetylation and detyrosination. Here, we used high-speed live imaging to monitor organelle dynamics in the prototypical polarized MDCK cell line and in adult primary retinal

pigment epithelial (RPE) monolayers. A key function of the RPE is the daily phagocytosis and degradation of shed photoreceptor outer segments, necessary for photoreceptor health and for vision. Over a lifetime, this high metabolic activity leads to the accumulation of visual cycle by-products called lipofuscin bisretinoids within the RPE endo-lysosomal system. Lipofuscin bisretinoids have been implicated in the pathogenesis of numerous retinal diseases including age-related macular degeneration, the most common cause of vision loss among older adults today. We have shown that bisretinoids trap cholesterol and bis(monoacylglycero)phosphate, an acid sphingomyelinase cofactor in RPE lysosomes. Acid sphingomyelinase activation increases cellular ceramide, which promotes tubulin acetylation on stabilized microtubules. Live imaging using spinning disc confocal microscopy revealed that long-range displacement of LC3-labeled autophagosomes and LAMP2-labeled late endosomes/lysosomes (LE/Lys) is significantly impaired in cells with abnormally acetylated microtubules. This results in incomplete autophagic flux and accumulation of canonical autophagic substrates. Calcium-induced fusion of LE/Lys with the plasma membrane is critical for membrane repair and removal of cellular debris. In RPE with lipofuscin bisretinoids or in MDCK with excess cholesterol, we observed decreased LE/Lys exocytosis after exposure to calcium ionophores or pore-forming toxins. Therefore, constrained LE/Lys trafficking due to tubulin acetylation interferes with both autophagy and membrane repair. Inhibition of acid sphingomyelinase decreased ceramide and acetylated tubulin levels, restored autophagy and LE/Lys exocytosis in RPE and MDCK cells. In contrast to its effect on LE/Lys and autophagosome motility, tubulin acetylation accelerated the trafficking of rab11-labeled apical recycling endosomes. This was associated with increased apical secretion of exosomes containing flotillin-1. Our data show that tubulin acetylation decreases transport of organelles in the degradative route and increases trafficking of organelles in the recycling route. Studies are currently underway to elucidate how selective recruitment of motors and scaffolding proteins drives organelle-specific motility in polarized epithelia and how this might contribute to disease processes.

Regulation of E-Cadherin Recycling by Discs Large (hDlg).

P. Massimi¹, L.M. Banks²;

¹Internatl Ctr Genetic Engrng/Biotechnol, Trieste, Italy, ²Tumour Virology, ICGEB, Trieste, Italy

E-cadherin is single pass type –I transmembrane glycoprotein that is localized to the adherens junction and basolateral membrane in epithelial cells and consists of a large extracellular domain, a transmembrane segment, and a conserved cytoplasmic domain. b-catenin is at the cytoplasmic site of the cell and binds to the intracellular domain of E-cadherin and is also complexed with a-catenin bound to actin. This adhesive pool ultimately links the cytoskeletal networks of adjacent cells, contributing to the maintenance of normal tissue architecture. The adhesive function of E-cadherin plays a vital role in epithelial physiology and changes in the level of cell-cell adhesion molecules are crucial for the development of aggressive carcinomas.

Control of epithelial architecture is a complex process involving also the coordinate activity of three multi-molecular signaling complexes: the Crumbs complex, the Par complex and the Scrib complex. The human hScrib complex consists of three proteins, hScrib, hDlg1 and Hugl-1, and loss of either Scrib or Dlg produces imaginal discs overgrowth and an invasive phenotype in *Drosophila*. In human cells, hScrib and hDlg1 appear to regulate important pathways governing cell polarity and cell attachment. Recently these proteins have been demonstrated to be involved in different signaling pathways and more interestingly also in vesicle trafficking inside the cell.

Since previous studies have demonstrated that perturbation of the scribe/hDlg module can impact negatively upon E-cadherin localization, we were interested in investigating how the hScrib/hDlg module affects E-cadherin trafficking. Using a variety of approaches we show that loss of hDlg results in a substantial decrease in membrane bound E-cadherin. Furthermore, this does not appear to be due by changes in the steady state levels of E-cadherin, but rather is a reflection of alteration in E-cadherin recycling. Current studies are focused on defining molecular mechanisms by which hDlg can modulate endosomal transport.

Board Number: B559

The cyclin-dependent kinase, Pho85/Cdk5 regulates the synthesis of the signaling lipid phosphatidylinositol 3,5 bis phosphate.

N. Jin¹, L.S. Weisman²;

¹Life Scis Inst and Departments of Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, ²Life Sciences Institute, University of Michigan, Ann Arbor, MI

Cyclin dependent kinases (CDKs) are key regulators of the cell cycle, cellular nutrient homeostasis, cell polarity and gene expression. Here we show an unexpected link between a CDK and an endosomal signaling lipid, phosphatidylinositol 3,5 bis phosphate (PtdIns(3,5)P₂). In *Saccharomyces cerevisiae*, PtdIns(3,5)P₂ is generated on endocytic organelles by the PtdIns(3)P 5-kinase, Fab1 and functions as a signaling molecule in multiple pathways including regulation of TORC1. PtdIns(3,5)P₂ is found in all eukaryotes and defects in its synthesis underlie multiple neurological diseases. Physiological signals cause rapid, and transient changes in PtdIns(3,5)P₂ levels. However, it was not known how the levels of PtdIns(3,5)P₂ are regulated during acute environmental change. Here we report results from a genetic screen for mutants defective in vacuole inheritance (*vac* mutant). Characterization of a subset of these mutants, as well as others, led to the discovery that the CDK, Pho85 and the cyclin, Pho80 are required for the acute elevation of PtdIns(3,5)P₂ upon hyper-osmotic shock. Pho85-Pho80 directly phosphorylate Fab1 and positively regulate the synthesis of PtdIns(3,5)P₂. Furthermore, we find that the phosphorylation of Fab1 may lead to a conformation change that activates its lipid kinase activity. Cdk5 and p35, mammalian homologue of Pho85 and Pho80, respectively, are particularly critical in neuronal physiology. Notably, we find that mammalian Fab1 (PIKfyve) is a direct target of Cdk5-p35 in tissue culture cells. Our studies reveal an upstream pathway that regulates the synthesis of PtdIns(3,5)P₂ through CDK and further show that this mechanism is conserved in yeast and mammalian cells.

P1221**Board Number: B560****Parkinson's Disease Causing Mutations Alters Retromer's Function.**J. Follett¹, S. Norwood¹, N. Hamilton¹, B. Collins¹, A. Bugarcic¹, R.D. Teasdale¹;¹Institute for Molecular Bioscience, University of Queensland, Brisbane, Australia

Mammalian Retromer is a protein complex composed of three proteins Vps26, Vps29 and Vps35, with an important role in the sorting and trafficking of transmembrane receptors within the endosome. The retromer complex forms a stable trimer, which associates with a range of other proteins, including sorting nexins (SNXs), which modulate its function. Recently, a pathogenic point mutation within the Vps35 subunit (D620N) was linked to the manifestation of Parkinson's disease (PD). Our initial characterization of the PD-linked Vps35 D620N mutant defined the impact this mutation has on Retromer's function in both model cell lines and fibroblasts isolated from a PD patient. Our recent work has focused on the contribution of retromer to cellular properties associated with PD including the formation of α -synuclein aggregates in neuronal cell lines which is increased when retromer levels are reduced in the cell. In addition, we have examined if other PD associated mutations within the three-retromer proteins have a detrimental effect on its function. For example, we find that expression of Vps35 R524W mutant disrupts the trafficking of cathepsin D, a CI-M6PR ligand and that this subunit is not able to efficiently interact with multiple sorting nexins.

P1222**Board Number: B561****Trafficking of moonlighting Glyceraldehyde-3-phosphate dehydrogenase to membrane and extracellular milieu is mediated via multiple non-classical secretory pathways.**A. Chauhan¹, H. Malhotra¹, N. Sheokand², M. Kumar¹, P. Jakhar¹, C. Raje³, M. Raje¹;¹Cell Biology and Immunology, Institute of Microbial Technology, Chandigarh, India, ²Cell Biology and Immunology, Inst Microbial Technology, Chandigarh, India, ³Biotechnology, National Institute of Pharmaceutical Education and Research, Mohali, India

Numerous pathological conditions like iron starvation, infection and cancer have been shown to be associated with the enhanced trafficking of the cytosolic moonlighting protein glyceraldehyde-3-phosphate dehydrogenase (GAPDH) to plasma membrane (PM) and also its secretion into extracellular milieu (ECM). One of its moonlighting functions at PM and in ECM involves the trafficking of the iron carrier proteins transferrin and lactoferrin into mammalian cells. However the exact molecular mechanism behind the recruitment of this cytosolic protein to PM and ECM is not known. In the current study we report that trafficking of GAPDH involves multiple pathways of non-classical protein secretion. Our results demonstrate that trafficking of GAPDH does not involve classical ER-Golgi pathway of protein

secretion as its presentation to the PM and ECM is not affected by brefeldin A. This finding is in accordance to the fact that GAPDH lacks any secretory signal. Further we report that enzymatically active GAPDH is secreted by cells in exosome free and exosome bound forms. Exosomes are nano vesicular structures enclosed in a larger assembly known as multivesicular bodies (MVBs). Presence of GAPDH inside the MVBs and exosomes was confirmed by co-localization confocal microscopy, western blotting and GAPDH specific enzyme activity. Modulation of the exosomal secretory pathway using pharmacological agents was shown to modulate GAPDH expression on PM and its release into ECM. We confirmed that GAPDH transport via this pathway accounts for 35% of the total secreted GAPDH. As an alternative pathway, we report that GAPDH trafficking also involves the secretory lysosomal pathway. We confirmed the presence of GAPDH in secretory lysosomes by confocal microscopy. Finally we confirmed the involvement of lysosomal secretory pathway in GAPDH trafficking to PM and ECM utilizing various small molecules like ATP, NH_4Cl , and MgCl_2 which affect lysosomal exocytosis. Translocation of GAPDH into these secretory lysosomes was found to be dependent on ABC transporters present in lysosomal membrane. Using live cell imaging and fluorescence recovery after photobleaching (FRAP) experiments we find that newly synthesized GAPDH is selectively recruited to the vesicles and these vesicles are transported towards the plasma membrane. Collectively our findings suggests for the first time that GAPDH is trafficked to PM and ECM via lysosomal and exosomal non-classical secretory pathways.

Lysosomal delivery modulates the toxicity of aminoglycoside antibiotics in mechanosensory hair cells.

D.W. Hailey¹, R. Esterberg¹, T. Linbo¹, E.W. Rubel¹, D.W. Raible¹;

¹University of Washington, Seattle, WA

The zebrafish lateral line system is a useful model for the study of mechanosensory hair cells. In the inner ear cochlea, hair cells detect mechanical stimulation caused by sound waves and convert physical movement into nerve impulses. These impulses are then conducted through the auditory system. Hair cell damage underlies the majority of hearing loss. While zebrafish do have an ear organ, they also have another sensory system that uses hair cells to detect external movements in their environment—the lateral line (LL). Many compounds known to cause hearing loss also kill lateral line hair cells. Unlike inner ear hair cells, LL hair cells are superficial and are therefore accessible and easy to observe. We have studied the response of LL hair cells to aminoglycosides—a family of antibiotics including neomycin and gentamicin that are well known to damage hearing. Here we look at how aminoglycosides enter LL hair cells, and identify trafficking events that modulate their hair cell toxicity. Aminoglycosides (AGs) can be fluorescently tagged without significantly altering their behavior. Fluorescent analogs of AGs reveal that initial AG loading occurs in the apical region of hair cells. This entry is gated by mechanotransduction (MET). Entry is blocked in both mutants that lack MET activity, and in wild type hair cells treated with known MET blocking agents like amiloride. AG entry can be perturbed by a diverse array of agents

including selective estrogen receptor modulators, a beta-adrenergic agonist, and quinoline ring derivatives. Most but not all AG uptake-blocking agents appear to act by altering MET activity. Following entry, aminoglycosides distribute into two visually distinct pools—a diffuse population present throughout the cell body, and bright membrane-bound punctae. Notably, AGs that rapidly kill hair cells distribute primarily to the diffuse pool. Those that kill hair cells more slowly distribute primarily to punctae. These punctae colocalize with lysosomal markers including Rab7 and LysoTrackers. Interfering with dynamin-dependent endocytic processes blocks the initial formation of punctae and increases the diffuse signal. However, slower lysosomal delivery still occurs through a pathway sensitive to 3-methyladenine treatment. Delaying lysosomal delivery of AGs increases aminoglycoside toxicity. Our trafficking studies indicate intracellular pools that differentially contribute to AG toxicity, and suggest that rapid damage from AGs likely comes from the diffuse pool, not the punctae. Delivery to the punctae may initially be cytoprotective by sequestering aminoglycosides. AG delivery to lysosomes can be monitored, and accelerating this delivery may provide a means to reduce the hair cell toxicity of AGs.

Spastic paraplegia proteins spastizin and spatacsin mediate autophagic lysosome reformation.

J. Chang¹, S. Lee¹, C.D. Blackstone¹;

¹NINDS, National Institutes of Health, Bethesda, MD

Autophagy allows cells to adapt to changes in their environment by coordinating the degradation and recycling of cellular components and organelles to maintain homeostasis. Lysosomes are critical organelles for terminating autophagy via their fusion with mature autophagosomes, generating autolysosomes that degrade autophagic materials. Therefore, maintenance of the lysosomal population is essential for autophagy-dependent cellular clearance. We demonstrate that the two most common autosomal recessive hereditary spastic paraplegia gene products, the SPG15 protein spastizin and SPG11 protein spatacsin, play pivotal roles in autophagic lysosome reformation (ALR), a pathway that generates new lysosomes. Lysosomal targeting of spastizin requires its intact FYVE domain, which binds phosphatidylinositol 3-phosphate. Moreover, loss of spastizin or spatacsin results in depletion of free lysosomes, which are competent to fuse with autophagosomes, as well as an accumulation of autolysosomes, reflecting a failure in ALR. Mechanistically, spastizin and spatacsin are essential components for the initiation of lysosomal tubulation. These findings uncover a specific link of the autophagy/lysosomal biogenesis machinery to neurodegeneration.

Niemann-Pick C disease (NPC) is a neurovisceral lipid storage disorder with a broad clinical spectrum typically comprising systemic dysfunction followed by variable onset of fatal, progressive neurodegeneration. NPC is transmitted in an autosomal recessive fashion by mutations in either *NPC1* or *NPC2* genes, which encode proteins thought to play a role in lysosomal export of free cholesterol. However, precise pathophysiological mechanisms are unclear, and no disease-modifying treatment exists. Here, we first provide a comprehensive lipidomic characterization of over 30 lipid subclasses including sterols, glycerolipids, glycerophospholipids, sphingolipids, and sphingoid bases in *Npc1*^{-/-} mice using state-of-the-art HPLC-coupled mass spectrometric analysis, unmasking heretofore undetected brain and liver lipid changes, most notably in dihydrosphingolipid metabolism. We further confirm these changes in U18666A drug-induced NPC1 models and in NPC1 patient-derived fibroblasts. Finally, we reverse a subset of sphingolipid changes through drug-induced stabilization of the retromer complex and then complement these findings with biochemical and confocal microscopy analyses. Hence, we provide new insight regarding the lipid pathways perturbed in NPC and offer evidence for a novel therapeutic strategy.

P1226**Board Number: B565****Characterization of human KCTD9: A novel autophagosome-associated protein.**F. Ladha¹, X. Teng¹, J. Hardwick¹;¹W. Harry Feinstone Department of Molecular Microbiology and Immunology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD

The human KCTD9 belongs to the K⁺ channel tetramerization domain-containing (KCTD) protein family and is an uncharacterized protein commonly deleted in cancers and proposed to mediate natural killer (NK) cell activation in chronic hepatitis B virus (HBV) infections. Our lab found the yeast homologue of the KCTD9, Whi2, is required to inhibit TOR kinase, and also required to activate autophagy. The KCTD/Whi2 proteins are very poorly studied, but contain a BTB domain and therefore have been proposed to act as adaptors for the E3 ligase Cullin-3, similar to other BTB-containing proteins. We sought to determine KCTD9's subcellular localization and its involvement in the autophagy pathway.

For the first time, we were able to confirm that KCTD9 forms cytoplasmic puncta, which localize to autophagosomes. KCTD9 puncta did not co-localize with endosomal markers, but specifically co-localized with autophagy proteins LC3, Vps34, and Atg5. In addition, KCTD9 associates to endoplasmic reticulum (ER) markers. These results suggest KCTD9 is a novel autophagosome-associated protein that potentially localizes to subdomains of the ER from which autophagosomes derive from. Further investigations will allow us to determine if KCTD9 plays a functional role in the autophagy pathway.

A unique PDZ domain and arrestin-like fold interaction reveals mechanistic details of endocytic recycling by SNX27-retromer.

M. Gallon¹, T. Clairfeuille², B.M. Collins², P.J. Cullen³;

¹University of Bristol, Bristol, United Kingdom, ²University of Queensland, Brisbane, Australia, ³School of Biochemistry, University of Bristol, Bristol, United Kingdom

The sorting nexin-27 (SNX27)-retromer is a major regulator of endosome-to-plasma membrane recycling of trans-membrane cargoes that contain a PDZ binding motif. Here we describe the core interaction in SNX27-retromer assembly and its functional relevance for cargo sorting. Crystal structures and nuclear magnetic resonance experiments reveal that an exposed β -hairpin in the SNX27 PDZ domain engages a groove in the arrestin-like structure of the VPS26A retromer subunit. The structure establishes how the SNX27 PDZ domain simultaneously binds PDZ binding motifs and retromer-associated VPS26. Importantly, VPS26A binding increases the affinity of the SNX27 PDZ domain for PDZ binding motifs by an order of magnitude, revealing co-operativity in cargo selection. With disruption of SNX27 and retromer function linked to synaptic dysfunction and neurodegenerative disease, our work provides the first step in the molecular description of this important sorting complex, and more broadly describes a unique interaction between a PDZ domain and an arrestin-like fold.

Conformational changes in Ist1 lead to distinct modes of Vps4 regulation.

J.A. Tan¹, B.A. Davies², J.A. Payne², L. Benson³, B. Madden³, D.J. Katzmann²;

¹Biochemistry Molecular Biology, Mayo Graduate School, Rochester, MN, ²Mayo Clinic, Rochester, MN, ³Proteomics Core, Mayo Clinic, Rochester, MN

The Endosomal Sorting Complexes Required for Transport (ESCRTs) mediate membrane remodeling processes that bud vesicles away from the cytoplasm or that dissect membrane tubules from within the structures. ESCRT-III in particular has been implicated in this membrane remodeling. Disassembly of ESCRT-III by the AAA-ATPase Vps4 is required for ESCRT function, however it remains unclear how Vps4 activity is regulated to permit proper ESCRT-III function. Ist1 is unique among the ESCRT-III subunits in

that it is able of both inhibiting and stimulating Vps4 ATPase activity, suggesting Ist1 may be an important regulator of Vps4. We have characterized three distinct modes of Vps4 regulation by Ist1 in vitro: (1) hyper-stimulation requiring the Ist1 MIT-interacting motif 1 (MIM1) element, (2) a lower level of MIM1-independent stimulation, and (3) inhibition requiring both the MIM1 element and a highly conserved ELYC motif. Furthermore, using analytical gel filtration and limited proteolysis, we demonstrate that conformational changes in Ist1 impacts modes of Vps4 regulation. Finally, in vivo analyses in yeast support a functional role for the putative Ist1 inhibitory and stimulatory domains. These observations suggest that Ist1 regulation of Vps4 changes as Ist1 is recruited to the ESCRT-III polymer and conformational changes occur.

Tracking Incipient Functional Diversification in the Rab GTPase Gene Family.

L.J. Bright¹, M. Lynch¹;

¹Department of Biology, Indiana University, Bloomington, IN

As membrane trafficking determinants, Rab GTPases drive fusion between subcellular compartments in a highly specific manner. As a result, during eukaryotic evolution, Rab duplication and diversification have paralleled the elaboration of trafficking pathways. While the most conserved Rabs appear to have conserved functions across all eukaryotic species, others are quite plastic, diversifying rapidly in different lineages. In an effort to understand both the biochemical and evolutionary sources of Rab plasticity, we are combining the wealth of existing structure-function data from previous Rab biochemical studies with sequence information and localization data from a large closely-related species complex of unicellular ciliates, the *Paramecium aurelias*. First, we have identified a subset of ciliate Rabs that are highly structurally conserved, particularly in key effector binding domains, when compared by homology modeling to crystal structures of orthologous human, mouse or yeast Rabs. These structurally conserved ciliate Rabs also share identical localization patterns with their orthologs, despite being only ~50% identical in amino acid sequence. Second, we have identified a set of ciliate Rabs that appear to be undergoing incipient diversification, i.e. they fall within conserved subfamilies phylogenetically, and have retained the conserved Rab backbone structure, but appear to be undergoing large conformational changes in their effector binding regions. We are in the process of localizing these putatively diversifying Rabs; preliminary work suggests that they now localize to new or different trafficking pathways when compared to more conserved Rabs in the same subfamily. By examining the nature of these modeled binding domains, and the amino acid changes that have accompanied them on a large scale (across 15 species and in several different subfamilies), we aim to better understand the 'rules' for Rab plasticity, and how they are able to bind new effectors and occlude others in the process of switching to new trafficking pathways in the cell.

P1230**Board Number: B569****The ER-resident Rab8A GTPase is involved in the trafficking of surface proteins necessary for phagocytosis in the enteric protozoan parasite *Entamoeba histolytica*.**Y. Hanadate^{1,2}, K. Nakada-Tsukui¹, T. Nozaki^{1,2}, Y. Saito-Nakano¹;¹National Inst Infectious Diseases, Tokyo, Japan, ²University of Tsukuba, Ibaraki, Japan

The phagocytosis is initiated by the specific recognition and attachment of ligands via plasma membrane receptors. During maturation, series of intracellular compartments, such as the ER, endosomes, and lysosomes, are associated with phagosomes. Engulfed particles are then subsequently degraded by the specific hydrolases. In these events, Rab GTPases play pivotal roles in membrane fusion and regulated transport. *Entamoeba histolytica*, an intestinal protozoan parasite, engulfs bacteria and host cells. Thus, phagocytosis is indispensable for the pathogenesis of *E. histolytica*. Interestingly, *E. histolytica* codes more than 100 Rab genes in their genome, whereas *Homo sapiens* possesses around 60 Rab genes despite of their multicellularity. Biological functions of most of Rab GTPases are still poorly understood in *E. histolytica*.

In our previous phagosomal proteome analysis, we identified 14 Rab proteins from the amoebic phagosomes. Among them, a homologue of Rab8, which plays a role in trafficking from the trans-Golgi network to the plasma membrane in other organisms, was isolated. This work is the first report that Rab8 participates in phagocytosis. First, small antisense RNA-mediated transcriptomic gene silencing (gs) was used to examine the physiological role of EhRab8A in phagocytosis. Down-regulation of EhRab8A caused remarkable reduction in phagocytic efficiency of erythrocytes, bacteria, and carboxylated latex beads. This was attributable to the reduced efficiency of adhesion to targets. Surface-biotinylation showed that the presentation of several surface proteins that may be involved in recognition of targets was reduced in EhRab8A-gs strain compared to the wild-type. Upstream of Rab8 lies the guanine nucleotide exchange factor (GEF), Rabin8, which is also identified as Rab11 effector in *Homo sapiens*. Thus, the colocalization of Rab11 and Rab8 in the recycling endosomes was often reported in other organisms. However, in *Entamoeba*, EhRab8A was not colocalized with EhRab11B, a representative isotype of four Rab11 proteins. Instead, EhRab8A was localized to the proximate region of the ER in the steady state. Accordingly, EhRab8A might have role in independent pathway from EhRab11B. These results indicate that EhRab8A regulates the receptor sorting at proximate region of the ER to the plasma membrane.

P1231**Board Number: B570****Rab32 is Essential for Maintaining Functional Acidocalcisomes and for Growth and Virulence of *Trypanosoma cruzi*.**S. Niyogi¹, R. Docampo², V. Jimenez³;¹Cellular Biology, University of Georgia/CTEGD, Athens, GA, ²Center for Tropical and Emerging Global Diseases and Department of Cellular Biology, University of Georgia, Athens, GA, ³California State University, Fullerton, CA

Trypanosoma cruzi, the causative agent of Chagas disease, is a unicellular parasite that possesses a contractile vacuole complex (CVC) which consists of a bladder and a loose network of interconnected tubules known as the spongiome. Similar to its role in free-living protists where the CVC is usually present, this organelle in *T. cruzi* also plays a vital role in the regulation of the cell volume and in the response to osmotic stresses in all the life stages of the parasite. In addition, we recently reported a role for the CVC in trafficking of glycosyl phosphatidylinositol (GPI)-anchored proteins to the plasma membrane. When performing the proteomic analysis of the CVC of *T. cruzi* we detected the presence of Rab32 (TcRab32) in addition to several other proteins involved in vesicle trafficking and fusion activities. Mammalian Rab32 is involved in the biogenesis of lysosome-related organelles (LRO) and as LROs of human platelets and mast cells, acidocalcisomes (ACCs) have rounded morphology, are acidic, and rich in calcium, pyrophosphate (PPi) and polyphosphate (polyP). Therefore we investigated whether TcRab32 is involved in the transport of membrane proteins to the ACC. In this study we report that similar to most Rab-GTPases, TcRab32 is geranylgeranylated and also confirm its localization to the CVC. A dominant negative mutant tagged with GFP (GFP-TcRab32DN) localizes to the cytosol, and epimastigotes expressing this mutant have a defect in growth and in their ability to respond to osmotic stress conditions. Mutant parasites are still able to differentiate into metacyclic forms and infect host cells but they are less virulent than wild type cells. Parasites expressing GFP-TcRab32DN have ACCs of altered morphology, which are deficient in pyrophosphate and polyphosphate. Acidocalcisomes are less electron-dense in mutant epimastigotes, fewer in number and have a defect in proton transport. Taking together these results reveal that TcRab32 is important for acidocalcisome function, suggesting its involvement in trafficking of membrane proteins to these organelles. As TcRab32 is a contractile vacuole resident protein, this study provides the long searched link between the contractile vacuole and the ACC further demonstrating the role of the CVC as a trafficking hub.

P1232**Board Number: B571****HCV Inhibits Lysosomal Fusion Through Suppression of a Rab7 Interacting Protein.**A.L. Wozniak¹, K.N. Jones-Jamtgaard², R. Ralston¹, S.A. Weinman¹;¹Internal Medicine, University of Kansas Medical Center, Kansas City, KS, ²Microbiology, Molecular Genetics, and Immunology, University of Kansas Medical Center, Kansas City, KS

Hepatitis C virus (HCV) modulates intracellular trafficking pathways to serve viral replication and particle production and to evade cellular antiviral responses. The mechanisms of how this occurs and its consequences are poorly understood. The aim of this study was to determine if HCV-induced defects in autophagy are due to changes in Rab GTPase function. We have previously shown that during HCV infection, flux through the autophagy pathway is greatly diminished compared to control cells. To determine if HCV suppressed autophagosome-lysosome fusion events, control and HCV-infected cells were transfected with tandem RFP-GFP-LC3, where the quenching of the GFP fluorescence indicates autophagolysosome formation. In HCV infected cells, there was no loss of GFP fluorescence from puncta indicating lack of fusion between autophagosomes and lysosomes. We next performed fusion assays with isolated subcellular organelles to assess whether lack of fusion was intrinsic to autophagosomes and lysosomes themselves. Vesicles isolated from HCV-infected cells fused with each other normally in this in vitro fusion assay suggesting that the cellular fusion defect resulted from trafficking rather than inability of vesicles to fuse. To test if there were effects on other trafficking steps, we assessed EGF-induced receptor degradation. HCV inhibited this endosome-lysosome fusion as well. Since Rab7 is involved in both fusion processes, we assessed the effect of HCV on Rab7-dependent processes. HCV infection of Huh7.5 cells caused a dramatic increase in Rab7 immunofluorescence without changing Rab7 protein or GTPase activity levels by western blot. This suggested conformation or binding partner changes in Rab7. HCV infection reduced the level of the Rab7 effector protein, Rab-interacting lysosomal protein (RILP) compared to control. Knockdown of RILP to a similar level produced by HCV suppressed EGFR degradation in a nearly identical fashion as HCV infection. In conclusion, HCV infection suppresses Rab7-dependent trafficking events due to a decrease in the Rab7 effector, RILP. Loss of RILP-dependent Rab7 function may be a mechanism by which HCV promotes its lifecycle or subverts antiviral mechanisms. Future studies will focus on defining alterations in the Rab7 complex and trafficking due to loss of RILP.

P1233**Board Number: B572****Starvation-induced phosphorylation of the exchange factor DENND3 by Unc-51-like kinases activates Rab12 inducing macroautophagy.**J. Xu¹, P.S. McPherson¹;¹McGill University, Montreal, QC

Unc-51-like kinases (ULKs) are the most upstream kinases in the initiation of autophagy, yet the molecular mechanisms underlying ULK function in autophagy are essentially unknown. By investigating two poorly characterized proteins, the guanine nucleotide exchange factor (GEF) DENN domain-containing protein 3 (DENND3) and its substrate, the small GTPase Rab12, we have now discovered a novel mechanism accounting for ULK function in autophagy. We demonstrate that both DENND3 and Rab12 play positive roles in starvation-induced autophagy. Furthermore, under starvation, ULK1/2 phosphorylates DENND3 at two sites, activating Rab12 through upregulation of DENND3 GEF activity. By binding to LC3 and associating with autophagosomes, active Rab12 facilitates autophagosome trafficking. Together, our data reveal a novel pathway from starvation-induced ULK signaling through DENND3 to Rab12-mediated membrane trafficking required for autophagy.

P1234**Board Number: B573****A Novel Rab10 Regulated Complex Essential for the Autophagic Engulfment of Lipid Droplets.**Z. Li¹, R. Schulze², H. Cao², M.A. McNiven²;¹Mayo Graduate School, Rochester, MN, ²Mayo Clinic, Rochester, MN

Autophagic digestion of lipid droplets (LDs) is a central mechanism by which cells catabolize lipids as an energy source. Currently, the mechanisms by which autophagosomes (APs) physically bind and envelope LDs for subsequent digestion are poorly defined. In this study we report that the small GTPase, Rab10, implicated previously in the Golgi to plasma membrane transport of nascent secretory cargo, plays an essential role in the autophagy of LDs in hepatocytes. We find that Rab10 activity is amplified significantly in cells stimulated to undergo autophagy, concomitant with an increased association of this GTPase to the LD-AP interface or "synapse". Importantly, disruption of Rab10 function by siRNA knock down or expression of a GTPase defective protein leads to LD accumulation. Finally, activation of Rab10 during an autophagic stimulus increases its association with EHD2 and EHBP1, two effector proteins known to support membrane remodeling within the endocytic pathway. These proteins are recruited to the LD-AP synapse in a Rab10- dependent manner and are essential for autophagic-based LD breakdown. These findings identify a novel protein complex essential for the engulfment of LDs during the autophagic process.

P1235**Board Number: B574****Loss of Rab6 results in mis-sorting of Cathepsin D, impaired autolysosome function and defective nutrient sensing in the larval fat body of *Drosophila melanogaster*.**C.I. Ayala¹, T. Neufeld^{1,2};¹Genetics, Cell and Developmental Biology, University of Minnesota, Minneapolis, MN, ²Genetics Cell Biology and Development, University of Minnesota, Minneapolis, MN

Autophagy is a lysosome-dependent degradative pathway used by organisms to maintain quality control of organelles, proteins and energy homeostasis in cells. The pathway is negatively regulated by the mechanistic target of rapamycin (mTOR) under basal conditions, and requires elements of the Rab-dependent secretory pathway for autophagosome biogenesis and function. However, the interactions between autophagy, mTOR and Rab proteins remain incompletely understood *in vivo*. Here, we show that loss of Rab6 causes a development-dependent accumulation of autophagosomes, reduction in cell size and expansion of the lysosomal compartment. Characterization of these phenotypes revealed that they result primarily from mis-sorting of Cathepsin D from lysosomes, rendering them with a reduced degradative capacity upon autophagosome-lysosome fusion. This autolysosomal dysfunction leads to a defective recovery of mTOR activity, likely due to a reduced nutrient flux out of autolysosomes. Interestingly, these defects can be rescued by inactivation of the mTOR inhibitor PTEN, but not by re-feeding of exogenous nutrients nor constitutive activation of amino acid signaling, indicating an additional novel role for Rab6 in regulation of the mTOR signaling axis. Our findings suggest that loss of Rab6 interferes with the reciprocal regulation between autophagy and mTOR during distinct nutrient conditions by affecting two distinct traffic routes.

P1236**Board Number: B575****Influenza A Virus Assembly Intermediates Fuse in the Cytoplasm.**S. Lakdawala¹, Y. Wu², P. Wawrzusin², A. Broadbent¹, J. Kabat³, E. Lamirande¹, E. Fodor⁴, N. Altan-Bonnet⁵, H. Shroff², K. Subbarao¹;¹Laboratory of Infectious Diseases, NIH/NIAID, Bethesda, MD, ²Section on High Resolution Optical Imaging, NIH/NIBIB, Bethesda, MD, ³Research Technologies Branch, NIH/NIAID, Bethesda, MD, ⁴Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom, ⁵NIH/NHLBI, Bethesda, MD

Reassortment of influenza viral RNA (vRNA) segments in co-infected cells can lead to the emergence of viruses with pandemic potential. Replication of influenza vRNA occurs in the nucleus of infected cells, while progeny virions bud from the plasma membrane. Rab11a-containing recycling endosomes have

been implicated in the transport of vRNA from the nucleus to the plasma membrane. However, the intracellular dynamics of vRNA assembly into progeny virions is not well understood. Here we used recent advances in microscopy to explore vRNA assembly and transport during a productive infection. We visualized four distinct vRNA segments within a single cell using fluorescent in situ hybridization (FISH) and observed that foci containing more than one vRNA segment were found at the external nuclear periphery, suggesting that vRNA segments are not exported to the cytoplasm individually. Although many cytoplasmic foci contain multiple vRNA segments, not all vRNA species are present in every focus, indicating that assembly of all eight vRNA segments does not occur prior to export from the nucleus. To extend the observations made in fixed cells, we used a virus that encodes GFP fused to the viral polymerase acidic (PA) protein (WSN PA-GFP) to explore the dynamics of vRNA assembly in live cells during a productive infection. Since WSN PA-GFP colocalizes with viral nucleoprotein and influenza vRNA segments, we used it as a surrogate for visualizing vRNA transport in 3D and at high speed by inverted selective-plane illumination microscopy. We observed cytoplasmic PA-GFP foci colocalizing and traveling together en-route to the plasma membrane. Our data strongly support a model in which vRNA segments are exported from the nucleus as complexes that assemble en-route to the plasma membrane through dynamic colocalization events in the cytoplasm.

ER-coordinated activities of Rab22a and Rab5a drive uptake, endosomal compaction and intracellular processing of *Borrelia burgdorferi* by primary human macrophages.

S. Linder¹, X. Naj¹;

¹Inst. for Medical Microbiology, University Medical Center Eppendorf, Hamburg, Germany

Borrelia burgdorferi is the causative agent of Lyme disease, a multisystemic disorder affecting primarily skin, joints and nervous system. Macrophages and dendritic cells counteract *Borrelia* dissemination in the human body through capturing, internalization and subsequent degradation of spirochetes. Here, we show that *B. burgdorferi* internalization by primary human macrophages involves compaction of spiral-shaped borreliae into endosomal vesicles. Compaction of borreliae is an active process that is driven by Rab22a and Rab5a, as shown by use of respective mutant constructs and siRNA-mediated depletion. RabGTPase-dependent trafficking is also important for maturation of borreliae-containing endosomes into LAMP1-positive and degradative lysosomes. Live cell imaging further shows that uptake of *Borrelia* is a multistep process, where Rab22a-positive endosomes enwrap elongated spirochetes, while endosomal compaction is mediated by contact with Rab5-positive vesicles at sites of membrane extrusion from endosomes. These sites are apparently coordinated by contact with the endoplasmic reticulum, as visualized by the ER marker Sec61beta. Collectively, these data identify Rab22a and Rab5a as crucial regulators of *B. burgdorferi* intracellular processing by primary macrophages. We also demonstrate that RabGTPase-driven endosomal compaction of borreliae is a crucial step in the vesicular

cascade that ultimately leads to elimination of spirochetes. Moreover, Rab22a and Rab5a exert their influence through discrete vesicular entities, whose activities are coordinated at ER contact sites.

P1238

Board Number: B577

Dysfunction of Rab3D is associated with increased secretion of tear cathepsin S, a tear biomarker of Sjögren's syndrome.

Z. Meng¹, M.C. Edman¹, C. Ding¹, C.T. Okamoto¹, S.F. Hamm-Alvarez¹;

¹Pharmacology and Pharmaceutical Sciences, University of Southern California, Los Angeles, CA

Purpose. Rab3 and Rab27 are two subfamilies of Rab proteins identified in many cell types, including lacrimal gland acinar cells (LGAC), which facilitate secretory vesicle (SV) exocytosis. LGAC produce and release tear proteins to the ocular surface. We explored the role that changes in Rab3D and/or Rab27 may play in the altered tear cathepsin S (CTSS) levels observed in non-obese diabetic (NOD) mouse, a Sjögren's syndrome (SS) disease model. SS is a chronic autoimmune disease characterized by lymphocytic infiltration and damage to lacrimal and salivary gland, leading to severe dry eye and xerostomia. Increased CTSS abundance and activity in NOD LGAC and in tears were reported in an earlier study, as well as clinical studies validating CTSS as a tear biomarker of SS.

Methods. Mice deficient in Rab27a (*ashen*), Rab27b (27bKO), Rab27a and b (DKO), Rab3D (3DKO) as well as parent C57BL/6 (C57) were used, in addition to NOD, and BALB/c mice. qRT-PCR was performed with mRNA extracted from whole mouse lacrimal gland (LG) or LGAC obtained with laser capture microdissection. Tear fluid was collected from mice by stimulating LG with carbachol *in situ*, and the activities of several tear proteins were analyzed including CTSS and β -hexosaminidase (β -hex).

Results. Compared with C57, Rab27-deficient mice (*ashen*, 27bKO and DKO) had significantly lower CTSS and higher β -hex activities in tears. However, 3DKO mice had significantly higher CTSS but equivalent β -hex activities in tears. In NOD mice LGAC, Rab3D but not Rab27 gene levels were significantly lower than that in BALB/c. Gene expression of Rab3D effector dynein light chain was decreased, whereas Rab27 effectors MyosinVa and Munc 13-4 were increased. In NOD mouse, CTSS had both a higher gene expression level in LGAC and increased activity in mouse tears, whereas β -hex remained unchanged.

Conclusions. Some secretion of CTSS and β -hex occurs through both Rab27- and Rab3D-enriched SV. However, our data suggest that CTSS is secreted mainly through Rab27-enriched SV, while β -hex is secreted mainly through Rab3D-enriched SV. When exocytosis of one set of SV is impaired, proteins may be secreted from the other subset through compensatory mechanisms. In our mouse model, decreased expression of Rab3D but not Rab27 in LGAC causes the expression of CTSS, a SS tear biomarker, to increase. Studies from other groups have shown that Rab3D protein levels and protein distribution are altered in acinar cells from lacrimal and salivary glands from patients with SS. These findings collectively suggest that Rab3D dysregulation is implicated in increased secretion of the CtsS biomarker in disease and that both represent potential therapeutic targets.

P1239**Board Number: B578****Requirements of Rab5-activity, growth factor-dependent in highly invasive breast cancer cell lines.**N. Porther¹, M.A. Barbieri¹;¹Biological Sciences, Florida International University, Miami, FL

Rab5 expression in cancer has been associated with diseases progression and prognosis. We have previously shown that growth factor-directed cell invasion and migration was dependent on Rab5 activation in non- invasive breast cancer cells. However, hardly any data is available regarding the role of Rab5 in invasive cells in the absence or presence of growth factor. In our present study, we report that the invasive and migratory properties of the highly invasive breast cancer cell line, MDAMB-231, were abrogated in cells expressing the inactive (GDP-bound) form of Rab5 irrespective of growth factor stimulation; while the invasive potential of breast cancer cell lines expressing the wild type and active (GTP-bound) form of Rab5 were noticeably greater. Interestingly, expression of Rin1, a Rab5 GEF, increases invasion and migration of MDAMB-231 cells even in the absence of growth factors. In contrast, Rin1 depletion partially mitigates both processes. Hence, it is reasonable to speculate that cell invasion and migration, a process that typically involves activation of growth factor receptor, can be intracellularly regulated without intervention of activation of growth factor receptor

P1240**Board Number: B579****Phospho-activation of Rab8 Guanine Nucleotide Exchange Factor Rabin8 by ERK1/2 in Response to EGF Signaling.**J. Wang¹, J. Ren¹, B. Wu¹, S. Feng¹, W. Guo¹;¹University of Pennsylvania, Philadelphia, PA

Regulation of exocytosis is essential for many basic physiological processes ranging from hormone release to epithelia formation. Rab8, a member of the Rab family of small GTPases, plays an important role in membrane trafficking from the trans-Golgi network and recycling endosomes to the plasma membrane. Rabin8 is a guanine nucleotide exchange factor (GEF) and primary activator of Rab8. Investigating how Rabin8 itself is activated in cells is thus pivotal to the understanding of the regulation of exocytosis. Here we show that phosphorylation is an important mechanism for Rabin8 activation. We identified Rabin8 as a direct phospho-substrate of Extracellular Signal-Regulated Kinases 1 and 2 (ERK1/2) in response to epidermal growth factor (EGF) signaling. At the molecular level, ERK phosphorylation relieves the auto-inhibition of Rabin8, thus promoting its GEF activity towards Rab8. We further demonstrate that blocking ERK1/2-mediated phosphorylation of Rabin8 inhibits vesicular

trafficking to the plasma membrane. Together, our results suggest that ERK1/2 phosphorylation of Rabin8 plays an important role in exocytosis in response to extracellular signaling.

The small GTPase RAB-10 regulates autophagy function in *C. elegans*.

N.J. Palmisano^{1,2}, D. Jimenez¹, B. Grant³, A. Meléndez^{1,2};

¹Dept. of Biology, CUNY Queens College, Flushing, NY, ²Dept. of Biology, CUNY Graduate Center, New York, NY, ³Dept. of Molecular Biology and Biochemistry, Rutgers University, Piscataway, NJ

Autophagy and endocytosis are two cellular pathways vital for development and tissue homeostasis. Autophagy is a catabolic process involving the formation of a double-membrane vesicle called the autophagosome that engulfs and degrades long-lived proteins and damaged organelles through the lysosomal pathway. Endocytosis involves the uptake and transport of cargo into the cell through the formation of single membrane vesicles termed endosomes. While several studies have shown crosstalk between autophagy and endocytosis, it is not clearly understood how specific endocytic compartments contribute to autophagy function. An example of crosstalk is the formation of an amphisome, the fusion of an autophagosome and an endosome, however the molecular mechanisms that regulate this fusion are not well understood. We have investigated the relationship between autophagy and endocytosis in *C. elegans*. We had previously shown that long-lived *daf-2* insulin-like/IGF-1 receptor (IIR) loss of function mutants have increased autophagy levels as measured by the formation of GFP::LGG-1 positive foci, a reporter for autophagosomes. If *daf-2/IIR* mutants are treated with RNAi against autophagy genes, the GFP::LGG-1 reporter aberrantly forms large aggregates. Thus, we screened for endocytic genes that, when depleted by RNAi, had a similar phenotype as the depletion of autophagy gene activity in *daf-2/IIR* loss of function mutants, that is the aberrant formation of GFP::LGG-1 large aggregates. We identified the small GTPase RAB-10, a mediator of basolateral endocytic trafficking in worms and mammals, as important for autophagy, particularly amphisome formation. We find that reduced activity of RAB-10, by RNAi or loss of function mutation, results in the formation of GFP::LGG-1 positive aggregates in *daf-2/IIR* mutants. Additionally, we find that RAB-10 depletion disrupts the colocalization of the GFP::LGG-1 positive foci and tagRFP::LMP-1 labeled lysosomes, suggesting that the autophagosomes in *rab-10* mutants are defective. Interestingly, under conditions that induce autophagy, such as *daf-2/IIR* loss of function, we observed an increase in the colocalization of GFP::RAB-10 positive endosomes and the autophagy marker mCherry::LGG-1, suggesting that RAB-10 endosomes fuse with GFP::LGG-1 positive autophagosomes. In summary, our findings suggest that RAB-10 is an important factor that coordinates endocytosis and autophagy during amphisome formation in *C. elegans*.

P1242**Board Number: B581****TLR sorting by Rab11 endosomes maintains intestinal epithelial-microbial homeostasis.**S. YU¹, Y. Nie^{2,3}, B. Knowles⁴, R. Sakamori¹, E. Stypulkowski⁵, C. Patel⁶, S. Das¹, V. Douard⁶, R.P. Ferraris⁶, E.M. Bonder¹, J.R. Goldenring⁷, Y.T. Ip^{2,3}, N. Compartmentalization of Toll-like receptors (TLRs) in intestinal epithelial cells (IECs) regulates distinct immune responses to microbes; however, the specific cellular machinery that controls this mechanism has not been fully identified. Here we provide genetic evidences that the recycling endosomal compartment in enterocytes maintains a homeostatic TLR9 intracellular distribution, supporting mucosal tolerance to normal microbiota. Genetic ablation of a recycling endosome resident small GTPase, Rab11a, a gene adjacent to a Crohn's disease risk locus, in mouse IECs and in *Drosophila* midgut caused epithelial cell-intrinsic cytokine production, inflammatory bowel phenotype, and early mortality. Unlike wild-type controls, germ-free Rab11a-deficient mouse intestines failed to tolerate the intraluminal stimulation of microbial agonists. Thus, Rab11a endosome controls intestinal host-microbial homeostasis at least partially via sorting TLRs.

P1243**Board Number: B582****Dual rab17 species have distinct biochemical properties.**A. Striz¹, P. Tuma¹;¹Department of Biology, Catholic Univ America, Washington, DC

Hepatocytes have a complex polarized membrane architecture which requires complex membrane trafficking pathways. These trafficking pathways are regulated, in part, by rab GTPases which are acylated for integration into lipid membranes and activated by GTP binding and hydrolysis. Particularly we have chosen to study rab17, whose expression is restricted to polarized epithelial cells and enriched in liver suggesting a role in the regulation of polarized protein trafficking. To initiate our studies, we generated three recombinant adenoviruses expressing wild type, constitutively active (GTP bound) or dominant negative (GDP bound) rab17. Like endogenous rab17, and as observed in other epithelial cell types, overexpressed wild type and the mutant rab17s were present at or near the apical membrane. Western blotting revealed immunoreactive species at 25 kDa (the predicted rab17 molecular weight) and 40 kDa. Mass spectrometry confirmed that both bands are rab17. When we expressed a

prenylation deficient rab17 isoform, the 40 kDa band was lost suggesting the shift in molecular weight is due, in part, to acylation. Because many rabs participate in vesicle docking with members of the SNARE machinery, and because rab17 has been shown to bind syntaxin 3 in kidney, we used GST pulldown assays with WIF-B cell lysates to analyze rab17-syntaxin interactions. We limited our studies to syntaxins 2 and 3 (the apical isoforms) and for our negative control, syntaxin 4 (the basolateral isoform). As predicted, syntaxin 4 did not bind wild type or the mutant rab17s. However, unlike in kidney, wild type and GTP bound rab17 bound syntaxin 2, not syntaxin 3. Interestingly, in both cases, only the 40 kDa rab17 species bound syntaxin 2 suggesting acylation is required for syntaxin binding indicating that the two forms have distinct binding properties. Blotting of total membrane fractions from WIF-B cells revealed that the 25kDa species is present in both the soluble and membrane fraction; however, the 40kDa species was detected only in the membrane fraction. We are currently investigating high molecular weight post-translational modifications (e.g., ubiquitination, sumoylation, poly-ADP ribosylation) that could cause the molecular weight shift and aid the rab17-syntaxin 2 interaction.

Rab35 limits glioblastoma growth in vivo.

M. Chaineau¹, F. Verginelli¹, R. Dali¹, M. Fotouhi¹, M. Daubaras¹, S. Stifani¹, P.S. McPherson²;

¹McGill University, Montreal, PQ, ²McGill University, Montreal, QC

The small GTPase Rab35 is localized to the plasma membrane, clathrin-coated pits and vesicles and endosomes, and mediates the recycling of numerous protein cargos. For example Rab35 is required for the recycling of cadherins, and loss of Rab35 function leads to decreased levels of cadherins on the plasma membrane and loss of cell-cell contacts. In addition, Rab35 recruits its effector ACAP2, a GTPase activating protein for Arf6, to endosomes. Thus, knockdown of Rab35 leads to increased Arf6 activity, which subsequently allows for increased recycling of integrins and enhanced cell migration. Activation of Arf6 following Rab35 knockdown also causes increased cell proliferation through enhanced EGFR recycling and signaling. Given that Rab35 silencing induces decreased cell adhesion and increased cell migration and proliferation, all well known features of invasive cancer cells, we sought to explore the function of Rab35 in cancer. We find that Rab35 mRNA levels are down regulated in surgically resected gliomas compared to normal brain tissues, with the most notable decrease in glioblastoma, the most common and malignant brain cancer. We thus used lentivirus to induce stable knockdown of Rab35 in human glioblastoma-derived brain tumor initiating cells (BTICs), which drive brain tumor growth when transplanted into host mice. Importantly, implantation of Rab35-silenced BTICs resulted in a massive increase in tumor size compared to non-silenced cells. This situation was correlated with a dramatic decrease in survival. Conversely, implantation of Rab35-overexpressing BTICs resulted in a robust decrease in tumor growth with significantly enhanced survival. Thus, Rab35 is a critical factor in controlling the growth of glioblastoma and provides a possible new target for therapy for this devastating brain cancer.

P1245**Board Number: B584****Nitric oxide regulates phagocytosis by S-nitrosylation of Rab5.**M. Hagiwara¹, N. Ishida¹, J. Wang^{1,2}, K. Matsushita^{1,2};¹National Center for Geriatrics and Gerontology, Obu, Aichi, Japan, ²Oral Disease Research, National Center for Geriatrics and Gerontology, Nagoya, Japan

Nitric oxide (NO), produced from L-arginine by nitric oxide synthases (NOSs) in cells, regulates post-translational proteins. Recent studies have been shown that covalent adduction of an NO moiety (NO•) to cysteines, called S-nitrosylation, is a key NO signaling pathway and that regulates protein functions. On the other hand, the small GTPase Rab5 is well known as a crucial protein for endocytosis; however, the mechanism by which Rab5 regulates endocytosis is not known. Here, we report that NO regulates phagocytosis by S-nitrosylation of Rab5. To confirm the effect of NO on phagocytosis, we treated RAW264 cells with an NO donor, GSNO. Phagocytosis was facilitated in RAW264 cells by treatment with GSNO. Inducible NOS (iNOS) was interacted with Rab5 in lysates of HA-Rab5-transfected and then LPS-stimulated Raw264 cells. We next tested the effect of NO on Rab5 activity. Results of a R5BD pull-down assay showed that Rab5 activity was enhanced by treatment with GSNO. Finally, we examined S-nitrosylation of Rab5 by using the biotin switch method. S-nitrosylation was observed more strongly in Rab5Q79L (recombinant, active) than in Rab5S34N (recombinant, inactive). Collectively, our data suggest a mechanism by which NO activates Rab5 and phagocytosis by S-nitrosylation.

P1246**Board Number: B585****Molecular supervisors of Golgi size control.**M.D. Bhave¹, B. Jain¹, P. Iyer¹, D. Bhattacharyya^{2,3};¹Bhattacharyya Lab, ACTREC, Kharghar, Navi Mumbai, India, ²Tata Memorial Centre, Advanced Centre for Treatment, Research and Education in Cancer (ACTREC), Kharghar, Navi Mumbai, India, ³Neurobiology, University of Chicago, Chicago, IL

Regulation of size and shape of intracellular organelles is a fundamental yet poorly understood phenomenon in eucaryotic cell biology. We are specifically interested in studying the regulation of size and shape of the Golgi apparatus in the budding yeast *S. cerevisiae*. From our previous study we have shown that ARF1 plays an important role in Golgi size regulation by altering cisternal maturation kinetics[1]. We are currently doing an extensive screening of other Golgi related important proteins for their potential roles in Golgi size regulation. We have deleted various Golgi associated GTPases as well as vacuolar protein sorting genes & studied their effect on size of the Golgi apparatus in *S. Cerevisiae*. Preliminary analysis of knock-out strains has revealed the importance of several GTPases & vacuolar protein sorting genes like Ypt6, Ypt11, Vps21, Vps74, Arl3 in controlling the Golgi size. Systematic study

of these targeted knock outs further will lead to detailed understanding of how these factors play role to control Golgi size.

Nck Regulate Endothelial Cell Morphogenesis by Modulating the Activity of Cdc42.

S.P. Chaki¹, R. Barhoumi², G.M. Rivera³;

¹Veterinary Pathobiology, Texas A M Univ, College Station, TX, ²Veterinary Integrative Biosciences, Texas A M Univ, College Station, TX, ³Veterinary Pathobiology, Texas AM Univ, College Station, TX

Scaffold and adaptor proteins specify the flow of information from activated receptors at the plasma membrane by coordinating the spatiotemporal assembly of intracellular signaling complexes. Here we demonstrate that Nck, an adaptor linking tyrosine phosphorylation with cytoskeletal remodeling, plays an important role in the orchestration of endothelial cell morphogenesis. Using a combination of three-dimensional cultures in collagen matrices, molecular genetics and microscopy, we show that Nck silencing impairs the ability of endothelial cells to self-organize into an interconnected network of tubular structures. Endothelial cells with abrogation of Nck signaling exhibited poor morphogenesis as a result of a reduction in extracellular matrix remodeling and chemotactic invasion. In addition, loss of Nck led to altered organization of the actin cytoskeleton and VE-cadherin-mediated cell-cell junctions. Control and Nck-rescued cells assembled into polarized tubular structures, as evidenced by the presence of patent lumens and apical localization of the marker podocalyxin. In contrast, Nck silenced cells failed to adopt a polarized luminal organization and accumulated vacuoles in their cytosol. Mechanistically, abrogation of Nck signaling impaired the spatiotemporal activation of Cdc42. Experiments to determine the role of Nck in the subcellular localization and activation of polarity pathways, including Par3/Par6/aPKC complex, are underway. Our results suggest an important role for Nck adaptors in the orchestration of the endothelial cell morphogenesis through a mechanism that involves modulation of polarity pathways.

P1248**Board Number: B588****Atypical PKC is dispensable for the maintenance of polarity in differentiated enterocytes. Lessons from the conditional Prkci knockout mouse.**R. Forteza¹, A. Mashukova², Y. Figueroa¹, P.J. Salas^{1,3};¹Department of Cell Biology, University of Miami Miller School of Medicine, Miami, FL, ²College of Medical Sciences, Nova Southeastern University, Fort Lauderdale, FL, ³Univ Miami Sch Med, Miami, FL

The polarity complex, originally described in *C. elegans*, comprises atypical PKC (aPKC) and scaffolding proteins (PARTition deficient) Par6 and Par3. In vertebrates, there are two aPKC isoforms: iota/lambda and zeta. These proteins are highly homologous but encoded by two different genes. They differ in their tissue specific expression. The PKC lambda knock out mouse is embryonic lethal, while the PKC zeta KO is viable and displays only a minor immunologic phenotype. We have shown before that PKC lambda is the major aPKC in intestinal epithelia. In addition, aPKC is deeply post-translationally downregulated in intestinal inflammation. Accordingly we wanted to understand the role of this kinase, considered to be key for polarity, in intestinal epithelia polarity and permeability. We developed a conditional knockout mouse in the C57BL/6 background with Flox sites flanking Exon 4 of Prkci (PKC iota/lambda, ID 18759). After backcrossing with the wild-type to randomize the genetic background, we crossed the animals with Villin-CRE mice. The phenotype was assessed using antibodies against the aPKC phosphorylated turn domain (active conformation) which is totally homologous in both lambda and zeta isoforms, and antibodies against peptides specific for each isoform. The Villin-Cre +;Prkci(flox/flox) offspring were born at the predicted mendelian proportions. These mice were found to have no detectable aPKC signal in the intestinal villus and the colon surface epithelia. Surprisingly, there was a diminished but clear phospho-turn domain signal within the deepest regions of the intestinal crypts. PKC zeta was upregulated specifically in that location and localized to the apical domain, just as PKC lambda in the littermate controls. PKC zeta signal was negative in the distal part of the crypts and the villus epithelium. Despite the lack of aPKC in the absorptive epithelium, the animals gained weight like the controls. There were no differences in 3 kDa fluorescent dextran intestinal permeability. Only 3/26 conditional PKC lambda ko mice showed spontaneous colitis at or before 6 months of age. Membrane polarity markers showed normal polarization. The tight junction marker ZO-1 was also normal, as well as the distribution of Par3. Localization and ultrastructure of TJ were indistinguishable from controls in TEM preparations. Bearing in mind that the life span of epithelial cells in the intestine from the mid-crypt to the tip of the villus is approximately 3 days, we conclude that aPKC is dispensable for the *maintenance* of apical polarity during that period of time. This is not surprising, because similar observations have been made in *Drosophila*. However, these results suggest a need to reconsider the interpretation of the role of aPKC in inflammatory processes and other phenomena involving rapid downregulation of aPKC.

P1249**Board Number: B589****CARACTERISATION OF CERES : A PROTEIN AT THE EDGE OF EPITHELIAL POLARITY AND ENERGY CONTROL.**E. Hardy¹, P. Laprise¹;¹BMBMP, Centre de Recherche sur le Cancer de l'Université Laval - CRCHU de Québec, Québec, QC

Epithelial cell polarization leads to the regionalization of the plasma membrane into apical, lateral and basal domains. The polarized architecture of epithelial cells is crucial for their functions, and also shapes tissues and organs during development. The protein machinery establishing epithelial polarity is conserved from flies to humans, reflecting its significance for the physiology of metazoans. We discovered that the protein Yurt (Yrt) is an evolutionarily conserved regulator of epithelial cell polarity. Yrt plays a critical role by limiting the activity of two master apical determinants, namely Crumbs (Crb) and atypical Protein Kinase C (aPKC). Thereby, Yrt preserves the identity of the lateral membrane and the functional architecture of epithelial cells. Understanding how Yrt acts is instrumental to illuminate the complex network that establishes and maintains epithelial polarity. Towards that goal, we performed a biochemical analysis of the Yrt interactome using mass spectrometry. Our objective is now to characterize the protein Ceres that emerged as a Yrt binding partner.

We produced anti-Ceres antibodies, and confirmed the physical interaction between endogenous Yrt and Ceres by standard co-immunoprecipitation. Ceres expression is dynamic throughout embryogenesis, with a transient accumulation during organogenesis. This suggests that Ceres contributes to epithelial tissue morphogenesis. Ceres subcellular distribution is mainly cytoplasmic, and this protein shows a punctate distribution that likely reflects an association with intracellular vesicles. To investigate Ceres function, we generate a null allele using the CRISPR/Cas9 system. *ceres* mutant embryos do not display polarity defects. However, loss of Ceres rescues the *yrt* mutant embryonic phenotype. This argues that Ceres antagonizes Yrt activity to fine-tune polarity regulation. Further analysis of the *ceres* mutant phenotype revealed that newly hatched mutant females produce fertile eggs, whereas ovarian follicles degenerate at stage 8 of oogenesis in older flies. A similar phenotype is encountered in starved wild type females. This suggests that flies devoid of Ceres are under a metabolic stress. In support of this hypothesis, *ceres* mutant animals show a higher activation level of the AMP-activated protein kinase when compared to their wild type counterparts.

Overall, our data identify a novel putative regulator of Yrt activity and epithelial cell polarity, which is crucial for animal development and physiology. In parallel, we established that Ceres controls the cellular energetic balance, suggesting that Yrt and other polarity regulators may also play a role in this process. Thus, our data highlight a possible link between polarity regulation and metabolism.

P1250**Board Number: B590****PAR3 and aPKC regulate Golgi organization through CLASP2 phosphorylation for cell polarity.**T. MATSUI¹, T. Watanabe¹, K. Kaibuchi¹;¹Nagoya University School of Medicine, Nagoya, Japan

The organization of Golgi apparatus is essential for cell polarization and its maintenance. A PAR complex, composed of PAR3, PAR6 and aPKC (atypical PKC), plays a central role in establishment of cell polarity through the several cellular processes. However, it remains largely unknown how the PAR complex participates in the regulation of the Golgi organization. By screening for Par3-associating candidates, we previously identified another polarity protein CLASP2, which controls Golgi ribbon organization for front-rear polarity in migrating cells. Focusing on CLASP2, we demonstrate a novel molecular mechanism of the PAR complex in the regulation of the Golgi apparatus. We found that PAR3 formed a complex with CLASP2 through direct interaction. Similar to the case of other PAR3-binding proteins, CLASP2 was phosphorylated by aPKC. In epithelial cells, knockdown of either PAR3 or aPKC induced the aberrant CLASP2 accumulation at the trans-Golgi network (TGN) concomitantly with disruption of the Golgi ribbon organization. The expression of the CLASP2 mutant, which inhibited the PAR3-CLASP2 interaction, disrupted the Golgi ribbon organization. CLASP2 is known to localize to the TGN through its interaction with the TGN protein GCC185. This interaction was impaired by PAR3- and aPKC-mediated phosphorylation of CLASP2. Furthermore, the non-phosphorylatable mutations enhanced the co-localization CLASP2 with GCC185, thereby impairing the Golgi organization. Based on these observations, we propose that PAR3 and aPKC control the Golgi organization by regulating CLASP2 binding ability to GCC185.

P1251**Board Number: B591****Par3 limits APP and BACE1 convergence by directing their trafficking to two distinct pathways.**M. Sun¹, H. Zhang¹;¹Department of Neuroscience and Cell Biology, Rutgers University, Piscataway, NJ

The aging process is intricately linked to cell polarity. Loss of cell polarity has been implicated in different age-related disorders such as cancer and stem cell aging. However whether brain aging represents a polarity defect is not known. Alzheimer's disease (AD) is the most common form of neurodegenerative diseases affecting the elderly. It is characterized by extracellular plaques made up of β -amyloid peptides (A β), which is derived from the transmembrane protein APP through cleavage by β - and γ -secretases. Previous studies suggest the intracellular trafficking properties of APP and its secretases determine how APP is processed, with amyloidogenic processing occurring mostly in endocytic compartments and non-

amyloidogenic processing occurring on the cell surface. However, how the trafficking properties of APP and its secretases are regulated is still not well understood. The Par polarity complex is emerging as a key regulator of vesicle trafficking. This complex consists of Par3, Par6 and atypical PKC (aPKC), which are conserved proteins that regulate cell polarization from worms to mammals. Here we show that loss of the polarity protein Par3 is associated with Alzheimer's disease pathogenesis. Knockdown of Par3 promotes amyloidogenic APP processing and increases A β generation, while overexpression of Par3 promotes non-amyloidogenic APP processing. We further show that Par3 regulates APP trafficking by promoting its targeting to the recycling pathway, while knockdown of Par3 leads to lysosomal targeting of APP. Unexpectedly, we found that Par3 also regulates the trafficking of the β -secretase BACE1. However, loss of Par3 does not seem to cause a global disruption of vesicular trafficking. Rather, Par3 regulates APP and BACE1 trafficking through two distinct mechanisms. While Par3 regulates APP trafficking through the small GTPase Rac, it promotes BACE1 retrograde trafficking to the TGN by recruiting aPKC, which phosphorylates BACE1 on the C-terminus. Finally, we found that Par3 protein level is decreased in both human AD brain samples and a mouse AD model, and treatment of neurons with A β leads to a decrease in Par3. This suggests that there exists a vicious cycle in the AD brain where A β leads to a decrease in Par3, which then causes APP and BACE1 convergence in the lysosomes, leading to a further increase in A β generation. Taken together, our studies reveal a novel role for the polarity protein Par3 in AD pathogenesis through a two-pronged mechanism that involves regulation of APP and BACE1 trafficking.

Mechanochemical feedback regulates the dynamics of the PAR system in *C. elegans* zygotes.

P. Gross^{1,2}, V.K. Kumar^{2,3}, N.W. Goehring⁴, J.S. Bois⁵, F. Jülicher³, S.W. Grill^{1,2,3};

¹Max Planck Inst-Molec Cell Biol/Genetics, Dresden, Germany, ²BIOTEC, Dresden, Germany, ³Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, ⁴London Research Institute, London, United Kingdom, ⁵Division of Biology and Biological Engineering, California Institute of Technology, Pasadena, CA

The interplay between regulatory biochemistry and cell mechanics is critical for a broad range of morphogenetic changes. Cell mechanics can induce transport via growth and flow-fields, which in turn affect concentration-fields of regulators. Such systems exhibit an intrinsic feedback-architecture between regulators of cell mechanics and mechanical deformation. While we anticipate that this feedback between biochemistry and cell mechanics is widespread in Morphogenesis, there are few examples that are studied with respect to their potential for generating spatiotemporal patterns.

Here we establish at a quantitative level that PAR polarization of *C. elegans* zygotes represents a coupled mechanochemical system. Using Fluorescence Recovery After Photobleaching (FRAP) and RNA interference (RNAi), we first demonstrate that the biochemistry in form of the PAR domains feeds back on the mechanics by establishing and maintaining a non-muscle myosin II (nmy-2) gradient. Additionally,

we characterize the effect of the polarity cue associated with the centrosome of the male pronucleus on the local myosin concentration at the posterior pole. We show that it induces a reduction in myosin concentration and thereby triggers the onset of cortical flows. Furthermore we measure the spatiotemporal profile of the anterior and posterior PAR concentration, the myosin II concentration and the induced flow-field.

Finally, we capture the feedback-architecture of the coupled actomyosin – PAR system in a quantitative model, based on coupling a thin film active fluid description of cortical mechanics [1] to a reaction-diffusion PAR patterning system [2]. We show that this mathematical model can quantitatively recapitulate the spatiotemporal profile of PAR polarity establishment. Furthermore, we demonstrate that the model predicts the existence of a threshold in cortical flow velocity, which separates the non-polarizing and the polarizing regime and confirm the existence of this threshold velocity in the living *C. elegans* zygote.

Taken together, we show that the spatiotemporal chain of events that constitute PAR polarization in *C. elegans* can be described quantitatively in terms of a coupled, active mechanochemical pattern generating system.

An Instructive Role for *C. elegans* HMR-1/E-cadherin in Translating Cell Contact Cues into Cortical Polarity.

D. Klompstra¹, D. Anderson¹, J. Yeh¹, Y. Zilberman¹, J. Nance¹;

¹Skirball Institute, NYU School of Medicine, New York, NY

Early embryonic cells in many species polarize radially by distinguishing their contacted and contact-free surfaces. The homophilic adhesion protein E-cadherin is required for contact-induced polarity in many cells. However, it is not clear whether E-cadherin functions instructively as a spatial cue, or permissively by ensuring adequate adhesion so that cells can sense other contact signals. In *C. elegans*, radial polarity begins at the four-cell stage, when cell contacts restrict the PAR polarity proteins to contact-free surfaces. We previously identified the RhoGAP PAC-1 as an upstream regulator that is required to exclude PAR proteins from contacted surfaces of early embryonic cells. PAC-1 is recruited specifically to sites of cell contact and directs PAR protein asymmetries by inhibiting the Rho GTPase CDC-42. How PAC-1 is able to sense where contacts are located and localize to these sites is unknown. We show that HMR-1/E-cadherin, which is dispensable for adhesion, functions together with HMP-1/ α -catenin, JAC-1/p120 catenin, and the previously uncharacterized linker PICC-1/CCDC85/DIPA to bind PAC-1 and

recruit it to contacts. Furthermore, we show that ectopically localizing the intracellular domain of HMR-1/E-cadherin to contact-free surfaces of cells recruits PAC-1 and depolarizes cells, demonstrating that HMR-1/E-cadherin plays an instructive role in polarization. Our findings identify an E-cadherin-mediated pathway that translates cell contacts into cortical polarity by directly recruiting a symmetry-breaking factor to the adjacent cortex.

The effects of PAM-1 suppressors on the polarization of *C. elegans* embryos.

W. Haussner¹, A. Kilner¹, A. Kurtz¹, K. Power¹, A. Kimble¹, E. Jaeger¹, R.L. Lyczak¹;

¹Biology, Ursinus College, Colledgeville, PA

In *Caenorhabditis elegans*, anterior-posterior axis formation begins shortly after fertilization. The goal of this project was to understand this process through the study of *pam-1*, a gene involved in polarization. When *pam-1* is compromised, the embryo fails to polarize and as a result, the embryo dies. This is due to the lack of the puromycin-sensitive aminopeptidase PAM-1 that is coded for by this gene. Without PAM-1 to initiate polarization, the embryo does not properly form an anterior-posterior axis. We study *pam-1* by isolating mutants that rescue the *pam-1* phenotype, called suppressors. We cross strains containing the *pam-1* suppressor and hatch tests are performed to determine if the mutations still exist. Once verified, genomic mapping is performed to identify the suppressor's chromosomal location. This mapping will allow us to identify each suppressor gene and understand how it interacts with *pam-1*. Another way we study *pam-1* is by observing the polarization of the one-celled embryo using both fluorescent proteins under a confocal microscope and differential interference contrast (DIC) microscopy. Using these techniques, time-lapse images of the single cell dividing into a two-celled embryo are recorded. Later, videos are analyzed and the time at which certain landmarks of anterior-posterior axis formation occur is noted and compared in suppressor strains. Knowing more about related genes will help us to better understand polarization. From our studies, we have isolated two strains, *lz2* and *lz5*, that suppress the lethality of *pam-1*. The suppressors have been outcrossed; the hatch rates of the mutant strains and rescue of polarity, as evidenced using DIC microscopy, have led to the conclusion that the suppressors display a semi-dominant phenotype. Progress has been made using SNP mapping of the suppressors to determine the chromosomal location of the suppressor mutation. With further tests and observations to characterize these strains, the targets of PAM-1 and its role in biological pathways can be further elucidated.

P1255**Board Number: B595****The Identification and Characterization of pam-1 Targets Through the Use of Suppressors in *Caenorhabditis elegans*.**T. Nguyen¹, A. Brewer¹, M. Kurland¹, S. Shah¹, E. Jaeger¹, R.L. Lyczak¹;¹Biology, Ursinus College, Collegeville, PA

Within the one cell embryo of *Caenorhabditis elegans*, cell polarity is established before the first cell division. A crucial part of this process involves the *pam-1* gene of the organism, which codes for a puromycin-sensitive aminopeptidase, or PAM-1 protein. The PAM-1 proteins are conserved in plants and animals, have a range of different functions which includes protein degradation, protein maturation, and aiding in protein stability and may play a role in neurodegenerative diseases such as Huntington's and Alzheimer's disease. PAM-1 plays an important role in the positioning of the centrosome in *C. elegans* embryos which allows them to establish the anterior-posterior (AP) axis and develop normally. Our study focused on the mutated *pam-1* gene. Embryos with this mutation demonstrate an embryo-lethality effect due to the failure to form the anterior-posterior (AP) axis. In order to identify regulators and targets of PAM-1, we identified suppressors, mutations that reverse the lethality effect. We worked with two suppressors, *lz3* and *lz4*, that suppress the lethality of a missense allele of *pam-1*. The goal was to genetically map the chromosomal location of *lz3* and *lz4* using single nucleotide polymorphisms (SNP) mapping. Strains of progenies of a genetic cross of the suppressor and the wild-type strain were validated for SNP mapping, and chromosome I or IV were identified to be the possible locations of *lz3* and *lz4*. Overall, we hope to characterize all the current suppressors of mutated *pam-1* and their genotypes in addition to verifying new, potential suppressors. The use of suppressor screens can also help identify other proteins involved in the processes regulated by PAM-1.

P1256**Board Number: B596****Role of centrosome in anterior-posterior axis formation in single-celled *Caenorhabditis elegans* embryos.**D.M. Saturno¹, D. Parikh¹, D. Stephens¹, D. Castanzo¹, M. Williams¹, R.L. Lyczak¹;¹Biology, Ursinus College, Collegeville, PA

The formation of the anterior-posterior (AP) axis in single-celled *Caenorhabditis elegans* embryos is crucial to achieving functional potential. The entrance of sperm into the oocyte triggers completion of meiosis and initiates polarity establishment. In wild-type (WT) cells, the protein PAR-6 is initially evenly distributed along the inner boundaries of the embryo, however interactions between the centrosome and posterior cortex prompt PAR-6 to accumulate at the future anterior end, indicating successful polarization. *pam-1* mutants lack an active puromycin-sensitive aminopeptidase (PAM-1) protein. In these embryos, which fail to completely polarize, PAR-6 demonstrates an inability to localize. Our

research seeks to determine the differences between *pam-1* mutants and WT embryos in the progress of polarity establishment, specifically centrosome contact with the posterior cortex. Time-lapse confocal microscopy was used to study the movement of GFP-tagged centrosomes and chromosomes in the WT and *pam-1* strains as the embryo polarizes. We found that in WT strains, the centrosomes interact with the cortex for about four minutes during the early pronuclear stage. In *pam-1* strains, the centrosome interacts with the cortex earlier in the cell cycle and for a shorter duration. Delayed meiotic exit in *pam-1* mutants, in addition to shorter centrosome-cortex contact, supports the idea that the centrosome must maintain contact with the cortex in order to sustain the polarization process. Our results suggest that both timing and duration of centrosome contact must be regulated to ensure axis polarization. PAM-1 is necessary for proper centrosome positioning.

Cadherin-Integrin independent epithelium formation depends upon ZEN-4/MKLP in *C. elegans*.

S.E. Von Stetina¹, J. Liang¹, S.E. Mango¹;

¹Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

How are polarized epithelia established and maintained? This question is of critical importance, as the loss of epithelial polarity is associated with human diseases, such as metastasis. The current paradigm is that adhesive signals, either at the junctional domain or at the basal surface, provide spatial cues that properly polarize the cell. Recent studies, however, have challenged this notion, suggesting the existence of a poorly-understood non-canonical polarity pathway. I have now shown that epithelial polarity in *C. elegans* is independent of the traditional 'outside-in' cues, making this an ideal system to identify factors involved in this alternative pathway.

We have begun an analysis of non-canonical epithelium formation using the *C. elegans* foregut. The nine arcade cells undergo a mesenchymal-to-epithelial transition (MET) at mid-embryogenesis, linking the foregut to the epidermis. The Mango lab performed an unbiased screen for defects in arcade cell MET. This screen revealed that ZEN-4/MKLP1 is essential for arcade cell polarization. In *zen-4* mutant arcade cells, markers of the apical and junctional domains are absent. Interestingly, my data indicate that ZEN-4 acts at the time of arcade cell birth rather than during polarization. This means that ZEN-4 is acting in the arcade cells ~100 minutes prior to the onset of any visible signs of polarity (e.g. PAR-6, E-cadherin). To elucidate the role of ZEN-4 in polarity, we performed structure-function analysis of this mitotic kinesin, which is thought to migrate toward microtubule plus ends and to bundle antiparallel microtubules to generate the central spindle during cytokinesis. Our studies revealed that the motor functions of this kinesin are dispensable for polarity, but not conserved residues important for binding its obligate partner in cytokinesis, CYK-4/GAP. How does this complex function in polarity? We focused on a conserved regulator of polarity, PAR-6/PDZ. In *par-6* mutants, apicobasal markers are detectable in arcade cells but not localized properly. Our model is that *zen-4* is required for PAR-6 expression in

arcade cells, which is then required to ensure proper localization of apical and junctional proteins. Our current experiments are testing this model.

Attenuation of N-glycosylation causes polarity and adhesion defects in the *C. elegans* embryo.

A. Spang¹, J. Stevens¹;

¹Univ Basel-Biozentrum, Basel, Switzerland

The one-cell stage *C. elegans* embryo is highly polarized, requiring sequestration of cytoplasmic polarity factors at the plasma membrane and compartmentalization of the plasma membrane itself. Compartmentalization would aid asymmetric distribution of lipids and proteins, being partially responsible for the fates of the future daughter cells. Since most plasma membrane proteins are glycosylated, we determined the effect of reduction of N-glycosylation on early development. We show that the polarity factor PAR-2 requires at least one N-glycosylated protein for efficient recruitment to the posterior cortex. More importantly, cell-cell adhesion was specifically lost only at the two-cell stage upon reduction of N-glycosylation. This loss-of-adhesion phenotype was rescued by interfering with polarity establishment, indicating that polarity establishment is upstream of plasma membrane segregation. Remarkably the epithelial adhesion complex components E-cadherin and MAGI-1 were found at contact sites at the two cell stage embryos. This localization was lost under reduced N-glycosylation, but was rescued by concomitant loss of PAR-2.

Regulation of apical-basal polarity during epithelial tissue regeneration.

R.G. Jaszczak¹, A. Halme¹;

¹University of Virginia, Charlottesville, VA

Almost all organisms have the capacity for some tissues to regenerate at certain times in development. However, little is known about the morphogenesis of regenerative tissues. In particular, how is established tissue architecture remodeled to incorporate regenerated tissues? In *Drosophila* larvae, imaginal discs – larval precursors to adult appendages – have substantial regenerative capacity. Imaginal discs are composed of a primary layer of epithelial cells and a secondary squamous epithelia. This simple structure has allowed us to study changes in epithelial tissue architecture during regeneration.

We have observed a transient loss of apical-basal polarity (ABP) during imaginal disc regeneration. Using two common markers for maintenance of cellular ABP, atypical protein kinase C (aPKC) and Discs large (Dlg), we observe disruption of apical and apical-lateral staining in a subset of cells within the

regenerating disc after tissue damage induced by irradiation. This disruption of ABP is seen when dying cells are just beginning to migrate basally, and persists for ~24 hours after damage is induced. This regenerative epithelia remodeling is reminiscent of neoplastic transformation in imaginal disc tumor models, suggesting that these may be mechanistically related processes. However, in contrast to neoplastic transformation, ABP disruption during regeneration appears to be quickly remodeled, with restoration of ABP taking place concurrent with the extrusion of dying cells from the imaginal disc epithelia. Within ~ 36 hours, polarity is restored; residual/extruded caspase positive cells remain present for almost ~ 48 hours following irradiation. Regions of polarity loss appear to include both dying and living cells, leading us to examine whether dying cells are capable of producing a non-autonomous polarity change in surrounding cells.

To this end, we are examining the *wingless* and JNK signaling pathways, which have been implicated in compensatory responses to tissue damage, to determine if these pathways function in reorganization of tissue polarity during the regenerative response.

Understanding how ABP is regulated following damage will provide new insights into regenerative morphogenesis, and may reveal pathways that regulate the loss of epithelial tissues architecture during tumorigenesis.

The *Drosophila* RhoGEF Cysts is essential for epithelial polarity.

J.T. Silver¹, S.d. Simões¹, F. Wirtz-Peitz², N. Perrimon², U. Tepass¹;

¹Cell and Systems Biology, University of Toronto, Toronto, ON, ²Department of Genetics, Harvard Medical School, Boston, MA

The function of RhoGEFs (Rho GTPase-specific guanine nucleotide exchange factor) is critical for development and reducing the risk of cancer. RhoGEFs promote the cyclic activation and localization of small GTPases like Rho, Rac, and Cdc42, which promote the apicobasal organization of epithelial cells through the dynamic regulation of polarity and adhesion complexes. How a wide diversity of RhoGEFs coordinate the activity of a limited number of small GTPases remains unclear. The purpose of this project is to characterize a novel RhoGEF in *Drosophila* that we named Cysts. Cysts is the single *Drosophila* orthologue of a group of four mammalian RhoGEFs (p114RhoGEF, p190RhoGEF, AKAP-13, and Lsc/GEF-H1). Using a maternal shRNA targeting approach we have found that Cysts is required for epithelial polarity. The loss of Cysts causes a disruption of adherens junctions and multi-layering by embryogenesis, followed by apoptosis of many epithelial cells. Depletion of Cysts also leads to the apical constriction and aberrant cortical enrichment of actin in small groups of cells, which go on to form cyst-like clusters (hence the gene name *cysts*), similar as seen in *crumbs* mutant embryos or embryos compromised for other polarity proteins. Our preliminary evidence suggests that aPKC is a downstream target of Cysts. Further, we have found that a Cysts::GFP fusion protein is apico-cortically enriched. Structure-function analysis of Cysts reveals that the DH-PH (RhoGEF, pleckstrin-homology) domain is

required for Cysts function, and that the N-terminal region is required for cortical localization. These results implicate Cysts as a novel RhoGEF that is required for the integrity of epithelial polarity in *Drosophila*. We are currently working to define the GTPase target of Cysts and generate a null mutant for *cysts* using CRISPR technology.

Regulation of planar cell polarity through Dachs-Sple and Ds-Sple interaction in *Drosophila melanogaster*.

A.A. Ambegaonkar¹, K. Irvine¹;

¹Rutgers University, New Brunswick, NJ

Planar cell polarity (PCP) is the polarization of cells in the plane of a tissue, orthogonal to their apical–basal axis. Two molecular systems are involved in establishment and maintenance of PCP: Frizzled PCP and Ds-Fat PCP. The Frizzled system regulates PCP locally whereas in Ds-Fat system, there are long-range patterning cues in the form of protein gradients, which orient this polarization with the axes of the tissue.

In the Ds-Fat PCP pathway, the receptor Fat (transmembrane cadherin protein) is activated upon binding to its ligand Dachsous (Ds) from neighboring cells. Four-jointed (Fj) is a Golgi-localized kinase that phosphorylates cadherin domains of Fat and Ds to modulate binding between them. Ds and Fj are expressed in opposing gradients, which influence Fat activity and result in polarization of the downstream effector Dachs (unconventional myosin) along the direction of these gradients. In the Frizzled PCP pathway, the membrane spanning protein Frizzled (Fz) on distal side of the cell forms heterotypic interaction with another membrane spanning protein Strabismus (Stbm) on proximal side of the cell. Flamingo (Fmi) is present on both the sides of cell and interacts homotypically. The cytoplasmic proteins Dishevelled (Dsh) and Diego (Dgo) are associated with Fz-Fmi complex whereas Prickle (Pk) is associated with the Stbm-Fmi complex. Prickle is present in two isoforms: Prickle (Pk) and Spiny-legs (Sple) and balance between these isoforms is crucial for normal PCP. Loss of a single isoform (Pk or Sple) results in more severe hair polarity phenotype than that caused by loss of both the isoforms (Pk-Sple). These cytoplasmic components interact with downstream tissue specific effectors to direct PCP.

Although the molecular mechanisms by which the Frizzled pathway mediate local polarity are known, it was not clear how this pathway interacts with Ds-Fat pathway to coordinate polarity along the axis of a tissue. Recently, it has been reported that Sple-Dachs interaction can polarize Sple along the gradient of Ds in wing disc. Here, we show that Sple can physically bind to both Dachs and Ds and its N-terminal domain is sufficient for this interaction. Loss of Dachs results in reversal of Sple polarity in wing disc and can suppress *pk* mutant hair polarity phenotype in wing. These observations indicate that the Ds-Fat pathway might influence the balance between Pk and Sple localization through Sple-Dachs or Sple-Ds interaction. Moreover, Sple is polarized in the same direction as Dachs in tarsal segments of the leg and abdomen, indicating that Sple-Dachs or Sple-Ds interaction can regulate PCP in these tissues as well.

Hence, this would provide a global mechanism for directional input from the Ds-Fat pathway to the Frizzled pathway.

The small GTPase Rac1 controls tubulogenesis in *Drosophila melanogaster*.

K. Sollier¹, F. Chartier¹, P. Laprise²;

¹BMBMP, Centre de Recherche sur le Cancer de l'Université Laval, QUEBEC, QC, ²BMBMP, Centre de Recherche sur le Cancer de l'Université Laval - CRCHU de Québec, Québec, QC

The plasma membrane of epithelial cells is segregated into an apical, a lateral and a basal domain. This polarization is orchestrated by several molecular modules that interact with each other to fine tune their respective activity, thereby ensuring the physiology and homeostasis of epithelial tissues. Failure of this crosstalk has been linked to morphogenesis defects. Epithelia can fold into tubes to build complex structures like the branched network of airways. However, how the establishment of such a three-dimensional architecture is coordinated at the cellular and subcellular levels remains elusive. To illuminate these issues, we use the *Drosophila* trachea as model. This tissue undergoes several morphogenetic processes to reach its correct diameter and length. These processes are controlled by an apical matrix pathway that requires functional septate junctions and secretion of the chitin-modifying enzymes Verm and Serp in the tracheal lumen. In addition, the Crb epithelial polarity module promotes apical membrane growth in tracheal cells, thereby specifying tube size. Consequently, overexpression of Crb results in an abnormally long trachea. Inhibition of Cora or Yrt modules, which antagonize Crb, leads to a comparable phenotype. Similar to Cora and Yrt, the GTPase Rac1 has been described to establish a reciprocally antagonistic relationship with Crb in the *Drosophila* ectoderm, suggesting that it may control epithelial tube morphogenesis.

Here, we show that expression of a dominant negative form of Rac1 in tracheal cells increases tube length without changing cell number. This phenotype is rescued by reducing *crb* dosage. This demonstrates that epithelial tube overgrowth results from an elevation of Crb activity, and suggests that Rac1 normally represses Crb activity to control tracheal tube length. Using genetic interactions, we established that Rac1 acts in parallel to *yrt* to control Crb activity. In addition, we observed decreased Rac1 activity in *cora* mutant or Cora knockdown embryos. This suggests that Rac1 is an effector of Cora regulating Crb activity and epithelial tissue morphogenesis. Accordingly, we found that Rac1 activity promotes secretion of Verm and Serp and septate junction integrity, as reported for Cora.

Overall, our data establish that Rac1 activity is required for proper tubulogenesis. It likely mediates Cora-dependent inhibition of Crb and apical membrane growth. In addition, Rac1 participates in the apical matrix pathway. Further characterization of these molecular mechanisms will allow for a better understanding of animal development and diseases associated with tube size defects.

P1263**Board Number: B605****The Balbiani body proteome in zebrafish.**A. Jamieson-Lucy¹, M.C. Mullins¹;¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

The Balbiani body is the first marker of polarity in vertebrate oocytes and presents a novel mechanism generating cell polarity. The Balbiani body is a conserved structure found in diverse animals including insects, fish, amphibians, and mammals. During early zebrafish oogenesis, the Balbiani body assembles as a transient aggregate of mRNA, proteins, and membrane-bound organelles at the presumptive vegetal side of the oocyte. As the early oocyte develops, the Balbiani body translocates from its initial perinuclear position to the vegetal cortex, where it disassembles and deposits its cargo of localized mRNAs and proteins. In fish and frogs, this cargo includes the germ plasm as well as gene products required to specify dorsal tissues of the future embryo. Despite its central role in establishing oocyte polarity, little is known about the mechanism behind the Balbiani body's action. Analysis of the few known protein components of the Balbiani body is insufficient to explain how the Balbiani body assembles, translocates, and disassembles. We isolated Balbiani bodies from zebrafish oocytes and performed mass spectrometry to define the Balbiani body proteome. We successfully identified 150 proteins associated with the Balbiani body sample, including known Balbiani body proteins and novel RNA-binding proteins. These results are a prerequisite to a comprehensive mechanism for Balbiani body function at a protein level. Furthermore, the number of proteins identified indicates that the Balbiani body is a complex structure that requires many proteins working in concert to generate oocyte polarity.

P1264**Board Number: B606****microtubule-actin crosslinking factor (Macf1) Functions in Animal-Vegetal Polarity Establishment In Zebrafish Oocytes.**M. Escobar-Aguirre¹, A. Jamieson-Lucy¹, R. Fuentes¹, M.C. Mullins¹;¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

In zebrafish oocytes, animal-vegetal polarity (AV) is established early in oogenesis through formation and translocation of the Balbiani Body (Bb) to the prospective vegetal pole of the oocyte where it disassembles at the end of stage I oogenesis. The Bb is a highly conserved structure present from insects to humans that contains mitochondria, ER, RNAs and proteins. Our lab demonstrated that the establishment of AV polarity depends on the function of the bucky ball and macf1 genes, which are required for Bb formation and disassembly, respectively. Loss of Macf1 function causes: 1) an enlarged Bb 2) asymmetric nucleus and 3) failure in Bb disassembly. Macf1 is a spectraplakins that connects actin, intermediate-filaments (IFs) and microtubules (MT) to functionally integrate them. Our aim is to elucidate the Macf1 dependent mechanism that -through interaction with the cytoskeleton- functions in

AV polarity establishment in oocytes. First, we determined that Macf1 protein localizes to the Bb and upon disassembly distributes along the vegetal cortex like Bb-localized mRNAs and other Bb components. Then, we examined the distribution of cytoskeleton components and assessed their function in Bb structure and nuclear positioning. To accurately determine the cytoskeleton distribution throughout stage I of oogenesis, we developed a MATLAB-based method to stage early oocytes. The algorithm accounts for oocyte size and Bb position to precisely determine the developmental stage of the oocytes. In early oocytes, Cytokeratins (CK) show a perinuclear distribution, and as stage I progresses CK distribute in the cytoplasm and accumulate in the Bb. In *macf1* mutants, CK enrichment in the Bb is greatly diminished. On the other hand, MT do not associate with the Bb and disruption of MT does not affect Bb structure or nuclear positioning. In *macf1* mutants, the asymmetric nuclear position coincides with the onset of the Bb enlargement defect, hence we genetically addressed whether the asymmetric nucleus is secondary to the Bb enlargement by examining *macf1*; *macf1* double mutants. Indeed, double mutants exhibit an asymmetric nuclear position, which demonstrates that Macf1 function in nuclear positioning is independent of Bb formation. In summary, we propose a model where CK maintain Bb structure until it reaches the vegetal cortex. Here, the Bb disassembles by Macf1 function in integrating cortical actin with CK and/or MT in a dynamic process culminating in AV polarity establishment. Ongoing live-imaging experiments will shed light on the Macf1-dependent cell polarity mechanism acting in developing zebrafish oocytes.

A GDI-independent mechanism to concentrate the Rho-GTPase Cdc42 during polarity establishment.

B. Woods¹, C. Wu¹, T. Zyla¹, N. Savage², D.J. Lew¹;

¹Department of Pharmacology and Cancer Biology, Duke University Medical Center, Durham, NC,

²Institute for Integrative Biology, Liverpool University, Liverpool, NC

The highly conserved Rho-family GTPase Cdc42 is a critical regulator of polarity in many fungal and animal cells. GTP-Cdc42 is concentrated in a region of the plasma membrane specifying the “front” of the cell, and interacts with downstream effectors to orient the cytoskeleton along the front-back axis. In the budding yeast, *Saccharomyces cerevisiae*, an autocatalytic mechanism enables resident GTP-Cdc42 to activate nearby GDP-Cdc42 via recruitment of a GDP/GTP exchange factor (GEF), creating a local GTP-Cdc42 enrichment over GDP-Cdc42. Subsequent delivery of more Cdc42 to that site would yield an overall increase in total Cdc42 (GDP+GTP) concentration. A GDP-dissociation inhibitor (GDI), Rdi1, is thought to deliver GDP-Cdc42 from distant parts of the membrane through the cytoplasm to the polarity site, where the GEF converts it to GTP-Cdc42. However, deletion of *RDI1* does not block Cdc42 concentration, so other Cdc42-delivery pathways must exist. One proposed mechanism involves delivery of Cdc42 via actin-directed vesicle trafficking, but we found that Cdc42 accumulated at the polarity site before exocytic vesicles in *rdi1Δ* cells. Furthermore, actin depolymerization did not block concentration of Cdc42 in *rdi1Δ* cells. Confocal imaging revealed a cytoplasmic pool of Cdc42 in *rdi1Δ*

cells, which could be reduced by additional lipid modification of Cdc42. Thus, Cdc42 can still exchange between the cytoplasm and the plasma membrane in *rdi1Δ* cells via an undiscovered parallel pathway, but at a slower rate. To search for components involved in that pathway, we conducted a genetic screen for mutants that are synthetically lethal with deletion of RDI1. We isolated several alleles of BEM2, a Cdc42-directed GTPase activating protein (GAP). Conditional *rdi1 bem2* double mutants arrested as large, round, and unpolarized cells. Our findings suggest that Cdc42 stills traffic through the cytoplasm without the GDI in a parallel pathway, and that cells relying on such traffic unexpectedly require the GAP Bem2.

RGS Proteins and Septins Cooperate to Promote Chemotropism by Restricting Polar Cap Mobility.

J.B. Kelley^{1,2}, G. Dixit², J.B. Sheetz², S. Venkatapurapu³, T.C. Elston^{1,3}, H.G. Dohlman^{1,2};

¹Department of Pharmacology, University of North Carolina, Chapel Hill, NC, ²Department of Biochemistry and Biophysics, University of North Carolina, Chapel Hill, NC, ³Curriculum in Bioinformatics and Computational Biology, University of North Carolina, Chapel Hill, NC

Septins are well known to form a boundary between mother and daughter cells in mitosis, but their role in other morphogenic states is poorly understood. Using microfluidics and live cell microscopy, coupled with new computational methods for image analysis, we have investigated septin function during pheromone-dependent chemotropic growth in yeast. We show that septins colocalize with the regulator of G protein signaling (RGS) Sst2, a GTPase-activating protein that dampens pheromone receptor signaling. We show further that the septin structure surrounds the polar cap, restricting its movement and ensuring that cell growth is directed toward the source of pheromone. Once formed, these structures constitute a dynamic barrier by scaffolding the RGS protein. When RGS activity is abrogated, septins are mislocalized and the polar cap travels toward septin structures and away from sites of exocytosis, resulting in a loss of gradient tracking. Thus septins promote chemotropic growth, and their function is dynamically controlled by RGS proteins.

P1267**Board Number: B609****Role of sterol-rich membrane domains in fission yeast cell polarity establishment and maintenance.**T. Makushok¹, P. Alves², S.M. Huisman³, D. Brunner⁴;¹Biochemistry and Biophysics Dept., University of California, San Francisco, San Francisco, CA, ²IGBMC, Illkirch, France, ³UZH, Zurich, Switzerland, ⁴Institute of Molecular Life Sciences, University of Zürich, Zurich, Switzerland

Fission yeast (*Schizosaccharomyces pombe*) is a model organism that is widely used for studying cell polarization. Polarization in fission yeast involves cytoskeleton-mediated positioning of growth sites. A complex consisting of the polarity factors Tea1 and Tea4 is transported on microtubules to the cell end regions. Tea4 interacts with the actin polymerization promoter For3. Selective activation of For3 in the cell end regions makes them rich in F-actin that contributes to localized cell growth. In this study, sterol-rich membrane (SRM) domains present at the growth sites are introduced as a new element in the picture, and their role in cell polarity establishment is analyzed. Since SRMs are absent from the plasma membrane in starved cells, imaging of cells recovering from starvation using the novel SRM marker GFP-Tna1 was performed to follow SRM domain formation *de novo*. Automated image analysis software was developed to analyze and correlate cell growth and SRM dynamics with an unprecedented level of precision. The results show that properly formed SRM domains are essential for fission yeast growth. SRMs, and with them the growth machinery, have to polarize before cell growth initiation. F-actin is required for selective removal of SRM domains in the cell middle region, and thus for polarizing SRMs. Fast removal of SRM domains in the cell middle region is not due to increased endocytic activity (mediated by F-actin). Tea1 controls the localization of polarized growth via Tea4 by affecting the positioning of SRM domains. Tea1 and Tea4 are essential for the stability of the SRM domains not associated with active growth sites. The importance of the microtubule cytoskeleton for the stability of SRM positioning stems from its role in the transport of the Tea1-Tea4 complex to the cell end regions. *Tea1Δ* and *tea4Δ* cells, known to grow monopolarly, grow faster at individual cell ends than wild type cells. Tea1 and Tea4 are required for proper timing of growth initiation. The proteins associated with the actin cytoskeleton, For3 and its activator Bud6, are important for the stability of SRM domains at both cell ends. For3 is also important for growth speed stabilization. Thus, a complex feedback loop links SRMs and cell growth. SRMs are essential for the polarization of the growth machinery, probably serving as platforms for its recruitment. The growth machinery, in turn, seems to stabilize SRM domains at sites that have initiated growth. The results of this study show that SRMs are a critical factor in *de novo* cell polarization, and not merely a player in its maintenance.

P1268**Board Number: B610****Systematic Analysis of Yeast F-box Proteins Reveals a New Role of Ubiquitination in Polarity Establishment.**J.B. Sheetz¹, J.B. Kelley^{1,2}, S.M. Miller², J.H. Hurst¹, E.G. Young¹, H.G. Dohlman^{1,2};¹Department of Biochemistry and Biophysics, University of North Carolina, Chapel Hill, NC, ²Department of Pharmacology, University of North Carolina, Chapel Hill, NC

Ubiquitination is a post-translational modification that regulates protein activity by tagging specific substrates for degradation. Regulation of proteins by ubiquitination has been demonstrated to help terminate the response to mating pheromone in budding yeast. The yeast pheromone response is comprised of two branches, one leading to MAPK activation and gene transcription, the other leading to cellular polarization and shmoo formation. The Skp1/Cdc53/F-box (SCF) ubiquitin ligase employs different F-box subunits to recruit specific substrates for ubiquitination. In yeast, F-box proteins have been identified as interchangeable components of the SCF complex. One of these, Cdc4, specifically targets pathway components including Gpa1, Far1 and Ste7. To identify additional pathway regulators, we conducted a screen in which we measured activation of the pheromone response in 16 yeast strains -- each lacking one of the known (or candidate) F-box genes. To gain an understanding of specific F-box functions, we characterized the abilities of these deletion mutants to affect either the MAPK or the polarity branch of the pathway. Our study reveals that one F-box protein, Pfu1, selectively regulates the polarity branch. Using live cell imaging in a microfluidic chamber, we demonstrate that Pfu1 is required to restrict the cell to a single polarity site. Cells lacking Pfu1 produce multiple polar caps and grow simultaneously during pheromone stimulation. In contrast, Pfu1 has no effect on MAP kinase activation or transcriptional induction. Candidate targets for Pfu1 are being evaluated using protein stability assays and mass-spectrometry sequencing. These findings are significant because they reveal new components of the cell polarization machinery. While polar axis formation is a fundamental and well characterized feature of budding, the mechanisms used to regulate cell polarity components during mating are largely unknown. The existence of an F-box protein exclusively involved in mating projection development reveals ubiquitination as a means to independently regulate branches of a signal transduction pathway.

P1269**Board Number: B611****Optogenetic control of symmetry breaking in *Saccharomyces cerevisiae*.**K. Witte¹, D. Strickland¹, M. Glotzer¹;¹Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

Polarization induces the shift from molecular symmetry to asymmetry and is critical to many cellular events including embryogenesis, motility, and cytokinesis. Polarization is inherently dynamic thereby enabling rapid responses to spatial and temporal cues. Optogenetic tools allow functional probing of

cellular polarization and spatial control of signaling molecules. Here, we use the optogenetic tool TULIPs to investigate one of the canonical polarization systems: bud site selection in *Saccharomyces cerevisiae*.

While wild type cells use landmark directed cues to define the polarization axis, cells lacking these spatial cues can spontaneously define an axis in a process known as symmetry breaking. The current model of symmetry breaking suggests that a stochastic accumulation of the active form of the Rho family GTPase, Cdc42, induces a positive feedback loop mediated by a polarity complex containing the Cdc42 GEF, Cdc24, the p21-activated kinase, Cla4, and a scaffold protein, Bem1. Though this model is consistent with a large body of data, it relies on a number of assumptions and it has not been directly tested.

Using TULIPs, we found that local accumulation of either Bem1 or Cdc24 is sufficient to induce recruitment of polarity regulators and effectors, and to promote bud emergence. The ability of Cdc24 to induce polarization depends on its GEF activity. These results are consistent with existing models. However, we find that the polarity proteins do not always function in a potent positive feedback loop. Specifically, membrane recruitment of Cdc24 induces Cdc42 activation early in the cell cycle, but Bem1 does not accumulate until late G1. Although Bem1 recruitment can induce Cdc42 activation in late G1, it is unable to do so during early G1. These results indicate that Cdc42 activation does not invariably induce Bem1-mediated positive feedback. Furthermore, we demonstrate that the switch to Bem1-mediated positive feedback activation requires Cdk1 kinase activity.

Optogenetics allows facile control of competing sites of polarization. We find that Cdc24-generated sites in early G1 can be self sustaining, but that they are readily squelched by a second site in the same cell. Conversely, in late G1, once Bem1 has been recruited, a single site of Cdc24 recruitment cannot outcompete an existing site. Collectively, our study reveals unexpected behaviors of the yeast Cdc42 activation module and demonstrates the utility of optogenetics in dissecting cellular signaling.

The Sequential Logic of Polarity Determination During the Haploid-to-Diploid Transition in *S. cerevisiae*.

S. Zapanta Rinonos¹, U. Rai², S. Vereb¹, K. Wolf¹, E. Yuen¹, C. Lin², A.M. Tartakoff^{2,3};

¹Case Western Reserve University, Cleveland, OH, ²Department of Pathology, Case Western Reserve University, Cleveland, OH, ³Departments of Molecular Biology and Microbiology, Cell Biology Program, Case Western Reserve University, Cleveland, OH

In many organisms, the geometry of encounter of haploid germ cells is arbitrary. In *S. cerevisiae*, the resulting zygotes have been seen to bud asymmetrically in several directions as they produce diploid progeny. What mechanisms account for the choice of direction and do the mechanisms directing polarity change over time? Distinct subgroups of cortical "landmark" proteins guide budding by haploid vs diploid cells, both of which require the Bud1/Rsr1 GTPase to link landmarks to actin. We observe that

as mating pairs of haploid cells form zygotes, bud site specification progresses through three phases. The first phase follows disassembly of components from the zone of cell contact and their reassembly to produce a large medial bud. Bud1 is not required for medial placement of the initial bud. The second phase produces a contiguous bud(s) and depends on axial landmarks. As the titer of the Axl1 landmark diminishes, the third phase ultimately redirects budding toward terminal sites and is promoted by bipolar landmarks. Thus, following the initial random encounter that specifies medial budding, sequential spatial choices are orchestrated by the titer of a single cortical determinant that determines whether successive buds will be contiguous to their predecessors.

Role of conserved NDR kinase Orb6 in translational control and the morphological response to caloric restriction.

I. Suarez¹, D.J. Wiley¹, M. Das², F. Verde¹;

¹University of Miami Miller School of Medicine, Miami, FL, ²Biochemistry, Cellular, and Molecular Biology, University of Tennessee, Knoxville, TN

NDR kinases are a highly conserved family of proteins that regulate morphogenesis, cell growth and proliferation, mitosis, and development. Our previous work has demonstrated a role for the fission yeast NDR kinase Orb6 in cell polarization through the spatial control of Cdc42 GTPase activation (Das et al, Curr Biol, 2009). Here we report a genetically separable function for Orb6 kinase in promoting cell viability by preventing translational repression. We found that Orb6 kinase phosphorylates the mRNA-binding protein Sts5, and that *sts5Δ* delays the morphological response to caloric restriction. Specifically, glucose deprivation leads to Sts5-GFP colocalization with Dcp1-mCh, which is a marker of cytoplasmic P-body structures where mRNAs are stored and/or degraded during stresses such as nutrient deprivation or osmotic stress. In addition, chemical inhibition of the analog-sensitive Orb6-as2 mutant kinase also resulted in Sts5-GFP colocalization with P-bodies, mimicking the glucose-deprivation response. Microarray analysis identified several classes of mRNAs that are more abundant in the *sts5Δ* strain, including transcripts involved in cell polarization and bipolar growth activation, cell wall formation, nutrient transport, and meiosis. qPCR analysis confirmed that *sts5Δ* increased levels of selected transcripts and that these levels were decreased upon Orb6-as2 kinase inhibition. We also found that the glucose-sensing PKA pathway synergizes with the Orb6 kinase pathway in the control of P-body formation. These results suggest that Orb6 kinase mediates translational control of specific transcripts by inhibiting the localization of the mRNA-binding protein Sts5 to P-bodies, thus promoting polarized cell growth in cooperation with nutritional response pathways.

P1272**Board Number: B614****Role of the microtubule cytoskeleton in the control of Cdc42 oscillatory dynamics.**M. Rodriguez¹, I. Suarez¹, F. Verde¹;¹University of Miami Miller School of Medicine, Miami, FL

Schizosaccharomyces pombe is a great model system to understand the signaling mechanisms regulating polarized cell growth. Upon the completion of mitosis, *S. pombe* cells grow in a monopolar fashion from their old tips in a process termed Old End Takes Off (OETO). Once the cell reaches a certain length, growth is activated in the second tip through a process called New End Take Off (NETO), resulting in bipolar growth.

Active Cdc42 GTPase, a key regulator of cell polarity, displays oscillatory dynamics that are anti-correlated at the two cell tips in fission yeast. This system globally controls active Cdc42 distribution, modulating cellular dimensions, and controlling the activation of growth at the secondary growing tip (Das, M. et al., *Science*, 2012). Mathematical modeling and experimental analysis suggest Cdc42 dynamic oscillations result from the coordinated function of Cdc42 regulators, including Cdc42 GEF proteins, Gef1 and Scd1, Cdc42 GAP protein, Rga4, and Cdc42-dependent Pak1 kinase, in an interplay of positive and negative feedback mechanisms.

Here, we report that the microtubule cytoskeleton is required for Cdc42 GTPase oscillations. Cells treated with the microtubule depolymerizing agent MBC show asymmetrical distribution of active Cdc42 and delay bipolar growth activation (NETO). Similarly, cells expressing a mutated form of the microtubule tip-associated protein Tea4, which is unable to target the phosphatase Dis1 to the growing tip, displayed asymmetrical Cdc42 activity, a phenotype that is also observed with *gef1Δ* mutants. We find that conserved NDR kinase Orb6 negatively regulates Cdc42 GEF Gef1, an orthologue of mammalian TUBA/DNMBP. A mutated form of Cdc42 GEF Gef1 that cannot be phosphorylated by Orb6 kinase can bypass the microtubule-mediated requirement for NETO. These results provide evidence that the self-organizing microtubule cytoskeleton informs Cdc42 regulation.

P1273**Board Number: B615****Effect of Connexin 43 Loss on Apical Polarity and Differentiation of Normal Breast Epithelium.**R.T. Talhouk¹, D. Bazzoun¹, S.A. Lelievre², H. Adissu²;¹Biology Department, American University of Beirut, Beirut, Lebanon, ²Purdue Univ, West Lafayette, IN

Recent evidence suggests a regulatory role for Connexin (Cx) 43, a gap junction (GJ) protein, in apical polarity establishment that is a key property of epithelial tissues and is disrupted early on during

tumorigenesis. We have previously demonstrated a Cx43 context-dependent tumor-suppressive role mediated partially by a GJ complex assembly that sequesters Cx43-associated proteins β -, α -catenin and ZO-1 proteins at the cell membrane of breast epithelial tumor cell lines and contributes to lumen formation and maintenance in non-neoplastic breast epithelial cells. However, the mechanism that governs Cx43 role in regulating tumor suppression is not fully elucidated. In this study, HMT-3522 S1 non-neoplastic breast epithelial cells were used to decipher the mechanism through which Cx43 contributes to the homeostasis of the normal mammary epithelium. For this purpose, Cx43 was stably silenced in S1 cells using Cx43-specific shRNA along with a nonspecific (NSS) shRNA as control. S1 cells were cultured in three-dimensional (3D) conditions that permit the formation of physiologically relevant epithelial glandular structures (acini). A significant rise in the proliferation rate of S1 cells was noted in response to Cx43 silencing, as reflected by an increase in the size of S1 acini. Enhanced proliferation was accompanied by improper acinar morphogenesis and loss of the ability of S1 cells to form monolayered acini. Moreover; preliminary data from invasion assays revealed that the loss of Cx43 gives the capability for S1 cells to invade, through a layer of diluted Matrigel, to a higher extent than the control and T4-2 cells, the tumorigenic counterparts of S1 cells. These changes, in addition to the disruption of apical polarity in acini and mislocalization of both ZO-1, an apical polarity marker, and β -catenin, a protein involved in the control of epithelial to mesenchymal transition (EMT), indicate a shift in the phenotype into one that enables neoplastic development. Furthermore, Cx43 silencing altered the apico-lateral localization in S1 acini of the protein Scrib, a key regulator of apical polarity and a tumor suppressor recently reported to be involved in the control of EMT in murine lens epithelium and in the regulation of murine mammary gland progenitor activity. We propose that Cx43 tumor-suppressive role may be mediated through an impact on pathways involved in EMT.

Prickle-3 defines the vertebrate PCP axis and controls ciliogenesis during embryonic development.

C. Chu¹, S. Sokol²;

¹Developmental Regenerative Biology, Icahn School of Medicine at Mount Sinai, New York, NY,

²Developmental Regenerative Biology, Icahn School of Medicine at Mount Sinai, NEW YORK, NY

Core PCP proteins, including vertebrate homologues of *Drosophila* Van Gogh and Prickle (Pk), maintain planar polarity in a number of vertebrate epithelial tissues and have been implicated in cilia positioning and growth in vertebrate embryos, but the underlying molecular mechanisms remain unclear. Prickle-3 (Pk3), an understudied member of the Pk family, has been shown to associate with the centrosome. Here we demonstrate a striking polarization of Pk3 in *Xenopus* embryonic ectoderm along the anterior-posterior body axis. This polarization of Pk3 in gastrula ectoderm was under the instructive influence of non-canonical Wnt ligands. The C-terminal domain of Pk3 was both necessary and sufficient for the plasma membrane recruitment of Pk3 by Van Gogh-like 2 (Vangl2), but not for Pk3 polarization. In loss-of-function studies Vangl2 homologues have been shown to regulate posterior positioning of cilia in the

frog gastrocoel roof plate (GRP) and the mammalian node, without affecting ciliary growth. By contrast, the knockdown of Pk3 from early *Xenopus* embryos altered both the location and the length of cilia in GRP cells. In cells depleted of Pk3, Vangl2 polarization was disrupted, suggesting that Pk3 functions to maintain Vangl2 distribution and regulate ciliogenesis. Mutagenesis studies attempting to discriminate these two functions of Pk3 will be discussed.

Plasma membrane PI(4,5)P2 levels are critical for actin assembly and polarity during both migration and cell division.

C.J. Janetopoulos¹, D.K. Jowhar², R.B. Khodadadi², M.J. Housman², B. Chen³, E. Betzig³, S. Rucker²;

¹Biological Sciences, Univ of the Sciences, Philadelphia, PA, ²Vanderbilt Univ, Nashville, TN,

³HHMI/Janelia Farm Research Campus, Ashburn, VA

We monitored signaling and cytoskeletal elements during polarity reversals of migrating *Dictyostelium discoideum* cells using a novel microfluidic device. We found that “backness” and “frontness” in regions of the cell were regulated by plasma membrane (PM) PI(4,5)P2 levels. PI 3’Kinase (PI3K) and Phospholipase C (PLC) activity reduce PI(4,5)P2 levels at the front, while high PI(4,5)P2 levels contribute to “backness”. The tumor suppressor PTEN catalyses the dephosphorylation of the 3’phosphate of PI(3,4,5)P3, producing PI(4,5)P2. PTEN contains a PI(4,5)P2 binding motif and helps maintain high PI(4,5)P2 levels at the back of the cell in a positive feedback loop. Interestingly, the activity of the GTPase Ras was reciprocally regulated with local PI(4,5)P2 levels during polarity reestablishment, suggesting that high PI(4,5)P2 levels inhibit Ras activity, supporting a negative feedback loop. Cells lacking PLC and treated with PI3K inhibitors are still able to reduce PI(4,5)P2 levels and break symmetry when receptors are activated, suggesting that other 4’ or 5’ phosphatases are activated by chemoattractant and contribute to “frontness”, providing yet another level of redundancy.

During cytokinesis, PM PI(4,5)P2 levels rise uniformly as cells round up at metaphase and contribute to the rounding up of the cell. These intermediate levels help reset polarity. PI(4,5)P2 levels subsequently rise in the furrow and are lowered at the poles triggering differential actin assembly, largely through localizing factors specific to the activity of the Rho GTPases, with Arp2/3 mediated filaments forming at the poles. Stimulating metaphase PTEN null cells with chemoattractant gives a transient PI(3,4,5)P3 and F-actin response. Interestingly, lack of PTEN leads to elevation of PI(3,4,5)P3 levels, but they are still regulated in response to chemoattractants at metaphase, suggesting that the threshold for Ras activity is different at this stage. These findings have important implications for cancer. Therapeutic strategies should consider targeting a host of enzymes that regulate PI(4,5)P2 levels, as cancers with low PM PI(4,5)P2 are likely to be highly metastatic.

We have suggested that PI 4’ and 5’ Kinases help terminate uniform chemoattractant-induced responses and contribute to the “backness” of migrating cells. The enzymatic activity that regulates increased PM PI(4,5)P2 levels is likely the inhibition component in the Local Excitation/Global Inhibition model that we

have proposed regulates chemotaxis. The responses seen during a global stimulation and the spatial distribution of signaling molecules when cells are in a chemical gradient may be explained largely by changes in PM PI(4,5)P2 levels, which influence actin assembly and cell morphology.

The MEX-5/6 concentration gradient controls PIE-1 segregation in the cytoplasm of the *C. elegans* zygote.

Y. Wu¹, E. Griffin¹;

¹Biological Sciences, Dartmouth College, Hanover, NH

Cell polarity is characterized by the asymmetric distribution of factors at the cell cortex and in the cytoplasm. While mechanisms that control the segregation of cortical proteins have been well characterized, less is known about how cytoplasmic proteins become asymmetrically distributed. During the asymmetric division of the one-cell *C. elegans* embryo, a collection of cytoplasmic CCH finger RNA binding proteins are partitioned along the anterior/posterior axis into opposing concentration gradients in response to the conserved polarity regulators, the PAR proteins. MEX-5/6 form a 3-fold anterior-rich concentration gradient while PIE-1, POS-1 and MEX-1 form 5-fold, 3-fold and 2-fold posterior-rich gradients, respectively (Guedes 1997, Mello 1996, Tabara 1999, Schubert, 2000 Ogura, 2003). It was previously demonstrated that the PIE-1 gradient results from its differential diffusion. An increase in PIE-1 diffusion in the anterior cytoplasm causes PIE-1 to be retained preferentially in the posterior where diffusion remains slow (Daniels 2009). The mechanisms that control PIE-1 diffusion are not known.

Using Fluorescence Correlation Spectroscopy analysis fit to anomalous diffusion models, we find that GFP::PIE-1, GFP::POS-1 and GFP::MEX-1 all have significantly slower rates of diffusion in the posterior cytoplasm compared to the anterior cytoplasm. The degree of differential diffusion correlates with the strength of their concentration gradients. For example, GFP::PIE-1 has an apparent diffusion rate of $7.0 \mu\text{m}^2/\text{s}$; $a = 0.64$ in the anterior and $0.4 \mu\text{m}^2/\text{s}$; $a = 0.35$ in the posterior whereas MEX-1 has an apparent diffusion rate of $1.5 \mu\text{m}^2/\text{s}$; $a = 0.51$ in the anterior and $0.5 \mu\text{m}^2/\text{s}$; $a = 0.42$ in the posterior (a is the anomaly coefficient). MEX-5/6 are epistatic to PAR-1 and PAR-3 with respect to the control of PIE-1 mobility, indicating that MEX-5/6 likely act downstream of PAR proteins. We progressively depleted MEX-5/6 levels in *par-1(it51)* mutant embryos by partial RNAi and find that PIE-1 diffusivity correlates with the concentration of MEX-5/6. These data support a model in which the MEX-5/6 concentration gradient controls the establishment of a PIE-1 diffusion gradient, which in turn, leads to the segregation of PIE-1.

Examining the Roles of Myosin II, Dynein, and Drebrin in Nucleokinesis of Migrating Neurons.

J.S. Ramahi¹, D. Solecki²;

¹Saint Jude Children's Res Hosp, Memphis, TN, ²developmental neurobiology, St. Jude Children's Res Hosp, Memphis, TN

Migration of neurons from their germinal zone to final location is an essential process in the developing brain. Following polarization of a developing neuron, nucleokinesis occurs in a two-stroke process. The nucleokinesis cycle is the saltatory motion of centrosome and cytoplasm transport into the leading process dilation of a neuron followed by somal translocation. A current debate in the field revolves around the roles of the actin and microtubule networks in the two-stroke nucleokinesis cycle and how they generate force within the cell.

We examined cytoskeleton elements and motors involved in neuronal migration through *in vitro* time-lapse imaging using the mouse cerebellar granule neuron system, conditionally perturbing motor function using small molecule inhibitors. We examined potential modes of actin/microtubule crosstalk through functional studies of drebrin, which interacts with both microtubule plus tips and actin. The leading process dilation of granule neurons is enriched with myosin II motors during the two-stroke nucleokinesis cycle and live imaging of venus tagged dynein motors showed that dynein flows from the soma toward the leading process dilation. We also show the leading process dilation is enriched with drebrin immediately preceding somal translocation.

Pharmacological inhibition of myosin II motor ATP-activity using blebbistatin retards movement of the centrosome. Using HPI-4 (Ciliobrevin A) to similarly inhibit dynein, organelle dynamics were tracked in migrating neurons using the centrosome, cilia, golgi, and nucleus as metrics to compare the effects of inhibiting myosin II to dynein. Single inhibition of myosin II or dynein motors slowed all organelles tested, however residual movement remained. While single inhibition of myosin and dynein phenocopied each other, dual inhibition of both myosin II and dynein completely halted organelle positioning and migration.

Functional inhibition of drebrin through dominant-negative constructs, shRNA, and pharmacologically with BTP2 all resulted in similar disruption of directed migration of granule neurons *in vitro*. Population analysis of drebrin inhibited cells show a lower occurrence of migration, and cells that migrated moved inefficiently. Leading process cytoskeletal dynamics of migrating neurons was examined in drebrin inhibited cells.

Overall these results indicate that both myosin II and dynein motor systems dually contribute to neuronal migration in the leading process of migrating granule neurons, potentially through drebrin linking actin and microtubule networks.

RhoGTPase Regulatory Signatures Define Distinct Stages of Synaptic Development.

K.A. Newell-Litwa¹, S. Martin-Vilchez², H. Asmussen¹, L. Whitmore¹, A.R. Horwitz¹;

¹Cell Biology, University of Virginia, Charlottesville, VA, ²Cell Biology, University of Virginia, Charlottesville, VA

Small RhoGTPases organize the actomyosin cytoskeleton to drive changes in post-synaptic spine shape that support learning and memory. RhoGTPase signaling pathways are major targets of synaptic disorders, such as Autism. During normal synaptic development, the small RhoGTPase, Rac, promotes the formation of filopodia-like spine precursors, which subsequently mature through RhoA-dependent myosin II activation into polarized mushroom-shape spines. Further excitatory stimulation associated with long-term potentiation leads to Rac-driven spine head expansion. We sought to identify novel regulators of synaptic RhoGTPase activity, and to determine whether different upstream RhoGTPase regulatory proteins, including GEF activators, GAP inactivators, and inhibitory GDIs, regulate specific stages of synaptic development. We performed an in-silico screen of genes identified from published synaptic proteomes and the SFARI database for association of these genes with Autism copy number variants (CNVs) to identify known and putative RhoGTPase regulatory proteins. This approach identified several candidate actin regulatory proteins, the majority of which localized to known Autism CNVs. We used shRNA to down-regulate expression of specific RhoGTPase regulatory proteins in rat primary hippocampal neurons during either early spine formation or subsequent maturation. Our data demonstrate that unique RhoGTPase regulators mediate distinct stages of synaptic development. Specifically, the Rac-GEF beta-Pix, ArhGAP23 and Frabin, affected early spine precursor formation, but not subsequent maturation. However, GDI-mediated attenuation of RhoGTPase activity stabilized mature spines; knockdown of either GDI-alpha or gamma resulted in significantly longer spines. The novel RhoGAP, ArhGAP39, regulated spine length and density specifically during spine maturation. Notably, RNA expression of these GDIs and ArhGAP39 increased significantly during neuronal development. We further characterized the function of the putative RhoGAP, ArhGAP39, in migratory CHO.K1 fibroblasts, which also express ArhGAP39. GFP-ArhGAP39 resulted in robust stress fiber formation and focal adhesion maturation, consistent with GAP activity towards Rac, resulting in a corresponding increase in RhoA-mediated myosin activation. Alternately, knockdown of ArhGAP39 resulted in round cells with an extensive lamellipodia associated with increased small nascent adhesions, indicative of increased Rac activity, which we confirmed with a Rac FRET biosensor. Our study demonstrates that specific combinations of RhoGTPase regulatory proteins temporally balance Rac and

RhoA activity to regulate post-synaptic spine development, and further shows that ArhGAP39 functions as a novel Rac GAP in post-synaptic spine maturation.

Regulation of actin dynamics by RhoA-LIMK-cofilin during axon retraction by rod photoreceptors after retinal injury.

W. Wang¹, E. Townes-Anderson¹;

¹Rutgers University, Newark, NJ

In response to injury, rod photoreceptors display synaptic plasticity including axon retraction and synaptic disjunction. Our previous studies demonstrated that the mechanism of retraction involves activation of RhoA and its downstream effector Rho kinase (ROCK). Here, we pursued further downstream events in order to develop possible therapies.

First, we measured axon retraction of isolated salamander rod cells over time with or without inhibition of LIM kinase, a downstream effector of ROCK. Our results showed that a LIMK inhibitor (LIMKi) can block retraction: 38% decrease of initial rod axon length in controls after 7 hours, compared with only a 25% decrease using 10uM LIMKi. We next studied the activity of cofilin, an effector of LIMK which regulates actin filament turnover. We created detachments of pig retina, incubated the retinal explants for 24 hours and examined both total and phosphorylated cofilin with Western Blots. P-cofilin increased over 24 hours whereas total cofilin remained relatively stable; treatment with LIMKi or the ROCK inhibitor Y27632 prevented such increases.

Since activity of cofilin leads to an increased turnover rate of actin filaments, we were curious whether or not actin depolymerization contributes to axon retraction in rod photoreceptors. We examined actin filaments by phalloidin staining and the barbed end assay. Isolated salamander rod cells were stained with phalloidin-Alex488 at 15 minutes, 2, 4, and 7 hours after retinal dissociation. Quantification of fluorescence signal suggested that after an initial increase during the first 2 hours (about 2 fold), actin filaments then depolymerize indicated by a 30% decrease in fluorescence intensity by 7 hours. The barbed end assay measures freshly severed actin filaments by labeling them with a biotin-actin monomer, which demonstrates activity of cofilin/p-cofilin. Severing of actin filaments was highest at 15 minutes and then decreased by 80% during the remaining 7 hours, likely attributable to fewer available actin filaments over time. Pretreatment of retina with either ROCK or LIMK inhibitor significantly reduced barbed end labeling 15 minutes after injury, by 70% and 90% respectively.

Immunocytochemistry also showed co-localization of p-LIMK, the active form of LIMK, with barbed end actin filaments in the axonal region of rod photoreceptors during retraction.

To summarize, our data showed that the RhoA-ROCK-LIMK-cofilin pathway is involved in axon retraction of rod photoreceptors after retinal detachment and works in part by up-regulating actin

depolymerization. Inhibition of this pathway can prevent axon retraction and stabilize synaptic structure presumably by stabilizing the actin filament cytoskeleton.

Rear accumulation of actin underlies nucleus-centrosome inversion type of nucleokinesis in migrating neocortical neurons.

A. Sakakibara¹;

¹Chubu Univ-Coll Life/Hlth Sciences, Kasugai, Japan

Neuronal migration is an integrative process involving leading process formation, nucleokinesis, and rear retraction, all of which depend on the function of cytoskeletons. Cytoplasmic microtubules (MTs) and dynein have been implicated in force generation for nucleokinesis. However, several lines of evidence suggest that the actomyosin system likely functions in co-operatively. To assess the contribution of MT and actin cytoskeletons in nucleokinesis, we employed *in situ* live imaging of migrating neocortical neurons in slice culture (Sakakibara et al. (2014) *Cereb. Cortex* 24:1301-1310). Lifeact-EGFP (F-actin), PACT-mKO1 (centrosome), and Histone-H2B-iRFP670 (nucleus) were used for simultaneous labeling and imaging by triple color fluorescence channels. During the locomotion of neurons, two types of nucleokinesis were observed (reviewed in Sakakibara et al. (2013) *Open Biol.* 3:130061). The first one is the nucleus-centrosome (N-C) coupling type of nucleokinesis. Centrosome proceeded into the leading process prior to the N-C coupling type of nucleokinesis; this move has been implicated in the dynein-dependent forward pulling of nucleus by MTs. Rear accumulation of F-actin was not necessarily observed during the N-C coupling type of nucleokinesis. The second type of nucleokinesis is the N-C inversion during which translocating nucleus overtake the centrosome. Rear accumulation of F-actin was evidently observed when the N-C inversion occurred. These data suggest that the actomyosin system underlies the N-C inversion type of nucleokinesis during which the MT-dynein system could not pull the nucleus.

A Dynamic Formin-dependent Axonal F-actin Network.

A. Ganguly¹, Y. Tang², K. Ladt², L. Wang², S. Roy²;

¹Pathology, University of California, San Diego, San Diego, CA, ²Pathology/Neurosciences, University of California, San Diego, La Jolla, CA

The cytoskeletal protein actin is involved in numerous aspects of neuronal physiology. Although actin organization and dynamics at growth-cones is well studied, much less is known about axonal actin. Using probes that specifically bind filamentous actin (F-actin), we found local zones of actin assembly/disassembly ('hotspots') distributed along axons. These hotspots are a nidus for vigorous

Formin-dependent actin assembly (“actin trails”) that appears to occur on the surface of stationary axonal vesicles. Intriguingly, the overall kinetics generate an anterogradely-biased flow of the F-actin population into axons and en-passant synapses, at rates consistent with slow axonal transport. Disrupting the Formin-mediated dynamics has little effect on microtubule-based transport, but interferes with axonal elongation and presynaptic function. Collectively, our studies reveal previously-unknown mechanistic details of an axonal actin-network with implications for neuronal physiology. We propose a model where an overall dynamism maintains axonal actin in an organized yet flexible state – allowing swift response to intrinsic and extrinsic cues.

Formin -2 in Neuronal Development.

A. Sahasrabudhe¹, K. Ghate¹, A. Jacob¹, A. Ghose¹;

¹Biology, Indian Institute of Science Education and Research (IISER), Pune, India

The establishment of proper neuronal connections during early embryonic development is tightly regulated by instructive cues that guide the exploring neuronal growth cone to find its synaptic targets. The growth cone steering is achieved by cue-dependent remodelling of the underlying cytoskeleton that regulates polarity, protrusion and generation of coordinated traction forces. We have screened the developing chick embryo for various actin nucleators and have identified Formin 2 (Fmn-2) expression to coincide with the window of spinal commissural neurite outgrowth and floor plate crossing. In vivo knockdown of Fmn2 results in defective midline crossing by the commissural interneurons. Using cultured primary neurons, we show that Fmn2 is involved in regulating growth cone motility. Studies in fibroblasts reveal that Fmn2 is involved in stabilizing cell-substrate interactions. Taken together our study identifies Fmn2 as central regulator of growth cone dynamics central to axonal outgrowth and pathfinding .

Molecular architecture of the Axon Initial Segment revealed by super-resolution microscopy.

C. Leterrier¹, J. Potier¹, B. Dargent¹;

¹Aix Marseille University, CNRS, CRN2M UMR7286, Marseille, France

The Axon Initial Segment (AIS), located within the first thirty microns of the axon, has two essential functions in neuronal physiology. First, it generates the axon potential through the concerted action of voltage-gated ion channels. Second, it maintains neuronal polarity by separating the somatodendritic and axonal compartments. This separation is ensured by a diffusion barrier at the AIS membrane, and a proposed intracellular transport filter that regulates cargo access to the axon. The molecular

composition of the AIS has been characterized in the recent years, and depends on the assembly of the ankyrin G (ankG) / β IV-spectrin scaffold. However, we don't know how AIS components are arranged to form the surface barrier and the transport filter. This motivated us to assess the molecular architecture of the AIS by elucidating the nano-organization of the scaffold proteins ankG and β IV-spectrin.

We used STochastic Optical Reconstruction Microscopy (STORM), which provide a ~ 10 times enhancement in spatial resolution over diffraction-limited microscopy. STORM recently uncovered a striking periodic submembrane structure for spectrin and actin in the axon. Using 2-color STORM on cultured hippocampal neurons, we detected rings of actin spaced every 185 nm along the AIS, connected by a periodic submembrane sheath of longitudinally-oriented β IV-spectrin proteins. Thanks to antibodies directed against several domains of the large ankG isoforms, we then mapped ankG positioning in the AIS. The spectrin-binding domain of ankG, located on its amino-terminal side, is organized periodically along the β IV-spectrin sheath. Strikingly, the opposite carboxy-terminal domain of ankG showed a less organized distribution, hinting at an extended conformation of ankG. Interestingly, 2-color 3D-STORM showed that the carboxy-terminus of ankG localizes further inside the AIS axoplasm than its spectrin-binding domain. Quantification of 3D-STORM images allowed us to determine a radial extension of 40 nm between these two ankG domains. Finally, the two features of the AIS nano-architecture, longitudinal β IV-spectrin and radial ankG, are robust to acute perturbation of the actin and microtubule cytoskeleton. Resolving the molecular architecture of the AIS allow us to foster new hypotheses on how the AIS scaffold can regulate protein transport and maintain polarity in neurons.

Board Number: B627

Nuts and bolts of the axon initial segment cytoskeletal architecture: Roles of β IV-spectrin.

S.L. Jones¹, T. Svitkina¹;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA

The axon initial segment (AIS) is a specialized compartment in polarized neurons essential for regulating action potential initiation and axon dendrite polarity. AIS function depends on the formation and maintenance of a specialized cytoskeleton at the plasma membrane, but the function of individual cytoskeletal components in the AIS remains unclear. Using platinum replica electron microscopy (PREM), we show that the AIS is highly organized into a multi-protein network containing plasma membrane integral proteins (e.g., ion channels and cell adhesion molecules), as well as core cytoskeletal components (e.g., ankyrinG, β IV-spectrin, and actin filaments) that have been hypothesized to serve as a molecular platform on which all other AIS proteins are organized and maintained. While it is clear that ankyrinG function as a master organizer responsible for the recruitment and stability of all other AIS proteins, the role of β IV-spectrin is unclear. Using immunoPREM combined with shRNA-based depletion methods, we investigate the role of β IV-spectrin as a key component of the core AIS cytoskeletal backbone and its role in the overall organization, assembly and maintenance of the AIS multi-protein

network. Consistent with recent studies, we show that β IV-spectrin is essential for long-term AIS maintenance and stability by promoting the retention of AIS-enriched proteins. Intermediate stages of AIS cytoskeleton disassembly following β IV-spectrin depletion reveal new features of the AIS cytoskeletal architecture.

Spectrin β III functions at the neck and base of dendritic spines to support their formation in hippocampal neurons.

N. Efimova¹, F.V. Korobova², T. Svitkina¹;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA, ²Dartmouth College, Riverside, RI

The neurodegenerative disorder spinocerebellar ataxia type 5 (SCA5) is linked to mutations in the SPTBN2 gene encoding a neuron-specific spectrin β III. At the cellular level, spectrin β III deficiency impairs formation of dendritic spines and reduces accumulation of some postsynaptic components, but underlying mechanisms remain unclear. The shape of the spine head is maintained by a dense branched actin network, whereas a cytoskeletal mechanism supporting for the constricted shape of the spine neck remains unclear, because of the absence of adequate actin cytoskeleton in the spine neck [Korobova & Svitkina, 2010, Mol. Biol. Cell, 21, 165-176]. Here, we show that spectrin β III in cultured rat hippocampal neurons is enriched at the base and neck of dendritic spines, where it comprises a part of the detergent-resistant cytoskeleton and exists in the form of thin fibrils with characteristic dimensions of spectrin tetramers. Silencing of spectrin β III markedly decreases formation of dendritic spines and postsynaptic specializations without significant effects on formation of presynaptic boutons. Accordingly, spectrin β III knockdown neurons exhibit increased occurrence of unopposed presynaptic boutons and boutons apposing weak postsynaptic structures in a dendrite shaft. We propose that spectrin β III functions as a part the membrane cytoskeleton to maintain the dendritic spine neck, which forms a diffusion barrier retaining postsynaptic molecules at the synapse. In the absence of the neck, increased diffusion of postsynaptic components leads to formation of weak synapses or their absence. Thus, our data significantly advance understanding of the molecular mechanisms of SCA5 and reveal parallels between spectrin functions in neurons and erythrocytes.

P1286**Board Number: B629****Regulation of neurofilament transport by a dynamic cycle of polymer severing and annealing.**A. Uchida¹, A. Brown¹;¹Department of Neuroscience, The Ohio State University, Columbus, OH

Neurofilaments are transported and distributed along axons by the mechanisms of axonal transport, moving anterogradely and retrogradely in rapid infrequent bursts of movement interrupted by prolonged pauses. We have discovered that axonal neurofilaments lengthen by joining end-to-end, called end-to-end annealing, and that they can also be shortened by a severing mechanism. To explore the significance of these novel phenomena for neurofilament transport, we developed a long-term multi-field tracking method that uses a motorized stage to follow single GFP-tagged neurofilaments along axons by time-lapse fluorescence microscopy for hundreds of μm across multiple fields of view. The tracked filaments ranged from 1.3 to 56.0 μm in length. Short filaments (20 μm in length; average=29.5 μm , n=51) exhibited more frequent severing (0.15 annealing events/filament/hour; 1.5 severing events/filament/hour). Filaments of all lengths were capable of rapid movement, but short filaments moved more persistently, pausing less and rarely reversing direction, whereas long filaments moved less persistently, pausing for long periods, and often reversing direction. Thus the kinetics of neurofilament transport are influenced by the length of these polymers. Since N-terminal phosphorylation is known to result in fragmentation and disassembly of intermediate filaments, we used site-directed mutagenesis to investigate whether N-terminal phosphorylation might regulate neurofilament length. GFP-fusions of NFL in which serines 2, 55, 57 and 66 in the N-terminal head domain were all mutated to either alanine (S4A-NFL) or aspartate (S4D-NFL) both assembled into filaments, contrary to previous reports, but filaments containing S4A-NFL were longer (average=13.5 μm , n=87) and moved less frequently (average=4.5/hour, n=23 axons) than wild type, whereas filaments containing S4D-NFL were shorter (average=5.1 μm , n=146) and moved more frequently (average=9.6/hour, n= 28). We propose that the length and transport of neurofilaments in axons is regulated by a dynamic cycle of polymer severing and annealing. Severing liberates short filaments that move more readily, whereas end-to-end annealing of these short filaments sequesters them in the form of long polymers that move less readily. We speculate that site-directed N-terminal phosphorylation of neurofilaments may be a mechanism for intermediate filament severing. We are currently testing this hypothesis.

P1287**Board Number: B630****A giant and KASH-less isoform of Nesprin1 underlies the molecular etiology of autosomal recessive cerebellar ataxia Type 1 (ARCA1).**D.M. Hodzic¹, D.S. Razafsky¹;¹Ophthalmology and Visual Sciences, Washington University School of Medicine, Saint Louis, MO

Linkers of the Nucleoskeleton to the Cytoskeleton (LINC complexes) designate evolutionary-conserved macromolecular complexes that span the nuclear envelope (NE) and physically connect the nuclear interior to cytoskeletal networks and molecular motors. LINC complexes assemble within the perinuclear space through direct interactions between the SUN domain of inner nuclear membrane Sun proteins (Sun 1 and Sun 2) and the KASH domain of outer nuclear membrane Nesprins (Nesprin 1, 2, 3 and 4). Nesprin1giant is encoded by a >27kb transcript which contains several internal transcription initiation and termination sites resulting in the expression of numerous smaller Nesprin1 variants. Patient's harboring mutations along the entire length of nesprin1 develop autosomal recessive cerebellar ataxia type 1 (ARCA1), a late onset disease characterized by diffuse cerebellar atrophy and progressive loss of coordination in movements and speech. Despite the identification of such mutations of nesprin1, the molecular etiology of ARCA1 remains unknown. Our characterization of LINC complexes in cerebellum indicates that Nesprin1 is present as nuclear rims exclusively in Purkinje cells. However, we found that in vivo disruption of LINC complexes in Purkinje cells has no effect on cerebellar development and mice display no symptoms of cerebellar ataxia. To date, Nesprin1 has only been studied in the context of its association with the NE; however, we recently discovered that the alternative splicing of Nesprin1 penultimate exon leads to the synthesis of KASH-less isoforms, an event that is strikingly predominant in CNS tissues. In agreement with our in situ hybridization results, which indicate that Nesprin1 transcripts are extremely abundant in the granule cell layer, we observed a strong Nesprin1 immunoreactivity in the shape of large speckles within the granule cell layer. These speckles correspond to cerebellar glomeruli, which are complex "synaptic hubs" composed of axonal and dendritic terminals of mossy fibers and granule cells, respectively as well as axonal and dendritic terminals of cerebellar Golgi cells. We therefore propose that ARCA1 mutations affect the essential function that a giant KASH-less isoform of Nesprin1 giant plays at cerebellar glomeruli. We are currently evaluating several mouse models that could provide additional details about the non-canonical functions of Nesprin1. These models may prove helpful to better characterize ARCA1 and to evaluate new therapeutics.

P1288**Board Number: B631****Shaping neurons by twist-tension coupling in chiral cytoskeleton networks.**M. Krieg¹, J.G. Cueva², M.B. Goodman²;¹Molecular and Cellular Physiology, Stanford University, Stanford, CA, ²Molecular Cellular Physiology, Stanford University, Stanford, CA

Many somatosensory neurons have evolved specialized molecular sensors that convert mechanical stress into behavioral responses. The genetics, development and physiology of the touch receptor neurons (TRNs) in *Caenorhabditis elegans* nematodes are especially well characterized and this animal has the particular advantage that the TRNs can be studied both in living animals and dissociated in culture. Moreover, *C. elegans* is a unique model organism to study the mechanics of neurons due to the low complexity of its nervous system, the known wiring diagram and stereotypic behaviors, thus permitting a systems perspective on cell function.

Like in other animals, the shape of neurons in *C. elegans* is intimately coupled to their function. Some neurons are highly branched and curved, while others are extremely straight. We have previously shown that a functional, pre-stressed spectrin network is critical for mechanosensation and neuron stability under body-evoked forces. How the constituent molecules of these different neurons establish a functional organization and how tiny molecules can determine cell shape that exceeds their size by orders of magnitude is barely understood. We first compared different neurons, and classified their shapes. TRNs were by far the straightest neurons in living animals, and its shape critically depends on functional TRN-specific microtubule bundles and a pre-stressed spectrin network. Specifically, TRNs undergo deformations reminiscent of a helical buckling instability similar to twisted rods under compression. In the limit, spectrin network deficiency leads to shorter microtubule bundles. These results, together with super-resolution data on spectrin cytoskeleton and mechanical modeling of the neuron under compression, suggest that a chiral cytoskeletal network and microtubule bundle mutually stabilize each other to produce an extremely straight cell shape, critical for mechanosensation.

P1289**Board Number: B632****Kinesin-powered microtubule sliding drives axonal regeneration in cultured *Drosophila* neurons.**W. Lu¹, M. Lakonishok¹, V.I. Gelfand¹;¹Department of Cell and Molecular Biology, Northwestern University, Feinberg School of Medicine, Chicago, IL

Previously we demonstrated that microtubule sliding by conventional kinesin (kinesin-1) is required for initial neurite outgrowth in cultured *Drosophila* embryonic neurons, and sliding is developmentally downregulated when neurite outgrowth is completed. Here we report that axotomy of *Drosophila*

neurons in culture triggers regeneration and axonal regrowth. Regenerating neurons contain sliding microtubules; this sliding, like sliding during initial neurite outgrowth, is driven by kinesin-1 and is crucial for axonal regeneration. The injury induces a fast spike of calcium and generation of microtubule arrays with mixed polarity. Both of these events are required for reactivation of microtubule sliding and regeneration. Furthermore, we reveal that the c-Jun N-terminal kinase (JNK) pathway promotes regeneration by enhancing microtubule sliding in mature neurons. Supported by NIGMS 52111.

Acceleration of Growth Cone Advance by Resveratrol Parallels Changes in Microtubule (MT) Acetylation and MT Tip Distribution.

T.J. Krzystek¹, N.T. Welnhof¹, E.W. Hogan¹;

¹Biology, Canisius College, Buffalo, NY

The process of growth cone advance requires a functional transition between dynamic, deacetylated MTs in the peripheral domain and stable, acetylated MTs (AcMT) in the axon. Resveratrol, a plant-derived polyphenol, activates Sirtuin 2: a NAD⁺ dependent tubulin deacetylase. Previously, we have shown that resveratrol enhances growth cone advance while AKG2, a Sirtuin inhibitor, slows growth cone advance. To determine if resveratrol decreases the amount of AcMTs in neurons, we used immunofluorescent analysis to quantitate the amount and distribution of (AcMTs) relative to all MTs in cultured E18 rat neurons and *Helisoma* neurons. While resveratrol treatment reduced the population of AcMTs in both types of neurons, the changes occurred in different regions of neurons. In E18 rat neurons, we detected a decrease in relative amount of acetylated tubulin in growth cones, while in *Helisoma* neurons, we observed a decrease in acetylated tubulin in axons. To understand how a decrease in AcMTs in the axon modifies growth cone advance, we examined the effect of resveratrol treatment on growth cone MTs in accelerating *Helisoma* growth cones. Our results revealed that the percentage of visualized microtubule tips at the leading edge of the growth cone significantly increased in response to resveratrol. Furthermore, threshold analysis of fluorescent deconvoluted images showed an increase in the percent area of total tubulin staining in the growth cone in response to resveratrol. These results suggest that decreasing AcMT levels in the axon accelerates growth cone advance by promoting advancement of dynamic MTs into the leading edge of growth cones. The inverse relationship between axonal AcMTs and dynamic growth cone MTs may reflect a role for AcMTs in regulating the distribution of MT tip proteins.

P1291**Board Number: B634****Microtubule transport in axons: theory and experiment.**E.M. Craig¹, A. Rao², K.A. Myers³, P.W. Baas²;¹Physics, Central Washington University, Ellensburg, WA, ²Department of Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA, ³Department of Biological Sciences, Misher College of Arts and Sciences, University of the Sciences, Philadelphia, PA

Microtubules (MTs) align in the axons of nerve cells to create a long parallel bundle of polar filaments extending from the cell body to the growth cone. While the longer filaments in the bundle are stationary, a number of short MTs (1-10 μm) within the bundle undergo rapid bi-directional movements that can be paused by proteins that impose a brake on the movements. The coordinated movement of short MTs along the axon is essential for establishment and maintenance of the MT bundle, and we posit for organizing MTs within the bundle. We used a combination of experimental and computational approaches to investigate how the transport of short MTs within the bundle may contribute to the preservation of its polarity pattern as well as its expansion as axons grow. Here, we present a computational modeling framework developed to investigate how mechanical interactions between molecular motor proteins and MTs produce the patterns of MT transport that have been measured experimentally. We modeled molecular motor-driven movement of individual MTs using stochastic simulations based on force-dependent binding and unbinding rates for subpopulations of molecular motor proteins that are known to interact with and regulate MT transport. We tested the predictions of the model by comparing simulated MT transport events with live-cell imaging of MT transport in developing axons.

Membrane Trafficking at the Synapse**P1292****Board Number: B635****SH3 domain-mediated interactions and F-BAR domain higher-order assembly regulate Nervous Wreck membrane remodeling.**C.F. Kelley¹, E. Messelaar¹, T.L. Eskin^{1,2}, A.A. Rodal^{1,2};¹Molecular and Cell Biology, Brandeis University, Waltham, MA, ²Brandeis University, Waltham, MA

Membrane trafficking requires the coordination of hundreds of interacting proteins, which act in concert to drive cargo sorting, membrane tubulation, fission, and fusion. While well characterized individually, it is not understood how their activities are regulated and targeted in vivo to fulfill diverse roles within cells. Nervous Wreck (NWK) encodes an F-BAR/SH3 protein that regulates the traffic and signaling output of synaptic growth receptors at the *Drosophila* neuromuscular junction (NMJ) through its interactions with the membrane, actin nucleation machinery, and other endocytic proteins including

dynamain and Dap160/Intersectin. Here, we find that the membrane binding and remodeling activities of the Nwk F-BAR domain are autoinhibited through direct interaction with its two C-terminal SH3 domains, and that this autoinhibition is important for Nwk localization and function in vivo. Unlike the isolated F-BAR domain, autoinhibited Nwk strictly requires self-assembly in order to stably interact with and remodel membranes. Previous models for autoregulation of BAR family proteins proposed that SH3 domains directly compete for membrane binding, controlling exchange of the protein between the cytosol and the membrane. We found that the Nwk auto-regulatory mechanism specifically limits promiscuous membrane binding and promotes higher order assembly. Further, we find that the endocytic scaffold Dap160, which regulates Nwk localization at the NMJ, relieves autoinhibition and increases both the rate and frequency with which Nwk associates with the membrane in vitro. These results suggest a complex regulatory mechanism, dependent on separable intra- and inter-molecular interactions, by which membrane remodeling is tightly regulated, and lend insight into the mechanisms employed by the cell to specifically target membrane remodeling.

An impaired expression of ascorbic acid transporter (SVCT2) at cellular surface would contribute to oxidative stress in Huntington's disease.

A.D. Covarrubias-Pinto¹, A.V. Parra¹, E. Papic¹, A.I. Acuna¹, M. Esparza¹, C. Kramm¹, I. Concha^{1,2}, S. Brauchi³, M.A. Castro¹;

¹I. Bioquímica, Universidad Austral De Chile, Valdivia, Chile, ²Bioquímica y Microbiología, Universidad Austral De Chile, Valdivia, Chile, ³I. Fisiología, Universidad Austral de Chile, Valdivia, Chile

Introduction. Huntington's disease (HD) is a neurodegenerative disorder characterised by progressive abnormalities in cognitive and motor control. HD is caused by an expansion in the first exon of the huntingtin gene (Htt). Htt participates as an integrator of vesicular and protein traffic. HD is characterised by an increase in oxidative stress. Ascorbic acid is a powerful antioxidant that is highly concentrated in the brain. Synaptic activity triggers the release of ascorbic acid from glial intracellular reservoirs. Ascorbic acid is transported into neurons via the Sodium-dependent Vitamin C Transporter-2 (SVCT2). In this study, we have examined SVCT2 expression at plasma membrane in cellular models of HD. **Materials and Results** Using immortalized striatal neurons derived from knock-in mice expressing mutant huntingtin (STHdhQ cells) we studied ascorbic acid transport and SVCT2 expression at plasma membrane. When extracellular ascorbic acid concentration increases (as occurs during synaptic activity) SVCT2 is translocated to the plasma membrane ensuring optimal ascorbic acid uptake for neurons. However, in HD cells, SVCT2 fails to reach the plasma membrane. Analyses using endocytosis and exocytosis inhibitors showed that SVCT2 cycling to and from the plasma membrane is impaired in HD cells. Co-immunoprecipitation and colocalization assays confirmed the existence of HAP1-SVCT2 interaction which is missing in HD cells. On the other hand, HD cells showed an increased SVCT2-HAP40 colocalization. Live cell imaging analyses revealed an impairment in ascorbic acid-induced calcium signaling. **Discussion.** Our results suggest that SVCT2 is being recycled constitutively. The loss of Htt

function disrupts SVCT2 translocation to the plasma membrane. Also, HD cells show an impairment in the signaling responsible to induce SVCT2 translocation to cellular surface. Ascorbic acid uptake is essential to maintain redox balance in the brain. Therefore, an early impairment of ascorbic acid uptake in HD neurons could promote neuronal death. Regulation of synaptic vesicles by the mitochondria-caspase-autophagy pathway.

Z. Li¹;

¹National Institute of Mental Health, National Institutes of Health, Bethesda, MD

Macroautophagy ('autophagy' hereinafter) is a process by which organelles and aggregated proteins are delivered to lysosomes for degradation. Autophagy for organelle degradation comes in various forms, such as mitophagy for mitochondria, ribophagy for ribosomes, pexophagy for peroxisomes, and reticulophagy for endoplasmic reticulum. In multicellular organisms, however, where the number of cells and variety of organelles are greatly increased, except for mitophagy, the physiological significance of autophagy for organelles, especially those specific to multicellular organisms (e.g. synaptic vesicles), remains elusive.

The number of synaptic vesicles at a synapse governs synaptic strength, which is dynamically regulated during development and by experience. A stable, yet flexible, pool of synaptic vesicles is therefore critical to ensure the reliability and adaptability of neural circuits. However, it remains largely unclear how the number of synaptic vesicles is maintained and regulated. Our study finds that autophagy controls synaptic vesicle number. In Atg protein knockout mice where autophagy is reduced, synaptic vesicle pools are enlarged. Conversely, in mice with enhanced autophagy, synaptic vesicle pools are smaller than normal. Moreover, we find that for controlling synaptic vesicles, autophagy is regulated by the BAD-BAX-caspase pathway. We also show that the autophagic trafficking of synaptic vesicles takes place in early and late endosomes. These findings elucidate a new, autophagy-mediated mechanism of synaptic vesicle turnover, and a new, non-apoptotic, presynaptic function for the BAD-BAX-caspase-3 cascade. They also demonstrate that caspase-regulated autophagic trafficking of synaptic vesicles is essential for both the homeostasis and activity-dependent regulation of synaptic vesicle pools.

P1295**Board Number: B638****PGRMC1 expression correlates with the sigma-2 fluorescent probe (SW120) staining in rat hippocampus cells.**C. Zeng¹, N. Garg¹, R.H. Mach¹;¹Radiology, University of Pennsylvania, Philadelphia, PA

Progesterone receptor component 1 (PGRMC1) is identified as the potential sigma-2 receptor binding site. PGRMC1/sigma-2 receptor is elevated in various types of human tumors and is identified as a biomarker for imaging solid tumors using the functional positron emission tomography (PET) technology. However, the function of PGRMC1/sigma-2 receptor in the central nervous system (CNS) is largely unknown. In the current study, we examined the PGRMC1 expression by immunohistochemistry and sigma-2 fluorescent probe (SW120) staining in primary cultures of neurons, astrocytes, oligodendrocytes and microglia cells of E18 rat hippocampus. Our data show that the expression of PGRMC1 and SW120 staining are prominent in neurons, moderate in oligodendrocytes and microglia cells, and very low in astrocytes. These results indicate that PGRMC1 expression levels correlate with sigma-2 receptor densities in four different rat brain cell types, supporting our previous finding that PGRMC1 is associated with the sigma-2 receptor binding site. The results imply that the sigma-2 receptor PET radiotracer can potentially be used to noninvasively image neuron/synapse densities in human CNS.

P1296**Board Number: B639****SYNAPTIC STABILITY AND GLIAL REACTIVITY DURING SENESCENCE IN MDX MICE.**G.F. Simoes¹, L.P. Cartarozzi², A.B. Spejo², A.L. Oliveira^{2,3};¹Faculty of Medical Sciences of the Santa Casa of São Paulo, São Paulo, Brazil, ²Structural and Functional Department, University of Campinas, Campinas, Brazil, ³Univ Campinas, Campinas, Brazil

Duchenne muscular dystrophy (DMD) causes degeneration of skeletal muscle fibers which can result in retrograde changes that affect the central nervous system. In this sense, spinal motoneurons show the typical signs of chromatolysis and loss of synapses in the early stages of disease. Further degeneration may occur with the aging process, although it has been poorly investigated. In this sense, the present work studied motor function and spinal cord microenvironment during senescence in MDX mice. C57BL/10 mice were used as the control strain. For this, we used fifteen mice from each strain, which were evaluated at six, twelve, and eighteen months old. The motor function was monitored using the walking track test (Catwalk system). The animals were sacrificed and the spinal cords processed for immunohistochemistry (GFAP and synaptophysin antisera). The results showed that MDX mice present a significant (107%) motor deficit as compared to control animals at six months old, that further

decreased at twelve months (80%) and eighteen months (39%). The Max Contact Max Intensity decreased 13%, 19% and 21% in MDX mice at six, twelve, and eighteen months, respectively. GFAP immunolabeling increased in both strains during senescence, being more evident in all groups of MDX mice. Synaptophysin immunolabeling decreased in MDX mice in all groups studied. Overall, the results herein indicate that the constant cycles of muscle degeneration/regeneration in MDX mice cause retrograde structural changes in the spinal cord microenvironment, directly affecting the homeostasis of the CNS during the course of Duchenne muscular dystrophy.

Ubiquitin-mediated regulation of diverse small-molecule receptors in *C. elegans*.

E. Zoicher¹, N. Ruth¹, P.C. Juo², L.L. Dahlberg¹;

¹Biology, Western Washington University, Bellingham, WA, ²Tufts Univ Sch Med, Boston, MA

Ubiquitin-mediated protein regulation is vital for general cellular maintenance, and, in particular, for neural function. In the model organism, *C. elegans*, we have shown that the deubiquitinating enzyme, USP-46, works in concert with two WD-40 domain proteins to regulate the abundance and trafficking of the glutamate receptor, GLR-1. Specifically, USP-46 is activated by WDR-20 and WDR-48 to deubiquitinate and stabilize GLR-1. Modulation of USP-46's activity via these WDR proteins determines the extent of ubiquitination on GLR-1, which in turn regulates the abundance of the receptor, and glutamate-dependent behavior of the animals. Ubiquitinated GLR-1 that is not processed by the USP-46 complex is degraded at the lysosome. Impeding lysosomal degradation by expression of a dominant negative enzyme (VPS-4), or perturbing ubiquitin homeostasis through over-expression of ubiquitin itself, reduces or enhances GLR-1 degradation, respectively. Based on our experience with the GLR-1 model system, we are employing cell-specific expression of these known modulators of ubiquitin-mediated degradation to disrupt behaviors that depend on small-molecule receptors in individual sensory neurons. These studies are ongoing, and will shed light on the protein-regulatory networks involved in modulating the abundance and trafficking of cell-surface receptors in diverse cell types.

Autophagy affects glutamate receptor localization at the *Drosophila* neuromuscular junction.

E. Isbell¹, F. Liebl²;

¹Biological Sciences, Southern Illinois University Edwardsville, Edwardsville, IL, ²Southern Illinois University Edwardsville, Edwardsville, IL

Glutamate, one of the most abundant neurotransmitters, is responsible for fast excitatory neurotransmission. Glutamate receptors (GluRs) have an important role in learning and memory and

synaptic plasticity can occur through the insertion or removal of postsynaptic glutamate receptors. We have found that autophagy-specific genes (*atg*) influence the localization of glutamate receptors at the *Drosophila* neuromuscular junction. Mutations of *atg1* and *atg8a* result in a significant decrease in postsynaptic GluRs, while cellular levels of GluR protein remain unaffected. Rescue experiments indicate *atg1* is required in neurons and muscle cells, while restoration of *atg1* in glial cells did not rescue GluR localization. To determine the mechanism by which the Atg proteins regulate GluR localization, we are assessing if pharmacological inhibition of autophagy affects GluR localization. In addition, we are trying to determine if inhibition of autophagy affects presynaptic glutamate metabolism thereby altering postsynaptic GluR localization. The results from these experiments will give further insight as to autophagy's role in glutamate receptor trafficking and localization.

Investigation of the active zone protein SYD-2 Liprin α as a substrate of the Anaphase-promoting complex ubiquitin ligase at the *C. elegans* Neuromuscular Junction.

D.K. Lester¹, K.M. Rush¹, H. Dube¹, J.R. Kowalski¹;

¹Biological Sciences, Butler University, Indianapolis, IN

Ubiquitin-mediated regulation of neuronal protein activity and abundance is critical for proper nervous system development and function. Misregulation of the ubiquitin enzyme system is observed in many neurological disorders where defects in synaptic transmission occur. While several ubiquitin ligases that control the levels and functions of synaptic proteins have been identified, the substrate specificities of many remain unknown. The Anaphase-promoting complex (APC) is a conserved, multi-subunit ubiquitin ligase that controls protein abundance during the cell division cycle. In neurons, the APC regulates post-mitotic functions ranging from axon outgrowth to cell survival and controls glutamatergic synapse formation and synaptic transmission in flies, worms, and mammals, where it is implicated in synaptic plasticity¹. We recently showed the APC also acts to control the balance of excitatory cholinergic to inhibitory GABAergic signaling (E:I balance) at the neuromuscular junction (NMJ) in *Caenorhabditis elegans*². We found the APC prevents excessive muscle excitation by acting in presynaptic inhibitory motor neurons to promote GABA release. Here we report the initial characterization of SYD-2 Liprin α as a potential substrate of the APC at the *C. elegans* NMJ. SYD-2 Liprin α is an active zone protein required for synapse development and function across phylogeny and has been implicated as an APC substrate in fly and mammalian neurons^{3,4}. In *C. elegans*, SYD-2 Liprin α acts presynaptically to promote normal GABA synapse development and NMJ function^{5,6}. SYD-2 Liprin α contains a conserved APC recognition motif (D-box), supporting its potential regulation by the APC. We found a GFP-tagged version of SYD-2 Liprin α accumulates at inhibitory NMJ presynapses in APC loss of function *C. elegans* mutants. Behavior assays with multiple loss of function alleles confirmed the requirement for SYD-2 Liprin α in promoting muscle contraction. Additional behavior experiments testing double loss of function mutants demonstrated loss of SYD-2 Liprin α can partially suppress the increased muscle contraction of APC mutants, suggesting

SYD-2 Liprin α may be one of multiple APC substrates at the NMJ. Mutagenesis studies assessing a requirement for the D-box in the ability of SYD-2 Liprin α to be controlled by the APC are ongoing. Future experiments will determine the effect of an altered APC recognition site on SYD-2 abundance and ubiquitination. 1) Puram SV and Bonni A. 2011. *Sem Cell Molec Biol.* 22:586-594, 2) Kowalski JR *et al. Inhibition of the reelin signaling pathway promotes dendritogenesis in mature hippocampal neurons.

E. Ampuero¹, B. Van Zundert², M. Marzolo³;

¹Universidad Andres Bello, Santiago, Chile, ²Center for Biomedical Research, Univ Andres Bello-Fac De Ciencias Biologicas, Santiago, Chile, ³Pontificia Univ Catolica Chile, Santiago, Chile

Introduction: Reelin is a protein of the extracellular matrix that is secreted by a subset of GABAergic neurons. By binding to the lipoproteins receptors ApoER2 and VLDLR, reelin regulates intracellular signaling modulating hereby several forms of neuronal plasticity. Here we studied how interference of reelin-mediated signaling in mature hippocampal neurons impacts dendritogenesis and the distribution of the synaptic proteins like NMDA receptor subunits (NR2B and NR2A), the scaffolding protein postsynaptic density 95 (PSD95) and the presynaptic proteins Bassoon and synapsin-I. We hypothesized that blocking of reelin signaling favors an immature state of dendritic tree allowing the presence of immature synapses containing NR2B and SAP102 preferentially. Material and Methods: Expression of reelin was analyzed by immunostaining during development of hippocampal neurons (0-20 days in vitro (DIV)). Mature hippocampal neurons (15DIV) were transfected with GFP alone or with ApoER2 Δ C by magnetofection and chronically treated with GST-RAP or CR-50 to prevent reelin-ApoER2 interactions. At 20 DIV, cultures were fixed with PFA. We analyzed the dendritic architecture and the expression of synaptic proteins using double immunostainings.

Results: With hippocampal maturation, gradually more neurons showed strong reelin immunoreactivity. We also found that exposure of cultures to either CR50 or GST-RAP leads to a significant increase in dendritogenesis relative to control neurons. Application of CR50 also significantly enhanced total dendritic outgrowth. Dendritogenesis was associated with an increment NR2B subunit and with a reduction in PSD95 clustering. Discussion: Our results show that blockage of reelin signaling in mature hippocampal neurons modify the expression of key synaptic proteins at the postsynaptic membrane and promotes dendritogenesis. Our evidence indicates that reelin maintains NR2A-NMDARs at the synapse by interacting with PSD95, occluding hereby the insertion of the NR2B-NMDAR and therefore limiting the dendritogenesis.

P1301**Board Number: B644****DBH and Copper-transporter ATP7B are Regulated by Neurotransmitters in SH-SY5Y Cells.**K. Schmidt¹, S. Lutsenko¹;¹Physiology, Johns Hopkins University School of Medicine, Baltimore, MD

Copper homeostasis plays an important role in the brain since it enables function of copper dependent enzymes such as dopamine-beta-hydroxylase (DBH). DBH is crucial for metabolism of catecholamines and function by converting dopamine into norepinephrine. Mice and human that are deficient in copper transporting ATPases (Cu-ATPases) ATP7A and ATP7B display abnormal levels of catecholamines implying an involvement of Cu-ATPases in DBH metabolism. We have examined whether catecholamines co-regulate Cu-ATPases and DBH in SHSY-5Y cells. We show that dopamine treatment induces trafficking of ATP7B from its basal localization in TGN to the plasma membrane and neurite extensions of differentiated SH-SY5Y cells, whereas ATP7A is not affected by this treatment. Norepinephrine also induced relocation of ATP7B away from the TGN, possibly to vesicles, and increased the amount of DBH secreted into the medium. The time course experiment shows that DBH secretion upon norepinephrine treatment occurs within 1-2 hours. This relatively short time suggests that norepinephrine induced DBH secretion may involve an intracellular signaling mechanism. In order to measure DBH activity, we applied a coupled enzymatic activity assay and measured conversion of tyramine, a surrogate substrate for DBH, para-hydroxybenzaldehyde. Measurement from culture medium of SH-SY5Y cells showed that increased DBH secretion level upon norepinephrine treatment correlated with increased DBH activity. Altogether, our findings indicate that norepinephrine specifically regulates Cu-transporter ATP7B and DBH in the absence of elevated copper thus demonstrating novel mode of regulation of cuproenzymes within the secretory pathway.

P1302**Board Number: B645****Masparidin's Interactions with Signaling Proteins.**L.E. Bailey¹, L.P. Lyman-Henley¹, L.J. Dangott², L.F. Lemanski¹;¹Biological Environmental Sciences, Texas AM University-Commerce, Commerce, TX, ²Biochemistry Biophysics, Texas AM University, College Station, TX

The hereditary spastic paraplegias (HSPs) are a group of upper motor neuron disorders characterized by continuous degradation of efferent neurons in the corticospinal tract. Mast syndrome (SPG21) is an autosomal-recessive complicated form of HSP that originates from a mutation of the ACP33/masparidin gene. Bone Morphogenetic Proteins (BMPs) are multifunctional growth factors that, along with forming bone and cartilage, influence axonal synaptic growth and function. Previous studies have shown multiple HSP-associated proteins to be inhibitors of BMP signaling. Thus, we propose that masparidin is involved in BMP signaling as an additional BMP inhibitor. In fact, previous results have demonstrated

that neurons that are depleted of maspardin exhibit increased axonal branching. My working hypothesis is that maspardin is indispensable in regulating BMP signaling via protein trafficking and degradation. Levels of phosphorylated Smad 1/5 were examined in mouse embryonic fibroblasts (MEFs) by western blot analysis and compared to total Smad levels after stimulation with BMP4 ligand. Comparable experiments were performed in primary neuron cultures from wildtype and knockout mice. Pixel densities were used to compare PSmad/Smad ratios in western blots, as well as confirm quantities of protein present. Results were statistically analyzed via unpaired two-tailed t tests. Increases in PSmad 1/5 signaling were insignificant in wildtype stimulated neurons when compared to controls ($P=0.0911$). In contrast, knockout neurons demonstrated significant increases in levels of PSmad 1/5 in stimulated cells versus controls ($P=0.0462$; $*P<0.05$). Significant increases were also observed between stimulated and control samples in knockout MEFs ($P=0.0466$; $*P<0.05$). These increases were similarly found to be insignificant in wildtype cells ($P=0.6061$). Further investigation is needed to determine the exact mechanism by which maspardin regulates these molecules. Focus has currently expanded to explore other molecules with which maspardin might be involved as a regulator or promoter of function. 6 month and 15 month old knockout and wildtype mouse brains were extracted and subjected to 2D-DIGE analysis. Preliminary results have found a few spots of interest that will be submitted for protein identification using Liquid Chromatography–Tandem Mass Spectrometry (LC-MS/MS) analysis. This is the first investigation of this type in the SPG21 $-/-$ mouse. Because of maspardin's ubiquitous nature, elucidation of proteins with which maspardin may be interacting could be useful in furthering our understanding of other neuronal signaling pathways.

Influence of Protein Size and Binding During Diffusion within the Postsynaptic Density.

T.P. Li^{1,2,3}, S. Yu⁴, T.A. Blanpied^{1,3}, S. Raghavachari⁵;

¹Department of Physiology, Univ of Maryland Sch of Med, Baltimore, MD, ²Medical Scientist Training Program, Univ of Maryland Sch of Med, Baltimore, MD, ³Program in Neuroscience, Univ of Maryland Sch of Med, Baltimore, MD, ⁴Department of Physics, Duke University, Durham, NC, ⁵Department of Neurobiology, Duke University Medical Center, Durham, NC

Mechanisms that regulate the insertion, movement, positioning, and removal of glutamate receptors determine the strength of neurotransmission at excitatory synapses. Two key processes that control synaptic receptor number are diffusion within the synaptic and extrasynaptic space and interactions between receptors and scaffold proteins within the postsynaptic density (PSD). Electron microscopy suggests that the PSD is highly crowded, potentially limiting the ability of receptors to diffuse and interact with scaffold proteins. However, the contribution of macromolecular crowding to receptor retention remains to be tested systematically. Here, we combine experimental and computational approaches to test the effect of synaptic steric hindrance on receptor mobility and enrichment. To examine the distinct contributions of crowding and receptor-scaffold binding, we developed a

computational model for AMPAR diffusion in the synaptic and extrasynaptic space, which contains immobile obstacles, representing scaffolding, receptor, and adhesion molecules in the PSD. The spatial distribution of scaffold proteins was determined directly from photoactivated localization microscopy measurements that mapped molecular positions with a resolution of ~ 30 nm. The AMPAR/scaffold association and dissociation rates were adjusted by computer simulations to fit single-particle tracking and fluorescence recovery after photobleaching measurements. The model predicts that variation of receptor size has the most influence on the recovery curves while variation of kinetic rates did not significantly alter receptor residence time or mobility. In order to directly address these questions experimentally and to verify model predictions, we used single-molecule tracking and bulk imaging techniques such as fluorescence recovery after photobleaching to quantify the diffusion dynamics of AMPARs and a set of uniquely designed transmembrane (TM) proteins that mimic receptors on living synapses. We find that diffusion of TM proteins is slowed in the synapse even in the absence of binding interactions (from 0.30 ± 0.005 to $0.24 \pm 0.01 \mu\text{m}^2/\text{s}$). Adding a single synaptic binding motif to a small TM protein also slows its diffusion within the synapse (from 0.15 ± 0.008 to $0.11 \pm 0.01 \mu\text{m}^2/\text{s}$), consistent with modeling results. These results suggest that both protein size and binding play important roles in retaining surface-diffusing TM proteins within the excitatory synapse and shed light on the biophysical mechanisms that lead to high density of AMPARs and other transmembrane proteins at synapses.

Size separation of large proteins and protein complexes under native conditions.

T. Granér¹, I. Salomonsson¹, L. Wang², J. Bergström³;

¹GE Healthcare Bio-Sciences AB, Uppsala, Sweden, ²GE Healthcare Bio-Sciences, Piscataway, NJ,

³Department of Public Health and Caring Sciences, Rudbeck Laboratory, Uppsala University, Uppsala, Sweden

Proteins do not carry out their functions in isolation but mainly through interactions with other proteins. The elucidation of the biological function of protein complexes is an area of intense research efforts but isolation and analysis of the complexes is challenging as they can be very large and unstable. Size exclusion chromatography (SEC) offers separation by size under mild, non-dissociative conditions. Lewy bodies are abnormal inclusions found in nerve cells in patients with Parkinson's disease and constitute mainly of aggregated forms of the protein α -synuclein. The oligomerization of α -synuclein was studied using SEC and Superose™ 6 Increase 3.2/300, a column with separation range up to Mr 5 000 000 for globular proteins. Two different oligomerization reactions of monomeric α -synuclein with different excess of the aldehyde ONE was compared. The separations showed that the material with ratio 1:15 was heterogenic and not oligomerized to the same extent as the material with ratio 1:30. Based on elution position, the size of the oligomerized material was estimated to Mr > 700 000.

P1305**Board Number: B648****Localization of heteromeric $\alpha 3\beta 4$ nicotinic acetylcholine receptors on the cell surface is regulated by N-cadherin homotypic binding and the actin cytoskeleton.**J.L. Bruses^{1,2};¹Natural Sciences, Mercy College, Dobbs Ferry, NY, ²Institute of Cell Biology and Neuroscience (IBCN), Buenos Aires, Argentina

Neuronal nicotinic acetylcholine receptors (nAChR) are widely expressed in the central and peripheral nervous systems and localize at synaptic and extrasynaptic sites of the cell surface. Various mechanisms control nAChR localization within distinct domains of the cell membrane including incorporation into cholesterol-rich membrane microdomains, and association with scaffolding proteins and the actin cytoskeleton. The homotypic cell adhesion molecule N-cadherin is commonly expressed at synaptic contacts and regulates the actin cytoskeleton through interactions of the cytoplasmic domain with β -catenin and p120-catenin. To examine whether N-cadherin homotypic binding regulates the cell surface localization of nAChR, Chinese hamster ovary (CHO)-K1 cells were transfected with N-cadherin and with $\alpha 3$ and $\beta 4$ nAChR subunits C-terminally fused to a myc-tag epitope. Cell surface expression levels of $\alpha 3\beta 4$ -nAChR within cell-cell contacts and contact-free cell membrane were analyzed by confocal microscopy. In cells not expressing N-cadherin, $\alpha 3\beta 4$ -nAChR was found evenly distributed over the entire cell surface including areas of contact between cells ($100 \pm 16.3\%$), while N-cadherin-mediated cell contacts were largely devoid of $\alpha 3\beta 4$ -nAChR ($3.8 \pm 2.2\%$). Expression of truncated N-cadherin ectodomains lacking the β -catenin binding domain or the entire cytoplasmic domain increased the expression levels of $\alpha 3\beta 4$ -nAChR within cell contacts to $78.3 \pm 13.0\%$ and $102.2 \pm 15.2\%$ respectively, indicating that the interaction of N-cadherin with β -catenin and p120-catenin was necessary for regulating $\alpha 3\beta 4$ -nAChR localization. Treatment with inhibitors of actin polymerization (latrunculin A [$10\mu\text{M}$] and cytochalasin D [$2\mu\text{M}$]) did not significantly affect $\alpha 3\beta 4$ -nAChR expression within N-cadherin-mediated cell contacts ($3.8 \pm 2.7\%$ and $8.2 \pm 2.7\%$ respectively). In contrast, treatment with a cell permeable RhoA inhibitor (C3-exotransferase [$1\mu\text{g/ml}$]) or with the ROCK inhibitor Y27632 [$10\mu\text{M}$] resulted in a significant increase in $\alpha 3\beta 4$ -nAChR levels within N-cadherin-mediated cell contacts ($34.9 \pm 7.1\%$ and $81.5 \pm 23.4\%$ respectively), suggesting that the $\alpha 3\beta 4$ -nAChR localization was regulated by RhoA-ROCK activity downstream of N-cadherin binding. Analysis of $\alpha 3\beta 4$ -nAChR localization in polarized Caco-2 cells showed expression exclusively on the apical cell membrane and colocalization with apical F-actin and with the actin nucleator Arp3. These results suggest that actomyosin contractility downstream of N-cadherin homotypic binding regulates the localization of $\alpha 3\beta 4$ -nAChR within the cell membrane through a mechanism involving N-cadherin cytoplasmic domain and the interaction of $\alpha 3\beta 4$ -nAChR with a pool of F-actin.

Myelin comprises concentric, tightly apposed layers of lipid-rich glial cell plasma membranes that surround, insulate, and trophically support axons in the vertebrate nervous system. Genetic defects in myelin formation and maintenance cause leukodystrophies, a large, heterogeneous group of brain white matter diseases whose mechanistic underpinnings are poorly understood. Hypomyelination and Congenital Cataract (HCC), one of these disorders, is caused by mutations in the FAM126A gene, which encodes FAM126A/hyccin, a protein of previously unknown function. Here, we show that FAM126A regulates the synthesis of phosphatidylinositol 4-phosphate (PI4P), a key determinant of plasma membrane identity. We demonstrate that FAM126A is an intrinsic component of the phosphatidylinositol 4-kinase complex at the plasma membrane, known to comprise PI 4-kinase III α (PI4KIII α) and two non-catalytic subunits, the peripheral membrane protein EFR3 and the putative scaffold TTC7. FAM126A directly binds to TTC7. A crystal structure of the FAM126A–TTC7 complex reveals an almost all- α -helical heterodimer with an unusually large protein-protein interface consistent with a high-affinity interaction and a conserved surface that may mediate binding to the kinase. Functional analysis of fibroblasts from HCC patients reveals reduced plasma membrane PI4P levels relative to controls. We propose that defects in PI4KIII α -mediated PI4P production in oligodendrocytes may be involved in HCC disease pathogenesis. The specialized function of oligodendrocytes in myelin formation is mediated by their property to massively expand their plasma membrane, and this property is highly dependent on the generation of PI4P and its downstream metabolites PI(4,5)P₂ and PI(3,4,5)P₃. We find that FAM126A is highly expressed in oligodendrocytes, and studies of FAM126A knockout mice support a primary role of this protein in such cells. Thus, our results imply a critical role of FAM126A and PI4P generation in supporting myelin formation, a process of essential importance not only in development but also during remyelination following injury, as occurs in multiple sclerosis and other demyelinating diseases.

P1307**Board Number: B651****The tomato defensin TPP3 induces tumour cell lysis through a conserved mechanism involving PIP2 binding and oligomerization.**A. Baxter^{1,2}, V. Richter¹, I.K. Poon^{1,2}, F.T. Lay¹, C. Adda¹, M. Kvensakul¹, M.D. Hulett^{1,2};¹Biochemistry, La Trobe Institute for Molecular Sciences, Melbourne, Australia, ²Hexima Ltd, Melbourne, Australia

Plant defensins are small innate immune peptides that often exhibit broad spectrum antifungal activity. NaD1 is an antifungal Class II defensin of the Solanaceae family that has also recently been shown to exhibit selective cytotoxic activity towards mammalian tumour cells and represents a promising candidate for the development of anti-cancer therapeutics. NaD1 acts through a novel phosphatidylinositol 4,5-bisphosphate (PIP2)-binding mechanism involving PIP2-mediated oligomerization of NaD1 leading to target membrane destabilization. The class II Tomato Pistil Predominant 3 defensin, TPP3, is a related yet poorly characterized homologue of NaD1. Here, we report through several biological and biophysical approaches that TPP3 shares structural and functional traits with NaD1, indicating an evolutionarily conserved lipid-binding and mechanism of action within this class of defensin. TPP3 exhibited comparable anti-tumour activity to NaD1, which was shown to be dependent on target cell membrane PIP2 to elicit efficient membrane lysis. Structural determination by X-ray crystallography revealed striking similarities between TPP3 and NaD1, with TPP3 adopting the lipid-binding 'cationic grip' dimer conformation of NaD1, indicating that TPP3 is likely to form an oligomeric complex in the presence of its ligand, PIP2. These findings contribute to our broadening understanding of Class II solanaceous plant defensins and their therapeutic potential as anticancer molecules.

P1308**Board Number: B652****“Structure of a lipid-bound extended synaptotagmin indicates a role in lipid transfer”.**C.M. Schauder¹, X. Wu², Y. Saheki³, P. Narayanaswamy⁴, F. Torta⁴, M. Wenk⁵, P. De Camilli³, K.M. Reinisch⁶;¹Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, ²Harvard Medical School, Boston, MA, ³Department of Cell Biology, Howard Hughes Medical Institute, Program in Cellular Neuroscience, Neurodegeneration and Repair, Yale University School of Medicine, New Haven, CT,⁴Department of Biological Sciences, National University of Singapore, Singapore, Singapore,⁵Department of Biochemistry, National University of Singapore, Yong Loo Lin School of Medicine,Singapore, Singapore, ⁶Department of Cell Biology, Yale University School of Medicine, New Haven, CT

It has become increasingly apparent that membrane contact sites, regions of close apposition between two distinct membrane components, facilitate lipid exchange. The mechanisms underlying this type of lipid transfer are largely unknown. SMP domains are proposed lipid binding modules that are found only in proteins localized to membrane contact sites. The extended synaptotagmins (E-Syts) are a family of proteins that tether the endoplasmic reticulum (ER) to the plasma membrane at contact sites and contain an N-terminal ER anchor sequence, an SMP domain and three or more C2 domains. Here we report at 2.44 Å resolution the crystal structure of an N-terminal fragment of human E-Syt2, which includes the SMP domain and two adjacent C2 domains (A,B). The C2A and C2B domains interact to form an arch, which likely is not rigidly positioned with respect to the SMP domain in solution. The SMP beta-barrel fold identifies these domains as members of the tubular-lipid-binding (TULIP) superfamily. In E-Syt2, the SMP domain dimerizes to form a 90-Å-long cylinder. A cavity lined almost exclusively with hydrophobic residues runs the length of the cylinder and is connected to solvent via a “seam”. The electron density within the SMP domain cavity revealed the presence of diacylglycerol lipids, which were subsequently identified as glycerophospholipids via mass spectrometry. These results strongly support a role for E-Syt2 in transferring glycerophospholipids between the ER and the PM and with the identification of the SMP domain as a lipid binding domain, have much farther reaching implications.

Plasticity of PI4KIII α interactions at the plasma membrane.

J. Chung¹, F. Nakatsu¹, J.M. Baskin¹, P. De Camilli¹;

¹Department of Cell Biology, Howard Hughes Medical Institute, Program in Cellular Neuroscience, Neurodegeneration and Repair, Yale University School of Medicine, New Haven, CT

Plasma membrane PI4P is an important direct regulator of many processes that occur at the plasma membrane and also a biosynthetic precursor of PI(4,5)P₂ and its downstream metabolites. The majority of this PI4P pool is synthesized by an evolutionarily conserved complex, which has as its core the PI 4-kinase PI4KIII α (Stt4 in yeast) and also comprises TTC7 (Ypp1 in yeast) and the peripheral plasma membrane protein EFR3. While EFR3 is implicated in the recruitment of PI4KIII α , the plasma membrane protein Sfk1 was shown to participate in this targeting and activity in yeast. Here we identify a member of the TMEM150 family as a functional homologue of Sfk1 in mammalian cells. We show that TMEM150A localizes at the plasma membrane and associates with the EFR3-PI4KIII α complex, but in a way that is mutually exclusive with the presence of TTC7 in this complex. In addition, we show that overexpression or knockdown of TMEM150A result in significant changes (increase and decrease, respectively) in the rate of PI(4,5)P₂ resynthesis upon its acute PLC-dependent hydrolysis by activation of a GPCR receptor, the M1 muscarinic receptor. Taken together, our data indicate that TMEM150A helps regulate the function of PI4KIII α at the plasma membrane. The property of PI4KIII α to assemble in two different complexes (TTC7-EFR3-PI4KIII α and TMEM150A-EFR3-PI4KIII α) reveals a plasticity of the molecular interactions that control its localization and function.

P1310**Board Number: B654****The Epidermal Growth Factor Receptor regulates phosphoinositide dynamics and clathrin-mediated endocytosis.**R.C. Delos Santos¹, C.N. Antonescu¹, L. Bone¹, S.J. Bautista¹;¹Department of Chemistry and Biology, Ryerson University, Toronto, ON

Clathrin-mediated endocytosis (CME) is the principal mechanism for internalization of diverse cell surface proteins (called cargo) from the cell surface, and thus is an important regulator of the surface proteome. CME initiates with the recruitment of clathrin, the adaptor protein AP-2, and many other proteins to cargo-enriched membrane invaginations termed clathrin-coated pits (CCP). After undergoing a maturation process that remains poorly understood, these CCPs eventually pinch off to form clathrin-coated vesicles (CCV). Although mechanistically well characterized, there is a paucity of knowledge of how CME can be regulated.

Phosphatidylinositol-(4, 5)-bisphosphate (PIP2) is a key regulator of CME, as it acts as a membrane ligand to recruit the adaptor protein AP-2 (and other proteins) to CCPs. The key regulatory role of PIP2 is evinced by the observation that either experimental increases or decreases of PIP2 levels impair transferrin receptor (TfR) internalization, a well-studied cargo receptor of CME (Antonescu et al. 2011 MBoC 22:2588-600). In resting (unstimulated) cells, PIP2 levels are dynamically controlled by synthesis by phosphatidylinositol-5-kinases (PIP5K) and turnover by inositol 5-phosphatases (e.g. Synaptojanin1, Sjn1). Stimulation of cells with ligands of various signaling receptors, such as epidermal growth factor (EGF) to activate the EGF Receptor (EGFR), results in activation of enzymes that alter PIP2 dynamics, namely phospholipase C β 1 (PLC β 1). In addition to activation of signaling molecules, ligand binding to EGFR also elicits CME of the receptor, suggesting that signaling and internalization must be coordinated. How activation of PLC β 1 by EGF stimulation alters PIP2 levels and dynamics and hence may control CME is poorly understood.

To determine how activation of PLC β 1 by EGF stimulation may regulate CME, we used biochemical ligand internalization assays in combination with siRNA gene silencing of PLC β 1. We find that silencing of PLC has no effect on internalization of TfR (a condition in which PLC β 1 is inactive). In stark contrast, silencing of PLC β 1 results in a decrease in EGFR internalization, suggesting that the requirement for PLC β 1 for CME is specific for certain conditions. Interestingly, TfR internalization is inhibited upon PLC β 1 silencing in cells also stimulated with EGF. Using total internal reflection fluorescence microscope (TIRF-M) of cells expressing fluorescently tagged protein components of CME coupled to customized image analysis, we have quantified the dynamic localization of TfR, EGFR, and PLC β 1 vis-a-vis CCPs. Our findings suggest that PLC β 1 activation by EGFR effects broad changes to PIP2 availability and dynamics at the plasma membrane, thereby regulating clathrin-mediated endocytosis.

P1311**Board Number: B655****Differential regulation of phosphatidylinositol 4,5-bisphosphate homeostasis by Nir2 and Nir3 at ER-Plasma membrane junctions.**C. Chang¹, J. Liou¹;¹University of Texas Southwestern Medical Center, Dallas, TX

Phosphatidylinositol (PI) 4,5-bisphosphate (PIP₂) at the inner leaflet of the plasma membrane (PM) governs many cellular processes, including endocytosis, cytoskeleton dynamics, and store-operated Ca²⁺ entry (SOCE). Importantly, hydrolysis of PIP₂ by receptor-activated phospholipase C (PLC) is pivotal to initiate signaling events via the production of inositol 1,4,5-triphosphate (IP₃) and diacylglycerol (DAG). Meanwhile, it is necessary to replenish the depleted PIP₂ to maintain PIP₂-dependent cellular functions and signaling. It has been shown that PIP₂ levels recovered within minutes following receptor-induced hydrolysis but the mechanisms of PIP₂ replenishment remains unclear. In this study, we demonstrate that non-vesicular delivery of PI originating from the ER is important for rapid PIP₂ replenishment at the PM. Two mammalian PI transfer proteins (PITPs) Nir2 and Nir3 sense phosphatidic acid (PA) production from PIP₂ hydrolysis, and translocate to ER-PM junctions to mediate PIP₂ replenishment. The abilities of Nir2 and Nir3 to mediate PIP₂ replenishment are dependent on their translocation to ER-PM junctions and PI in the ER, suggesting PI transfer at ER-PM junctions. With distinct PITP activities and PA sensitivities, Nir2 and Nir3 differentially regulate PIP₂ homeostasis. Altogether, our findings reveal the long-sought mechanism that couples PIP₂ hydrolysis to its replenishment via Nir2 and Nir3 at ER-PM junctions to maintain PIP₂ homeostasis.

P1312**Board Number: B656****Structure function studies of the sterol transport protein, STARD4.**D.B. Iaea^{1,2}, I. Dikiy¹, I. Kiburu¹, D. Eliezer¹, O. Boudker¹, F.R. Maxfield¹;¹Cornell University Weill Cornell Medical College, New York, NY, ²Tri-Institutional Program in Chemical Biology, Weill Cornell Medical College, New York, NY

Significant differences in lipid distribution are maintained between intracellular organelles. Cholesterol comprises ~30% of the lipid molecules in the plasma membrane and is also enriched in the endocytic recycling compartment (ERC). In the endoplasmic reticulum (ER), cholesterol accounts for 5% of the lipid molecules. There is substantial evidence for high rates of non-vesicular sterol transport in cells. The steroidogenic acute regulator-related lipid-transfer (START) domain containing proteins are involved in several pathways of non-vesicular trafficking of sterols. Among the soluble START proteins, STARD4 is expressed in several tissues and has previously been shown to transfer sterol. The mechanism of membrane interaction and sterol binding of STARD4 is unclear. From the crystal structure of STARD4, several positively charged residues that form a basic patch were identified and suggested to facilitate membrane docking through interaction with anionic lipids. To investigate the role of the basic patch, we

ablated the charge of the basic patch and examined the effect by using an in vitro sterol transport assay. Mutation of the basic patch resulted in a 4-7 fold reduction in sterol transport, indicating that this region interacts with anionic membranes and is required for efficient sterol transfer. Recently, the activity of two sterol transport protein were found to be modulated by PI(4)P in a membrane specific manner. This suggested a potential role of phosphatidylinositol phosphates (PIPs) to modulate STARD4 activity. To investigate this potential role, the anionic lipids of either donor or acceptor liposomes were removed and replaced with physiologic levels, 2 mol%, of individual PIPs. Utilizing bulk phosphatidylserine (PS) anionic lipids, STARD4 is able to transfer 7 molecules of sterol/STARD4/minute. We find that PI(4,5)P₂ increases STARD4 activity only in the donor while PI(5)P and PI(3,5)P₂, increases activity only in the acceptor. In each of these membrane specific PIPs, STARD4 transfers 1 molecules of sterol/STARD4/second indicating nearly a 10-fold increase in transfer rate. Additionally, the increase in STARD4 sterol transfer activity is PIPs dose dependent, with sterol transfer rates slow from 0-1mol% while increasing and maintained from 2-10mol%. This suggests that there is a minimal threshold of PIPs required for STARD4 activity to be increased. We have also found that the membrane specific PIP increase in STARD4 sterol transfer is maintained in the presence of bulk PS anionic lipids. Taken together, these studies provide a mechanism for rapid vectorial transport as STARD4 extracts sterol from PI(4,5)P₂ (donor) membranes and delivers to PI(5)P and PI(3,5)P₂ (acceptor) membranes.

The Serine/Threonine kinase Par1b regulates ORP3 localization via 14-3-3 binding.

D.M. Fernandez¹, F. Lazaro-Dieguez¹, A. Muesch¹;

¹Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY

Simple epithelial cells have distinct luminal (apical) surfaces separated by tight junctions from the intercellular and blood barrier-interacting (baso-lateral) surface. The maintenance of this apico-basal polarity is crucial for proper functioning tissues such as kidney tubules, liver, and gastric epithelia. Par1b is a serine/threonine kinase which is well known for its role in establishment and maintenance of epithelial polarity. In MDCK cells, loss of Par1b correlates with loss of polarity. Conversely, overexpression promotes the establishment of a hepatic-type polarity, where the apical surface forms between the lateral domain of neighboring cells. The mechanism of how Par1b regulates polarity is unclear; however, preliminary data suggests that its kinase activity is crucial for lumen development and polarity.

We report ORP3, Oxysterol Related binding Protein-3 to be a novel Par1b substrate in MDCK cells. ORP3 has three domains, a PH domain that binds to the plasma membrane (PM), an FFAT motif that binds to VAP (an integral membrane protein of the Endoplasmic Reticulum (ER)), and an ORD domain that is thought to be responsible for oxysterol binding. We identified two Par1b-phosphorylation sites in ORP3, which are both predicted 14-3-3 binding sites. We established that a phospho-deficient ORP3 (SA-ORP3) bound less 14-3-3 than the WT protein. WT-ORP3 localized mostly to the ER and the cytoplasm, while

the SA-ORP3 additionally localized to the nuclear envelope and in punctae surrounding the cell cortex. The localization of WT-ORP3 in Par1b knock down MDCK cells phenocopied the SA-ORP3 localization. Using live cell imaging in MDCK cells, we observed that upon compactation, the punctae appeared more strongly associated with cell-cell contacts. The punctae remained the same size for over 48 hours, regardless of ORP3 expression levels. This suggests that they are unlikely protein aggregates. While disruption of the actin cytoskeleton did not change the punctuated pattern, microtubule disruption induced larger punctae, suggesting that microtubules play a role in maintaining their structure. We hypothesize that 14-3-3 regulation of ORP3 contributes to its localization to membrane contact sites (MCS) at the interface of the PM and ER. Specifically, we predict that the absence of phosphorylation by Par1b, and the resulting lack of 14-3-3 binding better allow the ORP3 to contact the PM.

Differentiation of the Plasma Membrane Phenotype in Mesenchymal Stem Cells.

K. Levental¹, I. Levental^{1,2}, E. Stockenbojer³;

¹Integrative Biology and Pharmacology, The University of Texas Health Science Center at Houston, Houston, TX, ²Cancer Prevention and Research Institute of Texas, Austin, TX, ³Biomedical Engineering, Rice University, Houston, TX

The organization of metazoan membranes into functional domains is a key feature of their physiology. These domains, determined by lipid and protein composition and driven by specific intermolecular interactions, spatially organize membrane components to actively regulate signal transduction across the membrane. Despite the functional importance of membrane domains in cellular physiology, the differences in membrane organization between cell types, and how these impact cell-specific signaling, have not been explored. Moreover, despite the central role for lipid composition in membrane organization, the specific lipid repertoires of various cell lineages and their resulting regulation of plasma membrane (PM) organization and functionality remain to be determined. Mesenchymal stem cells (MSCs) are an ideal model system to investigate these questions, as they can be directed to differentiate into several functionally distinct lineages (e.g. adipocyte, osteoblast) with minimal biochemical perturbations under identical culture conditions. We used MSCs to evaluate the differentiation of the plasma membrane phenotype, defined by (1) the detailed, comprehensive lipid composition; (2) membrane structure; and (3) functional signal transduction. We observed dramatic divergence of all three aspects of the PM phenotype during MSC differentiation. Using quantitative comprehensive shotgun mass spectrometry, we determined the PM lipidomes of differentiated MSCs and found that adipocyte lipids are characterized by shorter and more saturated fatty acids than undifferentiated cells, while osteogenic cell lipids have longer fatty acid tails and are more polyunsaturated. These lipidomic rearrangements led to changes in the physical properties of the PMs, with a divergence of both membrane fluidity and the stability of lipid raft domains associated with MSC differentiation. Taken together, these observations elucidate the compositional determinants of biophysical properties in biological membranes, as well as identify lineage-specific PM features. These

features were used as design principles for rational remodeling of the PM phenotype to promote a specific cellular response. Namely, supplementation of MSCs with a lipid upregulated in osteoblasts (the ω -3 poly-unsaturated fatty acid DHA) promoted the osteogenic PM phenotype in undifferentiated MSCs and thereby potentiated osteogenic differentiation via the BMPR pathway. These results comprise the first observations of compositional and structural differentiation of cellular membranes, identify the compositional determinants of biological membrane structure, demonstrate the plasticity of cellular lipidomes, and enable rational engineering of the plasma membrane phenotype to promote MSC osteogenesis.

Switch-like precision of cholesterol-sensing proteins arises due to limited accessibility of membrane cholesterol.

A. Gay¹, D. Rye¹, D. Frias¹, A. Radhakrishnan¹;

¹Molecular Genetics, University of Texas Southwestern Medical Center, Dallas, TX

Cholesterol levels in mammalian cells are maintained within narrow limits by a network of proteins that measure cholesterol concentrations and then regulate its synthesis and uptake. This regulatory protein network resides in the ER membrane where the cholesterol concentration fluctuates around a set-point of 5 mole% of total lipids. The cholesterol sensor in this system is Scap, a transmembrane protein that regulates the transport and subsequent proteolytic activation of SREBP. The sensitivity of Scap as a sensor is sharp and switch-like; a small increase in ER cholesterol halts both synthesis and uptake. The molecular mechanism by which Scap can measure ER cholesterol with such precision is largely unknown. The sigmoidal response of Scap could arise from several mechanisms, including positive cooperativity (protein effects) and limited accessibility of cholesterol (membrane effects). A convenient model for eukaryotic membrane-bound Scap is a family of soluble bacterial toxins that show identical switch-like specificity for endoplasmic reticulum membrane cholesterol. Using this model, we show that sigmoidal responses can arise primarily due to membrane effects. Truncated versions of these toxins fail to form oligomers but still show sigmoidal binding to cholesterol-containing membranes. The non-linear response emerges because interactions between bilayer lipids control cholesterol accessibility to toxins in a threshold-like fashion. Around these thresholds, affinity of toxins for membrane cholesterol varies by >100-fold, generating highly cooperative lipid-dependent responses independent of protein-protein interactions. Such lipid-driven cooperativity may control the sensitivity of many cholesterol-dependent processes.

P1316**Board Number: B660****Structural determinants and functional consequences of transmembrane protein partitioning to membrane rafts.**I. Levental¹;¹Integrative Biology and Pharmacology, University of Texas - Houston Medical School, Houston, TX

The plasma membrane is the physical and functional interface between a cell and its surroundings, and is therefore responsible for a myriad of parallel processing tasks, each of which must be tightly regulated to avoid aberrant signaling. To achieve this complexity, the functionality of the plasma membrane is enhanced by its subdivision into functional lateral domains, including lipid rafts - ordered lipid and protein assemblies whose formation is driven by lipid interactions, and which recruit specific membrane proteins by virtue of their unique physicochemical environment. This selective protein recruitment underlies the functionality of membrane domains; however, the structural determinants of protein partitioning to membrane rafts remain almost wholly unexplored. We have developed and characterized a robust experimental system for isolating and observing intact plasma membranes, allowing the first direct, quantitative measurements of protein affinity for raft domains. Our observations confirm that protein transmembrane domains (TMDs) contain the necessary determinants for raft affinity, as chimeric combinations between TMDs and intra/extracellular protein domains retain the raft affinity of the isolated TMDs. To explore the structural bases for these observations, we tested raft partitioning for a panel of TMD variants and confirmed the long-standing theoretical prediction that longer TMDs would prefer the thicker hydrophobic core of membrane rafts, and thus that TMD length is a key determinant of raft partitioning. We have extended these experimental observations by Molecular Dynamics modeling of protein TMDs in a simulated membrane environment, generating testable predictions for protein-protein and protein-lipid interactions. Using these predictions, we have identified a novel PxxxG motif in transmembrane α -helices that appears to be both necessary and sufficient for raft targeting by the transmembrane domain of a specific immune system adapter protein - Linker for Activation of T-cells (LAT). This motif - related to the common GxxxG motif that mediates helix-helix oligomerization - drives lateral clustering of LAT to promote raft association. We have generalized these findings by bioinformatic approaches to generate predictive heuristics for protein affinity for membrane rafts. Finally, we are exploring the functional consequence of raft affinity, by the raft partitioning of LAT constructs with their efficiency in rescuing activation of leukocytes rendered unresponsive to antigen by a knockdown of endogenous LAT. In summary, our results identify proteins that rely on raft association for their function, define the physicochemical nature of this association, and clarify the mechanisms by which PM organization regulates cell physiology.

P1317**Board Number: B661****Multi-protein assemblies underlie the mesoscale organization of the plasma membrane.**S.K. Saka¹, A. Honigmann², C. Eggeling³, S.W. Hell², T. Lang⁴, S.O. Rizzoli¹;¹Department of Neuro- and Sensory Physiology, University of Göttingen Medical Center, Goettingen, Germany, ²Department of Nanobiophotonics, Max Planck Institute for Biophysical Chemistry, Goettingen, Germany, ³MRC Human Immunology Unit, Weatherall Institute of Molecular Medicine, Oxford, UK, ⁴Department of Membrane Biochemistry, Life and Medical Sciences (LIMES) Institute, Bonn, Germany

Most proteins have uneven distributions in the plasma membrane (Lang and Rizzoli, Physiology, 2010). This may be caused by mechanisms specific to each protein, or may be a consequence of a general pattern that affects the distribution of all membrane proteins. To find out if a general mechanism exists behind this observation, we introduced several imaging approaches that aim to investigate all proteins in the plasma membrane simultaneously rather than focusing on interactions of individual protein species. This was achieved by large-scale metabolic labeling of proteins in mammalian cells through extended incorporation of non-canonical amino acid analogues, followed by fluorescent tagging via click chemistry (Dieterich et al., Nature Neuroscience, 2010). By combining this direct labeling method with super-resolution stimulated emission depletion (STED) microscopy, we studied the protein patterning in plasma membranes of living cells, as well as in membrane sheets. We found that a general mosaic-like pattern governs the proteins organization (Saka et al., Nature Communications, 2014). Multiple proteins were heterogeneously gathered into protein-rich domains surrounded by a protein-poor background. We termed these long-lived high-abundance domains “protein assemblies” and examined the contributions of different factors to their formation and maintenance. We identified cholesterol as the main organizer of the assembly pattern and the actin cytoskeleton as a secondary factor that borders and separates the assemblies. To understand the relation of this mesoscale arrangement to the nanoclusters of individual protein species, we analyzed distributions of specific proteins with respect to the protein assemblies. All of the specific proteins we analyzed were enriched in the assemblies, but they displayed differential enrichment profiles. Many proteins were preferentially located in particular areas within the assemblies, such as their edges or centers. Functionally related protein groups showed similar preferences, suggesting that functional protein-protein interactions create specialized subdomains within the assemblies. We conclude that the assemblies constitute a fundamental principle of the mesoscale membrane organization, which affects the nanoscale patterning of most membrane proteins, and possibly also their activity.

P1318**Board Number: B662****Transbilayer coupling via long acyl chains and immobilized phosphatidylserine mediate actin-based nanoclusters of outer leaflet lipids.**A.A. Anilkumar¹, R. Raghupathy¹, A. Polley², R. Vishwakarma³, Z. Guo⁴, M. Rao^{2,5}, S. Mayor⁵;¹Cellular organisation and signalling, National Centre for Biological Sciences, Bangalore, India, ²Raman Research Institute, Bangalore, India, ³Indian Institute of Integrative Medicine, Bangalore, India,⁴Department of Chemistry, Wayne State Univ, Detroit, MI, ⁵National Centre for Biological Sciences (NCBS), TIFR, Bangalore, India

A significant percentage (10%) of eukaryotic membrane proteins are attached to GPI anchors which help them attach to the outer leaflet of the plasma membrane. The significance of the GPI anchor lies in the fact that it helps to localize these molecules to cholesterol and sphingolipid enriched domains. Work over several years from our laboratory has shown that a dynamic actin cytoskeleton plays a major role in the organization of GPI-APs into cholesterol-sensitive nanoclusters (Gowrishankar et al., 2012). A key question is how GPI-APs at the outer leaflet of the membrane bilayer couples to the actin cytoskeleton at the inner leaflet. A likely possibility is that dynamic actin filaments couple to the inner leaflet lipids either directly or indirectly, which in turn are connected to the outer leaflet via a transbilayer coupling mechanism involving long acyl chain lipids both in the GPI-anchors and the coupling lipid species at the inner leaflet. Phosphatidylserine (PS) which is known to interact with a number of actin binding proteins is the prime candidate for such a lipid species. We also hypothesize that these microdomains could lead to the local ordering of the membrane which could act as sorting platforms for a number of signaling molecules.

We study nanocluster organization of GPI-APs at the cell surface by FRET (specifically homo-FRET) between fluorescently labeled GPI-APs. We then make perturbations in lipid structure of the GPI-anchor by manipulating their acyl chains of GPI-AP by utilizing mutations in enzymes that have a role in fatty acid remodeling. We have also explored the inner leaflet linker that facilitates the transbilayer coupling by exogeneously adding different lipid species of varying chain lengths in cells deficient for PS biosynthesis. Atomistic molecular dynamic simulations of asymmetric, multicomponent membrane bilayers have also been used to explore the role of long acyl chain in the coupling of the inner and outer leaflet lipids. Our results suggest that long-saturated acyl chains in the GPI-anchor, and in PS at the inner leaflet lipid with adequate amount of cholesterol are necessary ingredients for nanocluster formation. These results provide evidence for a transbilayer link between the outer leaflet and the inner-leaflet required for GPI-AP nanoclustering.

P1319**Board Number: B663****Clustering of lipid rafts is accelerated by active coagulation factor IX via exposure to phosphatidylserine at the adhesion complex.**H. Kitano¹, A. Mamiya¹, T. Ishikawa¹, Y. Fujiwara¹, M. Yoshida¹, S. Kokubun¹, C. Hidai¹;¹Nihon Univ Sch Med, Tokyo, Japan

Introduction: Lipid rafts provide entrance for many types of materials. Recently, we reported that an EGF domain in active coagulation factor IX (EGF-F9) increases lipid raft formation and accelerates cell migration. However, the details of the mechanism are not well understood. **Materials & Methods:** A431 cells derived from human squamous cell carcinoma were treated with recombinant EGF-F9. Cells were immunostained and labeled with probes for lipid rafts or phosphatidylserine (PS) and observed with confocal or TIRF microscopy. **Results:** A431 cells adhered to the matrix at the bottom of the cell and the tips of filopodia via an adhesion complex consisting of integrin $\alpha 3\beta 1$ and paxillin. After treatment with EGF-F9 for 3 minutes, cholera toxin subunit B (CTxB) binding domains emerged at the adhesive tips of filopodia, and CTxB then stained the shafts of the filopodia. Finally, large clusters of CTxB domains were observed at the edge of the cell body. Markers for lipid rafts including caveolin-1 and a GPI-anchored protein colocalized with CTxB. Annexin V and p-SIVA staining revealed that PS was exposed at the tips of filopodia, flowed on shafts of the filopodia, and colocalized with CTxB in rafts. Immunocytochemistry showed that scramblase-1 protein was present at the tips of filopodia. PS exposure and lipid raft clustering induced by EGF-F9 were suppressed in the presence of Ca⁺⁺-free buffer or siRNA for scramblase-1, and thus, lipid raft clustering appears to depend on PS exposure by scramblase-1. **Discussion:** Active F9 accelerated PS exposure around adhesion complexes at filopodia and induced clustering of lipid rafts in the cell body. PS exposure is thought to be observed in cells undergoing apoptosis. However, PS exposure by active F9 was observed within 5 minutes of the stimulus with clustering of lipid rafts and appears to be involved in apoptosis. Because lipid rafts are involved in multiple cell signaling events, clustering may cause rapid and comprehensive changes in cell signaling. Because the EGF-F9 motif is present in other proteins, the function of the motif in signal transduction should be further studied.

P1320**Board Number: B664****Probing the dynamics of raft lipids induced by receptor-mediated signaling in living cells.**C. Hsieh¹, Y.R. Lin², C. Chou³;¹Institute of Physics, Academia Sinica, Taipei, Taiwan, ²Department of Chemistry, National Taiwan University, Taipei, Taiwan, ³Academia Sinica, Taipei, Taiwan

Lipid rafts, the relatively ordered and tightly packed membrane microdomains with enriched cholesterol and glycosphingolipids, play an important role in compartmentalizing cellular processes through the assembling of signaling molecules and regulating membrane protein trafficking. However, the dynamics of lipid rafts involving signaling pathways remain elusive. There are several issues in studying the dynamics of lipid raft. Firstly, most studies regarding lipid rafts used proteins as biomarkers instead of using lipid molecules. Secondly, multivalent toxins used for labeling lipids are also commonly applied despite they may cause some aggregation of lipids. Thirdly, it is rather challenging to observe the dynamics of lipid rafts induced by receptor-mediated process since the whole signaling process happens within only a few minutes. In this study, we investigated the dynamics of lipid rafts through fluorescence imaging by conjugating single fluorescent dyes to the lipid molecules. Sphingomyelin was used as the lipid raft marker while phosphoglycerolipid as the non-lipid raft marker. The whole process of signaling dynamics was slowed down from few minutes to hours by controlling the ligand-binding area to be within tens of nanometers. The movements of receptors were also recorded with nano-sized fluorescent bead. The raft lipids not only diffuse in and out the ligand-receptor binding area, but also aggregate in the raft domain while moving along with the receptors on cell membrane. During the co-migrating process of lipid raft with the receptors, the concentration of raft lipids dramatically increases 2.8-fold in an averaged area of $1 \mu\text{m}^2$. The increment in the concentration of raft lipids in a fixed area of raft domain correlates to a slower diffusion of the receptors. The diffusion coefficients of receptors are determined to be varying from 0.004 to $0.5 \mu\text{m}^2/\text{s}$ during the raft lipid aggregation process. To our knowledge, our study presents the first direct observation of the dynamics of lipid raft by following the early events of raft lipid aggregation induced by receptor-mediated signaling in a living cell.

P1321**Board Number: B665****Phosphorylation Control Coordinates Very Long Chain Fatty Acid Synthesis.**D.K. Olson¹, F. Fröhlich¹, R. Christiano¹, H. Hannibal-Bac², C. Ejsing², T. Walther¹;¹Genetics and Complex Diseases, Harvard School of Public Health, Boston, MA, ²Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense, Denmark

Eukaryotic membranes are composed primarily of lipids from three classes: glycerophospholipids, sterols and sphingolipids. Sphingolipids are particularly abundant in the plasma membrane, sealing cells from the environment. They are also important for membrane trafficking/ organization and as

messenger molecules. Sphingolipids are de novo synthesized from a very long chain fatty acid (VLCFA) and a sphingoid long chain base that are amide-linked to form ceramide, to which various head-groups are added. Little is known concerning the regulation of sphingolipid levels or the coordination of VLCFA levels with the availability of other sphingolipid synthesis intermediates. Here we show that this coordination is achieved by regulation of VLCFA synthesis through phosphorylation of Fen1, a key enzyme of the fatty acid elongation cycle in *Saccharomyces cerevisiae*. In addition, we show Fen1 phosphorylation to be dependent upon Rom2, a nucleotide exchange factor responsible for activation of Rho1. Our data reveal a key regulation point to maintain homeostasis between different sphingolipid metabolic branches. They also suggest that multiple signal transduction pathways from the plasma membrane cooperate to regulate lipid metabolism for membrane homeostasis.

On the symbiotic origins of eukaryotic plasma membranes.

S. Bansal¹, A. Mittal¹;

¹Kusuma School of Biological Sciences, Indian Institute of Technology Delhi, New Delhi, India

Formation of the cellular plasma membrane (boundary), driven by self aggregation of amphipathic molecules, was a crucial step in the origin of life. However, as compared to numerous sequence-structure-function studies on proteins and nucleic acids, literature on assembly of biological membranes from their major constituents (i.e. lipids) to form a variety of functional structures (including boundaries) is limited. In an earlier study we reported extraction of curvature preferences of individual lipids from molecular dynamic simulation data of several “flat” bilayers [1]. In spite of the “flatness” of the systems analyzed, we found curvature preferences exhibited by individual lipid components indicating possible mechanisms (at thermodynamic and kinetic levels) of asymmetric distribution of single-lipid molecules with specific shape parameters leading to segregated domains/phases, and possibly nanoscale curvatures even in the homogenous pure bilayer systems. In this work, we focus on possible origins of membrane bilayers as boundaries of living cells. Inspired by sequence-structure-function studies on nucleic acids and proteins, we analyzed ~3000 plasma membrane lipid constituents of 263 cellular species in the three life domains (archaea, eubacteria and eukaryotes). For membrane lipids common to plasma membranes of the three domains, number of carbon atoms in eubacteria was found to be higher than those in eukaryotes. However, mutually exclusive subsets of same data show exactly the opposite - number of carbon atoms in lipids of eukaryotes was higher than eubacteria. This remarkable statistical paradox, called Simpson’s paradox, was found to be absent for lipids in archaea and for lipids not common to plasma membranes of the three domains. This indicates presence of interaction(s) and/or association(s) in lipids forming plasma membranes of eubacteria and eukaryotes, but not for those in archaea. Further exploration of lipid structures, responsible for physico-chemical properties of plasma membranes, leads to the inference that the first compartmentalized cells, i.e. eukaryotic single cells, had symbiotic origins with emphasis on eubacterial components as a source of their plasma membranes. Thus, here we report the first evidence (to our knowledge) on symbiotic origins of eukaryotic cells, with

a larger role of eubacteria in formation of plasma membranes, based on the “third front” (i.e. lipids), in addition to the growing compositional data from nucleic acids and proteins.

Cell detachment induces Lyn and Fyn activation through the change in their membrane distribution.

T. Morinaga¹, K. Abe¹, S. Yanase¹, N. Yamaguchi¹, Y. Nakayama², N. Yamaguchi¹;

¹Department of Molecular Cell Biology, Chiba University, Chiba, Japan, ²Department of Biochemistry and Molecular Biology, Kyoto Pharmaceutical University, Kyoto, Japan

Dissociation of cell-matrix interaction normally induces apoptosis in epithelial cells. However, metastatic cancer cells can survive in suspension after detachment from the primary tissue. The Src-family, a family of non-receptor tyrosine kinases, is involved in cell survival, transformation and metastasis. Each member of Src-family kinases is located on the cytoplasmic side of cellular membranes via posttranslational lipid modification. To examine the regulation mechanism of the activity of Src-family kinases in suspension cells, we focused on the interplay between the kinase activity and the membrane distribution of Src-family kinases.

For the analysis of the membrane distribution of Src-family kinases, we used sucrose density gradient fractionation without detergent. We found that the main peak of the membrane distributions of palmitoylated members of Src-family kinases, such as Lyn and Fyn, were changed upon cell detachment from the low-density fractions to the high-density fractions. Cell detachment induces both cholesterol depletion in the plasma membrane and dynamin-dependent internalization of caveolae. Each main peak of the membrane distributions of Lyn and Fyn in suspension cells treated with cholesterol and the dynamin inhibitor dynasore was located in the low-density fractions similar to that in adherent cells. These results may suggest that the changes in the membrane distributions of Lyn and Fyn upon cell detachment involve cholesterol depletion and dynamin activity.

The autophosphorylation levels of Lyn and Fyn and the in vitro kinase assay of Lyn showed that the activities of Lyn and Fyn were increased upon cell detachment. Furthermore, Lyn activity in the high-density fraction was higher than that in the low-density fraction in adherent cells. Therefore, we hypothesized that the change in the membrane distribution of Lyn involves the activation of Lyn upon cell detachment. The incorporation of cholesterol into the cells in suspension interfered with not only the change in the membrane distribution of Lyn but also the kinase activation of Lyn in suspension cells. These results suggest that the cholesterol depletion in the plasma membrane may cause both the change in the membrane distribution of Lyn and the kinase activation of Lyn in suspension cells.

P1324**Board Number: B668****Peripheral nervous system plasmalogens regulate Schwann cell differentiation and myelination.**T. Ferreira da Silva^{1,2}, J. Eira¹, A. Lopes¹, A. Malheiro¹, V. Sousa^{1,2}, M. Sousa¹, P. Brites¹;¹Nerve Regeneration, Instituto de Biologia Molecular e Celular - IBMC, Porto, Portugal, ²Instituto de Ciências Biomédicas Abel Salazar - ICBAS, Porto, Portugal

Schwann cells, the myelinating glia in the peripheral nervous system (PNS) undergo several morphological and biochemical changes that are required for membrane outgrowth and wrapping of individual axons. Myelin is highly enriched in plasmalogens, a class of ether-phospholipids, which may account for 80% of the total glycerophosphoethanolamine pool. The importance of ether-phospholipids is highlighted by the severe clinical presentation of rhizomelic chondrodysplasia punctata (RCDP), a disorder caused by impairment in the plasmalogens biosynthesis. To investigate the role of these ether-phospholipids in Schwann cell biology and myelination, we examined two mouse models with complete impairments in their biosynthesis, i.e., the Pex7 and Gnpat knockout (KO) mice. The histological characterization of sciatic nerves from KO mice revealed impaired radial sorting and myelination. Impaired myelination was also evident in in vitro cultures of embryonic dorsal root ganglia from Gnpat KO mice, and following sciatic nerve crush. Myelin devoid of plasmalogens was less compact and showed abnormal appositions. Myelin compaction in the absence of plasmalogens was partially accomplished through the action of myelin-basic protein (MBP), as a combined defect in plasmalogens and MBP severely affected myelination. These changes in myelin and Schwann cell morphology ultimately lead to an adult-onset severe demyelination with axonal loss. A deficiency in plasmalogens impairs AKT-mediated signaling, causing a dysregulation in GSK3 β and modulates the defects observed in Schwann cell differentiation and myelination. In summary, our findings reveal the pivotal role of plasmalogens for myelination and highlight the importance of these phospholipids during neurodegeneration.

P1325**Board Number: B669****Rab1B role in LDs metabolism.**I. Nevo-Yassaf¹, Y. Yaffe², M. Lovelle¹, E.H. Sklan³, K. Hirschberg¹;¹Pathology, Tel Aviv University, Tel Aviv, Israel, ²Department of Cell and Developmental Biology, Tel Aviv University, Tel Aviv, Israel, ³Clinical Microbiology and Immunology, Tel Aviv University, Tel Aviv, Israel

Lipid droplets (LDs) are the principal organelles for the storage of cholesterol esters and neutral lipids in eukaryotes. Considered for a long time as mere inert deposits, LDs are now conceived as dynamic organelles implicated in numerous biological processes in health and disease. Despite the progress in lipid-droplets research, the molecular mechanisms that underlie LD formation, growth and movement as

well as interaction with other organelles remain for the most part unclear. Here we show for the first time that Rab1B protein, a small GTPase known for its role in ER-to-Golgi trafficking and Golgi biogenesis, has a role in LD metabolism. Our previously published data demonstrate that Rab1B GTPase activity is essential for the integrity of HCV LDs-associated viral replication complexes. Using live cell imaging we found that Rab1B is localized to LDs. Next, we asked whether Rab1 activity is associated with LD metabolism. Overexpression of Rab1B-WT and Rab1B constitutively active (Rab1B-CA) mutant resulted in a decrease in LDs size accompanied by a lower Bodipy staining intensity. Cells expressing Rab1B dominant negative (Rab1B-DN) mutant abolished all steady state LDs. Noteworthy is the fact that in the presence of Rab1DN the Bodipy stain strongly labeled ER membranes, suggesting that lipid synthesis was not affected. Affinity pull-down mass spectrometry analysis in Huh-7 cell line demonstrated that Rab1B interacts with flotillin-1, a protein that is localized to LDs upon oleic acid (OA) treatment and may have a role in lipid regulation or trafficking towards these organelles. Confocal images of live cells demonstrate co-localization of flotillin-1 and Rab1B-WT as well as Rab1B-CA. This co-localization was not seen for flotillin-1 and the DN mutant of Rab1B. Our results support that Rab1B activity is a prerequisite for LD metabolism. We hypothesize that Rab1B is responsible for the targeting of specific enzymes associated with triglycerides storage and catabolism.

Galectin-1 is critical for the structural integrity of mast cells.

V.M. Mazucato¹, J.C. Rosa¹, L.L. daSilva¹, M. Jamur¹, C. Oliver¹;

¹Department of Cell and Molecular Biology and Pathogenic Bioagents, Ribeirão Preto Medical School-USP, Ribeirao Preto, SP, Brazil

Gangliosides are active components of the outer leaflet of the plasma membrane of eukaryotic cells that jointly with cholesterol, sphingolipids and proteins with lipidic modifications are major constituents of lipid rafts. Lipid raft components can act as receptors for viruses and bacterial toxins as well as modulating receptor functions in several cell types, including mast cells. Because of the importance of gangliosides in mast cell biology, the aim of this study was to compare the protein profile of the rat mast cell line, RBL-2H3, with the RBL-2H3 mutant cell line D1 that is deficient in GM1 and the gangliosides derived from GD1b. A comparative proteomic analysis of total cell lysates from the two cell lines was done using 2D-Gel electrophoresis, gel image analysis and mass spectrometry. In addition to fourteen proteins differentially expressed between the cells lines, it was found that galectin-1 is expressed only in the wild type RBL-2H3 cells and not in the D1 cells. However, RT-PCR results showed that D1 cells do have transcripts for galectin-1. Galectins belong to a subgroup of animal lectins and are characterized by a carbohydrate recognition domain (CRD). In other cell types, several studies have shown the importance of galectin-1 in the regulation of cell adhesion, growth, immune response, and in lipid raft reorganization. In order to study the effects of galectin-1 on lipid raft organization, cellular morphology and degranulation in mast cells, both cell lines were transfected with EGFP-galectin-1. By scanning electron microscopy, the expression of galectin-1 in deficient cells led to fewer ruffles on the surface,

indicating that the absence of galectin-1 is reflected in plasma membrane alterations. By immunofluorescence, in the transfected D1 cells the microtubules were organized in a typical radial distribution, different from the D1 cells whose microtubules were organized circumferentially in a basket shape. In cells transfected with galectin-1 and stimulated via FcεRI, the receptor and LAT can be found in the lipid raft fractions, in contrast to the untransfected D1 cells. However, galectin-1 transfection was not sufficient to restore mast cell degranulation via FcεRI. These results show that galectin-1 has a role in preserving the structure of mast cells, which may be related to its function in plasma membrane organization.

Mast cell specific gangliosides modulate NFAT and NFκB activation in RBL-2H3 cells.

E. . Freitas Filho¹, V.M. Mazucato¹, C. Oliver¹, M. Jamur¹;

¹Department of Cell and Molecular Biology and Pathogenic Bioagents, Ribeirão Preto Medical School-USP, Ribeirao Preto, SP, Brazil

Mast cells are immunoregulatory cells that participate in diverse biological events. The action of mast cells is directly related to their activation and subsequent mediator release. Early signal transduction events occur in lipid rafts in the plasma membrane. In rodent mast cells, GD1b-derived gangliosides are known constituents of lipid rafts. The cross-linking of these gangliosides by mAb AA4 promotes a partial activation of mast cells, similar to that observed by activation via FcεRI. Since it is known that stimulation via FcεRI activates the transcription factors NFAT and NFκB, the ability of the cross-linked GD1b-derived gangliosides to activate NFAT and NFκB was investigated. The GFP-reporter cell lines VB9 (NFAT) and NFκB₂ were used to assess activation. The cells were stimulated for 1 h with mAb AA4, rinsed and incubated for 5h (NFκB) or 15 h (NFAT). As a positive control, IgE-sensitized cells were rinsed and stimulated with antigen (DNP₄₈-HSA; Sigma Aldrich) for 6 (NFκB) or 16 h (NFAT). The percentage of GFP positive cells was determined using a Guava Easy Cyte Mini System and the data analyzed using Cytosoft Blue (Guava Technologies). Cross-linking the GD1b-derived gangliosides activated both NFAT (35% GFP positive cells stimulated with 10 µg/mL mAb AA4) and NFκB (38% GFP positive cells stimulated with 5 µg/mL mAb AA4) in comparison with 91% (NFAT) and 57% (NFκB) in the positive controls. However, using GFP-reporter cell lines deficient in Syk, crosslinking of the gangliosides derived from GD1b did not activate either NFAT or NFκB. Proteomic analysis of the lipid rafts showed that when the gangliosides were aggregated by mAb AA4, the protein composition is altered in comparison with cells not exposed to mAb AA4. An understanding of the role of gangliosides in mast cell activation may lead to new therapeutic targets for allergy and inflammation.

P1328**Board Number: B672****Scaling up through teamwork: Ankyrin-G microdomains control large-scale cellular patterning through opposing endocytosis.**P.M. Jenkins¹, M. He², W. Tseng², V. Bennett^{1,3};¹Department of Biochemistry, Duke University, Durham, NC, ²Pharmacology and Cancer Biology, Duke University, Durham, NC, ³Howard Hughes Medical Institute, Duke University, Durham, NC

Spectrin and ankyrin are plasma membrane-associated proteins that are localized to discrete microdomains within the plane of the lateral membrane of columnar epithelia (1), yet they control biogenesis and identity of the entire lateral membrane. It remains unknown how these microdomains, which only cover ~40% of the lateral membrane surface at any time, can control cellular scale patterning. Ankyrin-G microdomains require DHHC5/8 palmitoyltransferases which mediate the palmitoylation of ankyrin-G necessary for its membrane association (1). β II-spectrin also is recruited to these domains both through interaction with ankyrin-G as well as through binding to plasma membrane phosphoinositide lipids (1). Here, using live imaging of MDCK cells, we demonstrate that ankyrin-G microdomains move within the plane of the lateral membrane in a microtubule-dependent manner and sample almost the entire lateral membrane surface within 30 minutes. We propose that these ankyrin-G/ β II-spectrin microdomains promote lateral membrane biogenesis through inhibiting bulk endocytosis from the lateral membrane. The locally dynamic ankyrin-G/ β II-spectrin microdomains likely act by preventing endocytic pit formation, which occurs on the order of 1-5 minutes in the case of clathrin. We found that loss of lateral membrane height caused by depletion of either ankyrin-G or β II-spectrin can be reversed by pharmacological inhibition of endocytosis or through shRNA-mediated silencing of clathrin heavy chain. In parallel studies in neurons, we have also found that a giant isoform of ankyrin-G, but not its C70 mutant lacking a palmitoylation site, localizes to extrasynaptic plasma membrane microdomains in pyramidal neurons and stabilizes GABAergic synapses on the somatodendritic membrane through interactions with the GABA receptor-associated protein GABARAP. Inhibition of endocytosis restores GABAergic synapses that are lost in the absence of giant ankyrin-G. These results suggest that inhibition of endocytosis by locally dynamic ankyrin-G microdomains dependent on palmitoylation, phosphoinositides and microtubule-based movement may be a general mechanism for higher order cellular scale patterning.

1. He M, Abdi KM, & Bennett V (2014) Ankyrin-G palmitoylation and β II-spectrin binding to phosphoinositide lipids drive lateral membrane assembly. *J Cell Biol* 206(2):273-288.

P1329**Board Number: B673****The essential yeast type IV P-type ATPase Neo1 plays a role in establishing phosphatidylethanolamine asymmetry of the plasma membrane.**M. Takar¹;¹Biological Sciences, Vanderbilt University, Nashville, TN

Phospholipid asymmetry is a key feature of the eukaryotic plasma membrane (PM) that is required for the proper functioning of integral and peripheral membrane proteins. Type IV P-type ATPases (P4-ATPases) establish phospholipid asymmetry across the PM by pumping aminophospholipids, such as phosphatidylserine (PS) and phosphatidylethanolamine (PE), from the exofacial leaflet to the cytosolic leaflet. The P4-ATPases are highly conserved among eukaryotes and loss of P4-ATPase function is implicated in pathological conditions such as type II diabetes, obesity, intrahepatic cholestasis, and male infertility. P4-ATPases also play crucial roles in vesicle-mediated trafficking from Golgi and endosomal membranes. Although a canonical substrate transport pathway is well defined for some ion-transporting P-type ATPases, it is still under investigation how P4-ATPases translocate their bulky and amphipathic phospholipid substrates across the hydrophobic environment of the membrane. Previous work by the Graham lab suggests that a non-canonical transport pathway is used for phospholipid recognition and translocation by the yeast P4-ATPases Drs2 and Dnf1, which translocate PS and lyso-phospholipids (phospholipids with one acyl chain), respectively. However, it is not clear if all P4-ATPases use the same pathway and it remains to be determined what the phospholipid substrates are for all 5 yeast P4-ATPases (Dnf1, Dnf2, Dnf3, Drs2, and Neo1). In the current study, we investigated Neo1, an essential yeast P4-ATPase with unknown substrate specificity, which has been previously implicated in COPI retrograde trafficking. Neo1 localizes to Golgi membranes and inactivation of Neo1 activity leads to aberrant exposure of PE at the PM, suggesting a loss of PE flippase activity. Furthermore, an ATPase-dead Neo1 mutant, which can no longer flip phospholipids, cannot suppress this PE asymmetry defect. This finding suggests that the PE asymmetry defect is specifically due to a loss of Neo1 flippase activity. Interestingly, overexpression of Neo1 partially suppresses the membrane asymmetry defects associated with loss of Drs2 flippase activity (PE and PS are exposed in exofacial leaflet), but does not suppress the asymmetry defects when Dnf1 and Dnf2 flippase activity is inactivated (lyso-PS and lyso-PE are exposed). In addition, overexpression of wild-type Drs2 does not suppress Neo1 deficiency, but a Drs2-[QQ→GA] mutant defective for PS recognition but with enhanced ability to flip PE effectively suppresses Neo1 deficiency. Based on these findings, we hypothesize that the essential function of Neo1 is to flip diacylated PE across the Golgi membrane to the cytosolic leaflet.

P1330**Board Number: B674****INVESTIGATING THE ROLE OF THE PHOSPHOLIPID CARDIOLIPIN IN THE REGULATION OF MITOCHONDRIAL BIOENERGETICS.**M. Sathappa¹, M. Greenwood¹, M. Baile², S.M. Claypool², N. Alder¹;¹Molecular and Cell Biology, University of Connecticut, Storrs, CT, ²Johns Hopkins University School of Medicine, Baltimore, MD

Lipids are known to be critical determinants of membrane protein topology, conformation, and function. Cardiolipin (CL) is involved in the assembly and operation of mitochondrial respiratory complexes. However, attempts to elucidate the molecular mechanisms by which CL activates OXPHOS complexes have been confounded by technical limitations. On the one hand, analysis of individual respiratory complex activity and redox potentials in intact mitochondria does not permit the evaluation of specific lipid composition and is hindered by the presence of other coupled complexes. On the other hand, individual complexes can be isolated in detergent micelles, but this leads to delipidation of annular lipids, misfolding and inactivation. The goal of this study is to analyze which physiochemical properties of CL are important in activating respiratory enzymes, using Cytochrome C Oxidase (COX) as a model. To this end, we have reconstituted the purified COX complex into soluble, monodisperse, and stable nanodiscs of precisely defined lipid composition with a range of CL variants. Specifically, we have addressed which properties of the CL head group and acyl chain regions are important for the enzymatic activity and heme coordination of this enzyme.

P1331**Board Number: B675****Role of ER-Golgi contact sites in sphingolipid synthesis in yeast.**L. LIU¹;¹NIDDK, NIH, BETHESDA, MD

Membrane contact sites are regions where two organelles come in close proximity and are thought to be sites where lipids and signals are exchanged between organelles. We wanted to investigate the role of close contacts between the ER and Golgi complex in nonvesicular lipid transfer. Ceramides are synthesized in the ER and are delivered to the Golgi by vesicular and non-vesicular pathways, where they are converted to sphingolipids. It has previously been shown that in yeast ceramide transfer from the ER to Golgi is partially blocked in mutants with defects in vesicular transfer such as *sec18-1ts* cells (which have a conditional defect in the yeast homolog of NSF) or in cells missing the oxysterol-binding proteins Osh2p, Osh3p, and Osh4p. The ER to Golgi ceramide transfer that is not blocked in these strains is thought to be nonvesicular and may occur at ER-Golgi contact sites. To better understand this nonvesicular transport, we engineered several artificial ER-Golgi tethers. Remarkably, these tethers significantly increased nonvesicular ceramide transfer in *sec18-1ts* cells and in *osh2-4Δ* cells, both in vivo and in vitro, suggesting that tethering of the ER and Golgi facilitates ceramide transfer. To identify

other proteins that facilitate ceramide transfer, we made use of the fact that *osh2-4Δ* cells are hypersensitive to aureobasidin A (AbA), an inhibitor of sphingolipid biosynthesis. We screened for proteins that when overexpressed allow *osh2-4Δ* cells to grow in the presence of AbA. Some of the proteins we identified may tether the ER and Golgi or facilitate ceramide transfer between these organelles. Characterization of these proteins will reveal more about the mechanism and regulation of nonvesicular ceramide transfer between the ER and Golgi complex.

Nir2 plays a central role in ER-PM junctions maintaining Phosphoinositide Signaling Competence

Yeun Ju Kim, Maria-Luisa Guzman-Hernandez, Eva Wisniewski and Tamas Balla

Section on Molecular Signal Transduction, Program for Developmental Neuroscience, NICHD, NIH, Bethesda, MD

During phospholipase C activation, large amounts of phosphoinositide lipids are consumed while generating the second messengers, diacylglycerol (DG) and InsP₃. The small PtdIns(4,5)P₂ pool is turned over multiple times and it has been evident that the plasma membrane (PM) inositide pools need to be replenished for sustained signaling with newly synthesized phosphatidylinositol (PtdIns) originating from the ER. Conversely, phosphatidic acid (PtdOH) generated via DG in the PM has to return to the ER where it is utilized for PtdIns synthesis. Although PtdIns transfer protein has been postulated to transport PtdIns from the ER to the PM, the protein responsible for PtdOH transport in the other direction has remained elusive. In this study we used a combination of methods all based on intact cells and found that depletion of Nir2, a homolog of the *Drosophila* RdgB protein, which has previously been identified as a PtdIns transfer protein, causes a defect both in the utilization of PtdOH at the PM and the synthesis of PtdIns in the ER during PLC activation. Conversely, overexpression of Nir2 facilitates PtdOH removal from the PM and its conversion to PtdIns in agonist-stimulated cells. These data together with the agonist-induced translocation of Nir2 into ER-PM contact sites suggest that Nir2 plays a critical role in the recycling of the lipid products of PLC activation and that the agonist-induced increased turnover of PtdIns described several decades ago is spatially confined to ER-PM contact zones.

P1333**Board Number: B677****Alterations in caveolar morphology produced by varying plasmalemmal cholesterol, revealed by quick-freeze, deep-etch electron microscopy.**A. Yoshimura¹, J.E. Heuser²;¹Institute for Integrated Cell-Material Sciences, Kyoto University, Kyoto, Japan, ²iCeMS, Kyoto University, Kyoto, Japan

The 'quick-freeze, deep-etch' technique of EM provides high-resolution, 3-D topology of biological structures and is ideal for studying the plasma membrane (PM) surface and associated structures. When applied to "unroofed" cells, it displays the striated coats on caveolae with unprecedented clarity. Although it has long been evident that caveolae display different degrees of curvature, the reason for this has never been understood. To begin to answer this, we here sought to determine whether caveolae are capable of changing their curvature, and capable of doing so reversibly. Using deep-etch EM, which allowed us to detect all the caveolae on the PM, we examined the effect of acute manipulations of PM cholesterol-levels on their curvature. For this study, we chose a suitable cell line with a simple morphology but with plenty of caveolae (T24 cells, originally from a human bladder cancer).

At normal 'control' cholesterol levels, T24 cells display caveolae with a whole range of curvatures, from completely flat to highly invaginated, all of which display the characteristic striated coats. Decreasing PM cholesterol levels by applying methyl-beta-cyclodextrin induces dramatic flattening of the majority of caveolae, as has long been known, but their striated coats remain unchanged. On the other hand, elevating PM cholesterol with cholesterol-charged cyclodextrin induces increase in caveolar curvature, and also causes a complete dissolution of their coats into unusually thin and dispersed 'stripes' that reveal for the first time the basic underlying organization of the caveolin proteins in their coats.

Importantly, these structural changes can be induced either by applying the agents that elevate or lower PM cholesterol to living cells and *then* unroofing them, or by applying the same agents to isolated PM sheets or 'lawns' made from cells unroofed *prior* to treatment. This demonstrates that the observed changes in caveolar morphology are purely biophysical phenomena that do not require any cellular metabolism or activity.

Additionally, we could show that these changes are *reversible*, since when PM cholesterol is first lowered in order to flatten the majority of caveolae, and then is re-elevated again, caveolae still swell and invaginate and their coats still disperse; and again, this works even if the re-elevation of cholesterol is not done until *after* the unroofing. These results demonstrate that caveolae are capable of re-invaginating from the flat state without any cellular activities, and that they respond *directly* to PM cholesterol-levels and the physical state of the bilayer, by majorly altering their curvature.

P1334**Board Number: B678****Reinforcement of organelle identity by the ERAD ubiquitin ligase Doa10.**A. Ruggiano¹, P. Carvalho²;¹Cell and Developmental Biology, Centre de Regulacio Genomica , Barcelona, Spain, ²Cell and Developmental Biology Programme, Center for Genomic Regulation (CRG), Barcelona, Spain

ER-associated protein degradation (ERAD) is a quality control pathway for clearance of misfolded proteins from the endoplasmic reticulum (ER) through the ubiquitin-proteasome system. Beyond this well-studied role, ERAD controls the levels of some functional but short-lived ER proteins by targeting them for degradation under a specific condition, thereby in a regulated fashion. Despite its importance in ER homeostasis, regulated degradation through ERAD accounts for only few examples. We identified novel endogenous ERAD substrates in the yeast *S.cerevisiae* by using quantitative proteomics. Among these were some lipid droplets (LDs) proteins. LDs are organelles originating from the ER, where LD-specific proteins are synthesized before being targeted to their surface. We show that some LD membrane proteins are degraded by the ERAD ubiquitin ligase Doa10 when localizing in the ER, and that the membrane anchor is necessary for this process. Accumulation of LD proteins in the ER leads to a growth defect, indicating that their degradation is important for maintaining organelle homeostasis. LD proteins misplaced in the ER represent a novel class of ERAD substrates and uncover a role for this pathway in reinforcement of organelle identity.

P1335**Board Number: B679****Very Long Acyl Chain Sphingolipids Prefer Tail-to-Tail interaction with Cholesterol, which Restricts Microdomain Formation.**K.C. Courtney¹, C. Zhang², X. Zha^{1,2};¹Department of Biochemistry, Microbiology Immunology, University of Ottawa, Ottawa, ON, ²Chronic Disease Program, Ottawa Hospital Research Institute, Ottawa, ON

Affiliation between cholesterol and sphingolipids is essential for the formation of lateral microdomains or lipid rafts in both model membranes and isolated plasma membranes. However, such microdomains are not observed in live cells and, particularly, little is known how cholesterol interacts with very long acyl chain sphingolipids (22:0-24:0), the most abundant species of sphingolipids in mammalian cell membranes. Here we report that cholesterol preferred a novel tail-to-tail interdigitation with 24:0 sphingomyelin (SM), contrast to its well-known side-by-side affiliation with 16:0 or 18:0 SM. In live cell plasma membrane where very long acyl chain sphingolipids are exclusively in the exofacial leaflet, such interdigitation restricted the majority of cholesterol to the cytoplasmic leaflet. Consequently, giant unilamellar vesicles (GUVs) with very long acyl chain SM in the outer leaflet do not form visible microdomains, although the ones with 16:0 SM do. Thus, interdigitation is the primary mode of

interaction between cholesterol and sphingolipids in mammalian cell membranes, thereby restricting microdomain formation.

Exploring semithin sections by atomic force microscopy to visualize cell structure.

L.F. Jimenez-Garcia¹, L.T. Agredano-Moreno², A.G. Almeida-Juárez³, C.D. Alonso-Murillo², G. Álvarez-Fernández⁴, R. Chávez-Rosales², R. Lara-Martínez², A.L. Zamora-Cura⁵, L. Segura-Valdez²;

¹UNAM, Facultad de Ciencias, Mexico City, Mexico, ²Cell Biology, UNAM, Facultad de Ciencias, Mexico City, Mexico, ³Cell Biology, UNAM, Facultad de Ciencias, FES-Iztacala, Mexico City, Mexico, ⁴Bioquímica, UNAM, Facultad de Medicina, Mexico City, Mexico, ⁵Instituto Nacional de Medicina Genómica, Mexico City, Mexico

Cell structure has been abundantly documented by light and electron microscopy. Recently visualization of by atomic force microscopy has been used as to explore different cell components at the nanoscale. Using an approach including the processing of samples as for transmission electron microscopy we have been able to visualize and recognize several different organelles and cell structures. We prepared different samples including plants as *Lacandonia schismatica*, *Allium cepa*, *Ginkgo biloba* and *Araucaria heterophylla* sp., animal cells as Hep" or HeLa cells lines or rat hepatocytes and thymus, as well as trophozoites of *Entamoeba histolytica* for standard transmission electron microscopy and analyzed stained or unstained semithin sections placed onto glass slides. Semithin sections about 250 nm width were obtained using a glass or diamond knife. They were then probed by atomic force microscopy operating either in contact or intermittent mode. Cell nuclei and nucleoli, nuclear bodies and particles and pores have been observed. Moreover, compact chromatin has been also recognized. In addition, chloroplasts and mitochondria were visualized and recognized among other cell structures. These observations allow us to consider using atomic force microscopy to study different cell structures and processes at the nanoscale (DGAPA-UNAM PAPIIT IN220713; PAPIIME PE211412).

P1337**Board Number: B681****Site-specific reactivity of non-enzymatic lysine acetylation.**J. Baeza^{1,2}, J.M. Denu^{1,2}, M.J. Smallegan²;¹Biomolecular Chemistry, Univ Wisconsin-Madison, Madison, WI, ²Epigenetics, Wisconsin Institute for Discovery, Madison, WI

Protein lysine acetylation is now considered a major regulatory modification affecting diverse cellular processes. Unlike nuclear acetylation, which is catalyzed by several lysine acetyltransferases (KATs) families, direct evidence for a mitochondrial acetyltransferase is lacking, raising the possibility that acetylation may be uncatalyzed whereby the lysine side chain reacts with the thioester of acetyl-CoA. Due to the higher pH and acetyl-CoA levels in mitochondria, non-enzymatic acetylation appears to be a viable mechanism. Consistent with this idea, *in vivo* studies in which acetyl-CoA levels in mitochondria are altered results in increased acetylation. Furthermore, *in vitro* incubation of protein with acetyl-CoA also leads to a time dependent increase in acetylation.

In order to establish the feasibility of non-enzymatic acetylation, the chemical kinetics of reactivity must be quantified. Here, we performed a kinetic study to determine the rate of reactivities of site-specific, non-enzymatic acetylation of purified mitochondrial and non-mitochondrial proteins using acetyl-CoA and acetyl-phosphate. By utilizing a newly developed mass spectrometry method, we determined the rates for 98 lysine sites, quantifying reactivities ranging over three orders of magnitude. We measured the highest reactivity for glutamate dehydrogenase lysine 503 with a 2nd order rate constant of 2.73 h⁻¹ mM⁻¹ (R² 0.9874). Together, this study indicates that non-enzymatic lysine acetylation is a viable mechanism and has implications on how we view regulatory, post-translational modifications.

P1338**Board Number: B682****Mitochondrial maintenance changes dynamically with age in *Caenorhabditis elegans* adult neurons.**N. Morsci¹, D.H. Hall², M. Driscoll³, Z. Sheng¹;¹National Institutes of Health, NINDS, Bethesda, MD, ²Neuroscience, Albert Einstein College of Medicine, Bronx, NY, ³Molecular Biology and Biochemistry, Rutgers University, Piscataway, NJ

Aging is associated with cognitive decline and increasing risk of neurodegeneration. Mitochondrial dysfunction has been implicated in etiology of neurodegeneration, raising a fundamental question: Does organismal aging affect mitochondrial maintenance in neurons? By *in vivo* analysis of mitochondria in individual *Caenorhabditis elegans* neurons, we performed a comprehensive analysis of age-associated changes in mitochondria morphology, density, trafficking, and stress resistance throughout adult life. Adult neurons display three distinct stages of increase, maintenance and decrease in mitochondrial size and density throughout adulthood. Mitochondrial trafficking in the distal mechanosensory process declines progressively with age starting from early adulthood. In contrast, long-lived *daf-2* mutants

exhibit delayed age-associated changes in mitochondrial morphology, constant mitochondrial density, and maintained trafficking rates during adulthood. Finally, reduced mitochondrial load at late adulthood correlates with decreased mitochondrial resistance to oxidative stress. Our study provides the first *in vivo* evidence of dynamic changes in neuronal mitochondrial maintenance during organismal aging.

Mechanism Removing Damaged Mitochondria from Axonal Terminals.

M. Lin¹, Z. Sheng²;

¹NINDS, NIH, Bethesda, MD, ²National Institutes of Health, NINDS, Bethesda, MD

Mitochondrial dysfunction, altered dynamics, and impaired transport emerge as central problems associate with major neurodegenerative disorders. Sequestration of damaged mitochondria into autophagosomes and subsequent degradation within mature lysosomes constitute a key cellular pathway in mitochondrial quality control. Mature lysosomes are relatively enriched in the soma. Thus, an important mechanistic question, critical toward understanding axonal degeneration emerges: How are damaged mitochondria at distal synapses efficiently eliminated? By chronically dissipating mitochondrial membrane potential ($\Delta\psi_m$) in mature cortical neurons, we previously demonstrated that Parkin-mediated mitophagy mainly occurs in the soma and proximal regions of processes (Cai et al., *Current Biology* 2012). Under these chronic stress conditions, the majority of neurons survive and a significant portion of mitochondria remains motile, thus better reflecting chronic mitochondrial stress *in vivo* under pathophysiological conditions. In the current study, we detected a significant decrease of axonal mitochondrial docking protein syntaphilin following chronic $\Delta\psi_m$ dissipation. Mitochondrial retrograde transport is increased after mitochondrial depolarization for 6 hr. This phenotype is correlated with reduced levels of syntaphilin. Using the syntaphilin KO mouse model, we further confirmed that degradation of syntaphilin is essential for the depolarization-induced retrograde transport. Immunostaining analysis revealed that syntaphilin-containing vesicles are derived from depolarized mitochondria, some of which target to LAMP1-labeled late endosomal/lysosomal organelles. Our study demonstrates that syntaphilin is highly regulated by sensing $\Delta\psi_m$. Degradation of syntaphilin is required for enhanced retrograde transport, thus preferring damaged mitochondria trafficking from distal axons to the soma where major lysosome are mainly localized. Altogether, our study provides new mechanistic insight into the fine coordination of mitochondrial motility and the quality control in neurons. (Supported by the Intramural Research Program of NINDS, NIH)

P1340**Board Number: B684****The large subunit of Rubisco functions in oxidative stress tolerance and in the control of RNA oxidation in the chloroplast of the green alga *Chlamydomonas reinhardtii*.**J. Dhaliwal¹, Y. Zhan¹, J. Uniacke², W. Zerges¹;¹Biology, Concordia University, Montreal, QC, ²Molecular and Cellular Biology, University of Guelph, Guelph, ON

The large subunit of the Calvin cycle enzyme, Rubisco (RBCL), binds to RNA and localizes to stress granule-like bodies under oxidizing conditions in the chloroplast of the green alga *Chlamydomonas reinhardtii*. This suggests that RBCL has a “moonlighting” function during oxidative stress in the chloroplast. Through analysis of Rubisco mutants, we reveal here that RBCL controls the level of RNA oxidation and determines cell survival and viability during hydrogen peroxide-induced oxidative stress. Cellular subfractionation experiments demonstrate that a minor pool of RBCL carries out this moonlighting function independently of the Rubisco holoenzyme complex. Moreover, immunofluorescence microscopy reveals that oxidized RNA is localized in the pyrenoid of the chloroplast, the major intracellular location of RBCL. Together these results reveal a novel factor involved in RNA quality control in chloroplasts which functions in oxidative stress tolerance.

P1341**Board Number: B685****Preferential Distribution of Intermembrane Space and Matrix Proteins May Contribute to Mitochondrial Function.**K.S. Nadhan¹, S.P. Alla¹, N.E. Hoffman¹, M. Muniswamy¹;¹Center for Translational Medicine, Temple University School of Medicine, Philadelphia, PA

Background: The proton motive force (pmf) in the mitochondrion fuels many metabolic processes in the body. Current theory states that one major component of the pmf is the electrostatic force, created by proton flux across the inner membrane as electrons move down the ETC. However, it is possible that non-permeable particles within the matrix and intermembrane space (IMS) contribute to the large electrostatic gradient and pH that is used to generate the pmf. As of now, the role played by the IMS and matrix proteins in the generation and maintenance of pmf is unclear. Consequently, we studied different characteristics of the proteomes in the matrix and IMS to see if they could potentially play a role.

Methods: The Human MitoCarta Database was used to make a library of proteins for both the matrix and IMS. We analyzed primary protein structures to determine the number of acidic and basic residues found in each amino acid sequence, and subsequently calculated their relative frequencies within each

protein. Then using a Scripps Institute software, we calculated the pI, mw, and charge density for each individual protein.

Results: Data analysis showed a statistically significant difference ($p < 0.001$; $n=39$, $n=114$) between the percentage of charged amino acids that exist in IMS (30.6%) and matrix proteins (26.8%). No significance was noted among the relative frequencies of basic residues within two groups of proteins. However, we found a significant difference ($p < 0.001$) between the percentage of acidic amino acid residues, glutamic acid (glu) and aspartic acid (asp), in the proteins of the IMS (14.7%) and the matrix (11.4%). IMS proteins have, on average, a 23.2% greater proportion of asp residues in their primary amino acid sequence ($p < 0.001$) and also an average a 34.5% greater proportion of glu residues ($p < 0.001$). Moreover, results show that matrix proteins have larger pI values ($p < 0.001$) and higher mw distribution ($p < 0.002$) than IMS proteins. Then by using the pI and the mw data, we compared the charge densities between the two compartments and found a statistical difference ($p = 0.001$).

Conclusion: Our data shows an intrinsic difference in the production- on a genetic, transcriptional, or translational level- of the proteins destined for either compartment. There is a larger proportion of acidic amino acids in IMS proteins than matrix proteins, contributing a larger negative charge to the IMS. This observed difference in charge supports the hypothesis that proteins within the mitochondrial compartments contribute to the electrostatic gradient required to produce ATP in the mitochondria. The observation that the proteins in the IMS have lower mw with larger value charge densities does not clearly contribute to our hypothesis and needs further exploration.

Yeast mitochondria as a model system to decipher the biogenesis of bacterial outer membrane proteins.

T. Ulrich¹, D. Rapaport¹;

¹University of Tübingen, Interfaculty Institute for Biochemistry, Tuebingen, Germany

The vast majority of outer-membrane proteins in Gram-negative bacteria belongs to the class of membrane-embedded β -barrel proteins. In addition to Gram-negative bacteria, the presence of β -barrel proteins is restricted to the outer membranes of the eukaryotic organelles mitochondria and chloroplasts, which according to the endosymbiotic theory arose from the engulfment of a prokaryote by the ancestral eukaryotic cell. The assembly of these proteins into the corresponding outer membrane is facilitated in each case by a dedicated protein complex that contains a highly conserved central β -barrel protein termed BamA/YaeT/Omp85 in Gram-negative bacteria, Tob55/Sam50 in mitochondria, and Toc75/Oep80 in chloroplasts. To date, little is known about how the aforementioned complexes allow for the integration of β -barrel precursors into the lipid bilayer. Interestingly, previous studies showed that during evolution, these complexes retained the ability to functionally assemble β -barrel proteins from different origins. Taking advantage of the evolutionary conservation in the biogenesis of β -barrel proteins we use yeast mitochondria as a model system to decipher the biogenesis of the

trimeric autotransporter protein Yersinia adhesin A (YadA). Upon expression in yeast cells YadA was assembled into the mitochondrial outer membrane in its native conformation in a process dependent on the TOM and TOB complexes. Interestingly, the mitochondrial targeting of the bacterial periplasmic chaperone Skp resulted in elevated levels of YadA. A similar effect could not be observed for the chaperones SurA or SecB. Taken together, these results demonstrate that during evolution, mitochondria preserved the ability to functionally assemble prokaryotic proteins belonging to a class that cannot be found in any eukaryotic cell.

Currently, we start to use this model system to decipher the biogenesis and assembly of bacterial secretins belonging to the type II, type III and type IV secretion systems.

Identification of mitochondria-associated mRNA through tight binding to Tom20 and Puf3.

T. Tsuboi¹, R. Murad¹, A. Mortazavi¹, S. Rafelski¹;

¹Developmental and Cell Biology, University California-Irvine, Irvine, CA

The localization of mRNAs to specific regions of the cell contributes to proper post-translational protein localization and function. Mechanisms that regulate the inheritance of proper types of maternal mRNA in the daughter cells are not yet well understood. The idea that organelles act as scaffolds for the localization of mRNAs has been tested. Some mRNAs expressed during S phase were localized actively to daughters by hitchhiking on the cortical endoplasmic reticulum (cER). Mitochondria are vital and well-characterized compartments in the cell and are inherited by the daughter cells. It is already well established that many nuclear-encoded mRNAs are localized to the outer membrane of the mitochondria (ML-mRNA) in a Tom20 and Puf3-dependent manner by microarray analysis of biochemical mitochondrial fractions. However, the relation between mitochondria inheritance and RNA inheritance is still in question. Tom20, a mitochondria transporter component, recognizes the MTS peptide coming out of the ribosome, then anchors the translating complex (mRNA, ribosome and nascent peptide) on the mitochondrial outer membrane. The Pumilio family RNA binding protein Puf3 binds to the ORF and the 3'-UTR of specific mRNAs to localize them to the mitochondria outer membrane independent of translation.

To determine how ML-mRNA localization is regulated by mitochondrial inheritance and how this affects intracellular function, we first performed an RNA-seq based screen for mRNAs that are associated with mitochondria through tight binding to GFP-tagged Tom20 and Puf3. Our results showed that GFP-tagged Tom20 and Puf3 are localized to mitochondria as expected. We verified that these tagged proteins fully complement *tom20Δ* and *puf3Δ* mutants in terms not only of the cell viability but also of mitochondrial health. The over-expression of Tom20 caused swollen, misshapen mitochondria. Therefore, the effect of expressing GFP-tagged Tom20 on mitochondrial morphology was evaluated to ensure that mRNA was purified only from healthy mitochondria with normal mitochondrial morphology. We confirmed that

several specific mRNAs (*FUM1*, *ATP2*, *OXA1*, *BCS1*) bind to Tom20 in a translation-dependent manner and to Puf3 in a translation-independent manner by preparing samples with and without Cycloheximide or EDTA. We are performing data analysis of RNA-seq to identify novel ML-mRNAs. We will visualize these mRNAs and quantify the changes in their localization during mitochondrial inheritance by using live-cell quantitative 3D microscopy. In doing so, this research will provide insights into how the molecular components surrounding mitochondria are influenced by mitochondria inheritance.

Actin as an integrator of mitochondrial behavior.

M. Podolski¹, N. Hong², M. Wojcik³, J. Friedman⁴, J. Nunnari⁴;

¹Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, ²Department of Cancer Biology, Vanderbilt University Medical Center, Nashville, TN, ³Physiology Course at Marine Biological Laboratory, Woods Hole, MA, ⁴Univ California-Davis, Davis, CA

In order to integrate with the intrinsic and environmental cues, mitochondrial networks in living cells are constantly changing. A balance between fusion and division rates is necessary for the maintenance of this network, but it is not sufficient: motility and tethering are additional activities needed for maintenance of correct mitochondrial morphology. Components that regulate these processes are known, but it is less understood how these activities are integrated at a systems level. Actin is a potential candidate integrator as it is a known polarity sensor and is involved in mitochondrial motility, positioning and division in many cell types. Using the relatively simple and well-characterized mitochondrial network system of budding yeast, we tested this idea by altering the actin cytoskeleton and examining mitochondria in wild type and mutant strains disrupted in activities that play a direct role in the maintenance of mitochondrial shape and distribution. Consistent with previously published work, treatment of wild type yeast cells with 100 μ M Latrunculin A, a concentration that causes complete depolymerization of F-actin in cells, caused massive fragmentation of the mitochondrial network, indicating that F-actin plays a critical role in maintenance of mitochondrial structure. In contrast, treatment of yeast cells with 10 μ M Latrunculin A, a concentration previously shown to preferentially disrupt actin cables and not actin patches, caused mitochondrial networks to transform into net-like structures - a phenotype similar to division mutants (e.g. Δ dnm1 cells), suggesting a role(s) for actin in mitochondrial division. We examined the effects of 10 μ M Latrunculin A on mitochondria in Δ dnm1 cells and did not observe an additive effect on mitochondrial net formation. However, we observed that cortically-localized mitochondrial nets in Δ dnm1 cells significantly expanded, as previously described. This phenotype suggests the possibility that F-actin could also play a role in tethering the organelle at the cortex. Accordingly, we examined the effect of 10 μ M Latrunculin A on mitochondria in cells lacking Num1, a key component of a mother-specific mitochondrial cortical tether. In Δ num1 cells, in the absence of Latrunculin A treatment, we observed that a population of mitochondria were still persistently tethered at the mother cortex, indicating the presence of a distinct Num1-independent cortical tether. Significantly, treatment of Δ num1 cells with 10 μ M Latrunculin A abolished the

association of mitochondria with the cortex, suggesting that the Num1-independent tether is actin-dependent. Together with published observations, our data indicate that actin is involved in mitochondrial division, tethering and motility. Therefore, we propose that actin functions as an integrator of the various processes required for maintenance of mitochondrial networks in budding yeast.

Neuronal Mitochondria changes morphology through the activities of phosphatases and kinases in *Caenorhabditis elegans*.

D. Kim¹, S. Lee¹, J. Ahn²;

¹BK21Plus BDR Team, Hanyang Univ, Seoul, Korea, ²Hanyang Univ, Seoul, Korea

Mitochondria are dynamic organelles that changes their shape and size via fission and fusion. Mitochondria is divided by Drp1 and Fis1, whereas mitochondria is fused by Fzo1, OPA1, and Mgm1 in mammalian cells. DRP-1 and EAT-3 of *Caenorhabditis elegans* are required for fission and fusion, respectively. Calcineurin and several kinases regulate the activity of Drp1. Dephosphorylation of Drp1 by calcineurin promote mitochondrial fission. Also, by regulating phosphorylation of Drp1, PKA inactivate mitochondrial fission, whereas Cdk1 and CaMK α activate mitochondrial fission. In this research, we studied about mitochondrial dynamics in neurons affected by phosphatases and kinases in *C. elegans*, using feeding RNAi approach. This research will provide the insight about mitochondrial dynamics in touch sensory neurons and help understand mechanosensory behavior in *C. elegans*.

The topology of Sequestosome 1/p62 in mitochondria and its effects on mitochondrial morphology.

Y. Du¹, L. Seibenhener², M. Wooten¹;

¹Biological Sciences, Auburn University, Auburn, AL, ²Biological sciences, Auburn Univ, Auburn, AL

Sequestosome 1/p62 is a highly conserved, ubiquitin-binding protein that is present within inclusions associated with many neurodegenerative diseases. Mitochondrial dysfunction is a major characteristic of neurodegenerative diseases. Growing lines of evidence correlates p62 with damaged mitochondria under stress conditions. However, the specific location and functions of p62 in mitochondria are poorly understood. We found p62 is localized in mitochondria under physiological conditions and defects of p62 lead to mitochondrial morphology change and dysfunctions. We hypothesized that the orientation in which p62 localized in mitochondria affects its function. The aim of this project is to investigate the topology of p62 in mitochondria and what roles it might play. Results of various truncated p62 constructs distribution in cells suggested that N-terminal aa62-115 is crucial for p62 mitochondria

localization. Tryptic digestion and protein solubility experiments indicated that p62 is localized to mitochondria with N-terminus associating with the mitochondrial inner membrane and C-terminus associating with the outer membrane. We also found that p62 might regulate dynamic interactions between the mitochondrial outer membrane and inner membrane sensed by the cell fission/fusion machinery. Immunofluorescence staining showed that the N-terminal p62 construct (1-266) recovered mitochondrial morphology of p62 KO MEF cells, but the C-terminal construct of p62 (230-440) did not. This result might be caused by the interaction between p62 and mitochondrial membrane receptor proteins relating to protein import. Further investigation is undergoing to clarify the mechanism. This study illustrated the topology of p62 in mitochondria and provided preliminary data to define the functions of p62 in mitochondria involved in neurodegenerative diseases.

Transient assembly of F-actin on the outer mitochondrial membrane contributes to mitochondrial fission.

S. Li¹, S. Xu¹, B. Roelofs¹, M. Karbowski¹;

¹Center for Biochemical Engineering and Technology, Univ Maryland, Baltimore, MD

Mitochondrial dynamics, including fission and fusion, are vital for supplying cellular energy as well as controlling other tasks including apoptosis, aging and cellular differentiation. Defective mitochondrial fission and fusion have been implicated in a wide spectrum of human diseases including Parkinson's disease, Alzheimer's disease and many others. Although recent findings point to a role of actin cytoskeleton in regulating mitochondrial fission, little is known about the molecular mechanism of how actin controls this process. Here, we report that transient *de novo* polymerization of F-actin on the outer mitochondrial membrane (OMM) contributes to Drp1-dependent mitochondrial fission in mammalian cells.

We found that in cells treated with mitochondrial inducing triggers, F-actin transiently accumulated on OMM prior to Drp1-mediated steps of this process. Furthermore, mitochondrial accumulation of F-actin was also detected in mitotic cells, in which mitochondrial fragmentation contributes to stochastic distribution of these organelles into daughter cells. Thus, mitochondrial assembly of F-actin occurs in both, stress-induced and physiological Drp1-dependent mitochondria fission.

Furthermore, pretreatment with Latrunculin B, a potent actin polymerization inhibitor, completely hindered the mitochondrial accumulation of F-actin in fission inducers-treated cells, indicating that *de novo* actin polymerization is required for mitochondrial assembly of F-actin. In addition, mitochondrial accumulation of F-actin was prolonged in Drp1^{-/-} MEFs and Mff^{-/-} MEFs, but not in Mfn2^{-/-} MEFs suggesting that inhibition of mitochondrial fission by loss of functional Drp1 also hinders disassembly of F-actin on the mitochondria. These results support the possibility that mitochondrial assembly of F-actin is a step in Drp1-dependent mitochondrial fission.

To identify actin-modifying proteins that are involved in this process, we performed an shRNA screen of various actin regulatory proteins. The data showed that downregulation of p34 and Arp2, two factors of Arp2/3 F-actin nucleation complex, as well as cortactin or cofilin, resulted in mitochondrial elongation, a phenotype consistent with the inhibition of mitochondrial fission. Consistent with the role of these proteins in the mitochondrial assembly of F-actin, quantitative colocalization analysis revealed significant increases in Arp2/3 complex, cortactin and cofilin association with mitochondria in Drp1^{-/-} cells, supporting a role for actin-modifying proteins in the mitochondrial assembly of F-actin. Together these findings shed light on the increasing importance of actin in the regulation of mitochondrial fission

The Effects of Pioglitazone on Liver Cell Bioenergetics.

D.F. Grimm*¹, L. Altamirano*¹, J. Herrera¹, L. Welker¹, S. Paudel¹, M.E. Konkle², M.A. Menze¹;

¹Biological Sciences, Eastern Illinois University, Charleston, IL, ²Chemistry, Eastern Illinois University, Charleston, IL

*These authors contributed equally to this work

Insulin resistance is linked to mitochondrial dysfunction and decreased oxidative capacity of metabolically active tissues. Pioglitazone is commonly used to treat type-II diabetes and was shown to interact with the small iron-cluster containing protein mitoNEET (mNT, CISD1), which localizes to the mitochondrion. We recently observed that human hepatocellular carcinoma cells (HepG2) cultured in presence of the glucose epimer galactose (10 mM) at low glucose concentrations (<1 mM) express significantly reduced levels of mNT compared to cells cultured in presence of 15 mM glucose alone. We hypothesized that pioglitazone treatment may alter cellular bioenergetics through interaction with mNT and employed respirometry and calorimetry to investigate the effects of pioglitazone treatment on HepG2 cells cultured in high glucose medium or low glucose plus galactose medium. After 24 h of pioglitazone treatment with concentrations ranging from 15 μ M to 60 μ M, only cells cultured in the galactose medium showed a reduction in cell proliferation rates. However, cells cultured in either medium showed significant decreases in proliferation rates at all pioglitazone concentrations investigated after 48 h of exposure. Respiration rates of permeabilized cells in the presence of mitochondrial substrates and ADP (OXPHOS) were significantly increased for HepG2 cells cultured in galactose ($45.8 \pm 1.96 \text{ pmol O}_2 \cdot \text{s}^{-1} \cdot 10^{-6} \text{ cells}$; $n = 6, \pm \text{SE}$) compared to cells cultured in 15 mM glucose alone ($30.5 \pm 2.94 \text{ pmol O}_2 \cdot \text{s}^{-1} \cdot 10^{-6} \text{ cells}$; $n = 6, \pm \text{SE}$). Acute exposure to 60 μ M pioglitazone caused a severe reduction in OXPHOS for cells cultured in either medium (galactose: $12.18 \pm 1.37 \text{ pmol O}_2 \cdot \text{s}^{-1} \cdot 10^{-6} \text{ cells}$; glucose: $10.1 \pm 1.01 \text{ pmol O}_2 \cdot \text{s}^{-1} \cdot 10^{-6} \text{ cells}$). Overall heat flow of intact cells was $55.6 \text{ mW} \pm 3.0 \text{ mW}$ per million cells in glucose medium and was significantly reduced to $47.2 \text{ mW} \pm 2.5 \text{ mW}$ per million cells ($n = 10, \pm \text{SE}$) if cells were cultured in presence of galactose. Surprisingly, acute treatment of cells with 60 μ M pioglitazone increased heat dissipation in cells grown in glucose medium by $\sim 20\%$, but the effect was significantly lower for cells cultured in the presence of galactose. Our results demonstrate that pioglitazone targets multiple components of the mitochondrial OXPHOS machinery, but reductions

in cellular proliferation are ameliorated in high glucose medium through an increase in anaerobic metabolic activity. Further studies are needed to elucidate the role of mNT in the impact of pioglitazone on cellular energy transduction. (The EIU College of Sciences is gratefully acknowledged for a generous stipend)

Inhibition of PGC-1 α is responsible for Mitochondrial Defects in Hutchinson-Gilford Progeria Syndrome.

Z. Xiong¹, E. Deboy¹, C.L. Ladana¹, H. Zhang², K. Cao²;

¹Cell Biology and Molecular Genetics, Univ Maryland-College Park, College Park, MD, ²Dept of Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

Mitochondrial dysfunction, including a reduction of mitochondrial biogenesis and accumulation of mitochondrial DNA (mtDNA) mutations, has been postulated as a core player in the normal aging process. Hutchinson-Gilford progeria syndrome (HGPS), caused by a single nucleotide mutation in the lamin A gene (*LMNA*), is a rare and fatal premature aging disease. To investigate the potential contributions of mitochondrial dysfunction in HGPS pathogenesis, we conducted morphological and functional characterizations of mitochondria in primary HGPS fibroblasts. Super resolution microscopy analysis revealed an increase in swollen and fragmented mitochondria and a decrease in mitochondrial mobility in HGPS cells. Importantly, PGC-1a, a key transcriptional regulator of mitochondrial biogenesis, was significantly downregulated in HGPS fibroblasts, suggesting PGC-1a reduction may contribute to the mitochondrial defects in HGPS. Moreover, we found that the treatment with an antioxidant methylene blue alleviated senescence and mitochondrial phenotypes associated with HGPS fibroblasts and prolonged life span. Together, our study supports that the mitochondrial dysfunction contributes to the premature aging phenotypes in HGPS and suggests possible new directions to treat this devastating disease.

Dantrolene attenuates calcium release from mitochondria during potassium induced depolarization in *Paramecium*.

W.E. Bell¹;

¹Biology, Virginia Military Institute, Lexington, VA

Paramecium are excitable cells whose swimming behavior is regulated by membrane potential. Backward swimming responses can be initiated by depolarizing the cell with an increase in external K⁺ added to the bathing solution. We have identified a ryanodine-sensitive calcium flux in *Paramecium* that can be observed under such depolarizing conditions. When *Paramecium* were treated with ryanodine

receptor antagonists, backward swimming responses initiated by K^+ depolarization were significantly reduced, but not eliminated. Our attempts to localize these channels led not to the endoplasmic reticulum (the expected site of ryanodine receptor/channels) but to mitochondria. Increasing evidence suggests that ryanodine sensitive channels can be found in mitochondria. In addition, recent sequence analysis of the *Paramecium* genome reveals several channels with conserved ryanodine domains, although none with significant overall homology. Since Ca^{2+} is a mediator of the backward swimming response, we used the mitochondrial calcium-sensitive dye Rhod-2 to assess mitochondrial calcium contributions to depolarization. During a K^+ – induced depolarization, Rhod-2 fluorescence in the mitochondria decreased by approximately 30%. When cells were treated with the ryanodine receptor antagonist dantrolene prior to depolarization, the loss of calcium from mitochondria was significantly attenuated. We conclude that mitochondrial calcium stores extend backward swimming responses in *Paramecium*.

The diversity of Mitochondrial Intermembrane Space and Matrix proteomes may potentially play a key role in tissue energetics and metabolic processes.

S.P. Alla¹, K.S. Nadhan¹, N.E. Hoffman¹, M. Muniswamy¹;

¹Center for Translational Medicine, Temple University School of Medicine, Philadelphia, PA

Background: The variety of tissues in our body have different energetic and metabolic needs. In order to appropriately meet these various levels of need, they constantly maintain the oxidative phosphorylation capacities of their mitochondria. This implies that the mitochondria themselves may also need to be fundamentally different; however, the source of this difference is unclear. One source of this possibility may be at the protein level. Hence, we studied the soluble or non-membrane proteomes present in the matrix (M) and intermembrane space (IMS) compartments of 14 different tissues to study the degree of ubiquity present among tissues.

Methods: The Human MitoCarta Database was used to create our library of proteins, and their specific tissue localization. Only 14 tissue locations were considered in this database and they include: cerebrum, cerebellum, brainstem, kidney, liver, heart, skeletal muscle, adipose, stomach, small intestine, large intestine, testis and placenta. Next, we filtered out the proteins only found in the M and IMS compartments by determining their sub-cellular localization using the GeneCard Database.

Results: Data analysis showed that 75.44% M proteins are ubiquitously shared between all 14 tissues. There are only 3.51% of known soluble proteins found in only 8 or fewer tissues. In contrast, to the IMS proteins, only 16.67% of known soluble proteins of the IMS are found in all 14 tissues. We must acknowledge that 19.44% of soluble proteins are found in 13 of the 14 tissues. However, this still leaves 63.89% of IMS proteins which are unique to a varying number of tissues. 13.90% exist in 5 or fewer tissues, in contrast to 2.63% in the M, which contributes to the high variability of IMS proteins. Homologous protein analysis of IMS proteins showed that 14 tissue proteins shared the most proteomic

homology with small intestine (95.7%), testes (95.9%) and placenta (96.8%) tissues while the least homology was shared with skeletal muscle (61.8%) tissue.

Conclusion: Our data shows that there is a considerable proteome difference between tissues in the IMS compartment of the mitochondria, but this difference is significantly less in the M compartment. The proteins found in the M compartment seem to be more ubiquitous, implying the majority of these proteins are essential to the functioning of most tissues. This ubiquity in the M compartment further highlights the peculiarity of the high variability in the IMS proteomic milieu. More experimentation and analysis needs to be done to determine whether this compositional variability plays a role in the diversity of energetic capacity and demand seen among tissues.

FoxO1 switches energy metabolism and stimulates mitochondrial fission in myocardial insulin resistance.

C. Quiroga¹, F. Acuña¹, C. Vásquez-Trincado¹, M. Pavez^{1,2}, T. Gomez³, M. Estrada², H. Verdejo³, P. Castro³, J. Hill⁴, S. Lavandero^{1,4};

¹Advanced Center for Chronic Diseases (ACCDiS), Faculty of Chemical and Pharmaceutical Sciences and Faculty of Medicine, University of Chile, Santiago, Chile, ²Biomedical Sciences Institute, Faculty of Medicine, University of Chile, Santiago, Chile, ³Advanced Center for Chronic Diseases (ACCDiS), Faculty of Medicine, Pontifical Catholic University of Chile, Santiago, Chile, ⁴Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX

Cardiomyocytes are highly differentiated cells responsible of myocardial contraction. They have large requirements of energy making them highly sensitive to changes in intracellular energy metabolism. Mitochondria are crucial for the production of ATP, and their morphology and function are regulated by the dynamic processes of fusion and fission. We have recently shown that mitochondrial morphology and metabolism are regulated by insulin in cultured cardiomyocytes (Parra et al. Diabetes, 2014), suggesting that the balance between demand and energetic support regulates mitochondrial morphology. Despite this apparent relationship between a dysregulation of mitochondrial dynamics and myocardial energy deficiency, the precise mechanism of how this contributes to diabetic cardiomyopathy is still unclear. The transcription factor Forkhead box protein O1 (FoxO1) is negatively regulated by insulin and connects multiple pathways associated to energy homeostasis. The cardiomyocyte-specific deletion of FoxO1 prevents loss of cardiac function triggered by high fat diet, preserving cardiomyocyte insulin responsiveness (Batripolu et al. J Clin Invest, 2012). In the present work we evaluate the role of FoxO1 on cardiomyocyte mitochondrial morphology and metabolism in basal and under down regulation of insulin signaling conditions. To this end, a constitutively active FoxO1 (FoxO1CA-GFP) was overexpressed in primary cardiomyocytes or silenced with a specific siRNA. We evaluated the number and mean mitochondrial volume through 3D-reconstruction of the mitochondria network using ImageJ software. Our results showed that FoxO1CA induces mitochondrial fission and decreases mitochondrial metabolism without altering mitochondrial mass. In spite of a

reduction in expression of most of the mitochondrial dynamics related genes (Opa-1, Mfn-2, Drp-1 and Fis-1) by expression of FoxO1CA we not observed significant changes in its protein levels. Under this condition, FoxO1 was mainly present in the nuclei of cardiac cells transduced with FoxO1CA. In addition, FoxO1CA reduces the mitochondrial membrane potential, oxygen consumption and ^3H -2D-glucose uptake with a lightly increase in ATP levels. These metabolic effects could be related with a decreased expression in crucial metabolic gene expression (HK-II, mCTP-1, UCP-2 among others). Finally, chronic exposure of cardiomyocytes to insulin reduces the mitochondrial metabolism and increases the fission pattern of mitochondrial network. Collectively our results suggest that FoxO1 stimulates a metabolic switch and mitochondrial fission in cardiomyocytes and could mediate those metabolic changes observed in myocardial insulin resistance.

Molecular regulation of receptor-mediated mitochondrial autophagy.

C. Quan¹;

¹Institute of Zoology, Chinese Academy of Sciences, Beijing, China

Mitochondria control both cell's life and death. To ensure the well-being of the cell, mitochondrial quality must be tightly monitored through a mechanism of mitochondrial autophagy or mitophagy, which selectively removes damaged or unwanted mitochondria. We recently have identified that mitochondrial outer membrane protein FUNDC1 harbors LC3-interacting region (LIR) and interacts with LC3 to mediate mitophagy upon hypoxic treatment. Under normoxic condition, FUNDC1 is highly phosphorylated by Src kinase and CK2 at Try18 and Ser13, respectively. Mitochondrial stresses and hypoxic treatment lead to the dephosphorylation of FUNDC1 that has higher affinity with LC3. Importantly, we have identified that mitochondrially localized phosphatase PGAM5 is able to dephosphorylate FUNDC1 at Ser-13. The phosphatase activities of PGAM5 is inhibited through its interaction with Bcl-xL, and the degradation of Bcl-xL could lead to the activation of PGAM5 for mitophagy. Our results delineate the signaling pathway linking mitochondrial stresses and hypoxia towards the activation of mitophagy.

Proteolytic processing of the amyloid precursor protein (APP) by the β - and γ -secretases releases the amyloid- β peptide (A β), which deposits in senile plaques and contributes to the etiology of Alzheimer's disease (AD). The α -secretase cleaves APP in the A β peptide sequence to generate soluble APP α (sAPP α). Upregulation of α -secretase activity through the 5-hydroxytryptamine 4 (5-HT4) receptor has been shown to reduce A β production, amyloid plaque load and to improve cognitive impairment in transgenic mouse models of AD. Consequently, activation of 5-HT4 receptors following agonist stimulation is considered to be a therapeutic strategy for AD treatment; however, the signaling cascade involved in 5-HT4 receptor-stimulated proteolysis of APP remains to be determined. Here we used chemical and siRNA inhibition to identify the proteins which mediate 5-HT4d receptor-stimulated α -secretase activity in the SH-SY5Y human neuronal cell line. We show that G protein and Src dependent activation of phospholipase C are required for α -secretase activity, while, unexpectedly, adenylyl cyclase and cAMP are not involved. Further elucidation of the signaling pathway indicates that inositol triphosphate phosphorylation and casein kinase 2 activation is also a prerequisite for α -secretase activity. Our findings provide a novel route to explore the treatment of AD through 5-HT4 receptor-induced α -secretase activation.

Differential Function of Type I Receptors in BMP Heterodimer-assembled Complexes.

J.A. Dutko¹, M.C. Mullins¹;

¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

Bone morphogenetic proteins (BMPs) are important biopharmaceuticals in the treatment of skeletal conditions and in applications of tissue engineering. In these clinical applications and throughout vertebrate development, BMPs provide differentiation and growth cues in a time- and dose-dependent manner. The earliest function of BMPs is to pattern the embryonic dorsoventral axis. In the zebrafish gastrula, high BMP signaling levels arise ventrally whereas BMP antagonists, emanating from the dorsal organizer, attenuate signaling dorsally. Here BMP signaling requires two ligands, Bmp2b and Bmp7a, functioning exclusively as a heterodimer, and their corresponding type I receptors, Alk3/6 and Alk8. Why

BMP heterodimers function as the obligate ligand, while BMP homodimers, although present, fail to signal is fundamental to the BMP signaling mechanism and relevant to biopharmaceutical applications. Furthermore, evidence supports the role of BMP heterodimers in at least three other developmental pathways in zebrafish. Our goal is to elucidate the mechanism for the obligate function of BMP heterodimers in DV patterning. One model for the obligatory function of BMP heterodimers is that BMP antagonists preferentially block BMP homodimers. To test this model, we depleted BMP antagonists in embryos devoid of BMP heterodimers. If antagonists block BMP homodimers, we expect BMP homodimers to signal when BMP antagonists are absent. Intriguingly, signaling was not observed in embryos lacking BMP antagonists and BMP heterodimers indicating that BMP antagonists do not preferentially block BMP homodimers in vivo. When overexpressed, however, Bmp2b homodimers can signal, but unexpectedly, they require Alk8, the Bmp7a associated receptor. This suggests that BMP heterodimers prevail by virtue of assembling two different classes of type I receptor in a signaling complex. To examine the function of each class of type I receptor in the signaling complex, we generated a series of kinase defective receptor mutants. Interestingly, embryos were patterned by unactivatable Alk3a receptors. In contrast, Alk8 kinase activity was required for patterning. These results suggest an unequal contribution of from each receptor in the signaling complex. The BMP signaling pathway is heavily studied yet the careful consideration of heterodimer activity is understudied and represents a significant gap in our knowledge of the BMP signaling mechanism, which we are elucidating here.

Role of PARKIN/PARK2 in Bone resorptive capacity of osteoclasts.

E. Kim¹, E. LEE¹, S. Kim¹, E. CHANG¹;

¹Department of Biomedical Sciences, University of Ulsan College of Medicine, Seoul, Korea

Dysfunction of PARKIN is associated with the progression of parkinsonism, which can contribute to a progressive systemic skeletal diseases characterized by low bone mineral density. However, the possible role of PARKIN in bone metabolism is not elucidated. In this study, we observed that PARKIN deficient mice exhibit a lower bone volume than wild-type (WT) mice from the micro-CT analysis. To determine whether the osteoporotic phenotype observed these mice is related by the activity of osteoclast (OC) or osteoblast (OB), we compared the mRNA expression level of PARKIN in bone-related cells. We found that PARKIN was markedly increased in mature OC and OB compared with its progenitor cells, respectively. Knock-down of PARKIN using siRNA significantly enhanced both OC differentiation and bone resorbing activity on dentin without any changes in OB differentiation. PARKIN deficient mice also showed higher rates of OC differentiation and subsequent bone resorbing activity than WT mice. Interestingly, we found that PARKIN co-localized with a microtubule and altered microtubule dynamics in mature OC, suggesting a negative regulatory role of PARKIN in osteoclastic bone resorption. Collectively, these results indicate that PARKIN can alter microtubule dynamics in mature OC and contribute to the maintenance of bone turnover balance by regulating OC functions.

P1357**Board Number: B804****Arhgap21 modulates CXCR7 in bone marrow of homozygous knockout mice.**R.C. Melo¹, C.L. Bigarella¹, K.V. Ferro¹, L. Ricon¹, J.M. Xavier², S.T. Saad²;¹Hematology and Hemotherapy Center, University of Campinas, Campinas, Brazil, ²Hematology and Hemotherapy Center, University of Campinas, UNICAMP, Campinas, Brazil

ARHGAP21 is a member of the RhoGAP family, which are negative regulators of RhoGTPases promoting the hydrolysis of GTP-bound Rho proteins to GDP. RhoGTPases are important regulators of cytoskeleton rearrangements that have been described in controlling migration, adhesion, cell cycle and survival. ARHGAP21 has been described to interact with PKC ζ and FAK which are downstream proteins of the CXCL12/CXCR4 pathway. CXCL12 is a chemokine produced by bone marrow stromal cells that binds to CXCR4. CXCR4 is a receptor expressed, among other cells, in hematopoietic progenitor cells. The activation of CXCR4 by CXCL12 can induce many processes such as migration, adhesion and homing of hematopoietic progenitor cells. Heterozygous knockout mice for ARHGAP21 (Arhgap21^{+/-} mice), produced by our group, exhibit reduced migration, adhesion and homing of progenitor cells suggesting that ARHGAP21 might be a strong candidate to regulate the CXCL12/CXCR4 signaling. Recently, CXCR7 was identified as another CXCL12-binding receptor, but its contribution to CXCL12-mediated effects in hematopoietic cells is still poorly explored, even though the CXCR7 relationship with tumor progression in non-hematopoietic malignancies is well established. Given that migration, adhesion and homing are altered in Arhgap21^{+/-} mice and that there is little information regarding CXCR7 in hematopoiesis, we investigated its expression in bone marrow cells of Arhgap21^{+/-} mice. In addition, we also investigated the expression of CXCR4 in these cells and CXCL12 levels in the supernatant cell. Bone Marrow was isolated from mice femurs, tibias and humerus by crushing the bones. Cells were passed through a 0.40 μ M cell strainer and red blood cells were lysed with lysis buffer solution. Afterwards, CXCR7 and CXCR4 mRNA expression was analyzed by Real-time PCR (normalized by HPRT) in bone marrow samples of 20 Arhgap21^{+/-} and 17 wild-type mice. The CXCL12 dosage was analyzed by ELISA. CXCR7 was significantly lower expressed in samples from heterozygous compared to wild-type mice (1.09 [0.24-2.49] versus (vs.) 0.60 [0.00-1.78]; $p=0.0161$, *Mann-Whitney* test). No difference in CXCR4 expression neither in the levels of CXCL12 was observed. These results suggest that, in bone marrow, CXCR7 is modulated by ARHGAP21 and could play a role in the impaired homing observed in Arhgap21^{+/-} mice.

P1358**Board Number: B805****The role of Thrombin in proliferation of human Müller Glial Cells.**I. Lee Rivera¹, M.G. Carranza-Pérez¹, E. López-Hernández¹, A. López-Colomé¹;¹Instituto De Fisiologia Celular UNAM, Mexico DF, Mexico

The breakdown of the blood–retina barrier (BRB) by trauma, ischemia, anoxia or metabolic imbalance has been shown to be a key factor for the progress of ocular proliferative diseases such as Proliferative Vitroretinopathy (PVR), retinal neovascularization and Diabetic retinopathy. Müller glial cells (MCs) play a central role in BRB maintenance: in pathological conditions, they also act as modulators of inflammatory responses. Depending on the severity of the challenge, MCs activate a proliferation program that, in mammalian retina, generates fibrotic scars that contribute to the formation of contractile epi-retinal membranes, which detach the retina, with the consequent loss of vision. Therefore, it is clinically relevant to understand the mechanisms involved in MCs proliferation. The pro-inflammatory Serine-protease Thrombin has been shown to participate in a myriad of cellular processes including proliferation and migration. Thrombin actions are mediated by the activation of G-protein coupled Protease Activated Receptors (PARs 1-4) through the cleavage of the N-terminal domain. The purpose of this study was to investigate the effect of thrombin on the proliferation of human MCs using the MIO-M1 cell line. We first demonstrated that human MCs express all four classes of PARs, both at the mRNA and protein level. Functionally, our results show that Thrombin dose-dependently stimulates MC proliferation by 44%, with a calculated EC_{50} of 0.86 nM. In contrast to our previous findings showing maximal Thrombin-induced RPE cell proliferation at 24 hours post-stimulation, MCs peak proliferation required sustained Thrombin treatment for 72 hours. These results suggest that duration of the stimulus influences the composition and possibly, contractility of epi-retinal membranes. The specificity of Thrombin action was demonstrated by the prevention of proliferation using the thrombin chelator Hirudin and its catalytic inhibitor PPACK in MTS reduction and wound healing assays. MAPKs have been shown to mediate c-fos expression, Cyclin D1 accumulation and RPE cell proliferation. To investigate the possible signaling mechanisms involved in thrombin-induced human MC proliferation, we analyzed Erk1/2 phosphorylation/activation. Results demonstrate that, as previously shown for RPE cells, MEK/Erk signaling pathway is activated by thrombin in human MCs. Since thrombin induces the proliferation of RPE and MCs, the main cellular components of epi-retinal membranes, the present results suggest that this protease may play an important role in proliferative blinding diseases such as PVR and gliosis. This study was partially supported by grants from CONACyT (176347) and PAPIIT-UNAM. We acknowledge the donation of MIO-M1 cells by Dr. GA Limb (University College London, UK).

P1359**Board Number: B806****A pivotal role for non-muscle myosin II in the negative regulation of signal transduction mediated by the B-cell antigen receptor.**W. Song¹, C. Liu², M.I. Lazzaro³;¹Department of Cell Biology and Molecular Genetics, University of Maryland, College Park, MD, ²Cell Biology and Molecular Genetics, University of Maryland, College Park, MD, ³Univ Maryland, College Park, MD

B-lymphocytes rely on B-cell antigen receptor (BCR) to sense pathogenic substances and initiate B-cell-mediated antibody responses. Upon binding to antigen, the BCR initiates signaling cascades, which can be up and down regulated based on the nature of antigen and the levels of antibody-antigen immune complexes. BCR activation requires actin-dependent receptor oligomerization into microclusters. We have recently shown that besides signaling initiation and amplification, actin remodeling is critical in the attenuation of BCR signaling, by driving B-cell contraction on the antigen-presenting surface and the coalescence of BCR microclusters into a central cluster. However, the cellular mechanism underlying the BCR-actin interplay during signal attenuation is unknown. In this study, we demonstrate that BCR activation induces the activation and recruitment of non-muscle myosin II (NMII) to the B-cell surface that interacts with antigen-presenting surface, first to BCR microclusters and later to the outer rim of the BCR central cluster. The NMII recruitment is dependent on SH2 domain-containing inositol 5-phosphatase (SHIP-1), as BCR-induced recruitment is blocked in SHIP-1^{-/-} B-cells and enhanced when the kinetics and magnitude of SHIP activation are increased by the colligation of the BCR with the inhibitory co-receptor Fc gamma receptor IIB (FcgammaRIIB) by immune complexes. Inhibition of NMII activation or motor activity by the Rho-associated protein kinase inhibitor or blebbistatin causes an increase in B-cell spreading on the antigen-presenting surface, a delay in B-cell contraction, and inhibition of BCR central cluster formation, consequently leading to increased levels of tyrosine phosphorylation in response to membrane-associated antigen. Furthermore, the inhibition of NMII releases B cells from the suppression of FcgammaRIIB on B-cell spreading, BCR clustering and tyrosine phosphorylation. These results suggest that NMII is a critical component of the negative regulation machinery in B cells. NMII functions downstream of SHIP and mediates the transition from actin-driven B-cell spreading to contraction, consequently controlling BCR clustering and signal attenuation.

This work has been supported by Maryland Stem Cell Research Fund to WS.

P1360**Board Number: B807****Evidence that TMEM184A functions as a receptor for heparin.**Y. Li¹, J.B. Slee^{2,3}, L.J. Lowe-Krentz¹;¹Biological Sciences, Lehigh University, Bethlehem, PA, ²Lehigh University, Bethlehem, PA, ³Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA

Besides its well-known role as an anticoagulant, heparin has also been revealed to have anti-proliferative effects on vascular smooth muscle cells (VSMCs). Heparin treatment of VSMCs has been shown to decrease ERK activity and the activation of down-stream transcription factors in addition to decreasing cell proliferation. In addition, VSMCs and endothelial cells have long been known to bind and take up heparin. Despite this evidence, the underlying mechanism(s) resulting in heparin effects on VSMC proliferation have remained unclear. Evidence supporting a cell surface receptor for heparin includes monoclonal antibodies that block heparin binding and mimic heparin effects in inducing PKG-dependent responses in VSMCs. Studies in our laboratory indicate that the protein product of TMEM184A is precipitated with these antibodies. Immunoprecipitation using our monoclonal antibodies that mimic heparin and commercial TMEM184A antibodies reveals apparently identical protein. Western blots of the immunoprecipitates stained by a second commercial TMEM184A antibody raised against an alternate epitope support the identification. Similar immunoprecipitation results are obtained with VSMCs and bovine aortic endothelial cells. Treatment of GFP-TMEM184A transfected VSMCs with rhodamine-heparin allows evaluation of heparin uptake. Confocal microscopy was used to identify early co-localization of the fluorescent labels and rhodamine-heparin uptake into vesicles coated with the GFP construct. These results suggest association between TMEM184A and its involvement in heparin internalization. Together these data provide evidence supporting the identification of TMEM184A as a heparin receptor on vascular cell membranes.

P1361**Board Number: B808****Mechanistic Study of the TRPM2-Ca²⁺ Signaling in ROS induced Switch between Apoptosis and Autophagy.**J. Yue¹;¹Biomedical Sciences, City University of Hong Kong, Hong Kong, Hong Kong

It is well known that reactive oxygen species (ROS) regulates autophagy, and vice versa. Yet, the molecular entities underlying the interplay between ROS and autophagy remain elusive. Transient potential receptor melastatin-2 (TRPM2) is a Ca²⁺-permeable cation channel, and is mainly activated by intracellular adenosine diphosphate ribose (ADPR) in response to oxidative stress. Here we found that ROS activated TRPM2 for Ca²⁺ influx via ADPR to inhibit early autophagy induction, which ultimately led

to apoptosis in TRPM2 expressing cancer cell lines. On the other hand, ROS induced autophagy, not apoptosis, for cell survival in cancer cell lines which do not express TRPM2, and autophagy inhibition converted cells to apoptosis upon ROS treatment. Likewise, TRPM2 knockdown or inhibition rewired cells from apoptosis to autophagy for survival in response to ROS in TRPM2 expressing cells. ROS-induced Ca^{2+} influx via TRPM2 actually activated calmodulin-dependent protein kinase II (CaMKII) to phosphorylate Ser295 on Beclin1. Phosphorylated BECLIN1, in turn, decreased the association between BECLIN1 and VPS34, but induced the binding between Beclin1 and Bcl2. Moreover, ROS induced Ca^{2+} influx via TRPM2 markedly augmented intracellular ROS levels in a positive feedback loop, which subsequently oxidized CaMKII to enable CaMKII binding with BECLIN1. In summary, our data demonstrated that the TRPM2/ Ca^{2+} /CaMKII/Beclin1 cascade is the molecular switch between autophagy and apoptosis in response to ROS.

Basigin regulates spermatocyte apoptosis through extrinsic apoptotic pathway.

C. WANG¹, H. Chen^{1,2}, H. Chan¹;

¹Epithelial Cell Biology Research Center, School of Biomedical Sciences, Faculty of Medicine, The Chinese University of Hong Kong, Hong Kong, Hong Kong, ²The second people's hospital of Shenzhen, Shenzhen, China

Basigin (BSG), also known as cluster of differentiation 147 (CD147) or extracellular matrix metalloproteinase inducer (EMMPRIN), is a transmembrane glycoprotein that plays an important role in spermatogenesis. Spermatogenesis is a physiological process tightly regulated by germ cell proliferation and apoptosis. Previous study has shown that BSG null mutant male mice are infertile. The percentage of apoptotic germ cell increases, and spermatogenesis is arrested in BSG knockout mice. Functional Blocking BSG with anti-BSG induces apoptosis in spermatocytes. However, it is still elusive that how BSG is involved in germ cell fate regulatory network. In this study, we aim to clarify the molecular mechanism underlying BSG-mediated germ cell survival/apoptosis with the mouse spermatocyte cell line GC-2 in vitro and mouse testicular germ cells in vivo. We found that the cleaved caspase 8 was dramatically increased in anti-BSG treated GC-2 cells and BSG-immunodepleted mice testis, indicating that anti-BSG induced extrinsic apoptosis in germ cells. Indeed, the expression of TNF- α and Fas, the stimulators of extrinsic apoptosis, were significantly increased in BSG-immunodepleted testis. Meanwhile, NF κ B signaling was down-regulated in both anti-BSG treated GC-2 cells and BSG-immunodepleted mice testis. These findings support an important role of BSG in regulating germ cell apoptosis.

P1363**Board Number: B810****Trehalose promotes selective secretion of Insulin-like peptide 3 through an adipokinetic hormone relay in *Drosophila*.**J. KIM¹, T. Neufeld^{1,2};¹Genetics Cell Biology and Development, University of Minnesota, Minneapolis, MN, ²Genetics, Cell and Developmental Biology, University of Minnesota, Minneapolis, MN

Secreted ligands of the insulin family play dual roles in promoting cell growth and maintaining organismal sugar homeostasis. Release of insulin is tightly regulated in response to levels of circulating nutrients, but the mechanisms by which insulin producing cells (IPCs) coordinate their response to distinct nutrient signals and other hormonal pathways during development are unclear. Here we show that regulation of insulin secretion in *Drosophila* larvae has been segregated into distinct branches: circulating sugars selectively promote the release of *Drosophila* insulin-like peptide 3 (Dilp3), whereas amino acids selectively promote secretion of Dilp2. Dilp3 is uniquely required for sugar-mediated activation of insulin signaling and suppression of autophagy in the larval fat body, a central regulator of Dilp secretion. We demonstrate that sugar levels are not sensed directly by the IPCs, but rather by the adipokinetic hormone (AKH)-producing cells of the corpora cardiaca, and that AKH signaling is required in the IPCs for sugar-dependent Dilp3 release. Thus, the IPCs integrate multiple cues to regulate selective secretion of distinct insulin subtypes, thereby maintaining homeostasis under varied nutrient conditions.

P1364**Board Number: B811****Surface Adhesion and Proliferation of 3T3-L1 Pre-Adipocytes Exhibit Sensitivity To Melanin-Concentrating Hormone: High Dose Effects Do Not Predict Low Dose Effects.**M. Cerasaro¹, C. King¹, L.B. Cook¹;¹Biology, SUNY Coll-Brockport, Brockport, NY

Melanin-concentrating hormone (MCH) participates in a variety of physiological processes, including regulation of sleep-wake cycles, appetite and energy expenditure. Although a great deal of research is focused on MCH signaling in brain, we can't rule out the potential significance of MCH receptor targets in tissues throughout the body including the gut, pancreas and adipose stores. We recently reported that MCH facilitates pre-adipocyte migration in scratch wound assays, providing evidence that MCH signaling may actually participate in the development of adipose tissue. Interestingly, in addition to cell migration, mitotic expansion of cells is also expected during the differentiation process. The purpose of this continuing study was to test the hypothesis that MCH influences the mitotic expansion of murine 3T3-L1 pre-adipocytes in culture. A crystal violet assay is simple and useful for obtaining quantitative

information about the relative number of cells adhering to multi-well plates. Crystal violet stains DNA and, upon cell lysis, the dye taken up by the monolayer can be quantitated in a spectrophotometer. We cultured 3T3-L1 pre-adipocytes in the presence of MCH for 6 days and discovered that incubation with just 1 nM MCH resulted in significantly more cells than control and neither 10 nM nor 100 nM had any measurable effect. To determine if this increase in cell number was influenced by changes in cell adherence to the culture dish, we performed a time-course growth assay where cells were incubated in 1 nM MCH for up to 72 hours. Using a hemacytometer to count cells in the media as well as adhering to the plate, we determined that low dose MCH results in less cells suspended in the media and more cells adhering to the plate, but that compared to control, the overall number of cells in MCH-treated wells significantly outnumbered those untreated. In conclusion, we have uncovered a previously unknown level of sensitivity in MCH receptor signaling, with 1 nM MCH facilitating adherence and mitotic expansion of 3T3-L1 preadipocytes that is undetectable with 100 nM MCH. Future experiments are aimed at determining whether differentiated 3T3-L1 adipocytes exhibit similar sensitivity to MCH and whether the observed effects translate to human pre-adipose and adipose cells as well.

The Contribution of Melanoregulin to Microtubule-Associated Protein 1 Light Chain 3 (LC3) Associated Phagocytosis.

A. Dhingra¹, L.S. Frost¹, V.S. Lopes², I.R. Rodriguez³, D.S. Williams², K. Boesze-Battaglia¹;

¹Biochemistry, University of Pennsylvania, Philadelphia, PA, ²University California-Los Angeles, Los Angeles, CA, ³National Eye Institute, Bethesda, MD

The degradation of shed photoreceptor outer segments by the retinal pigment epithelium (RPE) is necessary for photoreceptor renewal, function and survival. Phagocytic uptake, phagosome maturation and subsequent degradation of photoreceptor outer segment (OS) content require a coordinated series of processes regulated by several intracellular proteins. One such protein melanoregulin (MREG) is necessary for the complete digestion of OS; loss of MREG results in incomplete degradation of opsin positive phagosomes as well as lipofuscin accumulation over time. Here we explore the hypothesis that MREG-dependent processing of POS phagosomes links aspects of both autophagic and phagocytic processes in a pathway known as LC3-dependent phagocytosis (LAP). Opsin positive phagosomes were associated with LC3 as well as MREG both *in vivo* (by immuno-EM) and *in vitro* (by confocal imaging). The association of LC3 with OS was independent of nutrient deprivation mediated by rapamycin and dependent on the presence of Atg5. Phagosome maturation studies suggest that MREG is required for LC3 association with POS. Furthermore, the mechanism of MREG action is likely through an interaction with LC3, as determined by co-localization and immuno-precipitation studies. Lastly, the consequence of defective MREG-LC3 association results in the accumulation of cholesterol and 7-ketocholesterol. We posit that POS degradation is a complex process likely requiring convergence of the phagocytic and autophagic pathways in a process that involves LC3 and MREG.

P1366**Board Number: B813****Exploration of a novel signaling pathway implicated in the regulation of insulin secretion from β -cells.**G. Li¹, S. Shao¹, H. Xu¹, Y. Bee²;¹Dept of Clinical Research, Singapore General Hospital, Singapore, Singapore, ²Dept of Endocrinology, Singapore General Hospital, Singapore, Singapore

Insufficient insulin release and/or defective insulin action lead to the development of diabetes. Insulin secretion from islet β -cells is controlled by a complex signaling network. Lysophospholipids constitute a group of important lipid mediators, among which lysophosphatidic acid (LPA) exhibits multiple biological functions e.g. platelet aggregation, smooth muscle contraction and cell proliferation. LPA may evoke its effects through G-protein-coupled receptors followed by activation of various signaling pathways such as phospholipases C and D, and mitogen-activated protein kinase. LPA can be generated via hydrolysis of phosphatidic acid (PA) by phospholipase A1 (PLA1) and A2. This study investigated the possible role of a cytosolic PLA1 with a strong preference for PA (PA-PLA1) in insulin-secreting cells. The activity of this PA-PLA1 was originally identified in the supernatant fraction of bovine testis and brain. We observed high expression of PA-PLA1 in isolated rat islets and also in insulin-secreting INS-1 β -cells as determined by real-time RT-PCR and immuno-blotting. By contrast, PA-PLA1 expression was undetectable in isolated pancreatic acinar cells. The function of PA-PLA1 in β -cells was assessed after its knockdown by small RNA interference. Transfection of INS-1 cells with a mixed pool of 3 siRNA oligos targeting PA-PLA1 mRNA for 3 days reduced its expression by 80%. PA-PLA1 knockdown caused a decrease of LPA levels in INS-1 cells as determined by thin-layer chromatography, but had no effect on the cell proliferation as assessed by flow cytometry. Glucose metabolism was lowered after PA-PLA1 knockdown as measured by a tetrazolium-based MTS assay. Importantly, high glucose (11.1-22.2 mM)-stimulated insulin secretion was significantly reduced by >75%, with a severer inhibition on the late phase secretion. Moreover, insulin secretion induced by the sulfonylurea glibenclamide and by membrane potential depolarization with high K⁺ was markedly diminished. However, PA-PLA1 knockdown did not alter glucose-stimulated insulin release in the presence of forskolin and GLP-1 which can increase cAMP levels. In parallel, PA-PLA1 knockdown inhibited glucose-induced increase of cAMP levels but an addition of forskolin or GLP-1 could rescue such inhibition. Our data suggest that PA-PLA1 might be a novel lipase which play an important role in the regulation of insulin secretion in β -cells via cAMP-implicated signaling pathway.

P1367**Board Number: B814****Endocytosis and Vacuolar Degradation of the Yeast Cell Surface Glucose Sensors Rgt2 and Snf3.**A. Roy¹, J. Kim²;¹Biochemistry and Molecular Medicine, George Washington University, Washington, DC, ²George Washington University, Washington, DC

Sensing and signaling the presence of extracellular glucose is crucial for the yeast *Saccharomyces cerevisiae* because of its fermentative metabolism, characterized by high glucose flux through glycolysis. The yeast senses glucose through the cell surface glucose sensors Rgt2 and Snf3, which serve as glucose receptors that generate the signal for induction of genes involved in glucose uptake and metabolism. Rgt2 and Snf3 detect high and low glucose concentrations, respectively, perhaps because of their different affinities for glucose. Here, we provide evidence that the glucose sensors are removed from the plasma membrane through endocytosis and targeted to the vacuole for degradation upon glucose depletion. The turnover of the glucose sensors is inhibited in endocytosis defective mutants, and the sensor proteins with a mutation at their putative ubiquitin-acceptor lysine residues are resistant to degradation. Of note, the low affinity glucose sensor Rgt2 remains stable only in high glucose grown cells, and the high affinity glucose sensor Snf3 is stable only in cells grown in low glucose. In addition, constitutively active glucose sensors do not undergo endocytosis, whereas signaling defective sensors are constitutively targeted for degradation, suggesting that the actively signaling state of the glucose sensors is protected from endocytosis. Taken together, our findings demonstrate that the amount of glucose available dictates the stability of the two glucose sensors with different affinities for glucose, enabling yeast cells to maintain glucose sensing activity over a wide range of glucose concentrations.

P1368**Board Number: B815****A Novel Transfluor BacMam Reagent for Monitoring GPCR Activation.**A. Forsyth¹, P. Gedraitis¹, J.A. Hesley¹, E.F. Cromwell¹;¹Molecular Devices, Sunnyvale, CA

G-protein-coupled receptors (GPCR) participate in many disease pathways and represent the largest family of therapeutic targets. Thus, great investments are made to discover drugs modulating GPCR-mediated events. Transfluor is a functional high-content imaging based GPCR assay that measures redistribution of cytosolic beta-arrestin following binding to an activated GPCR and can be used for drug screening. By attaching a fluorescent label to beta-arrestin, the location of the receptor-arrestin complex can be monitored. Since desensitization only occurs with an activated receptor, monitoring beta-arrestin translocation and subsequent receptor recycling provides a method to detect the activation of any GPCR. BacMam viruses are modified baculoviruses that contain mammalian expression cassettes for viral gene delivery and transient expression in mammalian cells. Here we show the

applicability of a novel BacMam-based reagent for performing Transfluor assay. A virus engineered to express the labeled beta-arrestin protein can be used to transduce cell lines expressing the GPCR of interest. Here we show data generated, using the ImageXpress Micro XLS high-content imaging system, from a CHOK1 cell line stably expressing the Angiotensin II receptor type 1 (AT1). We observed a diffuse cytoplasmic GFP fluorescence signal in unstimulated cells, that became punctate upon stimulation with receptor-specific agonists, indicative of the relocation of the receptor-arrestin complex to clathrin-coated pits on the cell membrane and then to endocytic vesicles. This response was quantified by the MetaXpress Imaging Software's Transfluor application module and allowed the generation of dose-response curves and EC₅₀ values. In addition, inhibition of receptor trafficking by antagonists was also demonstrated. This combination of BacMam and Transfluor technology allows a flexible, versatile and universal GPCR cell-based assay able to screen for GPCR ligands regardless of the interacting G-Protein or signaling pathway utilized.

G-protein beta-gamma regulation of Golgi to cell surface transport.

L.M. Klayman¹, P.B. Wedegaertner²;

¹Biochemistry and Molecular Pharmacology, Thomas Jefferson Univ, Philadelphia, PA, ²Department of Biochemistry and Molecular Biology, Thomas Jefferson University, Philadelphia, PA

Non-canonical G-protein signaling has been shown to regulate intracellular transport and secretory pathways at the Golgi. G-protein beta-gamma localizes to the trans-Golgi network, activating effector phospholipase C to increase local diacylglycerol and recruit members of a kinase signaling cascade. Subsequent activation of protein kinase C results in phosphorylation and activation of protein kinase D (PKD). Numerous PKD substrates are phosphorylated at the TGN, resulting in recruitment of vesicle fission machinery and consequent fission of vesicles destined for the plasma membrane. While basolaterally-targeted (BL) or secretory vesicle release is known to be downstream of PKD activation, apically-targeted (AP) vesicle release from the Golgi occurs via a PKD-independent pathway. A similar cargo selectivity for beta-gamma has not been tested. Here, we generate GRK2ct variants that inhibit beta-gamma in a spatial or temporal manner to test regulation of AP and BL cargo trafficking. We find that a lipid-association mutant of GRK2ct fails to inhibit beta-gamma function at the Golgi, but forced targeting to the Golgi recovers inhibition of beta-gamma. We use this lipid-association mutant of GRK2ct to generate an inducible system of recruitment of GRK2ct variants to distinct subcellular locations, towards the goal of inhibiting solely Golgi-localized beta-gamma signaling. We aim to use these tools to separate different signaling pools of beta-gamma, depending on sub-cellular localization. We follow model cargo trafficking via transport of temperature-sensitive cargoes to the plasma membrane, as well as secretory cargo delivery to the media. We find that beta-gamma inhibits only BL cargo delivery, in both PM-destined and secretory cargo. The results indicate that beta-gamma functions upstream of PKD as a regulator of BL (but not AP) vesicle transport from the Golgi to the cell surface.

P1370**Board Number: B817****Up-regulation of N-cadherin by collagen I-activated DDR1 requires Shc1.**H. Huang¹, R.A. Svoboda², J. Saowapa², K.R. Johnson^{2,3};¹Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE, ²Oral Biology, University of Nebraska Medical Center, Omaha, NE, ³Fred Pamela Buffett Cancer Center, University of Nebraska Medical Center, Omaha, NE

Pancreatic ductal adenocarcinomas are highly malignant cancers, characterized by extensive invasion into surrounding tissues, metastasis to distant organs at a very early stage, and a limited response to therapy. One of the main features of pancreatic ductal adenocarcinomas is desmoplasia, which leads to extensive deposition of collagen I. Our lab has demonstrated that collagen I can induce epithelial-mesenchymal transition (EMT) in pancreatic cancer cells. A hallmark of EMT is an increase in the expression of a mesenchymal cadherin, N-cadherin. Our previous studies have shown that up-regulation of N-cadherin can promote tumor cell invasion, and collagen I-induced EMT is through two collagen receptors $\alpha 2\beta 1$ integrin and discoidin domain receptor 1 (DDR1). DDR1 is a receptor tyrosine kinase widely expressed during embryonic development and in many adult tissues. It is also highly expressed in many different cancers. However, the role of DDR1 in pancreatic cancer is largely unknown. In the collagen I-induced up-regulation of N-cadherin signaling pathway, we have shown that focal adhesion kinase (FAK)-related protein tyrosine kinase (Pyk2) is downstream of DDR1. In this study, we found that isoform b of DDR1 is responsible for collagen I-induced up-regulation of N-cadherin and that it is Tyrosine513 of DDR1b that is involved. Knocking down Shc1, which binds to Tyrosine513 on DDR1b, eliminates N-cadherin up-regulation. Interestingly, we also found Shc1 directly binds to Pyk2 and that collagen I-DDR1b signaling induces the phosphorylation of Tyrosine402 on the Pyk2 that is associated with Shc1.

P1371**Board Number: B818****Micro-patterned surfaces as a superior tool for the quantitative analysis of protein-protein interactions in living cells.**P. Lanzerstorfer¹, Y. Yoneyama², U. Mueller¹, G. Kreindl³, S. Takahashi², O. Hoeglinger¹, M. Buenemann⁴, G. Schuetz⁵, J. Weghuber¹;¹School of Engineering and Environmental Sciences, University of Applied Sciences Upper Austria, Wels, Austria, ²Department of Animal Sciences, The University of Tokyo, Tokyo, Japan, ³EV Group GmbH, St. Florian/Inn, Austria, ⁴Institut für Pharmakologie und Klinische Pharmazie, Philipps-Universität Marburg, Marburg, Germany, ⁵Vienna University of Technology, Institute of Applied Physics, Vienna, Austria

The plasma-membrane of living cells is a major organelle for cellular signaling cascades. To warrant the diverse functions of a cell, communication between the cytoplasm and the extracellular space is crucial.

Thus, membrane-localized proteins activated by various messenger molecules are essential to transmit signals into the cell. Defective regulation of these signaling cascades may lead to cell death or uncontrolled proliferation. An important issue is the interaction of these membrane proteins with cytosolic proteins. To analyze such interactions we have recently introduced a method based on the combination of micro-structured surfaces and TIRF microscopy. This technique was developed to detect and quantify also weak or short-lived protein-protein interactions in live cells. In a first attempt we used our assay to validate the efficacy of medically relevant receptor tyrosine kinase (RTK) modulators. Bait-EGF/Insulin/IGF1 receptor molecules were forced into microscopic domains on the surface of living cells, while monitoring co-recruitment of fluorescent intracellular prey molecule such as Grb2/IRS1-3, respectively. HeLa cells expressing the prey Grb2 enabled us to quantify the EGFR-Grb2 interaction. Pretreatment with pharmacologically active ingredients used for the treatment of human cancers significantly reduced the inducibility of the signaling system. In addition, we performed fluorescence recovery after photobleaching (FRAP) experiments with RKT class II receptors (IR and IGFR) and different cytosolic insulin receptor substrate (IRS) proteins. Our results indicate prominent differences in the interaction strength of IRS1 and IRS2 to the IR/IGF1-R, compared to the one of IRS3. In a second attempt we studied the interaction of the G-protein coupled receptor β 2-adrenoceptor (β 2AR) with arrestin-3. By measuring arrestin-3 recruitment and the stability of arrestin-3-receptor complexes in real time using FRAP analysis on micro-patterned surfaces, we could demonstrate that arrestin-3 dissociates quickly, and almost completely from the β 2AR, whereas the interaction with a hyper-phosphorylated β 2AR was significantly prolonged. Finally, we investigated the activation of the EGFR by transactivation via β 2AR. This process of transactivation is highly complex and appears to depend on a number of factors including the cell line, the type and class of the GPCR and the cellular environment. Using the micro-patterning approach we studied the localization and dynamics of key molecules involved in β 2AR-EGFR transactivation. An important issue which we are currently addressing is the production of a micro-structured and functionalized multiwell plate. This development step will set a milestone in terms of throughput rates and increase the number of potential users interested in our methodology.

P1372**Board Number: B819****Reactome Knowledgebase: Exploring biological pathways and networks.**R.A. Haw¹, R. Team¹, H. Hermjakob², P. D'Eustachio³, L. Stein¹;¹Informatics and Bio-computing, OICR, Toronto, ON, ²Proteomics Services, EBI, Hinxton, United Kingdom,³Departments of Biochemistry and Molecular Pharmacology , NYUMC, New York, NY

Modern health initiatives and drug discovery are focused increasingly on targeting diseases that arise from perturbations in complex cellular events. Consequently, there has been a tremendous effort in biological research to elucidate the molecular mechanisms that underpin normal cellular processes. A reaction-network pathway knowledgebase is the tool of choice for assembling and visualizing the “parts list” of proteins and functional RNAs, as a foundation for understanding cellular processes, function and disease. The Reactome Knowledgebase (www.reactome.org) is a publicly accessible, open access bioinformatics resource that stores full descriptions of human biological reactions, pathways and processes. Curated pathway knowledgebases, like Reactome, are uniquely powerful and flexible tools for extracting biologically and clinically useful information from the flood of genomic data. Specific features of Reactome support the visualization of interactions of many gene products in a complex biological process, and the application of bioinformatics tools to find causal patterns in expression data sets. To maximize Reactome’s coverage of the genome, we have supplemented curated data with a conservative set of predicted functional interactions (FI), roughly doubling our coverage of the translated genome. We have developed a Cytoscape app called “ReactomeFIViz”, which utilizes this FI network to assist biologists to perform pathway and network analysis to search for gene signatures from within gene expression data sets or identify significant genes within a list. Pathway and network-based tools for building and validating interaction networks derived from multiple data sets will give researchers substantial power to screen intrinsically noisy experimental data in order to uncover biologically relevant information.

Signaling from the PM/Cytoplasm to the Nucleus**P1373****Board Number: B820****SH2B1 β Interacts with STAT3 and Enhances Fibroblast Growth Factor 1-Induced Gene Expression during Neuronal Differentiation.**K. Chen¹, L. Chen¹;¹Institute of Molecular Medicine, National Tsing Hua University, Hsinchu, Taiwan

Neurite outgrowth is an essential process during neuronal differentiation as well as neuroregeneration. Thus, understanding the molecular and cellular control of neurite outgrowth will benefit patients with neurological diseases. We have previously shown that overexpression of the signaling adaptor protein

SH2B1 β promotes fibroblast growth factor 1 (FGF1)-induced neurite outgrowth. SH2B1 β also undergoes nucleocytoplasmic shuttling and regulates a subset of neurotrophin-induced genes. Although these findings suggest that SH2B1 β regulates gene expression, the nuclear role of SH2B1 β was not known. In this study, we show that SH2B1 β interacts with the transcription factor, signal transducer, and activator of transcription 3 (STAT3) in neuronal PC12 cells, cortical neurons, and COS7 fibroblasts. By affecting the subcellular distribution of STAT3, SH2B1 β increased serine phosphorylation and the concomitant transcriptional activity of STAT3. As a result, overexpressing SH2B1 β enhanced FGF1-induced expression of STAT3 target genes *Egr1* and *Cdh2*. Chromatin immunoprecipitation assays further reveal that, in response to FGF1, overexpression of SH2B1 β promotes the in vivo occupancy of STAT3-Sp1 heterodimers at the promoter of *Egr1* and *Cdh2*. These findings establish a central role of SH2B1 β in orchestrating signaling events to transcriptional activation through interacting and regulating STAT3-containing complexes during neuronal differentiation.

Decision-making in *C. elegans* chemotaxis to alkaline pH: Competition between two sensory neurons, ASEL and ASH.

T. Murayama¹, T. Sassa¹, I. Maruyama¹;

¹Okinawa Inst Science Technol, Okinawa, Japan

The monitoring of environmental and tissue pH is crucial for the survival of animals. The nematode *C. elegans* is a model organism suitable for the analysis of neural circuits that regulate animal behaviors. The animal is attracted to mildly alkaline pH, and avoids strongly alkaline pH. Our genetic dissection and Ca²⁺ imaging demonstrate that ASEL and ASH are the major sensory neurons responsible for the attraction to mildly alkaline pH and repulsion from strongly alkaline pH, respectively. In ASEL, a transmembrane guanylyl cyclase, GCY-14, is activated by environmental alkalization, and in turn, a cGMP-gated channel serves for Ca²⁺ influx into the sensory neuron (Ref. 1). In ASH, TRPV channels are found to be required for the neural activation upon stimulation with strongly alkaline pH (Ref. 2). To understand the animal's behavioral switch at molecular and cellular levels, we have also analyzed behaviors of mutants defective in ASEL and/or ASH under various alkaline pH, and have found that activities of ASEL and ASH compete each other for the behavioral switch. While mildly alkaline pH preferentially activates ASEL, strongly alkaline pH activates both ASEL and ASH, and ASH activity overrides the activity of ASEL (Ref. 3). Neural circuits responsible for this decision-making will be discussed. References: (1) Murayama et al., *Curr. Biol.* 23, 1007 (2013). (2) Sassa et al., *Neurosci. Lett.* 555, 248 (2013). P1375**Board Number: B822****Interleukin-22 enhances osteoclastogenesis by inducing the production of RANKL in osteoblast.**E. LEE¹, S. KIM², E. KIM², E. CHANG¹;¹Department of Biomedical Sciences, University of Ulsan College of Medicine, Seoul, Korea, ²Department of Biomedical sciences, University of Ulsan College of Medicine, Seoul, Korea

Interleukin-22 (IL-22) is a cytokine that mediates cellular inflammatory response. Although IL-22 was found to be increased in the patients with Rheumatoid arthritis (RA), the role of IL-22 in inflammatory bone disease has yet to be defined. We found that the level of IL-22 was elevated in inflammatory osteolytic condition characterized by trabecular bone destruction and high osteoclastogenesis. TNF α treatment elevated the IL-22 expression of osteoblasts. Exogenous IL-22 did not directly affect differentiation of osteoblast and osteoclast. However, when pOBs and precursor OCs were co-cultured, exogenous IL-22 significantly increased the number of tartrate-resistant acid phosphatase-positive multinucleated cells by increasing mRNA expression and protein secretion of RANK ligand (RANKL) in OBs. We also show that IL-22 significantly induces activation of ERK but not JNK in pOBs. IL-22 slightly induced phosphorylation of AKT on Thr308 as well as phosphorylation of STAT5 on tyrosine residues. Furthermore, IL-22 knockout mice were less susceptible to LPS-induced inflammation than were wild-type mice, as evidenced by their increased bone volume and increased trabecular thickness. The less severe form of bone loss in IL-22 $-/-$ mice might associate with production of RANKL in bone. These findings suggest that IL-22 is one of the pro-inflammatory mediators that contribute to the deteriorating osteolytic condition of inflamed bone.

P1376**Board Number: B823****The TRIP6 LIM domain protein is a positive regulator of the Hippo signaling pathway.**S. Dutta¹, D. McCollum²;¹Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, ²Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA

The LIM domain proteins have diverse functions, including roles in coordinating cytoskeletal organization with signal transduction and gene expression. A screen in our lab identified TRIP6 as binding partner of the Hippo signaling kinase LATS2. The Hippo signaling pathway is a tumor suppressor pathway that regulates organ size and stem cell fate by maintaining a balance between cell proliferation, differentiation, and cell death. The core pathway consists of the MST1/2 and LATS1/2 kinases and a transcriptional co-activator YAP. When the hippo pathway is inactive, YAP accumulates inside the

nucleus and promotes cell proliferation. When hippo pathway is active, LATS phosphorylates and inactivates YAP. Phosphorylated YAP comes out into the cytoplasm where it is either sequestered or degraded. Other LIM domain proteins such as Ajuba and Zyxin have been shown to be inhibitors of Hippo signaling. In contrast, we find that TRIP6 is a novel activator of Hippo signaling. Depletion of TRIP6 promotes YAP activity by causing decreased LATS-dependent YAP phosphorylation, enhanced YAP nuclear localization, and increased expression of YAP target genes. TRIP6 binds to both LATS2 and MST2 and is required for their activation. Several recent studies have shown that the Hippo pathway is regulated in response to mechanical tension through unknown mechanisms. Interestingly, TRIP6 localizes to cell junctions in a tension dependent manner. TRIP6 also co-localizes with LATS2 at cell junctions implicating it as a potential mediator of the effects of mechanical tension on Hippo pathway signaling.

Human neutrophil Fc gamma receptors activate different cell functions.

E. Uribe-Querol¹, N. Mora², C. Rosales³;

¹Fac. de Odontología - UNAM, Mexico City, Mexico, ²Inst. Invest. Biomedicas-UNAM, Mexico City, D.F, Mexico, ³Inst. Invest. Biomedicas-UNAM, Mexico City, Mexico

Neutrophils (PMN) are the most abundant leukocytes in the blood. PMN migrate from the circulation to sites of infection, where they are responsible for antimicrobial functions. PMN use phagocytosis, degranulation, and formation of neutrophil extracellular traps (NETs) to kill microbes. PMN also activate genes to produce and release various cytokines. Many of these cellular functions are induced by antigen-antibody complexes engaging specific Fc receptors. However, it is not clear what functions are initiated by a particular Fc gamma receptor. In order to determine what particular neutrophil Fc receptor is capable of inducing phagocytosis, nuclear factor activation, or NET formation, each of the two human Fc gamma receptors was stimulated by specific monoclonal antibodies and these cell responses were evaluated. Fc gamma RIIA crosslinking induced efficient phagocytosis of antibody-coated particles. But it did not induce activation of ERK and Elk-1 in the PMN nucleus, nor it promoted NET formation. In contrast Fc gamma RIIIB crosslinking did not promote phagocytosis, but induced efficient ERK and Elk-1 activation, and also efficient NET formation. Interestingly Fc gamma RIIIB-induced NETs were formed independently of ERK. These data strongly suggest that different Fc gamma receptors promote independent human neutrophil functions.

P1378**Board Number: B825****Modulation of transcriptionally productive BMP4-Smad5 signaling along the endocytic pathway by MxA, a dynamin-family GTPase induced by interferon.**H. Yuan¹, P.B. Sehgal²;¹Cell Biology and Anatomy Department, New York Medical College, Valhalla, NY, ²New York Med Coll, Valhalla, NY

Bone morphogenetic proteins (BMPs) are required for cellular differentiation and mammalian development. Dysfunction of BMP signaling due to mutations in BMPR2 is thought to contribute to pathogenesis of diseases such as idiopathic pulmonary arterial hypertension (IPAH). In humans, PAH is a side-effect of interferon- α (IFN- α) therapy. We investigated the regulation of transcriptionally productive BMP4-Smad5 signaling along the endocytic pathway by MxA, an interferon-inducible dynamin-family GTPase. A BMP4-Smad5-responsive reporter (Id1-Luc) was constructed by using two BMP-response elements from the promoter of the human Id1 gene, a direct BMP4-Smad5-responsive gene. In transient transfection experiments in human HEK293T kidney epithelial cells, this reporter showed a low-level basal level of expression which was induced \sim 100 fold by exposure to BMP4 (10 ng/ml) for 15 hr. The involvement of endocytosis in productive BMP4 transcriptional signaling was confirmed by the observation that cotransfection the reporter construct with dominant negative Dyn2K44A or Epsin2a expression constructs inhibited both basal and inducible Id1-Luc reporter activities. In contrast, overexpression of human MxA markedly enhanced the basal expression by \sim 50-fold, but the maximal inducible levels were unaffected. However, overexpression of MxA could dramatically rescue the Dyn2K44A- or Epsin2a-inhibited basal BMP4 signaling suggesting that MxA increased the basal transcriptional BMP4 signaling probably by enhancing the endocytosis process. We then investigated the ability of MxA to rescue BMP4 signaling in cells overexpressing PAH-disease related BMPR2 mutants (F14 and KDF) which have a dominant-negative effect on BMP4 transcriptional signaling. MxA enhanced signaling from the wt- and KDF-BMPR2 species, both of which reach the plasma membrane. However, MxA could not rescue signaling from the F14 mutant which remains trapped in the endoplasmic-reticulum. Finally, while IFN- α itself inhibited BMP4 signaling, overexpression of MxA rescued this signaling. Taken together, this study links the MxA GTPase to modulation of productive transcriptional signaling elicited by BMP4, and provides evidence for the importance of the endocytic pathway in this process.

P1379**Board Number: B826****Syntaxin4 regulates the surface localization of a promyogenic receptor Cdo thereby promotes myogenic differentiation.**B. Kim¹, M. Ryu², H. Jeong¹, G. Bae², J. Kang³;¹School of Medicine, Sungkyunkwan University, Suwon, Korea, ²College of Pharmacy, SOOKMYUNG WOMEN'S UNIVERSITY, Seoul, Korea, ³Sungkyunkwan Univ Sch Med, Suwon, Kyunggi-do, Korea

Syntaxins are a family of membrane proteins that are involved in docking and fusion of vesicles in exocytosis. Syntaxin 4 is expressed highly in skeletal muscle and regulates the cell surface translocation of the glucose transporter GLUT4. Thereby it regulates insulin-mediated glucose uptake in skeletal muscle which is critical for regulation of whole body insulin resistance. However its role in other processes such as myogenic differentiation has not been investigated. Here we report that overexpression or knockdown of Syntaxin 4 enhances or inhibits myogenic differentiation, respectively. Syntaxin 4 binds to the cytoplasmic tail of a promyogenic cell surface protein Cdo and this interaction seems to be critical for its promyogenic function, including activation of p38MAPK activation and myotube formation. Syntaxin 4 depletion results in a specific decrease in the cell surface resident Cdo without altering another promyogenic membrane protein N-cadherin. Taken together, Syntaxin 4 promotes myogenic differentiation by binding to Cdo and regulating its cell surface translocation.

P1380**Board Number: B827****Reactive oxygen species play a critical role in RANKL-induced osteoclast differentiation.**I. Kang¹, C. Kim²;¹Pharmacology, Inha University, Inchen, Korea, ²Inha University, Incheon, Korea

Osteoclasts are formed by cellular fusions of bone-marrow derived mononuclear/macrophage precursors (BMMs) and are responsible for organic bone resorption. Reactive oxygen species play an important role during osteoclast differentiation. Nicotinamide adenine dinucleotide phosphate (NADPH) oxidase transfers an electron from NADPH to molecular oxygen (O₂) to produce superoxide anion (O₂⁻), and its deficiency results in decreased superoxide production in myeloid cells. In this study, we investigated the role of superoxide in osteoclastogenesis, and the target signaling molecules. Treatment of BMMs with antioxidants, such as, superoxide dismutase, *N*-acetylcysteine and diphenylene iodonium significantly inhibited osteoclast formation. This result suggests that NADPH oxidase-derived superoxide may play a critical role in osteoclastogenesis. The membrane subunit of NADPH oxidase, gp91phox deficient mice have defect in superoxide production. The bone volume of gp91phox-null mice was increased compare to wild-type. The osteoclast formation of gp91phox-null mice was decreased to 60% of that of wild-type mice. Moreover, the expression of osteoclast-specific markers, such as, tartrate-

resistant acid phosphatase (TRAP) and cathepsin K were decreased in gp91phox-null osteoclasts, and TRAP activity was also decreased. Nuclear factor of activated T cell 1 (NFATc1) is a master switch for regulating terminal differentiation of osteoclast. Receptor activator of nuclear factor- κ B ligand (RANKL) increased NFATc1 expression, which was decreased in gp91phox-null osteoclasts. In addition, to examine whether oxygen radical can restore the defect in gp91phox-null osteoclasts, we treated gp91phox-null BMMs with H₂O₂, and 0.1 μ M H₂O₂ increased osteoclast numbers to wild-type level. These results suggest that NADPH oxidase-derived superoxide regulates osteoclast differentiation through NFATc1.

Dystrophin is involved to translocation of nuclear factor erythroid 2-related factor 2 under menadione-induced oxidative stress.

S. Choi¹, A. Moon¹, H. Kim¹;

¹Biological science, Ajou University, Suwon, Korea

Duchenne muscular dystrophy (DMD) is an X-linked muscular disorder caused by mutations in the dystrophin gene. Although it has been well-known that DMD muscle is more vulnerable to oxidative stress than normal muscle, not much is known about the responsible signal transduction mechanisms. Nuclear factor erythroid 2-related factor 2 (Nrf2) is a transcription factor and regulates the expression of antioxidant enzyme such as Bcl-2, NAD(P)H:quinone oxidoreductase 1 (NQO1) and glutathione S-transferase (GST). In addition, oxidative stress is known to induce translocation of Nrf2 from cytoplasm to nucleus. To study on the responsible signaling pathway, dystrophin knock-downed (dmd) C2 cell line was established by infecting lentivirus particles with dystrophin shRNA. We found that the rearrangement of actin cytoskeleton was impaired when dmd cells were exposed to menadione-induced oxidative stress. To address involvement of Nrf2 under oxidative stress, we examined the expression and translocation of Nrf2 during differentiation of dmd cells. We found that undifferentiated myoblast cells showed no divergence of Nrf2 expression, whereas differentiated myotubes showed that translocation of Nrf2 to nucleus was decreased in dmd cells compared to normal cells under menadione-induced oxidative stress. Moreover, the ChIP assay/PCR analysis showed that the binding of Nrf2 to Bcl-2 antioxidant response element (ARE) was debilitated, as well the transcriptional level of Bcl2 was decreased. These results suggest that the dystrophin is closely linked to translocation and accumulation of Nrf2 to nucleus under oxidative stress.

P1382**Board Number: B829****Retinoic Acid Induces Neuroblastoma Differentiation by Activation of CRABP II.**N. McAndrew¹, G. Gomez²;¹Biology, University of Scranton, Scranton, PA, ²Biology, University of Scranton, Scranton, PA

Retinoic acid (RA) plays a role in cancer cell growth, and is a known chemotherapeutic agent. New evidence has shown the presence of two different proteins in the cell that can directly transport RA to the nucleus: CRABP II shuttles RA to its one nuclear receptor RAR α , triggering differentiation into neuronal phenotypes. In contrast, FABP5 shuttles RA to its other nuclear receptor, PPAR β , and promotes cell proliferation. Studies suggest that the ratio of FABP5 to CRABP II determines which pathway (RAR α or PPAR β) is activated. This ratio is determined either by endogenous expression of these two proteins, or by a RA concentration-dependent activation of the different receptor pathways. To test the latter possibility, SK-N-SH neuroblastoma cells were grown in culture and treated with different concentrations of RA over a four-day time period. RA concentrations varied in increments from 0.01 μ M to 100 μ M by log steps. Cells were subsequently immunostained for RAR α , CRABP II, or FABP5, and relative abundance of each protein was quantified from fluorescence images. Cell growth and differentiation were assessed by cell counts with Trypan Blue stain and quantification of staining density in the nucleus, and then used to determine which receptor, either RAR α or PPAR β , was likely activated. At higher retinoic acid concentrations (1.0-10 μ M), cell differentiation increased. Qualitative immunochemistry showed an increase in RAR α and CRABP II localization in the nucleus, and localization of FABP5 near the cell membrane. At lower concentrations of RA (0.01 μ M -0.1 μ M) FABP5 localized to the nucleus, while CRABP II was localized near the cell membrane. Thus, it appears that the differentiation pathway is determined by RA concentration. These results provide useful insights into neuroblastoma cell differentiation and the potential use for RA as a chemotherapeutic agent.

P1383**Board Number: B830****Effects of a pyrrole-based microtubule poison on RAW264.7 macrophage activity.**J. Ciemniecki¹, C. Lewis¹, J. Gupton², K. Stenger¹;¹Biology, University of Richmond, Richmond, VA, ²Chemistry, University of Richmond, Richmond, VA

The inflammatory response is initiated when macrophages detect a pathogen in the tissues leading to the activation of intracellular signaling pathways. One of these pathways triggers the phosphorylation and subsequent degradation of the I κ B inhibitory protein that is bound to the NF- κ B transcription factor. NF- κ B is then released from its inactive state and translocates into the nucleus, binding to the promoter region of pro-inflammatory genes. This increases the synthesis of several cytokines including tumor necrosis factor- α (TNF- α), as well as the synthesis of enzymes that catalyze the production of reactive molecules. These molecules are integral to destroying the pathogen and recruiting other immune cells to the site of infection. The poly-substituted pyrrole 3,5-dibromo-4-(3,4-dimethoxyphenyl)-1H-pyrrole-2-

carboxylic acid ethyl ester (JG-03-14) is a known microtubule poison and potential anti-tumor agent [i], [ii], [iii]. RAW264.7 macrophages were subjected to treatment with JG-03-14 in order to study its effects on the inflammatory response. After activation with lipopolysaccharide, macrophages exposed to JG-03-14 produced lower levels of intracellular TNF- α and demonstrated a decrease in TNF- α secretion when compared to untreated cells. These cells also showed reduced production of the enzyme inducible nitric oxide synthase resulting in a decrease in the reactive inflammatory molecule, nitric oxide. Further studies indicated that exposure to JG-03-14 decreased the translocation of NF- κ B into the nucleus, which could explain the diminished production of the inflammatory molecules. We conclude that JG-03-14 may act as an anti-inflammatory agent by reducing the production of pro-inflammatory molecules and by altering the secretory pathway of cytokines.

Estrogen and bisphenols A S regulate lysosomal proteolysis: implications for Lupus.

R. Powers¹, T. Pham¹, D. Cuva¹, S. Ha¹, E. Lee¹, J. Mbaluka^{1,2}, R.A. Roberts¹;

¹Biology, Ursinus College, Collegeville, PA, ²Ursinus College, Collegeville, PA

Cathepsins are proteases involved in general protein turnover and play important roles in immune function. Specifically, lysosomal cathepsins are responsible for major histocompatibility class II antigen processing. Systemic Lupus Erythematosus (SLE) is an autoimmune disease that is more prevalent in women than in men. The correlation between high estrogen levels and increased severity of the disease implicates this hormone as a regulator of immune function, potentially through binding to the estrogen receptor. Environmental endocrine disruptors such as Bisphenol A (BPA), which are found in many plastic products including food containers, may also be immune regulators. BPA can be absorbed by the foods and liquids that are held in the plastic containers and then can enter the human body. Because of its structural similarity to estrogen, BPA is able to bind to estrogen receptors, which could potentially lead to adverse effects on the body and autoimmune diseases such as SLE. BPA has gained negative

media attention and its removal from products aimed at children was supported by the U.S. FDA in 2013, resulting in its recent replacement in some products by Bisphenol S (BPS). Previous studies in our lab have shown that estrogen and BPA can regulate cathepsin activity in immune cells (B cells and macrophages) and that the regulation varies between control C57Bl/6 mice and lupus-prone NZB/WF1 mice. We now show that cathepsins in non-immune cells are also differentially regulated by physiological and environmental estrogens. To investigate these effects, liver and kidney cells were gathered from lupus-prone NZB/WF1 mice and control C57Bl/6 mice. The cells were treated with either 5 or 50 nM estrogen, BPA, or BPS. The effects of these treatments on cathepsin L activity in liver and kidney cells were analyzed using a fluorescence activity assay. Additionally, to investigate how estrogen may be regulating cathepsins, we examined cathepsin activity in samples pretreated with Fulvestrant, an estrogen receptor antagonist. Our findings show that cathepsin L is being regulated through an estrogen receptor pathway by estrogen and BPA in the liver. Experiments also suggest BPS regulates cathepsin L in the liver. Preliminarily, our results also indicate that estrogen is being regulated through the estrogen receptor pathway in the kidney. We have observed statistically significant differences in cathepsin L activity in liver between mouse strain, type of treatment (estrogen and BPA), and dose of treatment. This suggests that the normal and lupus-prone mice react differently to both physiological and environmental estrogens and that the response is dose-dependent.

Identification and characterization of a new component of the JAK/STAT signaling pathway that regulates cell migration.

A. Saadin¹, M. Starz-Gaiano²;

¹Biological Sciences, University of Maryland Baltimore County, Baltimore, MD, ²Univ Maryland-Baltimore Co., Baltimore, MD

The Janus Kinase and Signal Transducer and Activator of Transcription (JAK/STAT) signaling pathway is involved in essential biological processes including cell fate determination, cell migration, cell proliferation, normal function of immune system, and stem cell maintenance in mammals and fruit fly. We are particularly interested in cell migration since it is not only required for normal embryonic development but can also lead to detrimental outcomes, such as tumor metastasis. Migration of a cluster of cells termed border cells in the *Drosophila* ovary is an excellent example of collective cell migration, which resembles metastasis of some carcinoma cells. Availability of several tools for genetic manipulation and *in vivo* imaging in *Drosophila* make it a suitable model organism to study cell migration. Border cells arise within the follicular epithelium, and are required to migrate to the oocyte to contribute to a fertilizable egg. The requirement for some components of the STAT signaling pathway, including the activating cytokine, its receptor, JAK, STAT and APONTIC, during border cell migration is well-studied, however, the functions of other potential regulators of the pathway during this process are not yet known. To find new components of the pathway that govern cell migration, we knocked down predicted STAT modulators using RNAi expression in follicle cells, and assayed for

defective cell movement. We have shown that BRAHMA (BRM), the *Drosophila* counterpart of yeast SWI/SNF, functions during cell invasion. Target specificity of the RNAi-mediated reduction was verified via rescue experiments by overexpressing the gene in its depleted background. Genetic interaction of *brm* with *stat* is currently being studied through suppression/enhancement assays using different alleles of each gene. To investigate the regulatory effect of BRM on STAT activity further, STAT immunofluorescence intensity in the *brm* mutant egg chambers are being compared to that in wild-type egg chambers. This work could suggest a novel role for BRM in STAT mediated gene expression.

Maintenance of EGFR plasma membrane levels involves transcriptional control of early secretory pathway machinery.

S. Scharaw¹, M. Iskar², G. Boncompain³, F. Perez³, P. Bork², R. Pepperkok¹;

¹Cell Biology and Biophysics, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany,

²Structural and Computational Biology, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany, ³CNRS UMR144, Institut Curie, Paris, France

COPII is the molecular coat machinery that drives vesicle budding from the endoplasmic reticulum. Different COPII coat protein paralogs co-exist in cells, raising the possibility that they form distinct COPII vesicles to transport specific cargo proteins. Interestingly, the activity of the early secretory pathway machinery including COPII is proposed to be regulated by external stimuli such as epidermal growth factor (EGF) [1,2]. Upon EGF stimulation, the EGF-receptor (EGFR) is internalized and degraded by the endo-lysosomal pathway raising the question of how correct plasma membrane levels of EGFR are restored in this situation. Here we show, by applying the Retention Using Selective Hooks (RUSH) system [3], that EGF stimulation specifically increases the transport efficiency of newly-synthesized EGFR from the endoplasmic reticulum to the plasma membrane. This increased transport efficiency is accompanied by transcriptional up-regulation of the inner COPII coat paralogs SEC23B, SEC24B and SEC24D but not of others. These paralogs are required for EGFR transport, as their siRNA-mediated knock-down inhibits EGFR delivery to the plasma membrane. We further show that up-regulation of SEC23B, SEC24B and SEC24D requires the ring finger protein RNF11, which translocates from the cytoplasm to the nucleus upon EGF stimulation. Altogether, our data demonstrate that specific COPII inner coat proteins are transcriptionally up-regulated in response to EGF stimulation. This facilitates the transport of newly-synthesized EGFR from the endoplasmic reticulum to maintain the correct physiological EGFR levels at the plasma membrane after its EGF-induced degradation.

P1387**Board Number: B834****Inside the destruction complex: APC's mechanistic role in downregulation of Wnt signaling.**M. Pronobis^{1,2}, N.M. Rusan³, M. Peifer⁴;¹GMB, UNC, Chapel Hill, NC, ²HHMI, Chevy Chase, MD, ³Cell Biology and Physiology Center, NHLBI, NIH, Bethesda, MD, ⁴Department of Biology, University North Carolina, Chapel Hill, NC

Adenomatous polyposis coli (APC), a key negative regulator of Wnt signaling, is mutated in 80% of sporadic colon cancer cases. APC acts in the destruction complex (DC) with the scaffold protein Axin and the kinases GSK3 and CK1 to target β catenin (β cat) to an E3-Ligase for ubiquitination and subsequent proteasomal degradation. Over 20 years of research on the Wnt pathway identified roles for Axin and both kinases. However, APC's function in the destruction complex remains mysterious. Current models generally view the DC as a static protein complex into which β cat is recruited, phosphorylated and then handed over to the E3-Ligase. Axin is thought to have a very slow assembly/disassembly rate in the DC, and increased Axin dynamics has been shown to interfere with β cat destruction, suggesting that formation of a stable complex is key for Wnt signal downregulation. In previous work from our lab, we identified two regions in APC, 20R2 and region B, which appear to negatively regulate association with Axin and are essential for APC's function in the DC. This prompted us to explore the dynamics of APC and Axin in the DC. Our data suggest that the turnover of Axin inside the DC is regulated by binding to APC. We found that APC binds to Axin via two association sites, the well characterized SAMP motifs and a novel Axin-association site that we identified in APC's Arm rpts domain. Both regions are crucial to reduce Axin's dynamics in the DC to form a stable platform for β cat destruction. To investigate this further we used OMX super resolution microscopy and found that changes in the dynamics of Axin caused by APC are associated with changes in the overall structure of the DC. Complexes formed by Axin alone consist of circular Axin cables/sheets in which Axin has a highly dynamic turnover rate. Interestingly, the internal structure of the DC increases in complexity and size in the presence of APC; more Axin cables associate with one another. We propose that APC stabilizes the Axin complex by slowing down Axin's dynamics inside the DC, leading to growth of the Axin scaffold/cables which then increases the overall size of the APC-Axin complex. Besides APC's role in the stabilization of the Axin complex our study also proposes a model of APC's mechanistic function inside the DC. Our data suggest that APC's function in the DC depends on two essential regions, 20R2 and region B. These two adjacent motifs undergo phosphorylation by GSK3 and CK1 and this in turn leads to the disassociation of the novel Axin association site, the Arm rpts, from Axin. Our data suggests that this is a key step in APC's catalytic cycle, facilitating destruction of β cat.

Mechanical compression of well-differentiated primary airway epithelial cells causes cellular unjamming and the release of exosomes containing adherens junction proteins.

J. Park¹, N.T. Qazvini¹, J. Mitchel¹, J. Kim¹, C. Park¹, J.P. Butler^{1,2}, E. Israel², S.H. Randell³, S.A. Shore¹, J.M. Drazen^{1,2,4}, J.J. Fredberg¹;

¹Harvard School of Public Health, Boston, MA, ²Brigham and Women's Hospital, Boston, MA, ³University of North Carolina, Chapel Hill, NC, ⁴The New England Journal of Medicine, Boston, MA

Injury of the airway epithelium impairs barrier function and is thought to contribute to asthma pathogenesis. A hallmark of epithelial responses to an injury is initiation of collective cellular migration, but the mechanisms linking injury to migration in airway epithelium has not yet been studied. We have previously shown that mechanical compressive stress (30 cm H₂O) that mimics bronchospasm triggers signals that mediate airway remodeling in asthma. Here, we show that compressive stress also causes stunning changes in collective cellular migration and we propose novel mechanisms that might account for these changes.

Primary human bronchial epithelial cells (HBECs) from normal and asthmatic subjects were grown in air-liquid interface (ALI) culture to differentiate into goblet and ciliated cells. To quantify cellular motion using particle image velocimetry (PIV), we captured time-lapse images of these cells. As metrics of cellular motion we computed cellular mean square displacements (MSD) and we also quantified the lifetime and the size of cooperative cellular clusters or eddies.

Within the first few days of initiating ALI culture (e.g., ALI day3), primary HBECs, whether from non-asthmatic or asthmatic donors, were highly motile and unjammed as indicated by peaks of faster-moving clusters of 10~26 cells. During ALI cultures, the layer of cells became jammed by day 6 in normal cells, while jammed status was not reached until day 14 in asthmatic cells. These results indicate that during differentiation in ALI cultures, the layer of primary HBECs undergoes a phase transition from an unjammed to a jammed state. Compared with cells from normal donors, the transition is delayed in cells from asthmatic donors.

Surprisingly, in well-differentiated and jammed normal cells, mechanical compressive stress drives the jammed phase back to the unjammed phase, as indicated by an over 1000-fold increased in MSD. In uncompressed cells the eddy lifetime could not be quantified within time windows less than 144 minutes, but with mechanical compression eddy lifetime fell to 42 minutes and eddy size was roughly 71 cells. These observations demonstrate a dramatic transition of the well-differentiated epithelial layer from a jammed to an unjammed state. Along with the phase transition, compressive stress induced release of exosomes containing adherens junction proteins, including folliculin. We detected more folliculin in BAL of mice sensitized and challenged with ovalbumin, compared to control mice.

Taken together, our data establish that mechanical compressive stress as expected during bronchospasm cause the monolayer of normal HBECs to transition from a jammed to an unjammed state that is possibly mediated by release of exosomes containing adherens junction prot

Hemodynamic Flow Promotes Mitochondrial Homeostasis in Endothelial Cells.

L.D. Wang¹;

¹Inst. of Medical Sciences, School of Medicine, Tzu-Chi University, Hualien, Taiwan

The hemodynamic shear flow-induced adaptive responses in vascular endothelial cells have been intensively studied. However, the effects of shear flow on mitochondrial homeostasis in endothelial cells are not clear. We examined the dynamic changes of mitochondrial phenotype and its regulatory proteins associated with mitochondrial functions in endothelial cells under physiological shear stress. Cultured human umbilical vein endothelial cells (HUVECs) were subjected to a constant shear stress (12 dynes/cm²) with a parallel-plate flow chamber system. Mitochondrial biogenesis, dynamics and function were analyzed from ECs after shear treatment. Sheared ECs increased mitochondrial biogenesis as well as a time-dependent increment of mitochondrial fusion revealed by an increase of elongated tubular formation. This phenomenon was coupled with an increased expression of fusion proteins (MFN2, OPA1) but decreased fission protein (FIS1). Consistently, an increase of phosphorylation at S637 but decreased at S616 on Drp1 indicates that shear flow promotes mitochondrial fusion process. Moreover, shear flow increased the expression of mitophagy proteins (PINK1, PARKIN) suggesting that a quality control of mitochondria was enhanced under flow. Shear flow increased the expression of mitochondrial antioxidant enzymes MnSOD2, TRX2, PRX3 and PRX5. As a consequence, an increased mitochondrial membrane potential, ATP production and a decreased intracellular reactive oxygen species (ROS) levels were observed in shear-treated ECs. Our results suggest that hemodynamic flow promotes endothelial function by enhancing mitochondrial homeostasis. Thus, hemodynamic shear flow plays an important role in promoting mitochondrial function in ECs, further substantiates the protective role of shear flow to ECs.

Mechanical compression, Physical Forces and Fluidization in Asthmatic Airway Epithelial Cells.

J. Kim¹, M. McGill², N.T. Qazvini¹, J. Park¹, R.L. Steward¹, S. Burger², D. Khabibullin³, D. Medvetz³, J. Notbohm¹, S.H. Randell⁴, J.P. Butler^{1,3}, E.P. Henske³, J.M. Drazen^{1,3,5}, J.J. Fredberg¹;

¹Harvard School of Public Health, Boston, MA, ²Northeastern University, Boston, MA, ³Brigham and Women's Hospital, Boston, MA, ⁴University of North Carolina, Chapel Hill, NC, ⁵The New England Journal of Medicine, Boston, MA

In asthma, mechanical compression applied to airway epithelium during bronchoconstriction is thought to trigger a sequence of events that lead to airway remodeling. Initiation and progression of airway remodeling involves epithelial injury-repair processes that require coordinated cellular motions, but the mechanism behind such motions remains obscure. We recently showed that mechanical compression applied to human bronchial epithelial cells causes fluidization of the epithelial layer from a solid-like to a fluid-like phase with associated increase of cell motility and hyper-secretion of the intercellular junction protein folliculin (FLCN) (Park et al. 2014 AJRCCM meeting abstracts). Here we report that this striking phase transition is accompanied by intensified physical forces and altered mechanical cell-cell interaction. To measure local tractions exerted by each cell upon its substrate, and local intercellular forces exerted by each cell upon its immediate neighbors across cell-cell junctions, we used Monolayer Stress microscopy. We discovered that mechanical compression imposed on the epithelial layer causes tractions to increase by 1.2-fold, and intercellular forces to increase by 1.5-fold. Surprisingly, compared to unperturbed normal HBECs, those from the asthmatic airway exhibited 1.3 to 11-fold higher cellular tractions, 1.5 to 5-fold higher intercellular forces, but faster spatial decay of intercellular forces. This demonstrates stronger forces with weaker but more fluid-like cooperativity. To better understand a link between the fluidization and the secretion of FLCN from airway epithelium, we transfected HBECs with short hairpin (sh) RNA targeting FLCN. Remarkably, FLCN deficiency caused tractions to increase by 3-fold, intercellular forces to increase by 2-fold, and collective cell guidance by cooperative mechanical cell-cell interactions to become ablated. Moreover, FLCN deficiency replicated the high mobility observed in compressed HBECs. Finally, the spatial decay of intercellular forces was faster in FLCN shRNA cells, again suggesting a fluidized state with intensified physical forces. Together, these results suggest that mechanical compression mimicking that occurring during bronchoconstriction causes a phase transition of the epithelial layer from a solid-like jammed state to an unjammed fluid-like state, which may be mediated by altered mechanical cell-cell interaction and intensified physical forces.

Modulating primary cilia length restores osteocyte mechanosensing.

M. Spasic¹, C.R. Jacobs¹;

¹Biomedical Engineering, Columbia University, New York, NY

Osteocytes are regarded as mechanosensing cells within bone, potentially using primary cilia as mechanotransducers; yet targeting the primary cilium to modulate osteocyte mechanotransduction is relatively unexplored. Primary cilia are single immotile organelles protruding from the surface of most mammalian cells, and when osteocyte primary cilia are impaired, the cells lose their osteogenic response to fluid flow. A previous study showed that when endothelial primary cilia are elongated, the cells have a greater response to mechanical stimuli. Thus, we hypothesized that increasing osteocyte primary cilia length enhances flow-induced osteogenic gene expression. To increase cilia lengths, MLO-Y4 osteocyte-like cells were treated for 16 hours with 10 μ M fenoldopam (Fen), 500 μ M lithium chloride (LiCl), or vehicle control. Cilia were fluorescently labeled with an antibody against acetylated- α

tubulin, imaged on a confocal microscope, and analyzed with ImageJ. Fen treatment increased cilia lengths by $25.4 \pm 9.1\%$ and LiCl increased cilia lengths by $46.0 \pm 8.9\%$ compared to vehicle control. To examine the response of these cells to mechanical stimulation, cells were seeded onto glass slides, treated with Fen, LiCl, or vehicle control, and exposed to 1 hr oscillatory fluid flow at 1Hz and 1Pa wall shear stress. RNA was isolated immediately after flow and RT-qPCR was used to measure gene expression of osteogenic markers cyclooxygenase-2 (COX-2) and osteopontin (OPN) relative to GAPDH endogenous control. Both Fen and LiCl treatment induced over 50% increases in COX-2 and over 25% increases in OPN expression in response to mechanical stimulation, suggesting that cells with longer cilia are more mechanosensitive. To discern the role of Fen on cilia formation from other potential cellular mechanisms, cilia formation was impaired by siRNA knockdown of IFT88, a gene necessary for proper cilia formation, resulting in a decrease in cilia length and incidence compared to scramble control; and still, Fen treatment was able to restore cilia length and incidence. When exposed to fluid flow, cells with stunted cilia displayed decreased OPN expression compared to scramble control— 7.65 ± 0.58 versus 13.45 ± 0.52 —while Fen rescued this impaired response— 11.59 ± 0.09 . Together, these data suggest that cilia length plays a critical role in cellular mechanotransduction. Furthermore, we have demonstrated that osteocytes with longer cilia are more mechanosensitive, and that this response can be easily modulated by a variety of small molecules. Therefore, increasing cilia length to enhance cellular signaling is a prospective therapeutic strategy that has the potential to rescue malfunctioning cells from ciliopathies that impair primary cilia function.

The vinculin network regulates cytoskeletal remodeling and contractile function in aging myocardium.

G. Kaushik¹, A. Spenlehauer², A.O. Sessions³, A. Trujillo⁴, A. Fuhrmann¹, Z. Fu⁵, V. Venkatraman⁵, D. Pohl⁶, J. Tuler², M. Wang⁷, E. Lakatta⁷, K. Ocorr⁸, R. Bodmer⁸, S. Bernstein⁴, J. Van Eyk⁵, A. Cammarato⁹, A.J. Engler¹;

¹Bioengineering, University of California, San Diego, La Jolla, CA, ²Bioengineering, University of California, San Diego, San Diego, CA, ³Biomedical Sciences, University of California, San Diego, La Jolla, CA, ⁴San Diego State University, San Diego, CA, ⁵Cardiology, Johns Hopkins University School of Medicine, Baltimore, MD, ⁶Iowa State University, Ames, IA, ⁷National Institute on Aging, Bethesda, MD, ⁸Sanford-Burnham Medical Research Institute, La Jolla, CA, ⁹Medicine, Johns Hopkins University, Baltimore, MD

Advanced age is accompanied by significant molecular and cellular remodeling events in the heart which for the past several decades have been thought to contribute to dysfunction. Remodeling of actin-associated proteins, such as those in vinculin/catenin family, has been previously observed in age-related heart failure patients. However, causative mechanisms and functional consequences of remodeling in aged myocardium are still not fully appreciated. Therefore, we examined age-related cytoskeletal remodeling by: 1) assessing conservation of cytoskeletal changes in simian and rat aging

models and 2) examining the functional impact of cytoskeletal remodeling in the rapidly aging and genetically tractable *Drosophila* heart model. High-throughput proteomic quantification of adult and aged simian (11 vs. 22 years) and rat (6 vs. 24 months) left ventricles found significant age-related remodeling of the vinculin network, which was confirmed via histology and western blotting. A screen of wildtype *Drosophila* revealed genotype-dependent vinculin overexpression with age. Cytoskeletal remodeling correlated with cortical stiffening but preserved, not impaired, contractility. We hypothesized that conservation of age-related cytoskeletal remodeling and negative correlation with dysfunction in aging *Drosophila* suggested that vinculin overexpression was a compensatory or beneficial aging response. Therefore, we performed cardiac-specific perturbations of vinculin expression in healthy and myosin-deficient hearts. Vinculin overexpression resulted in cytoskeletal reinforcement, as indicated by increased cortical stiffness, and enhanced fractional shortening and contractile velocities, an index of relative force production, in all adult tissues. Overexpression of vinculin in a myosin-deficient heart was able to rescue cytoskeletal integrity and cellular contractility and partially rescued fractional shortening. To probe a potential mechanism by which the vinculin network could regulate contractility, we performed transmission electron microscopy on sarcomere cross-sections and observed increased myofilament order, as indicated by reduced interfilament spacing variance, in vinculin-overexpressing hearts. Thus, we propose that the vinculin network reinforces the cortical cytoskeleton, resulting in cortical compression, enhanced myofilament organization, and increased contractile efficiency. In sum, these data suggest that cardiac cytoskeleton is a potent regulator of cardiac performance and that cytoskeletal remodeling is a highly-conserved aging event, existing from arthropods to simians, which serves as a compensatory mechanism to maintain mechanical function.

Reading the force map to find centrosome coordinates.

E. Vitiello¹, K. Mandal¹, I. Wang¹, M. Balland²;

¹UJF/UMR 5588, Laboratoire Interdisciplinaire de Physique, Grenoble, France, ²Materials, Optics and Instrumental Techniques for the Life Sciences (MOTIV), Laboratory of Interdisciplinary Physics (LiPhy), Grenoble, France

In 2003 an interesting observation was reported by Burakov and colleagues (Burakov et al, 2003): in vivo, cells maintain actively the centrosome at the cell centre. In a chaotic and constantly changing environment as the cytosol, it is hard to imagine how a specific structure can find its right position and, moreover, how it will keep it. As a wayfarer with a compass, scientists speculate that the centrosome is guided to the right position by microtubules (MTs) (Koonce et al, 1999). Despite scientists agree on the key role of MTs in the coordination of centrosome positioning, nevertheless, it has not been elucidated if MTs respond to a particular signal within and/or outside the cell.

It is increasingly recognised that forces play an important role in the coordination of basilar processes such as polarity establishment, migration, proliferation and differentiation. Forces can derive from the microenvironment and act onto cells, or exerted by the cells themselves onto the surroundings. Forces

are sensed and/or transmitted by dedicated structures named focal adhesions, which represent the anchorage point of actin cables within the cell, and the attachment sites to the extracellular matrix. Changes perceived by focal adhesions trigger signal cascades and lead to actin fibre rearrangements. Here, we speculate that intracellular and extracellular forces resulting in actin remodelling can act as molecular map that will dictate the centrosome coordinates, via MT organisation.

In our set up we prepare polyacrylamide hydrogels that we micropatterned with specific geometries. Definition of a precise geometry let us manipulate cellular force axes. Because the hydrogels are embedded fluorescent nanobeads, we can then calculate cellular forces by measuring beads displacement (experiments of traction force microscopy-TFM). We obtain therefore a complete map of forces within the cell. From the analysis of cellular force map, we noticed the preferential directions of force vectors pointed towards specific coordinates. Furthermore the same position emerged from the analysis of the adhesive site map for the same cells. Curiously, when we stained for the centrosome, we always were able to detect the centriol structures at these coordinates. In conclusion, we propose a new model whereby cellular forces can be interpreted as a map to direct centrosome positioning.

Simultaneous mapping of intra- and extracellular forces at the focal adhesion sites.

B.R. Sarangi¹, M. Gupta², R. Mege¹, N. Tissot¹, N. Borghi¹, B. Ladoux^{1,2};

¹Institut Jacques Monod, Université Paris Diderot CNRS, Paris, France, ²Mechanobiology Institute, National University of Singapore, Singapore, Singapore

Focal adhesions (FAs) work as mediators of cell-substrate interaction. One of the important read-outs of such an interaction is the traction forces generated at the FAs. The transmission of these forces to the intracellular acto-myosin network is largely facilitated by a complex protein architecture at the FAs. However, how these proteins respond individually to the traction stress is a matter of great interest. Vinculin is a key protein in the regulation and stabilization of FAs. At FA sites, vinculin binds to both actin and talin¹. Hence the tension across vinculin bears the signature of the traction forces at the FAs. We used Förster resonance energy transfer (FRET) based vinculin tension sensor². Briefly, an intramolecular FRET sensor separated by a stretchable peptide linker is incorporated between the vinculin head and tail domains. Therefore the FRET efficiency of the sensor is an effective signature of the tension across vinculin. To measure the traction forces we plated fibroblastic cells on polydimethylsiloxane (PDMS) micropillars³. Such substrates are then used as micro force sensing arrays (μ FSA) wherein deflection of individual micropillar is a read-out for traction forces generated at the corresponding FAs. By combining FRET microscopy with μ FSA techniques, we demonstrate that a simultaneous measurement for both the vinculin tension and the traction forces can be performed at individual FAs. Our results indicate that tension across vinculin exhibit an instantaneous response to traction forces at the corresponding FAs. Furthermore, we used laser ablation technique to control the tension exerted at FA sites. By ablating the stress fibers linked to the FAs we observed an instantaneous decrease of the traction force. The

signature of this perturbation is also seen for vinculin with corresponding increase in the FRET efficiency indicating a strong relaxation of the tension across the molecule. Altogether these data show that the tension across vinculin maps synchronously to the changes in the traction force at the FAs.

Mechanotransduction via the nuclear lamina.

D.E. Discher^{1,2};

¹Molecular and Cell Biophysics Lab, University of Pennsylvania, Philadelphia, PA, ²Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA

How cells respond to physical cues in order to meet and withstand the physical demands of their immediate surroundings has been of great interest for many years, with current efforts focused on mechanisms that transduce signals into diverse phenotypes. Pathways that mechano-regulate the entry of transcription factors into the cell nucleus are emerging, and our most recent studies show that mechanical properties of the nucleus itself are actively controlled in response to the elasticity of the extracellular matrix (ECM) in both mature and developing tissue [1]. The mechano-responsive properties of nuclei are largely determined by the stoichiometry of intermediate filament lamin proteins that line the inside of the nuclear envelope and that also impact upon transcription factor entry and broader epigenetic mechanisms. Signaling pathways are emerging for regulation of lamin levels and cell-fate decisions in response to a combination of ECM mechanics and other molecular cues [2]. Nuclear mechanics also synergize with niche anchorage and cell motility during development, at least in the contexts of adult hematopoiesis [3] and tumor growth [4].

P1396**Board Number: B844****IN VITRO STUDY OF AGE RELATED HUMAN VASCULAR CELL INTERACTIONS WITH SURFACE MICRO-TOPOGRAPHIES.**H. Chen¹, A. Sales², R. Kemkemer³, A. Greiner¹;¹Zoology, Karlsruhe Institute of Technology, Karlsruhe, Germany, ²New Materials and Biosystems, Max Planck Institute for Intelligent Systems, Stuttgart, Germany, ³Applied Chemistry, Reutlingen University, Reutlingen, Germany

In this work we studied the morphology, migration, and proliferation of primary human endothelial cells (ECs) and smooth muscle cells (SMCs) from donors of different age on differently sized microgrooves made of poly (dimethylsiloxane). We detected cell type-dependent differences in cell morphology but not in cell alignment with respect to the microgroove dimensions. The cell migration of both ECs and SMCs was guided and accelerated by the microgrooves and the proliferation rate of ECs and SMCs was negatively influenced by the microgrooves the deeper the grooves were. While cell morphology and motility on the microgrooves were not influenced by cell age, the proliferation rate of both cell types from old donors was more reduced compared to the cells from young donors. To explain the microgroove-induced reduction of the cell proliferation rate, we investigated the localization of the transcriptional co-activator YAP/TAZ complex. We observed differences in YAP/TAZ localization depending on the dimensions of the microstructure and on the cell age. We elucidated the linkage between environmental physical signals and intracellular responses which influences the cell proliferation. Overall, our work could help to better understand how cell responses to a surface microtopography are dependent on cell type and cell age.

P1397**Board Number: B845****The minimal cadherin-catenin complex forms a catch bond with filamentous actin.**C.D. Buckley¹, J. Tan², B. Pruitt³, B. Weis³, W. Nelson², A.R. Dunn¹;¹Chemical Engineering, Stanford University, Stanford, CA, ²Stanford University, Stanford, CA, ³Stanford Univ Sch Med, Stanford, CA

The linkage between the adherens junction (AJ) and the actin cytoskeleton is important for cell-cell adhesion during tissue development and homeostasis and is often disrupted in diseases such as cancer. Genetic and cell biological studies suggested a model in which the AJ proteins E-cadherin, β -catenin, and the actin binding protein α E-catenin form a minimal cadherin-catenin complex that links cell-cell adhesions to filamentous (F-) actin. Cell culture studies supported this model by showing that E-cadherin is under actomyosin-generated tension that requires α E-catenin, and that E-cadherin-based complexes remodel in response to mechanical stimuli. However, biochemical studies challenged this model by

showing that the minimal cadherin-catenin complex reconstituted from purified components does not bind F-actin stably. Here we reconcile these differences. Using an optical trap-based assay, we find that the minimal cadherin-catenin complex forms stable bonds with F-actin that can survive for several seconds under 5-15 pN of load. Bond dissociation kinetics are explained by a two-state catch bond model in which force shifts the bond from a force-independent, weakly bound state to a force-dependent, strongly bound state. This model may explain how the cadherin-catenin complex binds F-actin and senses mechanical stimuli at cell-cell junctions.

Establishing Mechanical Polarization of the Cell Cortex.

P.W. Oakes¹, M.L. Gardel¹;

¹James Franck Institute, Institute for Biophysical Dynamics and Physics Department, University of Chicago, Chicago, IL

Polarization plays an important role in a diverse array of physiological processes, including adhesion, migration and cell spreading. Polarized cells spatially regulate protrusive activity, focal adhesion assembly, and traction forces to guide cell migration and tissue morphogenesis. This polarization originates within the actomyosin cortex but the physical and molecular mechanisms are largely unknown. Using micropatterning to control cell shape in conjunction with genetic perturbations to alter the actin cytoskeleton, we identified mechanisms of symmetry breaking within the actin cortex of fibroblasts that establish polarization. We first demonstrated that changes in cell shape promoted a redistribution of traction stresses, but did not alter the total contractile work of the cell. We then identified geometric factors that induced polarization in adherent cells and found that polarization was coincident with the formation of peripheral bundles within the lamella. Hypothesizing that peripheral bundle formation played an important role in mechanical polarization, we sought to identify factors regulating their assembly. Reduced expression of activity of these factors impaired peripheral bundle assembly and, consequently, the onset of cytoskeletal polarization. Our work demonstrates an important mechanical role for peripheral bundle assembly in establishing polarization of adherent cells and creating spatial heterogeneity in the cortex. These processes thus act as self-reinforcing mechanisms through which cells work to actively maintain their shape. In all, these works suggest that the actin cytoskeleton organization could serve as a mechanical mechanism to scale molecular interactions into cellular scale phenomena and polarize cellular activity.

P1399**Board Number: B847****Force Scaling in Stress Fibers.**

L. Kurzawa¹, V. Timothee¹, B. Fogelson², F. Senger¹, A. Mogilner³, L. Blanchoin¹, M. Théry⁴;
¹iRTSV, CEA, Grenoble, France, ²Mathematics, UC Davis, Davis, CA, ³Department of Biology, Courant
Institute of Mathematical Sciences, New York, NY, ⁴iRTSV, CEA, Paris, France

Cells have the remarkable ability to sense geometrical and physical cues from their environment and adapt their architecture accordingly. This process requires a tight regulation of the permanent remodeling of the acto-myosin network, that can both transmit and generate intra-cellular forces. Despite numerous works on the molecular composition of stress fibers, little is known about the mechanism determining the magnitude of force production in these structures. In addition, the relationship between actin cytoskeleton dynamics and intra-cellular force production has yet to be investigated. Here we studied the scaling of contractile force magnitude in stress fibers and investigated the role of actin network dynamics and architecture in this process.

We used micropatterned substrates to control the length and spatial organization of stress fibers in adherent cells and measured the traction forces they produced on deformable substrates. Thereby, we demonstrated that forces scaling exhibit a biphasic behavior. Force magnitude first increased with the length of the stress fibers and then dropped above a critical length. Strikingly, very long cells appeared capable to produce only weak forces. This typical force scaling appeared independent of substrate elasticity and conserved in various cell types having distinct intrinsic cell size limitation.

Monitoring stress fiber relaxation upon laser nano-surgery, we showed that stress fibers were connected to the surrounding actin meshwork all along their length. A theoretical model accounting for the biphasic behavior of force scaling established friction between actin stress fibers and their surrounding cytoskeleton as being a key parameter in the regulation of force production by the cells. It contributed to dissipation of myosin work outside of the fiber. Efficiency of force transmission to focal adhesions appeared regulated by myosin motors distribution and dynamics along the stress fiber, dissipation of stress in adjacent meshwork and connection strength between these stress fibers and focal adhesions. All parameters were further validated experimentally using drugs or actin-binding protein down-regulation.

P1400**Board Number: B848****Protein Tyrosine Kinase AXL and ROR2 Participate in Rigidity Sensing Mechanics.**B. Yang¹, F.M. Hameed¹, Z. Lieu¹, A.D. Bershadsky^{1,2}, M.P. Sheetz^{3,4};¹Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ²Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel, ³Mechanobiology Institute, National University of Singapore, Singapore, NY, ⁴Biological Sciences, Columbia University, New York, NY

Matrix rigidity is an physical cue in the microenvironment that can cause changes in cell morphology, migration, and differentiation. But the mechanism of how cell tests the substrate rigidity is not clear. Recently, submicron pillars study showed that early sensing of substrate rigidity by fibroblasts involves local contractions to a fixed distance of 60 nm irrespective of rigidity (Ghassemi et al., 2012). In a siRNA screen of the human tyrosine kinases, several kinases were found to be required for the cell rigidity sensing (Prager-Khoutorsky et al., 2011). In particular, while control human fibroblasts were less polarized and formed smaller focal adhesions on compliant (5 kPa) substrates than on the rigid ones, the fibroblast lacking receptor tyrosine kinases AXL or ROR2 were shown to have a reduced ability to distinguish between soft and stiff substrate. Using the sub-micron pillar arrays we analyzed the local pillar deflections at an early stage of cell spreading. After AXL knockdown cells produced dramatically larger deflections (pulling distances) than control cells, whereas after ROR2 knockdown cells demonstrated a significantly longer duration of deflections (pulling time). These phenotypic alterations can be rescued by expression of GFP-fused mouse AXL or ROR2 constructs, respectively. In addition, a small molecule inhibitor of AXL, R428, produced the same effect as AXL knockdown, strongly increasing the pillar deflections in the acts of pulling, while the AXL ligand, Gas6, produced the opposite effect. Furthermore, during initial spreading, phospho-AXL and ROR2 were found to localize to the pillar-cell interface. Thus, our studies revealed novel and specific mechanisms for receptor tyrosine kinases AXL and ROR2 involvement in the regulation of cell rigidity sensing.

P1401**Board Number: B849****Optogenetic Spatio-Temporal Control of RhoGEF2 Modifies Cell-Mechanical Activity.**K. Hennig¹, A. Kerjouan², O. Destaing², C. Albiges-Rizo², M. Balland¹;¹Materials, Optics and Instrumental Techniques for the Life Sciences (MOTIV), Laboratory of Interdisciplinary Physics (LiPhy), Grenoble, France, ²Differentiation and Cell Transformation, Institute Albert Bonniot (IAB) Inserm U823, Grenoble, France

Exertion of cell-generated traction forces is crucial for living cells to sense physical properties of their microenvironment. Mechanosensors transduce those mechanical cues into biochemical ones, and vice

versa, by involving various signaling proteins. Here we report an optogenetic approach based on light-induced Cry2-CIBN dimerization to probe to internal dynamics of mechanotransduction. The central regulator protein of acto-myosin cytoskeleton dynamics and cell contractility RhoA was activated by controlling the localization of its upstream activator RhoGEF2. The spatio-temporal control of the biochemical cue of genetically modified REF52s cultured on poly-acrylamide hydrogels was enabled by applying a focalized laser (FRAP-module, 488 nm) at low intensity. Coupling the dynamic biochemical perturbation with traction force microscopy (TFM) at the single cell level allowed examining the cellular force response in terms of contractile energy over time. The light induced diffusion of cytoplasmic RhoGEFCry2mCh to cell membrane located CIBNeGFPcax was observed within seconds and in the range of microns, followed by a dissociation within minutes. Furthermore, subsequent cycles of photoactivation could be triggered. Upon light-induced RhoA activation local stress fiber formation was observed. Counterintuitively, a global decrease in cell contractility was measured during photostimulation. A subsequent regeneration of contractile energy demonstrated the active control of internal forces implying the principle of tensional homeostasis. To conclude, the optogenetic Cry-CIBN system allowed the spatio-temporal control of RhoGEF2 modifying the activity of RhoA leading to a global force response within a rapid temporal scale (seconds). Moreover, the mechanical response in terms of actin reinforcement and phenotype change was dependent on the spatial position of photoactivation and occurred within the minute-range. Hence, it was observed that RhoA mediates cell-mechanical processes which happen at distinct spatial and temporal scales.

Elastic silicone gel substrates control stem cell differentiation, increase growth of brain endothelial cell explants, and promote rapid cancer cell spheroid formation.

E. Gutierrez¹, E. Tkachenko², M. Lopez Ramirez², G.K. Vertelov³, L. Stafford⁴, I. Lian⁴, A. Groisman¹;

¹Physics, University of California, San Diego, La Jolla, CA, ²Medicine, Univ California, San Diego, La Jolla, CA, ³Stemmedica, San Diego, CA, ⁴Biology, LAMAR Univ, Beaumont, CA

Substrate rigidity impacts cellular migration, gene expression, development, and tumorigenesis, especially in a range of elastic moduli, E , of 0.1 to 100 kPa. Soft substrates commonly used for cell rigidity sensing studies and cell traction force microscopy (TFM) are hydrogels, such as polyacrylamide gels. Elastic moduli of hydrogels can change due to drying, swelling, aging, and hydrolysis of molecular bonds. In contrast, silicone gels are long-term mechanically stable in cell culture media. Here, we formulated a series of mammalian cell-compatible silicone gels with E from a 0.2 to 100 kPa, effectively covering the rigidity range of animal soft tissues. Primary brain endothelial cells (ECs) directly explanted and cultured on 24 kPa silicone gels showed significantly increased growth and better cell-cell contact formations as compared with ECs cultured on plastic dishes. The differentiation of stem cells cultured on the silicone gel substrates had a strong dependence on the substrate rigidity. We also systemically tested the effect of substrate rigidity on multiple cancer cell lines by culturing them on silicone gel substrates with elastic moduli from 0.2 kPa to 96 kPa. Interestingly, we observed that several cell lines,

notably breast (MDA-453) and ovarian (HeLa) tumor lines, consistently form 3D spherical structures on soft gel substrates (

Stem cells integrate multiple internal and external cues in making lineage-choice decisions. Mechanical cues embedded in the environment powerfully modulate stem cell fate. For instance, matrix stiffness strongly influences whether neural stem cells differentiate along a neuronal or glial lineage. The molecular mechanisms linking matrix mechanics to intracellular signaling pathways of differentiation remain unclear. Here we use a multi-disciplinary approach to uncover a new player in mechanosensitive lineage commitment. We find that human neural stem/progenitor cells (hNSPCs) express the stretch-activated ion channel, Piezo1. Mechanical stimulation of hNSPCs elicited a Piezo1-mediated ionic current. In the absence of external mechanical stimulation, cellular traction forces activated Piezo1, resulting in spontaneous calcium transients, which vary with substrate stiffness. Piezo1 knockdown evoked nuclear exclusion of the transcriptional co-activator Yap, suggesting a downstream effector of channel activity. Pharmacological or genetic inhibition of Piezo1 activity reduced neurogenesis and enhanced astrogenesis, demonstrating a role for Piezo1 in neural stem cell fate. We propose that the mechanically-gated ion channel Piezo1 is an important determinant of mechanosensitive lineage choice in neural stem cells and that it may play similar roles in other multipotent stem cells.

EPAC-1 regulates vascular endothelial cell adaptation to fluid shear stress and atheroprotective gene expression.

S. Rampersad¹, F. Hubert², M.B. Umana², P. Brzezinska², S. Freitag², A. Wudwud¹, N. Butler², D.H. Maurice²;

¹Pathology and Molecular Medicine, Queen's University, Kingston, ON, ²Biomedical and Molecular Sciences, Queen's University, Kingston, ON

Forming the innermost lining of all blood vessels, vascular endothelial cells (VECs) are continuously exposed to the fluid shear stress (FSS) exerted by blood flow. VECs situated in the linear portions of macrovascular structures experience high laminar shear stress (HSS) and adapt by elongating and aligning in the direction of flow. They also display an anti-inflammatory and anti-thrombotic phenotype. At vascular bifurcations and large curvatures, however, FSS dramatically declines. Here, VECs are cobblestone-like in appearance and do not align to flow. Exposure to this low shear stress (LSS) also reduces the expression of numerous vasculoprotective genes, such as Kruppel-like factor 2 (KLF2), endothelial nitric oxide synthase (eNOS) and thrombomodulin (TM), making these areas preferential targets of atherosclerosis development.

Herein, we report a novel role for cAMP-signaling in human aortic endothelial cell (HAEC) adaptation to FSS. Our results showed that cAMP levels increased at flow onset and that inhibition of its synthesis using adenylyl cyclase inhibitor, 2'5'-dideoxyadenosine, reduced elongation and alignment of HAECs cultured under LSS for 48hrs compared to controls. This effect was mediated by cAMP-effector molecule, exchange protein activated by cAMP (EPAC)-1, since EPAC-1 activation improved elongation and alignment compared to controls. Furthermore, knockdown of EPAC-1 and the cAMP-hydrolyzing enzyme, phosphodiesterase (PDE) 4D, abrogated any adaptation to LSS, suggesting that EPAC1 and PDE4D play key roles in shear stress mechanotransduction.

Previously in the lab, we demonstrated that EPAC-1 and PDE4D form a mechanosensory complex with vascular endothelial-cadherin (VECAD) to regulate VEC permeability. VECAD has also been shown to signal with platelet-endothelial cell adhesion molecule (PECAM)-1 and vascular endothelial growth factor receptor (VEGFR)-2 in a mechanosensory complex that facilitates VEC adaptation to flow. Our results show that EPAC-1 and PDE4D knockdown impaired mechanosensory complex signaling by increasing VEGFR-2 phosphorylation and reducing phospho-AKT levels at onset of flow compared to controls, thus abrogating HAEC alignment.

Changes in VEC morphology and cell alignment typically correlate with changes in gene expression. Using quantitative PCR, we demonstrated that flow-mediated increases in KLF2, eNOS and TM mRNA expression were reduced in EPAC-1 and PDE4D knockdown HAECs exposed to LSS, HSS and oscillatory shear stress conditions. Additionally, EPAC-1 knockdown increased leukocyte extravasation across HAEC monolayers *in vivo* and EPAC-1 activation significantly reduced LPS-induced leukocyte rolling flux in mice. Collectively, our data suggests that EPAC-1 plays an important mechanosensory role and may be a potential therapeutic target in atherosclerosis development.

Characterization of higher-ordered septin structures in *Drosophila* cells.

Z. Dragieva¹, Y. Ruella², A. Kechad³, G.R. Hickson^{4,5};

¹Molecular Biology, Universite de montreal, Montreal, QC, ²Pathology and Molecular Biology, Universite de Montreal, Montreal, QC, ³Chu Sainte Justine, Montreal, QC, ⁴Universite de Montreal, Montreal, QC, ⁵UHC Ste-Justine, Montreal, QC

Septins are highly conserved GTP binding proteins whose deregulation contributes to diseases such as cancer and neurodegenerative disorders. Septins scaffold other proteins and act as diffusion barriers at the plasma membrane and at the midbody during cytokinesis. They also interact with the actin and microtubule cytoskeletons and have been observed to form ordered complexes that can polymerize into higher-order structures such as filaments and rings. The principles of assembly and disassembly of such filaments and rings and their cellular roles are yet to be elucidated. *Drosophila* offers a simple system for studying septins as there are only 5 septin genes: peanut, sep1, sep2, sep4, and sep5 in contrast to 13 septin genes in humans.

We find that 20% of cultured *Drosophila* S2 cells contain tubular structures, up to several microns in length, that label with Peanut immunostaining. These cytoplasmic tubes are present in both mitosis and interphase, suggesting they are not cell-cycle regulated. To investigate the composition and dynamic properties of these higher-ordered structures, we have generated S2 cell lines stably expressing Sep2-GFP, which also localizes to septin tubes. Peanut depletion completely disrupts Sep2-GFP organization, yielding a uniform GFP signal throughout the cell, whereas Sep1 depletion disperses Sep2-GFP tubes into clumps. This indicates that Sep1 and Peanut are required for the formation of the tubular structures and is consistent with previously reported Sep1/Sep2/Peanut complexes. FRAP analysis of Sep2-GFP revealed no recovery over several hours, indicating that the structures are stable and long-lived. However, breakage and re-annealing events were also observed. We have explored the potential relationship between septin tubes and the actin cytoskeleton. Although the tubes did not label for F-actin, treatment with the inhibitor of actin polymerization, Latrunculin A, led to their relatively rapid (

P1406**Board Number: B854****EGF/Ras signaling and the AFF-1 fusogen control seamless tube auto-fusion and shaping in the *C. elegans* excretory system.**F. Soulavie¹, M.V. Sundaram¹;¹Department of Genetics, University of Pennsylvania, Philadelphia, PA

Seamless unicellular tubes are found in the mammalian vasculature and in some invertebrate organs, including the *Caenorhabditis elegans* excretory (renal-like) system. Seamless tubes can form either by hollowing or by cell wrapping followed by auto-fusion. In this work, we are interested in the latter mechanism, which occurs in the *C. elegans* excretory duct. We know that duct cell differentiation is triggered by EGF/Ras signaling. However targets of the EGF/Ras pathway involved in duct differentiation remain unknown. The membrane fusion of the duct cell requires the fusogen *aff-1*. We hypothesize that EGF/Ras signaling upregulates *aff-1* expression to promote duct auto-fusion, and that auto-fusion is important for lumen architecture and function. Here, we used transcriptional reporters to analyze the *aff-1* expression pattern. We already showed that a 5.4kb promoter of *aff-1* is sufficient to promote expression in the differentiating excretory duct cell. Next we will reduce the promoter length to identify which region is required to promote expression in the excretory duct, and test responsiveness of the promoter to EGF/Ras signaling. Next, we used tissue specific expression of *aff-1* cDNA to rescue the auto-fusion of the duct in *aff-1(tm2214)* mutants. First, the same *aff-1* promoter used for transcriptional reporter is able to fully rescue *aff-1(tm2214)* mutants. Second, the *grl-2* promoter, which triggers expression in early excretory duct and pore, rescues duct auto-fusion but is also sufficient to promote ectopic fusion of the duct and pore cells. Finally, the *lin-48* promoter, which is specific to the duct at later stages, is surprisingly unable to promote duct auto-fusion. We demonstrated that only early expression of *aff-1* cDNA in duct is able to rescue duct auto-fusion. Furthermore, these results show a limit in AFF-1 fusogen activity and suggest that AFF-1 may need specific partners or a specific cellular environment in order to promote duct auto-fusion. Furthermore, we investigated the morphological phenotype of the duct cell in these mutants. The duct cell extension is shorter and the lumen also appears thicker and shorter in *aff-1(tm2214)* compared to wild-type. It appears that both excretory duct shape and luminal architecture are altered by loss of duct auto-fusion. These results show that AFF-1 is a key effector of duct tube differentiation. Its early expression specifically in the duct cell makes it a good candidate to be a direct target of the EGF/Ras pathway. By upregulating *aff-1*, the EGF/Ras pathway could promote both seamless-ness and the characteristic elongated duct tube shape. Next we need to confirm *aff-1* as an EGF/Ras target and investigate the relationship between cell fusion and lumen elongation.

P1407**Board Number: B855****Septin filaments recognize micron-scale positive plasma membrane curvature.**A.A. Bridges¹, P. Occhipinti², A.S. Gladfelter²;¹Dartmouth College, Hanover, NH, ²Biological Sciences, Dartmouth College, Hanover, NH

Septins are conserved filament forming GTPases that maintain cell polarity by restricting diffusion of proteins in the plasma membrane and endoplasmic reticulum while acting as a molecular scaffold for cytosolic proteins. Septin higher-order structures form on and associate with the plasma membrane and cells carrying mutated septin genes display irregular cell polarity, abnormal cell shape, are defective at cytokinesis, and are generally inviable. Though it has been shown that Cdc42 drives the accumulation of septins at incipient sites of cell polarity, properties of the plasma membrane that influence and maintain their localization have not been established. Here, we show that septins preferentially bind the plasma membrane in numerous cell types at sites of micron-scale positive curvature, a common topology of polarized cells. In regions of the cell devoid of positive curvature, septin filaments preferentially minimize interacting with negative plasma membrane curvature. Using phospholipid bilayer coated glass microspheres we show that curvature recognition is an intrinsic property of septin filaments. This work demonstrates that septins are a filamentous system capable of sensing plasma membrane shape on the micron-scale. Utilizing this property, septins respond to large scale changes in cell shape and communicate these changes to the cytoplasm.

P1408**Board Number: B856****Furrow ingression drives disassembly of remote microvillar F-actin to liberate membrane for cell surface growth.**L.R. Figard¹, A.M. Sokac²;¹Biochemistry and Molecular Biology, Baylor College of Medicine, Houston, TX, ²Verna and Marrs McLean Department of Biochemistry and Molecular Biology, Baylor College of Medicine, Houston, TX

Morphogenesis is driven by cell shape change, which often requires cell surface growth. Key aspects of this remodeling are still mysterious: What is the source of membrane for cell surface growth? How is membrane transferred to the site of growth? How is membrane transfer regulated? To address these questions, we study *Drosophila* cellularization, a dramatic tissue-building event that expands the embryo's surface area by ~25 fold. We previously showed that microvilli unfold to provide membrane for cleavage furrow ingression during cellularization. We showed that microvillar disassembly is controlled by furrow ingression, and that microvillar membrane slides along the plane of the cell surface into ingressing furrows (Figard et al., 2013). These results provide the first direct evidence for plasma membrane unfolding, which has long been suspected as a broadly conserved mechanism of cell surface growth. But how does furrow ingression drive unfolding and the necessary disassembly of microvillar F-actin cores? We propose that furrow pulling increases plasma membrane tension, antagonizing F-actin

polymerization in microvilli and ultimately causing them to unfold. To validate this proposal, first, we used fluorescence recovery after photobleaching (FRAP) and drug studies to show that microvillar F-actin is constantly polymerizing and depolymerizing. Second, we used 3D time-lapse imaging to show that microvillar F-actin is depleted in sync with furrow ingression. Third, we analyzed a genetic mutant for furrow ingression and found that furrow ingression controls the depletion of microvillar F-actin. Fourth, we used physical force assays to show that furrow ingression exerts a pulling force that is transmitted to far-away microvillar F-actin. In all cells, the surface folds holding the largest membrane stores will likely be supported by F-actin. Our results suggest that plasma membrane tension is a critical regulator of unfolding, acting on F-actin to control the liberation and transfer of membrane during cell surface growth.

Substrate-dependent filament assembly by liver phosphofructokinase-1, the gatekeeper of glycolysis.

B.A. Webb¹, J.M. Hansen², J.M. Kollman^{2,3}, D.L. Barber¹;

¹Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA, ²Department of Anatomy and Cell Biology, McGill University, Montreal, QC, ³Dept. of Biochemistry, University of Washington, Seattle, WA

Emerging evidence demonstrates that metabolic enzymes regulating diverse pathways can assemble into filaments that comprise a structural component to eukaryotic cells. We report that phosphofructokinase-1 (PFK1), the first rate-limiting step of glycolysis, assembles into filaments *in vitro* and in cells. We showed by transmission electron microscopy (TEM) and light scattering measurements that *in vitro* filament assembly of PFK-1 is regulated by the substrate fructose 6-phosphate (F6P). In the presence of F6P the liver isoform of PFK1 (PFKL) predominantly formed long filaments measuring up to 250 nm. PFKL filaments are less rigid than actin polymers, displaying right angles in contiguous assemblies. Negative stained EM images showed that filaments are made of stacked tetramers that rotate $\sim 45^\circ$ with each rise. Contacts between PFKL tetramers occur such that the catalytic sites are positioned along the edge of the filament. EM images of PFKL filaments showed that the repeating subunit of the polymer is similar to our recently determined crystal structure of the active tetramer form of PFK1, suggesting that formation of the tetramer precedes formation of the elongated polymer. We confirmed activity-dependent filament assembly with an inactive but tetrameric mutant, PFKL-His199Tyr, that did not form filaments in the presence of F6P, as determined by TEM and light scattering. We next determined PFKL dynamics and filament formation in cells expressing PFKL-GFP. Live-cell confocal microscopy revealed that cytosolic PFKL-GFP was localized to the distal margin of lamellipodia that were devoid of mitochondria where PFKL co-localized with the glycolytic enzymes pyruvate kinase isoform M2 and lactate dehydrogenase A. Live-cell TIRF microscopy revealed that PFKL-GFP formed dynamic punctae. Punctae size was regulated by glucose availability; PFKL-GFP punctae displayed increased size in the presence of the glycolytic inhibitor 2-deoxyglucose. We tested if filament

formation was specific to the PFKL isoform and found that neither the platelet nor the muscle isoforms formed filaments with F6P *in vitro* and in cells. These data indicate that only active PFKL assembles into tetramer-aligned filaments, suggesting filament formation regulates enzyme activity in cells. We hypothesize the activity-dependent recruitment and assembly of PFKL filaments at the plasma membrane provides a scaffolding and structural framework for localized ATP production in lamellipodia which lack mitochondria.

Understanding the underlying mechanisms driving nuclear movement to the periphery in skeletal muscle.

W. Roman¹, E. Gomes², J. Schmoranzer³;

¹UMR 974 Inserm-Groupe Myologie, Univ Pierre Et Marie Curie, Paris, France, ²UMR S 787 Inserm-Groupe Myologie, Paris, France, ³Biochemistry, Freie Universität Berlin, Berlin, Germany

Nuclei are often schematically represented as a spherical organelle fixed in the center of the cell. This view has greatly changed in the last decades in which nuclear positioning was shown to be essential for vital cellular processes that include cellular division, differentiation and migration. Nuclear dynamicity is particularly active in skeletal muscle where nuclei begin aggregated in the center of the myotube to end dispersed at the periphery of the mature myofiber following a sequence of various types of nuclear movements. We previously reported the underlying mechanisms driving nuclei to aggregate and spread in the center of the myotube to be dependent on microtubules, microtubule-associated proteins (Map7) and motors (kif5b). Furthermore we showed that this process is not dependent of nesprins, nuclear envelope proteins that link the nuclei to the cytoskeleton. We focus here on understanding the later movement of how nuclei move from the center to the periphery of the myofiber.

We developed an *in vitro* system in which we can differentiate myoblasts to fuse into myofibers with peripheral nuclei, aligned sarcomeres and transversal triads. The entire process of nuclear movement of muscle fiber growth can be observed, beginning with nuclei from myoblasts aggregating to the center of the newly formed cell to end with nuclei being anchored at the periphery of the myofibers.

We found that nuclei spread along the center of the myotube before moving to the periphery where they continue to move longitudinally along the fiber. It is only at a later stage that peripheral nuclei become anchored. We demonstrate that peripheral nuclear positioning pre-requires spreading of nuclei along the myofiber, dependent on microtubules, Map7 and Kif5b pathway but independent of nesprins and actin. The movement towards the periphery is however driven by actin and nesprins and is independent of microtubules. We establish that nuclear movement to the periphery of the myofiber is triggered by Amphiphysin 2, a gene mutated in Centronuclear Myopathy (CNM), which recruits and activates N-WASP to regulate actin dynamics. We also show that mutations in amphiphysin-2, associated with CNM, disrupt N-WASP localization and consequentially peripheral nuclear positioning. This work provides evidence for a switch between microtubules and actin-dependent mechanism of

nuclear positioning during myofiber development. Furthermore we establish that nesprins and actin are involved in the movement of nuclei from the center to the periphery prior to anchoring of nuclei at the periphery of the myofiber.

Dynamic remodeling of the airway epithelial cell's contractile machinery in response to cigarette smoke exposure.

C. Kliment^{1,2}, V. Srivastava¹, P. Mandke², D. Robinson^{1,3}, R. Sidhaye²;

¹Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Pulmonary and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, ³Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine, Baltimore, MD

Chronic obstructive pulmonary disease (COPD) is the 3rd leading cause of death in the US with cigarette smoke being the primary insult leading to disease progression. The lung epithelium becomes reactive and undergoes remodeling after exposure to cigarette smoke. The role of cytoskeleton and cell mechanics in the airway response to cigarette smoke is not well understood. We know that cytoskeletal proteins, such as myosin II, actin, alpha-actinin, the catenins, and E-cadherin, are involved in cell-cell adhesion formation and barrier function of the lung. Furthermore, E-cadherin levels decrease in primary epithelial cells from COPD patients. Therefore, we hypothesized that cigarette smoke drives key cytoskeletal protein changes that lead to alterations in barrier function and epithelial repair capacity. To test this, we studied major cytoskeletal (actin and nonmuscle myosin II isoforms) and cell adhesion proteins (E-cadherin) in normal human bronchial epithelial cells (NHBE, collected directly from human patients) or 16HBE cells (primary human bronchial epithelial cell line) grown on an air-liquid interface. Using a Vitrocell smoke chamber, we found that in response to acute smoke exposure (three cigarettes in 36 hours), myosin IIB and actin assembled into apical stress fibers, which are not normally found in airway epithelial cells. Cigarette smoke exposure also resulted in decreased total E-cadherin levels, as well as, decreased E-cadherin at the basolateral surface. Thus, cigarette smoke promotes dramatic acute cytoskeletal changes that likely lead to altered cell mechanical properties (tension, elasticity), which in turn lead to reduced epithelial barrier function. The loss of epithelial barrier function contributes to chronic remodeling leading to COPD progression.

P1412**Board Number: B860****E-cadherin oligomerization regulates the strength of adhesion and collective cell migration.**P. Strale^{1,2}, L. Duchesne³, G. Peyret¹, L. Montel⁴, E. Png⁵, S. Troyanovsky⁶, S. Hénon⁴, B. Ladoux^{1,2}, R. Mege¹;¹Institut Jacques Monod, Université Paris Diderot CNRS, Paris, France, ²Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ³Institut de génétique et développement de Rennes, CNRS, Rennes, France, ⁴Laboratoire Matière et Systèmes Complexes, CNRS, Université Paris Diderot, Paris, France, ⁵Singapore Eye Research Inst, Singapore, Singapore, ⁶Northwestern University, Feinberg School of Medicine, Chicago, IL

Oligomerization of weakly interacting cell adhesion molecules provides the necessary stability and strength to ensure tissue cohesion. Cadherins mediate cell-cell adhesion by forming adhesive bonds between EC1 domains of molecules presented by adjacent cells. Trans interacting cadherins allows the formation of cadherin clusters by a diffusion-trap mechanism further stabilized by anchoring to actin filaments, prefiguring *adherens* junctions found in tissues. Structural and biochemical data show that cadherins also interact in cis via bonds formed between EC1 and EC2 domains of adjacent molecules. These “weak energy” bonds are predicted to shift cadherin clusters from a fluid to an ordered (oligomeric) phase. However, no evidence has been provided so far for the existence of ordered cadherin clusters in vivo and for the cellular impact of cadherin oligomerization. Using nanoparticles to visualize single GFP-tagged proteins in cell membrane at a nanometric resolution, we demonstrate that Ecad molecules arrange in ordered lattices of a few to tens of molecules spaced by less than 10 nm, providing the first demonstration of the existence *in cellulo* of the predicted nanometric arrays of oligomeric cadherin. In contrast Ecad mutated for the two amino-acids responsible for cis-oligomerization display a random distribution. We further studied the consequences of the disruption of the cis interface on cadherin complexes dynamics, *adherens* junction formation, strength of cadherin adhesions and collective behaviour of A431D cells. Bead-cell adhesion assay and electron microscopy analysis shows that the cis interface is not essential for cell adhesion and *adherens* junction formation. Analysis of protein dynamics by FRAP reveal that disruption of the cis interface increases the mobility of junctional Ecad but also of α -catenin as well as of the underlying actin cytoskeleton. Using magnetic tweezers to apply forces on Ecad-Fc coated beads, we demonstrate that this moderate destabilization has a major impact on the stiffness of the anchoring of cadherin clusters to actin. Further analysis of collective cell behaviour in a controlled monolayer expansion assay shows that cis interface disruption increases monolayer fluidity and individual cell migration as a result of decreased cell-cell coordination. Altogether, these data demonstrate that cadherin oligomerization occurs in a cellular context. Unexpectedly, the formation of ordered clusters of Ecad is not required for *adherens* junction formation, but primarily controls the anchoring of the adhesion complexes to the actin cytoskeleton and finally the mechanical stability of cell-cell contacts having a strong impact on collective cell behaviour.

P1413**Board Number: B861****ADENOSINE A_{2B} RECEPTOR INDUCES TRANSITION OF PODOCYTE TO A LESS DIFFERENTIATED STATE.**C. Jaramillo¹, S. Alarcón¹, C. Quezada¹, R.E. San Martín²;¹Bioquímica y Microbiología, Universidad Austral De Chile, Valdivia, Chile, ²Instituto de Bioquímica y Microbiología, Universidad Austral de Chile, Valdivia, Chile

Introduction. It has been described that diabetic glomerulopathy progresses with alterations of the podocyte cells function. The most remarkable feature is the deterioration of the filtration barrier. Interestingly, the nucleoside adenosine increases locally during the progression of diabetic glomerulopathy, probably having a pathogenic role. Our aim will be to determine the role of adenosine in mediating the dysfunction of podocyte cells.

Results. Primary cultured podocytes expressing specific markers were obtained from glomeruli of rats. Exposure of podocytes to adenosine leads to actin redistribution, changes in cellular morphology, decreases of the expression of adhesion molecule integrin $\alpha 3$ and induction of the expression of α -SMA, a marker of epithelial to mesenchymal transition. Further, these changes were accompanied with an increased rate to migration. The above effects were blocked using an antagonist of the adenosine A_{2B} receptor subtype. Moreover, using an antagonist of adenosine A_{2B} receptor *in vivo*, abolished the effacement of foot process of podocytes and the increased levels of proteinuria was blocked in diabetic rats.

Conclusions. Loss of function of podocytes could be mediated by increased levels of adenosine such as in diabetic nephropathy. This effect is relevant because affects the integrity of the glomerular filtration barrier. Furthermore, *in vivo* intervention using an antagonist of adenosine A_{2B} receptor ameliorates the proteinuria in diabetic animals.

Cell processes in any physiological environment ubiquitously involve changes in cell shape, which must be accommodated by their physical envelope – the bilayer membrane. However, the fundamental biophysical laws by which the cell membrane allows for and responds to shape changes remain unclear. Here we show that in response to mechanical stimuli cells rearrange their membrane through a fast passive physical process prior to any active remodeling. Upon application of biaxial stretch, cells recruit membrane area by flattening existing ruffles in lamellipodia. Upon subsequent stretch release, membrane area is stored in the form of tubular invaginations at the cell-substrate interface. In contrast, membrane adaptation in response to changes in medium osmolarity is driven not by area requirements, but rather by the storage of liquid flows expelled by cells. This leads to the formation of the large membrane invaginations in the shape of spherical caps usually described as vacuole-like dilations (VLDs). In both cases, we demonstrate that the shape of the invaginations can be explained by passive minimization of membrane elastic and adhesive energies, constrained by the requirement to store membrane area (in the case of stretch) or volume (in the case of osmotic shocks). Further, we show that by reducing the requirement for adhesion and elastic energy, existing invaginations can act as seeds for additional deformation. By being passive and not depending on specific molecular components, the principles unveiled provide a general mechanism for the adaptation and rearrangement of a significant portion of cell membrane area. Additionally, the local curvature induced by membrane invaginations could potentially trigger downstream mechanotransduction events by affecting curvature-sensitive proteins.

P1415**Board Number: B863****Control of tissue mechanical properties by cellular micro-architecture: cell size, C-cadherin (cdh3) mediated F-actin assembly, and actin bundling.**J.H. Shawky¹, L.A. Davidson^{1,2};¹Bioengineering, University of Pittsburgh, Pittsburgh, PA, ²Developmental Biology, and Computational and Systems Biology, University of Pittsburgh, Pittsburgh, PA

To understand the connection between genetics, the environment, and birth defects we are particularly interested in physical and genetic factors that regulate tissue mechanics in the developing embryo. Tissues within embryos of the aquatic frog *Xenopus laevis* increase in stiffness six-fold as they gastrulate (form the three germ layers) and neurulate (form the central nervous system), however, the origin of this increase is not well understood.

We compare the mechanics of embryonic tissues to the predictions of the cellular solids model (CSM; Gibson, L.J. and M.F. Ashby, Cellular solids: structure and properties. 2nd ed 1997, New York: Cambridge University Press) which has been used to understand the mechanical properties of natural and man-made closed-cell foam materials. The CSM relates bulk stiffness of a foam to the density, or unit-size of individual cells, their microstructural organization, and their material properties. CSM suggested that cell size could be responsible for changes we observe in bulk tissue stiffness. We took advantage of the biology of cell division in *Xenopus* embryos to produce tissues with controlled cell sizes. To generate large cells in tissue explants, we arrested the cell cycle using a combination of cell cycle inhibitors, hydroxyurea and aphidicolin (HUA). Tissues treated with HUA showed a 34% decrease in nuclear density equating to a 50% increase in cell volume. CSM predicts a 23% decrease in tissue stiffness and we found a 25% decrease in the measured elastic modulus. Since cell size plays a role in the large increase in stiffness we sought to test other CSM predictions.

Additional factors contributing to bulk stiffness in closed-cell foams include the thickness and material stiffness of the "cell-wall". To manipulate these factors we sought to reduce F-actin assembly in the cell cortex by expressing a dominant negative C-cadherin (extracellular-domain deleted EP(C)-cadherin; EPΔE) in dorsal tissues. We observed both a reduction in the amounts of cortical F-actin and found dorsal tissues exhibited a 32% decrease in elastic modulus. Efforts are underway to regulate cortical F-actin levels and their degree of cross-linking to test further predictions of the CSM model.

Understanding how cell size, cell cohesion and actin bundling affect tissue stiffness is imperative to uncovering the programs in development responsible for stiffening the embryo.

P1416**Board Number: B864****Elucidating the biomechanics of actin purse-string contraction during epithelial gap closure.**

G. Peyret¹, S. Vedula², I. Cheddadi³, T. Chen², A. Brugués⁴, H. Hirata², H. Mendez-Lopez¹, Y. Toyama², X. Trepas⁵, L. Almeida³, C. Lim², B. Ladoux^{1,2};

¹Institut Jacques Monod, Université Paris Diderot CNRS, Paris, France, ²Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ³Laboratoire Jacques-Louis Lions, Université Pierre et Marie Curie, Paris, France, ⁴Institute for Bioengineering of Catalonia, Universitat de Barcelona, Barcelona, Spain, ⁵Institute for Bioengineering of Catalonia, Barcelona, Spain

Wound healing is crucial to maintain epithelial integrity. Two major mechanisms are widely accepted to regulate epithelial gap closure: cell crawling and actin purse-string contraction. Both mechanisms can coexist and could even influence each other. Here we developed an original in-vitro assay using micro-fabrication techniques, including micro-contact printing, to directly study the closure of model wounds over non-adhesive circular areas. Our observations show that the absence of extracellular matrix is sufficient to exclusively promote an actin-purse string mechanism preventing lamellipodia formation. It appears that the actin cable does not begin as a continuous entity but instead, comes from the assembly of multiple actin cables intermittently anchored to the substrate around the gap edges. This first step is followed by the formation of a continuous contractile cable running across multiple cells. By varying the diameter of the gaps between 100 and 200 μm , we determined a critical length scale over which the forces generated by actin cables contraction remained insufficient in closing the gap. We then determined the influence of cell proliferation and cell-cell junctions in epithelial gap closure. Combining our micropatterning approach with traction force microscopy, we show that the forces exerted by cells on the substrate at the edge of the gap first point away from the center of the gap but then increase in the radial direction pointing towards the gap as closure proceeds. Our results thus provide direct measurements of the forces generated by acto-myosin contraction during epithelial gap closure showing an increase of the radial forces over time and suggesting a possible reinforcement of the acto-myosin cable around the gap. To complete our observations, we performed numerical simulations for which tissues were modeled as visco-elastic materials. These in silico data confirmed the actin reinforcement to explain the dynamic of closure. All together, our experimental data provide the framework for understanding the assembly and the mechanics of contractile actin cables.

P1417**Board Number: B865****Functional coupling between adhesion strength and cell stiffness depends on cytoskeletal tension modulation.**H. Sreenivasappa^{1,2}, S.P. Chaki³, S. Lim^{2,4}, J.P. Trzeciakowski², M.W. Davidson⁵, G.M. Rivera³, A. Trache^{1,2};¹Biomedical Engineering, Texas AM University, College Station, TX, ²Medical Physiology, Texas AM Health Science Center, College Station, TX, ³Veterinary Pathobiology, Texas AM University, College Station, TX, ⁴Chemistry, Texas AM University, College Station, TX, ⁵National High Magnetic Field Laboratory and Department of Biological Science, Florida State University, Tallahassee, FL

Integrin mediated cell-matrix adhesions play a critical role in regulating adaptive cellular responses to stress. Our study investigates the role of cytoskeletal tension on integrin binding strength and cellular remodeling. Adhesion force spectroscopy measurements using a fibronectin functionalized atomic force microscope probe were performed on cells expressing either RhoA or Src variants (wild-type, constitutively active and dominant negative mutants). Cell stiffness at point of contact and adhesion strength of integrin $\alpha 5\beta 1$ to fibronectin were measured. Cell stiffness significantly increased with both RhoA and Src activation. However, the incremental change in cell stiffness was higher in RhoA- than in Src-expressing cells. Consistent with these findings, confocal imaging results showed that RhoA had a significant effect on stress fiber modulation, while Src activation had only a modest effect on actin morphology. The adhesion force of $\alpha 5\beta 1$ integrin to fibronectin also followed a similar trend. The force-stiffness experimental data modeled with a piecewise algorithm, presented a segment showing a flat dependence of force vs. stiffness, while a second segment presented a rapidly increasing positive dependence. The intersection coordinates provided a stiffness threshold corresponding to about 17 kPa, below which the integrin-fibronectin adhesion force is about 37 pN without significant variations. However, above the threshold, the force increases rapidly with the increase in cell stiffness. These results suggest that soft cells present no significant variation in the adhesion force to the matrix until cell stiffness reaches a threshold, after which cells exhibit a significant increase in adhesion strength with increase in cell stiffness, most likely, through a mechanism that involves integrin activation. To further investigate the differential regulation of cytoskeletal tension and cell-matrix adhesions by RhoA and Src, we tested if Src-induced cytoskeletal tension involves modulation of the RhoA pathway. We used SU6656, a specific Src kinase inhibitor, in cells expressing RhoA constitutively active mutant to test mechano-sensitive response of cells to Src inhibition. SU6656 treatment suppressed the increase in both cell stiffness and adhesion strength induced by RhoA activation, by releasing RhoA-induced contractile tension. Moreover, western blots showed decreased Src and myosin phosphorylation due to SU6656 inhibition. Taken together, these results suggest that Src modulates the RhoA pathway through regulation of myosin activation, which is a downstream effector of RhoA.

P1418**Board Number: B866****Cytoskeletal forces during T cell activation.**K. Hui¹, A. Upadhyaya²;¹Physics, Institute of Physical Science and Technology, College Park, MD, ²Physics and IPST, University of Maryland, College Park, MD

T cell activation is critical for the adaptive immune response in the body. The binding of the T cell receptor (TCR) with antigen on the surface of antigen presenting cells (APC) triggers signaling cascades and cell spreading. Physical forces exerted through the TCR have been shown to induce signaling events, but the origin of how these forces are generated and maintained is unknown. Here, we use traction force microscopy to measure the forces exerted by Jurkat T cells during TCR activation. We used anti-CD3 coated elastic polyacrylamide gels to stimulate Jurkat T cells and measured the spatially resolved traction stress map exerted by these cells as they were activated. Perturbation experiments revealed that stresses were largely generated by actin assembly and disassembly and regulated by the flow speed of actin. Our experiments further suggest that TCRs are structurally linked to the actin cytoskeleton through the Arp2/3 complex. On the other hand, we found that myosin II motor activity was dispensable for maintenance of traction stresses, but was important for traction stress generation. Finally, we investigated calcium influx in Jurkat T cells when activated on substrates of physiologically relevant stiffnesses. Our results highlight the importance of cytoskeletal forces for receptor activation in T cells.

P1419**Board Number: B867****Formation of transcellular tunnels by mechanical force.**W. Ng^{1,2}, K.D. Webster^{2,3}, C. Stefani⁴, E. Lemichez⁴, P. Bassereau⁵, D.A. Fletcher^{3,6,7};¹Graduate Program in Bioengineering, University of California, Berkeley, Berkeley, CA, ²Bioengineering, University of California, Berkeley, Berkeley, CA, ³Biophysics Graduate Group, University of California, Berkeley, Berkeley, CA, ⁴INSERM, Nice, France, ⁵PhysicoChimie Curie, Institut Curie, Paris, France, ⁶Department of Bioengineering, University of California, Berkeley, Berkeley, CA, ⁷Physical Biosciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA

The endothelial monolayer in blood vessels serves as a physical barrier that separates the underlying tissue from the bloodstream. A group of bacterial toxins comprising EDIN or C3, two ADP-ribosyltransferases targeting RhoA, and several adenylate cyclases disrupt this protective barrier by inducing the formation of transcellular tunnels through fusion of the dorsal and ventral plasma membrane of a cell. These transcellular tunnels enlarge by a physical phenomenon of cellular dewetting. However, the mechanism of the initial fusion event during tunnel formation remains poorly understood. All these toxins reduce actomyosin contractility either by inactivating RhoA directly or by inducing a cAMP/EPAC/Rap pathway. Relaxation of the cytoskeleton is believed to increase the likelihood that the dorsal and ventral membranes of the cell come into contact and fuse to form a transcellular tunnel. To

test whether a tunnel will form when membranes are brought into close apposition, we used atomic force microscopy (AFM) to apply a localized mechanical force and combined this technique with total internal reflection fluorescence (TIRF) microscopy to visualize the formation of transcellular tunnel formation. We found that mechanical forces are sufficient to induce the formation of transcellular tunnels in HUVECs in the absence of toxin, and we observed localization of the I-BAR domain of MIM and actin around the edges of the transcellular tunnel, similar to toxin-induced tunnels. We also found that cells exposed to the EDIN/C3 toxin formed transcellular tunnels at lower forces than cells not exposed to the toxin. Our study suggests that the cytoskeleton provides resistance against spontaneous formation of transcellular tunnels, a mechanism that could be hijacked by bacterial pathogens to breach the protective endothelial barrier.

A novel frameshift mutation in caveolin-1 associated with pulmonary arterial hypertension down-regulates caveolin-1 levels, reduces caveolae stability, and decreases the buffering capacity of caveolae.

B. Han¹, C.A. Copeland¹, K.R. Drake¹, J. West², E. Austin², J. Loyd³, A.K. Kenworthy¹;

¹Mol Physiol Biophys, Vanderbilt University Medical Center, Nashville, TN, ²Medical center, Vanderbilt University, Nashville, TN, ³Medical Center, Vanderbilt University, Nashville, TN

Caveolin-1 is a major structural component of caveolae, flask-shaped invaginations of the plasma membrane found in multiple cell types. Recently, C-terminal frameshift mutations in the CAV1 gene have been identified in patients with pulmonary arterial hypertension (PAH), a lethal disease of the pulmonary microvasculature (Austin et al. *Circ Cardiovasc Genet.* 2012;5:336-343.) These findings suggest that defects in caveolae may contribute to the pathogenesis of PAH. To test this idea, in the current study we probed for defects in caveolae in human skin fibroblasts obtained from PAH patients heterozygous for mutant CAV1. We found that levels of caveolin-1 and some of its known accessory proteins such as caveolin-2, cavin-1 and EHD2 were significantly decreased in patient fibroblasts compared to controls as assessed by Western blotting. Peptides from the new C-terminus of mutant CAV1 were identified by mass spectrometry from patient cell lysates, suggesting the down-regulation of caveolin-1 is not simply due to haploinsufficiency. Despite the decreased levels of caveolae-associated proteins, intact caveolae could be detected by electron microscopy and biochemical fractionation in patient fibroblasts, and immunofluorescence microscopy revealed that both caveolin-1 and its accessory proteins colocalized normally in caveolae. However, the stability of caveolin-1 complexes and caveolae were decreased in patient fibroblasts compared to controls, implying that the presence of the mutant protein impacts caveolae stability. Furthermore, the viability of patient's cells significantly decreased under hypoosmotic stress compared to controls, indicating that the decreased of number and/or stability of caveolae impair the ability of caveolae to function as a membrane reservoir. These findings suggest that the decreased levels of caveolin-1 and reduced stability of caveolae resulting from expression of mutant CAV1 may both contribute to the development of PAH.

P1421**Board Number: B869****Confocal microscopy and solution NMR studies of cytoskeletal proteins from *Tetrahymena thermophila*.**R.C. Sterner¹, A.M. Kilpatrick², J. Honts³;¹Biology, Drake University, Des Moines, IA, ²Physics, Drake University, Des Moines, IA, ³Drake University, Des Moines, IA

Organisms derive their complexity from the associations of cells to form tissues with unique structures and functions. Although the fresh water ciliated protist *Tetrahymena thermophila* is only a single cell, it demonstrates remarkable complexity in its cortical cytoskeleton. From cell to cell, this intricate cell surface architecture must be faithfully replicated. The molecular mechanisms of its organization and regulation during division are not completely documented. In previous studies, we have identified nearly three dozen proteins through proteomic analysis of calcium-dependent contractile fibers isolated from the cortical cytoskeleton of *Tetrahymena thermophila*. Proteins investigated include a putative calcium-binding protein (Tcb2), a filament-forming structural protein (Epc1), and a protein kinase (Epk1), among others. These proteins have been hypothesized to function in the calcium-dependent regulation of ciliary motion and are believed to play key regulatory and structural roles. Confocal laser scanning microscopy as well as solution NMR have been employed in order to further investigate these dynamic protein interactions over the course of the cell division cycle to form the complex scaffold of protein fibers and filaments and to better comprehend their structure-function relationship. Through the use of confocal microscopy, we have found that these protein localizations are present in only a narrow layer in the cells cortical cytoskeleton, specifically the epiplasm. This narrow epiplasmic distribution is consistent with the purification results we have seen from the membrane skeleton of this cell. In addition, we have reconstituted calcium triggered contractile fabrics with Tcb2 *in vitro*. The C-terminal domain of Tcb2 is highly soluble and amenable to structural characterization while full-length Tcb2 forms filamentous structures and becomes insoluble in the presence of calcium and/or upon concentration. NMR spectra indicate that the C-terminal of Tcb2 is well folded in the presence and absence of calcium, and upon calcium addition, a dramatic conformational change occurs. In order to quantify the calcium binding properties of this domain, we are utilizing NMR spectroscopy. In the future, Tcb2 interactions with other cortical cytoskeleton proteins such as Epk1 and subdomains of Epc1 will be explored through NMR experiments. The distribution of these cytoskeleton proteins relative to one another will be investigated through both FRET and double labeling studies.

P1422**Board Number: B870****Intracellular crystallization of insect virus and polyhedra revealed by quick-freeze, freeze-fracture electron microscopy.**N.i. Morone¹, H. Mori², J.E. Heuser¹;¹iCeMS, Kyoto University, Kyoto, Japan, ²Kyoto Institute of Technology, Kyoto, Japan

Natural silkworm (*Bombyx mori*) as lepidopteran larvae can be infected by cytoplasmic polyhedrosis viruses (Cypoviruses) of icosahedral ds-RNA viruses. The cypoviruses quickly become embedded in elaborate protein crystals called "polyhedra". X-ray diffraction about the internal crystal structure of these purified polyhedra has been succeeded (Coulibaly et al., 2007), but the molecular mechanism by which they assemble and incorporate virions in the cytoplasm of infected insect cells remains obscure. Here, we have examined their molecular mechanisms of assembly in their natural environment inside intestinal and silk gland cells of larval silkworms, and in Sf21 cells in tissue culture. Avoiding the artifacts and difficulties of previous EM-approaches, all specimens were here prepared by "quick-freezing" directly from life, followed by freeze-fracture to gain entry into the cells, and then "deep-etching" and rotary Pt-replication to achieve true-to-life, topologically accurate 3-D images of the polyhedra and their associated virions. This approach yielded novel and definitive images of polyhedra crystallization in situ, and thereby revealed unique differentiations within cellular environs wherein polyhedra organize, and the exact mechanism of inclusion of nascent virions into the polyhedra. Specifically, it allowed us to focus directly on the edges of polyhedra, right where the nascent viruses are being captured and engulfed during the growth of the polyhedra. This allowed us to compare the success of virion-capture and polyhedron-assembly in a variety of different experimental conditions, including the substitution of mutant viruses and incomplete virions lacking critical recognition-factors. Additionally, it allowed us to determine exactly how the cytoskeletal architecture of the infected cells is altered, to permit this elaborate crystal-formation and virus-incorporation to occur. Especially, we found the crystal formation in the silk gland cell with cypovirus-free system, which we have succeeded in the preparation. In this presentation, our observations and results will be described and illustrated by means of realistic three-dimensional images presented in "anaglyph" stereo form.

P1423**Board Number: B871****Tcb2: a novel *Tetrahymena* calcium-binding protein that is part of a contractile assembly.**

J.E. Honts¹, H.G. Sleister¹, A.M. Kilpatrick², H.M. Garcia¹, T. Gurrola¹, R.C. Sterner¹, L. Hovey³, M.A. Shea³;
¹Biology, Drake University, Des Moines, IA, ²Physics, Drake University, Des Moines, IA, ³Biochemistry, Carver College of Medicine, University of Iowa, Iowa City, IA

Tetrahymena thermophila, a ciliated protozoan, exhibits a complex cell surface architecture, organized by a membrane-associated cytoskeleton. Two specific proteins, Epc1, a coiled coil protein, and Tcb2, an EF-hand calcium-binding protein were major components of a contractile gel that formed when an alkaline extract of the *Tetrahymena* membrane skeleton was adjusted to neutral pH in the presence of calcium ions. These two proteins co-assembled to form cross-linked filament networks. To study Tcb2 in detail, we engineered genes for optimized expression of Tcb2 protein, as well as its N-terminal and C-terminal domains. Purified full length Tcb2 protein (a) exhibited a clear calcium-dependent shift in electrophoretic mobility in native polyacrylamide gels, and (b) formed fibrous aggregates when calcium ions were added. Electron microscopy revealed the presence of globules and short filaments. Steady-state fluorescence spectroscopy was used to monitor conformational changes in the Tcb2 C-terminal domain (Tcb2-C) during titration with calcium ions. This indicated the presence of one high affinity calcium-binding site, with a low micromolar dissociation constant. The affinity of Tcb2-C for calcium falls within the range of calcium concentrations shown to trigger specific biological functions within the ciliate cortex. The shift of peaks observed during calcium titrations of Tcb2-C monitored by (1)H-(15)N HSQC-NMR provided complementary evidence for calcium-dependent conformational changes. We have obtained protein crystals of Tcb2-C that diffract to $\leq 2.7 \text{ \AA}$, and work is underway to determine the atomic structure of this domain. The N-terminal domain (Tcb2-N) has demonstrated very different properties, especially aggregation in the presence of calcium ions, which may explain why the intact protein readily formed filamentous aggregates in vitro.

Comparison of the effect of the vinexin family proteins on vinculin-mediated mechanosensing.

T. Ichikawa¹, M. Kita¹, T. Sezaki¹, S. Chiang², A.R. Saltiel², Y. Kimura¹, K. Ueda^{1,3}, N. Kioka¹;

¹Agriculture, Kyoto University, Kyoto, Japan, ²Life Sciences Institute, University of Michigan, Ann Arbor, MI, ³iCeMS, Kyoto University, Kyoto, Japan

The vinexin family protein, also called the Sorbs protein, is composed of one sorbin homology (SoHo) domain and three SH3 domains. This family is conserved among multicellular animals and includes vinexin (or Sorbs3), CAP (or Sorbs1) and ArgBP2 (Sorbs2). They are localized at focal adhesion (FA) sites or cell-cell adhesion sites, and have common binding proteins including cytoskeletal molecules like vinculin, as well as signaling molecules such as c-Abl and c-Cbl. However, they have different functions in vivo; vinexin is involved in wound healing, CAP regulates insulin signaling and ArgBP2 functions as a tumor suppressor. Recently we reported that the interaction of vinculin with vinexin plays a key role in sensing extracellular matrix (ECM) stiffness. In addition, Bharadwaj R. et al. reported that Sorbs protein in *Drosophila* regulates assembly and function of two tension sensing organs and Martin M. et al. reported that ArgBP2 maintains endothelial contractility and vessel lumen integrity. These emerging reports suggest that Sorbs proteins work as a ‘mechanosensor’. Because cells usually express one or more Sorbs proteins, it is difficult to compare the functions of Sorbs proteins exactly. In this study, we established Sorbs-triple depleted mouse embryonic fibroblast cells (referred to TKO MEF), and then compare the functions of Sorbs proteins using the cells re-expressing each Sorbs protein. We first analyzed the localization of Sorbs protein in TKO MEF. Immunostaining revealed that vinexin and CAP were co-localized with vinculin at FAs, while ArgBP2 was co-localized with alpha-actinin on actin stress fibers. We also found the area of FAs defined by vinculin was increased in each Sorbs protein re-expressing cells. Previous our results that vinexin is required for ECM stiffness-dependent behaviors of vinculin prompted us to examine the effect of Sorbs protein on vinculin status. Interestingly, both vinexin and CAP significantly increased the Triton X-100 insoluble vinculin on rigid ECM compared to on soft ECM, whereas ArgBP2 did not. Fluorescent recovery after photobleaching (FRAP) analysis revealed that both vinexin and CAP significantly increased the immobile fraction of vinculin on rigid ECM, whereas ArgBP2 did not. These results suggest that both vinexin and CAP, but not ArgBP2, are required for ECM stiffness-dependent stabilization of vinculin at FAs. To uncover the mechanism of these differences, we investigate the interaction of Sorbs proteins with vinculin using purified protein. Pull-down experiment showed that both vinexin and CAP strongly interact with vinculin but ArgBP2 hardly. Taken together, in MEFs, both vinexin and CAP, but not ArgBP2, interact with vinculin and contribute to vinculin-mediated mechanosensing. This is a first report of the comparison of Sorbs proteins using cell lines expressing a single Sorbs protein and purified Sorbs proteins.

P1425**Board Number: B874****Desmoplastic 3D-adhesion structures orchestrate a tumor-associated ECM induced myofibroblastic phenotype.**J. Franco-Barraza¹, T. Luong¹, N. Shah¹, R. Madhani¹, G. Cukierman², K. Alpaugh¹, K. Devarajan¹, J. Hoffman¹, R. Uzzo¹, E. Dulaimi¹, E. Cukierman¹;¹Fox Chase Cancer Center, Philadelphia, PA, ²University of North Carolina, Chapel Hill, NC

The desmoplastic microenvironment plays a pivotal role in tumor development/progression. This fibrotic niche is produced by myofibroblastic cells and is commonly observed in tumors such as pancreatic adenocarcinoma (PDAC) and renal cell carcinoma (RCC). We have shown that quiescent fibroblasts become activated, undergoing a desmoplastic (i.e., myofibroblastic) phenotypic switch triggered by tumor-associated (TA) but not by normal fibroblast-derived extracellular matrix (ECM). However, the molecular mechanisms responsible for this process remain unclear.

Using syngeneic human fibroblasts harvested from patient-matched normal and tumor samples, we produced a human mimetic pancreatic and renal 3D stromal system to study the role of myofibroblastic activator TGF β and ECM integrin receptors $\alpha_v\beta_5$ and $\alpha_5\beta_1$ in the TA-ECM-induced phenotypic switch. We assessed the role of known integrin downstream effectors, non-receptor tyrosine kinases FAK and Src, and tested their roles in the observed TA-ECM-induced phenotypic switch. Approaches included the use of specific inhibitor and activator drugs as well as genetic manipulations. Our data suggest that while TGF β is indeed needed for the production of the particular TA-ECM, it is no longer required during the matrix induction of the phenotypic switch. Results suggest a cross-talk between integrins $\alpha_v\beta_5$ and $\alpha_5\beta_1$ necessary for maintaining the phenotypic switch.

We uncovered a mechanism whereby $\alpha_v\beta_5$ -integrin activity, in a Src/FAK-dependent manner, triggers the redistribution of FAK-independent $\alpha_5\beta_1$ -integrin activity away from desmoplastic 3D-adhesion structures. This in turn prevents this integrin from inhibiting the TA-ECM-dependent phenotypic switch. To validate the *in vitro* results, we used a multi-fluorescent labeling approach to simultaneously detect tumoral vs. stromal compartments and question the localization and activity levels of $\alpha_5\beta_1$ -integrin in the original pathological tissue samples. Finally to establish clinical relevance, the same approach was combined with a novel computational code applied, as a batch analysis, on a large human renal and pancreatic tissue cohort.

We conclude that outcome-predictive and TGF β -dependent matrix-induced stroma activation is maintained by Src/FAK-dependent $\alpha_v\beta_5$ -integrin activity. This activity triggers the exclusion of myofibroblastic-inhibitory and FAK-independent $\alpha_5\beta_1$ -integrin activity from altered 3D-adhesions. We propose that this desmoplastic mechanism may not only comprise a clinically important occurrence but also a new bio-marker to assess stromal index in cancer patients.

P1426**Board Number: B875****Pro-Leu-Gly hydroxamate inhibited adhesion and differentiation of CD133+CD44+ prostate cancer stem cells via Rho associated Kinase1 (ROCK1) and Focal Adhesion Kinase (FAK) pathway.**S. Rentala¹;¹GITAM University, Department of Biotechnology (GIT), Visakhapatnam, India

Prostate cancer has become a global health concern and is one of the leading causes of cancer death of men after lung and gastric cancers. In this study, we examined whether Pro-Leu-Gly hydroxamate, an inhibitor of Matrix metalloproteinases (MMPs) has any effect on adhesion and differentiation of prostate cancer stem cells. To this end, we analyzed the influence of Pro-Leu-Gly hydroxamate on the cell adhesion and differentiation of CD133+CD44+ cells derived from prostate cancer biopsies and peripheral blood. CD133+CD44+ cells were treated with Pro-Leu-Gly hydroxamate (20 - 50 μ M) for different time periods. Cell adhesion to endothelial cell monolayers and differentiation into prostate cancer cells were evaluated. α 1, β 1 and α 2 β 1 integrins adhesion receptors and the Rho-dependent kinase (ROCK) and focal adhesion kinase (FAK) were analyzed by Western blot. Further blocking studies with the ROCK inhibitor H1152, anti-FAK antibody and anti-integrin α 1 and β 1 antibodies were carried out. Pro-Leu-Gly hydroxamate treatment inhibited dose-dependently cell attachment to endothelium and differentiation. The inhibitory effect of Pro-Leu-Gly hydroxamate on cell adhesion was associated with decreased expression of integrins α 1 and β 1 and phosphorylated MYPT1 and FAK. Furthermore, Pro-Leu-Gly hydroxamate strongly reduced ROCK1 and FAK mediated differentiation of CD133+CD44+ cells, which was confirmed by antibody treatment. Pro-Leu-Gly hydroxamate modified the expression of cell adhesion molecules and differentiation markers. These beneficial effects of Pro-Leu-Gly hydroxamate may be mediated by ROCK and FAK signaling pathway. The data presented may point to novel treatment options for prostate cancer

P1427**Board Number: B876****Characterization of the mechanotransduction in response to the secreted protein Netrin-1.**K. Uriot¹, P. Girard¹, M. Coppey-Moisan¹, O. Faklaris¹, F. Lam¹, O. Blanc¹;¹Institut Jacques Monod, Paris, France

Netrin-1 is a secreted protein known to attract neurons expressing the membrane receptor DCC (Deleted in colorectal cancer) during nervous system development. However, Netrin-1 is present in many tissues where it interacts with plasma membranes and proteins of the extracellular matrix such as heparin. Thus, it can modulate cell adhesion and migration and notably in colorectal epithelia where Netrin-1 is secreted at the basis of the crypt and DCC is present at the surface of the villi where they

have been implicated in carcinogenesis. Moreover, Netrin-1 has been shown to interact with integrins alpha6beta4 and alpha3beta1. Since DCC as well as integrins can directly bind to FAK (Focal Adhesion Kinase ; known for its role in mechanical responses) and potentially lead to its phosphorylation, we propose to decipher the molecular mechanisms leading to Netrin-1-induced mechanotransduction by the mean of different mutants. At the cell level, we evaluate the ability of the protein to diffuse toward and to bind to its receptors in colorectal cell lines or in primary neurons. At the single molecule level, we mimic the immobilization of Netrin-1 on coated substrates and we observe how certain domain deletions impact on DCC dynamics in the plasma membrane when we control the interaction Netrin-1/integrins and Netrin-1/DCC. To do so, we use superresolution microscopy in 3D (PALM/dSTORM) or in live (sptPALM). Moreover, we evaluate the importance of integrins and other force-transducing partners such as FAK or actin in DCC-expressing cells in order to characterize how mechanotransduction is involved in Netrin-1 signaling in cancer and during development.

The extracellular matrix (ECM) affects many aspects of cell growth and behavior. Not only do cells respond to the composition of the ECM, but they also respond to its physical properties. In a seminal paper, Pelham and Wang observed that cells develop large integrin-based adhesions on rigid surface, whereas on soft substrate adhesions remain immature and small. Since this cellular response to ECM stiffness is central in various aspects of biology, from physiology to disease, many efforts have been directed recently to understand how cells “sense” and respond to the stiffness of their environment. However this remains, so far, an open question. In this study, we investigated the role of micro RNAs (miRNAs) in the cellular response to matrix rigidity. Comparing miRNAs expression in fibroblast cultured on soft (1kPa) and stiff substrates (25kPa), we observed that ECM rigidity induced a decrease in miR-625# and miR-206 expression. Interestingly, inhibition of myosin II increased miR-625# and miR-206 expression, indicating that cell-generated tension regulates miR-206 and miR-625# expression. Previous work have shown that fibronectin is a direct target of miR-206, consistent with this we found that miR-206 expression in cells cultured on stiff substrates decreased fibronectin expression. Additionally, we found that miR-625# expression decreased cell spreading and survival on rigid ECM. These data indicate that miR-206 and miR-625# regulate the cellular response to ECM rigidity. We are currently pursuing this work to identify miR-625# targets which impact cell adhesion and survival.

P1429**Board Number: B878****Compliance-dependent Extracellular Matrix Remodeling in Salivary Gland Morphogenesis.**S.B. Peters¹, D.A. Nelson¹, M. Larsen¹;¹Biological Science, University at Albany, SUNY, Albany, NY

Mechanical properties of the microenvironment regulate cell morphology and differentiation within complex organs. However, the mechanisms through which mechanical signals are translated within a tissue are poorly understood. Using mouse submandibular salivary gland organ explants that are mechanically sensitive, we investigated whether alterations in the extracellular matrix and basement membrane occur as the organ responds to changes in extracellular compliance. We examined the assembled, DOC-insoluble extracellular matrix (ECM) in organ explants that were grown on polyacrylamide gels having high compliance (similar to in vivo embryonic conditions), low compliance (i.e. high stiffness, similar to pathologic conditions) and in explants that were grown at low compliance for 72 hours and then transferred to high compliance gels for 24 hours, which we referred to as “mechanical rescue.” ECM assembly was disrupted in the glands grown at low compliance compared to those grown at high compliance, which was evident by thinner BM around the proacini. Incomplete clefts, indicative of defective morphogenesis, were also detected in glands at low compliance, which correlated with a decrease in the myoepithelial cell marker protein, smooth muscle α -actin. Mechanically rescued glands demonstrated a substantial recovery of the basement membrane and cleft progression, together with an increase in myoepithelial cell differentiation. We detected a basal accumulation of active integrin b1 in the differentiating myoepithelial cells that formed a continuous peripheral localization around the proacini, as well as localizing in clefts within active sites of morphogenesis, in explants that were grown at high compliance or that were mechanically rescued. This activation of integrin b1 in clefts and adjacent to the basement membrane in proacini was interrupted in explants grown at low compliance. Exogenous TGFb1 delivered to glands grown at low compliance stimulated ECM and basement membrane assembly and localization of active integrin b1 in the myoepithelial cells, while inhibition of TGFb receptor signaling with SB431542 during mechanical rescue prevented restoration of ECM/basement membrane, myoepithelial cell differentiation, and localized integrin b1 activation. These results indicate that ECM and basement membrane assembly and myoepithelial differentiation are compliance-dependent during salivary gland development. Further, our results indicate that TGFb-signaling is required for this compliance-dependent tissue remodeling, which may require integrin b1 activation. Supported by NIH/NIDCR R21DE02184101 and R01DE022467.

P1430**Board Number: B879****Role of the fibronectin synergy site in modulating integrin recruitment and molecular-scale force generation.**A.C. Chang¹, A.H. Mekhdjian¹, M. Morimatsu¹, A.R. Dunn¹;¹Chemical Engineering, Stanford University, Stanford, CA

Integrins are heterodimeric transmembrane adhesion receptors that connect the cell to the extracellular matrix, and play central roles in transducing mechanical cues into intracellular signaling cascades that control cell migration, differentiation, and survival. Mammalian cells possess at least 24 integrin heterodimers. In most cases, the molecular mechanisms by which different integrins fulfill their distinct physiological roles remain poorly understood. In particular, relatively little is known about how different integrin heterodimers may function in the context of mechanotransduction. Here, we use single-molecule fluorescent molecular tension sensors (MTSs) to measure the forces experienced by $\alpha_5\beta_1$ and α_v -class integrins, two classes of fibronectin-binding integrins that are thought to play distinct roles in cell adhesion and mechanotransduction. We developed MTSs that incorporate the full 9th and 10th type III fibronectin domains, here termed MTS_{FN9-10}. Importantly, these probes include a secondary binding site, termed the synergy site, which is specifically required for maximal binding strength and activation for $\alpha_5\beta_1$ but not α_v -containing integrins. We observe that fibroblasts seeded on MTS_{FN9-10} form large, plaque-like adhesions rich in $\alpha_5\beta_1$ integrins, a phenotype that is lost in the absence of a functional synergy site. At the single-molecule level, preliminary data indicate that the force per integrin lies between 1 to 5 pN for cells adhering to MTS_{FN9-10}-coated surfaces, a range similar to that observed for cells adhering to MTSs containing only a linear RGD binding epitope. In ongoing work, we use MTS_{FN9-10} and related probes to parse out the contributions of the synergy site to traction force generation and force sensing at both $\alpha_5\beta_1$ and α_v -containing integrin complexes.

P1431**Board Number: B880****Rigidity sensing by tropomyosin-regulated nanometer steps in local contractions.**H. Wolfenson¹, G. Meacci¹, S. Liu¹, M.R. Stachowiak², T. Iskratsch¹, S. Ghassemi¹, P. Roca-Cusachs^{3,4}, B. O'Shaughnessy², J. Hone¹, M.P. Sheetz^{5,6};¹Columbia University, New York, NY, ²Department of Chemical Engineering, Columbia University, New York, NY, ³Institute for Bioengineering of Catalonia (IBEC), Barcelona, Spain, ⁴University of Barcelona, Barcelona, Spain, ⁵Mechanobiology Institute, National University of Singapore, Singapore, NY, ⁶Biological Sciences, Columbia University, New York, NY

The rigidity of the extracellular matrix (ECM) affects processes such as cell migration, apoptosis, proliferation, and differentiation. To sense the rigidity of the ECM, the leading edge of the cell protrudes forward, encounters a new matrix, and pulls on it via nascent integrin adhesions. At its most basic sense, rigidity sensing is taken as the decision to reinforce the adhesions during the initial period of force

application. Thus, with increased rigidity, cells build stronger adhesions that can withstand higher forces. This indicates the existence of a tight regulation mechanism between rigidity, force production, and adhesion reinforcement, all occurring at the sub-micrometer level within a short time window of up to few tens of seconds. However, it is unknown how this rigidity/force feedback loop is regulated. Addressing this question requires ultra-high resolution analysis of cellular forces, both in time and space. Thus, in the current work, we measured myosin force production within cells at the nanometer and millisecond level during rigidity sensing. Using arrays of Polydimethylsiloxane (PDMS) micropillars as substrates for spreading of mouse embryonic fibroblasts, we found that local contractile units that bear resemblance to sarcomeres pulled opposing pillars in nano-level myosin-II-generated step-wise contractions. Surprisingly, cells produced the same step size of 2.1-2.4 nm, regardless of rigidity. What correlated with rigidity was the number of steps taken before reaching a ~20 pN force level, which activated the recruitment of α -actinin to the pillars. The constant step size suggested a structural restriction for the myosin motors; indeed, when we knocked-down tropomyosin-1 (a known a regulatory protein that wraps around actin filaments), the step-wise movements were dramatically altered and larger steps were observed. Further, after tropomyosin-1 knock-down, the cells could not sense the rigidity properly, indicating that tropomyosin-1 is directly involved in rigidity sensing. Importantly, tropomyosin-1 was previously implicated as a tumor suppressor whose extremely low expression levels in malignant cells allows them to grow on soft agar (i.e., anchorage-independent growth). When we tested a non-malignant vs. malignant cell line, we verified that the absence of tropomyosin correlated with higher forces, suggesting that anchorage-independent growth depends upon the production of high forces that activate the signaling cascades required for proliferation even on soft matrices.

Integrin-beta3 clusters recruit clathrin-mediated endocytic machinery in the absence of traction force.

C. Yu^{1,2}, A. Krishnasamy², M.P. Sheetz^{3,4};

¹Department of Anatomy, The University of Hong Kong, Hong Kong, Hong Kong, ²Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ³Mechanobiology Institute, National University of Singapore, Singapore, NY, ⁴Biological Sciences, Columbia University, New York, NY

Matrix-integrin activation triggers cell adhesion. Force development at integrins can differentially regulate adaptor protein recruitment, and micro-partitioned RGD-membrane provides a unique substrate to study force-dependent signal transduction. Previously, we have used RGD-membrane to investigate initial activation of integrin clustering and podosome formation. Here we report that clathrin-associated adaptor protein Dab2 progressively binds to integrin-beta3 after 20-min of cell adhesion on mobile RGD-membrane. When a single cell adheres on the substrate with both mobile and immobile ligands, Dab2 is preferentially recruited to integrin-beta3 at mobile RGD regions. Intriguingly, Dab2 is mutually excluded with other integrin-binding proteins, including talin, kindlin, focal adhesion

kinase, paxillin, and vinculin. Point mutations of tyrosine residues of integrin-beta3 block Dab2 binding. Increase cellular contractility by RhoA-Q63L and phospho-mimic MRLC mutant impedes Dab2 recruitment on mobile RGD membrane. More importantly, decrease myosin-II activity by blebbistatin promotes Dab2 binding to integrin-beta3 on immobile matrices. As a result, Dab2 recruits clathrin-mediated endocytic machinery and results in RGD-integrin endocytosis. We propose that absence of traction force causes recruitment of Dab2/clathrin and endocytosis of integrin-beta3.

Low adhesive scaffold collagen, inducing spheroid formation, promotes the cell crawling of fibroblasts.

S. Kunii¹, Y. Horiuchi², K. Morimoto¹;

¹Biology-Oriented Science and Technology, Kindai University, Kinokawa, Japan, ²Kindai University Faculty of Medicine, Kindai University, Osakasayama, Japan

[Background] Fibroblasts exist in the connective tissues and are generally separated by extracellular matrices (ECMs). One of functions in fibroblast is synthesis, secretion, and deposition of the ECM proteins such as collagen molecules. In addition, fibroblasts can migrate in connective tissues for remodeling and renewal. In vitro, we observe that cell crawling, associated with the actin polymerization, is a highly complex integrated process. However, the molecular mechanism of crawling still remains to be clarified. We succeeded in developing low adhesive scaffold type I collagen (LASCOL) by enzyme treatment (patent pending), and we found that fibroblasts cultured on LASCOL spontaneously form an aggregated sphere body (spheroid). In this study, we report the cell motility and the expression patterns of mRNAs of fibroblast spheroid. [Materials & Methods] We purchased pepsin-treated collagen (Pep-Col) and obtained LASCOL by enzyme treatment of pig type I collagen. The culture dish (φ35 mm) was coated with LASCOL solution or Pep-Col solution. Subsequently, mouse NIH/3T3 cells or normal human dermal fibroblasts (NHDF) were cultured on each dish. After 24 hrs, to confirm spheroid formation, we observed cell morphology by using a phase-contrast microscope. To investigate the cell motility, we stained filamentous actin (F-actin) with DyLight 555-labeled phalloidin. To further clarify the relationship between spheroid formation and epithelial mesenchymal transition (EMT), we stained spheroid with DyLight 555-labeled polyclonal antibodies specific against EMT molecular markers. Finally, cell crawling was monitored for a period of 24 hrs and analyzed by a time-lapse observation with a VW-9000PC software (KEYENCE, Japan). [Results] Each of NIH/3T3 and NHDF cells formed the spheroid morphology by culturing on the LASCOL scaffold. By SEM observation, single cells cultured on Pep-Col adhered strongly on the scaffold, showing flat and smooth appearance. In contrast, we showed that a lot of protrusions existed on the surface of NIH/3T3 cells of spheroid. F-actin was highly expressed in each cell of spheroid, as compared with a single flat cell. Interestingly, the crawling rate was drastically accelerated by formation of spheroid. In conclusion, we demonstrated that the adherence of fibroblasts to the LASCOL scaffold is weak, and cells gather and adhere each other to form spheroid. [Funding] This

work was supported by Adaptable and Seamless Technology Transfer Program through target-driven R&D, Japan Science and Technology Agency (AS2414037P to K.M.).

ECM Stiffness Enhances Integrin Signaling to Alter Tumor Cell Metabolism.

L.D. Cassereau¹, J.K. Mouw¹, M. Barnes¹, J. Lakins¹, V.M. Weaver¹;

¹Center for Tissue Engineering and Regenerative Medicine, University of California, San Francisco, San Francisco, CA

Tumors exhibit altered cellular metabolism supportive of continuous cell growth. Nevertheless, the fundamental molecular mechanisms through which altered metabolism regulate tumor behavior remain unclear. We previously demonstrated that elevated ECM stiffness and epithelial cell tension drive squamous carcinoma and mammary transformation, identifying integrin signaling as a key conduit of ECM mechanical cues and a potent regulator of pro-tumorigenic signaling. We hypothesized that elevated ECM stiffness potentiates cell metabolism by increasing the expression and activity of key metabolic targets driven by enhanced pro-tumorigenic signaling via integrin activity to regulate malignant progression. To test this hypothesis, we profiled metabolic markers using a combination of H1 NMR, quantitative RT-PCR, immunoblotting and immunofluorescence of MMTV-PyMT transgenic tumors (\pm ECM crosslinking) and breast tumor mammary epithelial cells grown on tunable hydrogel substrates in vitro. To determine the role of integrin signaling, we inhibited integrin signaling used small molecule inhibitors and, conversely, facilitated integrin signaling through ectopic expression of a β 1 integrin clustering construct. We used pharmacological inhibitors targeting glucose uptake, glycolysis, lactate transport, or oxidative phosphorylation to assess the interplay between ECM stiffness, metabolism and tumor cell behavior, including invasion, migration, and proliferation. Our data suggests that ECM stiffening induced elevated tumor cell glycolysis downstream of integrin signaling by targeting key regulators of glycolysis such as the glucose and lactate transporters and lactate dehydrogenase. Additionally, inhibitors of metabolism abrogated tumor cell proliferation and invasion in vitro and in vivo. These data suggest that elevated ECM stiffness drives tumor progression through modulation of tumor cell metabolism. Additional studies are underway to further clarify how ECM-driven metabolic dysregulation drives tumor behavior.

P1435**Board Number: B884****Integrin Signaling via Traction Forces Regulates Early Endoderm Specification.**H. Taylor-Weiner¹, N. Ravi¹, A.J. Engler¹;¹Bioengineering, University of California, San Diego, La Jolla, CA

Morphogenic events during early development, including gastrulation, require force-mediated motility and coincide with initial fate specification of embryonic stem cells (ESCs), resulting in the formation of the definitive endoderm (DE) and mesoderm layers of the trilaminar embryo. Pluripotency also inhibits contractility, suggesting a switch that is initiated upon differentiation. However, the onset of contractility during differentiation and whether integrin-signaling regulates fate choices is not well understood. To address the requirement of traction forces for differentiation, we examined mouse ESCs grown in DE inductive medium on fibrillar fibronectin labeled with a FRET probe to assess deformation. We found that inhibition of contractility via blebbistatin, an inhibitor of non-muscle myosin, prevented expression of the DE marker SOX17. When blebbistatin was removed, DE induction medium was sufficient to activate ESC traction forces, resulting in a decrease in the observed fibronectin FRET intensity ratio. By contrast ESCs grown in pluripotency medium did not exert significant tractions against the FN matrix. Laminin isoforms have been reported to improve DE induction efficiency, but it is not clear whether traction forces mediate this effect. Mouse ESCs grown in DE inductive medium on fibrillar matrices with varying amounts of laminin-111 decreased their fibronectin traction forces in a laminin-dependent manner, suggesting preferential binding to laminin over fibronectin. When the laminin-binding alpha3 integrin was blocked, TGF-beta signaling was inhibited by increased Smad7 expression, and the laminin effects on traction forces and differentiation were reversed. These data imply that traction forces and integrin-signaling are important regulators of early fate decisions in ESCs.

P1436**Board Number: B885****DNA nanostructures as a nanometer-scaled patterned substrate for controlling cell adhesion.**J. Fern¹, D. Kim², D. Wirtz^{2,3}, R. Schulman^{1,4};

¹Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, ²Physical Sciences-Oncology Center, Johns Hopkins University, Baltimore, MD, ³Department of Pathology and Oncology and Sydney Kimmel Comprehensive Cancer Center, Johns Hopkins University School of Medicine, Baltimore, MD, ⁴Computer Science, Johns Hopkins University, Baltimore, MD

Integrins and other cell surface receptors involved in cell adhesion play a crucial role in cancer cell migration, survival and tumor resistance to anti-cancer pharmaceuticals [1]. Knowledge of how these receptors sense multiple signals in the extracellular environment to influence cell adhesion and migration is important to understanding tissue organization as well as how failures in these organizational processes underlie disease [1]. One of the most salient features of the sensing process is

that cells are sensitive not only to types of chemical cues but also to, among other properties, the density of chemical ligands and their spacing at the nano- and microscale [2]. These interactions have been elucidated by studies in which these variables are tightly controlled and easy to observe within the cell's environment. Currently, most studies investigating how cells integrate integrin signals use only a single type of adhesion peptide (e.g. RGD) or full extracellular matrix proteins such as collagen or fibronectin [2]. In the latter case, multiple ligands are presented to cells, but their density and spacing are difficult to control. To understand quantitatively how cells integrate information about multiple ligands, there is a need for an assay enabling control over the nanoscale spacing and density of different types of cell adhesion ligands within a single environment.

We have developed a method to control the density and nanoscale spacing of multiple types of ligands using two-dimensional DNA origami nanostructures. The DNA origami method involves folding a long single strand of DNA into a specified structure using multiple short DNA strands into a 2 nm-high template structure bearing about 200-250 DNA sequence addressable binding sites for peptides and other small molecules such that the binding sites' positions are known to a 3-6 nm resolution [3]. The DNA origami structures we have can position peptide ligands on a surface with controlled density and nanoscale spacing. Fluorophores on the DNA origami enable these ligands to be localized precisely and biotins attached to the templates anchor the structures securely to PEGylated coverslips using Neutraavidin-biotin binding chemistry.

As a proof of concept, we show that mouse embryonic fibroblast (MEF) cells bind specifically to DNA origami nanostructure substrates that present RGD ligands and not to DNA origami nanostructures with no attached ligands or to PEG surfaces alone. For origami nanostructures presenting RGD ligands, the fraction of cells that spread as well as their average area is controlled by DNA nanostructure/RGD surface density. Future studies will investigate how nanostructures with a heterogeneous nanopattern of cell adhesion ligands influence the cell adhesion process.

Stiff substrates enhance leukocyte recruitment from fluid flow.

J.L. MacKay¹, D.A. Hammer^{2,3};

¹Bioengineering, University of Pennsylvania, Philadelphia, PA, ²Department of Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA, ³Department of Bioengineering, University of Pennsylvania, Philadelphia, PA

Many inflammatory diseases such as atherosclerosis, obesity, and diabetes, are driven by the excessive recruitment of circulating monocytes, which differentiate into macrophages and can promote chronic

inflammation. Monocytes exit the bloodstream through a multistep process called the leukocyte adhesion cascade, in which they first attach to endothelial cells by binding selectins, then roll across the endothelium until integrin-based adhesions promote cell arrest, and finally they transmigrate through the vessel wall. This process has been widely studied both in vitro and in vivo and is known to depend on both shear stress and protein density. However, very little is known about whether the stiffness of vessel walls could also play a role in leukocyte adhesion, which is surprising given that arterial stiffening is a known predictor of cardiovascular mortality and increases with age, smoking, obesity, and diabetes. In addition, stiff substrates have been shown to strengthen integrin-based adhesions in cells under static conditions (without fluid flow), and both selectins and integrins are known to exhibit force-dependent, catch bond behavior. In this study, we investigated whether substrate stiffness could directly alter the adhesion of monocytes from flow by using an in vitro model for blood flow, in which human monocytic THP1 cells were perfused across polyacrylamide gels with elastic moduli ranging from that of healthy arteries (1-5 kPa) to diseased arteries (24-84 kPa). To enable cell attachment, the gels were functionalized with prescribed densities of recombinant P-selectin or E-selectin, which both bind the ligand PSGL-1 on the surface of leukocytes. Interestingly, we found that cell attachment from fluid flow (at 100s^{-1}) did not depend on substrate stiffness when the gels were coated with P-selectin alone. On the other hand, coating gels with E-selectin revealed a strong dependence on substrate stiffness, in which more cells attached to stiff gels than soft gels. In addition, stiff gels supported firm cell arrest at high E-selectin densities, while soft gels promoted continuous cell rolling. These contrasting results of stiffness-independent adhesion through P-selectin binding and stiffness-dependent adhesion through E-selectin binding may be due to the fact that E-selectin engages other ligands besides PSGL1, including CD44 and ESL-1. Another possibility is that structural differences between P-selectin and E-selectin lead to different force-dependent bond behavior. Overall, our results demonstrate that E-selectin-mediated capture of THP1 cells from flow is enhanced by substrate stiffness, while P-selectin-mediated capture is stiffness-independent. The goal of future work is to investigate whether this also holds true for primary leukocytes.

Cell Biological Analysis of VRK1 and its Role in Regulating Cell Proliferation and Migration.

A. Mon¹, P. Traktman²;

¹Microbiology and Molecular Genetics, Medical College of Wisconsin, Milwaukee, WI, ²Microbiology and Molecular Genetics, Med Coll Wisconsin, Milwaukee, WI

Vaccinia-related kinase (VRK1) is a nuclear ser/thr kinase that is considered to be “pro-proliferative”; it is highly expressed in proliferative tissues and several cancers. Moreover, VRK1 expression turns off as cells enter G0 and as mammary epithelial cells form differentiated, non-proliferative acini in 3D culture. We have shown that VRK1 depletion significantly slows proliferation of both normal and malignant mammary epithelial cells in 2D culture. Furthermore, VRK1 has been identified by others as one of the

22 genes whose expression is down-regulated during normal acinus formation in a 3D culture system. Our lab has also shown that depletion of VRK1 in malignant MDA-MB-231 cells reduces tumor size and the incidence of distal metastases in engrafted mice.

VRK1 has been identified as part of a 19 gene signature whose overexpression is correlated with poor prognosis in a subset of breast cancers. We have taken several approaches to the analysis of how constitutive and/or elevated VRK1 expression might alter cell behavior. We have studied control MCF10a cells and a matched cell line that constitutively expresses elevated levels of 3xFlag-VRK1 from a CMV promoter. In conventional 2D culture, VRK1 overexpression did not affect the proliferation rate of cells cultured in either 5% or 0.25% serum. However, in 3D culture, we found that VRK1-overexpressing MCF-10a cells form enlarged and distorted acini compared to control cells. These data suggest that VRK1 overexpression may modulate cellular survival, proliferation, polarity and/or migration in the presence of an extracellular matrix (ECM). Our recent microarray analysis of control vs. VRK1-overexpressing cells revealed that several proteins involved in cell:cell and cell:matrix interactions, as well as proteins involved in cell migration, are upregulated in VRK1-overexpressing cells. We have examined the potential roles of VRK1 in adhesion and spreading in the absence or presence of ECM proteins (collagen, fibronectin, laminin). We observed that VRK1 overexpression slows the rate of cell spreading, although it has no impact on cell adhesion. Finally, we assessed cell migration in vitro using a wound healing assay; surprisingly, we found that overexpression of 3xFlag-VRK1 significantly decreased the rate of sheet migration. In sum, we conclude that VRK1 overexpression can exert an influence on cell proliferation, spreading and migration, which may have its contribution to tumorigenesis.

Integrins and dystroglycan compensate each other to mediate BM assembly and epiblast morphogenesis.

J. Hsu¹, Y. Qi², J. Liu¹, S. Li³, P.D. Yurchenco⁴;

¹Department of Surgery and Pathology, Rutgers University Robert Wood Johnson Medical School, New Brunswick, NJ, ²Rutgers-Robert Wood Johnson Med Sch, New Brunswick, NJ, ³Robert Wood Johnson Med Sch, New Brunswick, NJ, ⁴Rutgers-RW Johnson Med Sch, Piscataway, NJ

Cell-extracellular matrix (ECM) interactions in general, and cell-basement membrane (BM) interactions in particular, regulate cell survival, proliferation, differentiation and polarity, which are all essential for tissue development and maintenance. Integrin and dystroglycan (DG) are major cell surface receptors that link the BM to the actin cytoskeleton. Integrins also activate intracellular signaling pathways. While it has been previously thought that DG primarily serves as a mechanical link, there are data that argue for a signaling role as well. However, identification of unique signaling roles arising from DG has been hampered because of compensation from integrin contributions. This question has been particularly difficult to study in tissues because of the presence of several classes of interacting integrins. In our studies of BM-receptor interactions during epithelial morphogenesis, we employ embryonic stem (ES) cell-derived embryoid bodies (EBs). EB tissue is structurally similar to the peri-implantation embryo

tissue. We found that ablation of integrin beta1 blocks endoderm formation and BM assembly. Treatment of integrin beta1-null EBs with 100 microg/ml laminin-111 induces the assembly of a BM on the EB surface and promotes epiblast differentiation and polarization without recruitment of “focal adhesion” proteins to the cell-BM interface. The data strongly indicate that DG is capable of mediating epithelial differentiation in the complete absence of integrins. To test this hypothesis, we generated integrin beta1/DG double knockout ES cells. Analysis of EB differentiation demonstrated that ablation of both integrin beta1 and DG completely eliminates laminin-induced BM assembly and epiblast epithelial differentiation. Blocking experiments using alpha-DG neutralizing antibody that recognizes the ligand-binding carbohydrate epitope suggest that the BM-DG interaction is required for epiblast polarization. In addition, incubation of integrin beta1-null EBs with laminin and F3, a laminin alpha1-agrin hybrid protein that enhances laminin-DG interactions, significantly increases BM assembly. Altogether, these results suggest that integrins and DG compensate each other to mediate BM assembly and epiblast differentiation. The ligand binding activity of DG is required for its functions in the absence of integrins.

Cell traction force and mechanosensing in cell–substrate interaction.

S. He¹, Y. Su², B. Ji¹, H. Gao³;

¹Biomechanics and Biomaterials Laboratory, Department of Applied Mechanics, Beijing Institute of Technology, Beijing, China, ²Northwestern University, Evanston, United States, ³Brown University, Providence, United States

Cells constantly probe their surrounding microenvironment by pushing and pulling on the extracellular matrix (ECM). While it is widely accepted that cell induced traction forces at the cell-matrix interface play essential roles in cell signaling, cell migration and tissue morphogenesis, a number of puzzling questions remain with respect to mechanosensing in cell-substrate interactions. Here we show that these open questions can be addressed by modeling the cell-substrate system as a pre-strained elastic disk attached to an elastic substrate via molecular bonds at the interface. Based on this model, we establish analytical and numerical solutions for the displacement and stress fields in both cell and substrate, as well as traction forces at the cell-substrate interface. We show that the cell traction generally increases with distance away from the cell center and that the traction-distance relationship changes from linear on soft substrates to exponential on stiff substrates. These results indicate that cell adhesion and migration behaviors can be regulated by cell shape and substrate stiffness. Our analysis also reveals that the cell traction increases linearly with substrate stiffness on soft substrates but then levels off to a constant value on stiff substrates. This biphasic behavior in the dependence of cell traction on substrate stiffness immediately sheds light on an existing debate on whether cells sense mechanical force or deformation when interacting with their surroundings. Finally, it is shown that the cell induced deformation field decays exponentially with distance away from the cell. The characteristic length of this decay is comparable to the cell size and provides a quantitative measure of how far cells feel into the ECM.

P1441**Board Number: B890****Axo-glia interaction preceding CNS myelination is regulated by bidirectional Eph-ephrin signaling.**L.S. Laursen¹, C. Linneberg¹;¹Department of Molecularbiology and Genetics, Aarhus University, Aarhus, Denmark

In the central nervous system, myelination of axons is required to ensure fast saltatory conduction and for survival of neurons. However, not all axons are myelinated, and the molecular mechanisms involved in guiding the oligodendrocyte processes towards the axons to be myelinated are not well understood. Only a few negative or positive guidance clues that are involved in regulating axo-glia interaction prior to myelination have been identified. One example is laminin, known to be required for early axo-glia interaction, which functions through $\alpha6\beta1$ integrin. Here we identify the Eph-ephrin family of guidance receptors as novel regulators of the initial axo-glia interaction, preceding myelination. We demonstrate that so-called forward and reverse signaling, mediated by members of both Eph and ephrin subfamilies, has distinct and opposing effects on processes extension and myelin sheet formation. EphA forward signaling inhibits oligodendrocyte process extension and myelin sheet formation, and blocking of bidirectional signaling through this receptor enhances myelination. Similarly, EphB forward signaling also reduces myelin membrane formation, but in contrast to EphA forward signaling, this occurs in an integrin-dependent manner, which can be reversed by overexpression of a constitutive active $\beta1$ -integrin. Furthermore, ephrin-B reverse signaling induced by EphA4 or EphB1 enhances myelin sheet formation. Combined, this suggests that the Eph-ephrin receptors are important mediators of bidirectional signaling between axons and oligodendrocytes. It further implies that balancing Eph-ephrin forward and reverse signaling is important in the selection process of axons to be myelinated.

P1442**Board Number: B891****Rupture behaviors of receptor-ligand bond at ultralow loading rate.**D. Li¹, B. Ji¹;¹Biomechanics and Biomaterials Laboratory, Department of Applied Mechanics, Beijing Institute of Technology, Beijing, China

The rupture behaviors of molecular bonds at the ultralow loading rates have recently intrigued intensive attentions because of its scientific importance as well as its distinct features compared with those at the faster loading rates. It was observed that many so-called “mechanical” proteins exhibit a nonzero asymptotic strength limit of unfolding at a vanishing loading rate. And the mean rupture force of single receptor-ligand bond shows a similar asymptotic manner. This study is to understand the rupture behaviors of molecular bond at ultralow loading rate by using both theoretical analyses and Brownian dynamic simulations. We showed that when the loading rate is smaller than a critical value the rupture force becomes no longer dependent on the loading rate, implying a nonzero strength of molecular bond at a quasi-static loading. We found that this saturation behavior is caused by bond rebinding at the ultralow loading rate. We further derived an analytical solution of the limiting loading rate below which the bond rebinding dominates the rupture process. This solution will assist us to determine which DFS data are valid for calculating the properties of energy landscape by fitting the $F \sim \ln(Kv)$ plot using conventional methods, and thus to improve the predictions. It would also provide guidelines for preparing DFS experiments and simulations on how to choose the loading rates according to the stiffness of loading devices.

Cell–Cell Junctions 2**P1443****Board Number: B892****Unraveling the Life and Times of Gap Junctions: Comparison of Gap Junction Structures with High Resolution, Transmission and Light Microscopy.**S.A. Murray¹, M.M. Steed², T.I. Shakespeare³, B. Nickel¹, M.E. Bisher¹;¹Cell Biology, Univ Pittsburgh Sch Med, Pittsburgh, PA, ²Biology, Winston-Salem State University, Winston-Salem, NC, ³Biology, Fort Valley State Univ, Fort Valley, GA

In most of the cells of the body, cellular function is thought to be modulated by cell-cell communication through gap junction channels. This communication is regulated by the rate of delivery of gap junction channel proteins to the plasma membrane, gap junction channel assembly, aggregation of these

channels into gap junction plaques, the subsequent opening or closing of these channels and the removal of these channels from the cell surface. It is clear that channels can be removed by internalization of the entire gap junction plaques or fragments of the plaques by an endocytosis process that results in the formation of spherical annular gap junction vesicles. To unravel the molecular machinery needed for formation, endocytosis and the processing of annular gap junctions, reliable and efficient methods for visualizing and distinguishing gap junction structures are critical. In this study, we use conventional and high resolution light microscopy, transmission electron microscopy, and time lapse imaging to positively identify gap junction structures and to characterize the details of their formation, internalization to form annular gap junctions, and the intricate processing needed for degradation. In the past, gap junction puncta seen with conventional immunocytochemical light microscopy have been classified as annular gap junctions mainly based on the size of the puncta. Here we demonstrate that size alone is not enough to distinguish annular gap junction vesicles from secretory vesicles and establish that some of the vesicles that would have been classified as secretory vesicles are really annular gap junctions. Annular gap junctions were shown to undergo a unique fission process that results in the release of small buds from the vesicle as well as in some cases the division of the annular gap junction vesicle into two smaller vesicles. Information on the processing of annular gap junction vesicles is critical to the understanding of gap junction turnover and degradation. Methods to analyze the details of annular gap junction processing will add in our understanding of gap junction function. Grants: NSF #MCB-1408986 and #NIH 5T36GM008622

The structure and activity of the gap junction Nexus signaling complex is regulated by the C-terminus of connexins.

R.F. Stout Jr.¹, D.C. Spray¹;

¹Dominic P. Purpura Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY

Gap junction connections perform both essential channel and non-channel functions. These functions are regulated by posttranslational modifications that are primarily applied to the carboxyl-termini (CT) of connexins that comprise the dodecameric gap junction channels. The different connexins vary widely in the amino acid sequences and length of their cytoplasm-localized CTs. Connexin CTs bind numerous other proteins, where binding depends on the CT sequence and on posttranslational modifications. Gap junctions and their binding partners, therefore, make up a specialized signaling structure that we termed the Nexus.

We report new aspects of the gap junction Nexus that we uncovered using fluorescence recovery after photobleach (FRAP) and other imaging techniques. Specifically, we found that the amino acid residues within the CT of connexin 43 (Cx43) beyond amino acid 257 are necessary and sufficient to establish an extremely stable arrangement of gap junction channels within the plaque. Analysis of mobility of connexin sectional deletions, single amino acid mutations, and hybrid connexin-type mutant channels

with live confocal microscopy revealed that a cysteine residue at position 260 (of 381 total amino acids) is sufficient to stabilize the Nexus.

Cysteine residues in the CT of other receptors and channels regulate the formation of membrane-associated structures (e.g. aquaporins and glutamate receptor subunits). The extreme CT of Cx32 has been previously reported to be palmitoylated. Therefore, we used FRAP to compare the mobility of other connexins with potentially palmitoylated cysteines (Cx32 and Cx47) in the CT and those without cysteine residues in the CT (Cx26 and 30) fused to new-generation fluorescent proteins in conjunction with the FRAP technique. We will continue to test the hypothesis that palmitoylation controls Nexus stability using pharmacological inhibitors of palmitoylation.

These findings are very clearly demonstrated through both qualitative and quantitative analysis of FRAP experiments and other optical techniques. This includes quantitative analysis of four dimensional microscopy with FRAP experimentation and video representations of time-lapse 3D reconstruction of photoconvertible proteins within the Nexus.

Gold Nanoparticle-Mediated Laser Perforation as a New Method to Analyze Dye Transfer and Gap Junctional Coupling.

D. Begandt¹, A. Bader¹, R. Lorbeer², M. Schomaker², S. Kalies², H. Meyer², A. Ngezahayo^{1,3};

¹Institute of Biophysics, Leibniz University Hannover, Hannover, Germany, ²Biomedical Optics Department, Laser Zentrum Hannover e. V., Hannover, Germany, ³Center for Systems Neuroscience Hannover, University of Veterinary Medicine Hannover, Hannover, Germany

We present the possibility to use the gold nanoparticle-mediated (GNOME) laser perforation (LP) method for a quantitative high throughput analysis of gap junction coupling in a cell monolayer as an advantageous alternative to the scrape loading/dye transfer (SL/DT) technique. During SL/DT membrane impermeable but gap junction permeable dyes like Lucifer Yellow (LY) are introduced into a cell monolayer by the mechanical opening of cells with a sharp razor. During GNOME LP, the interaction of a laser beam with large, membrane-adhered gold nanoparticles (200 nm) results in a heat-generated effect which leads to the permeabilization of cell membranes, thereby allowing the introduction of the dye into the cells. In our experiments, we applied the laser beam with 88 μm in diameter on GM-7373 endothelial cells grown to a monolayer on a tissue culture dish. After LY incubation we observed a LY positive cell band of 179 μm . The width of this LY positive cell band was reduced to 95 μm when the cells were treated with carbenoxolone (CBX) indicating that a) inhibition of diffusion through gap junctions only leads to LY-loaded cells encompassed by the laser beam and b) the large band of LY positive cells observed in absence of CBX was due to dye diffusion through gap junctions. Moreover, a forskolin-induced enhancement of gap junction coupling previously shown by the mechanical SL/DT

could be observed using the GNOME LP. Taken together, the results show that the GNOME LP can be used to study the cellular gap junction coupling, similar to SL/DT. The GNOME LP offers the advantage that it can be performed by a computerized system when cells cultivated in a multiwell plate are mounted onto an automatized microscope stage. Additionally, the fluorescence imaging can be performed automatically and is followed by a semi-automatic quantification of the images using a java-based ImageJ plugin. The automation of the process represents a gain of time and accuracy in experimentation that could not be achieved for mechanic SL/DT experiments because of the variability of the mechanical scraping. Furthermore, the usage of SL/DT technique is limited only to cells that strongly adhere to the culture surface. The permeabilization of the cells by GNOME LP is a non-contact process and could be applied on cells such as the rat brain endothelial cells RBE-4, which form a monolayer that did not support the mechanical SL/DT. Taken together the report shows that the GNOME LP is a promising technique for a high throughput analysis of gap junction coupling in cell monolayers.

Fusion to fluorescent proteins causes previously unrecognized effects on gap junction mobility and Nexus arrangement.

R.F. Stout Jr.¹, D.C. Spray¹;

¹Dominic P. Purpura Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY

Gap junctions are comprised of connexins that form channels connecting adjacent cells. They also act as the core of a signaling complex called the Nexus. Much insight into the structure and dynamic morphology of the Nexus has been gained from the use of electron and optical microscopy. Fluorescent protein fusions to connexins are important tools for studying the unusually rapid, responsive, and regulated cycle of connexin production, channel formation, channel regulation and degradation.

We used connexin-fluorescent protein fusions with live confocal microscopy to perform fluorescence recovery after photobleach (FRAP) experiments. We used new-generation fluorescent proteins to reveal two previously unrecognized qualitative characteristics of the Nexus: A) Plaque formation does not require plaque stability; B) Mixing of different connexin types within the Nexus is affected by the type and site-of-attachment of fluorescent proteins. Specifically, we find that the degree of mixing of different gap junction types varies not only with connexin type as previously described, but also varies according to the fusion-site of the fluorescent protein tag. We found that two immobile connexins can remain separated into distinct parts of the same gap junction plaque, as previously described. However, when we co-transfected stable connexin 43 (Cx43) with more mobile connexins (superfolderGFP-Cx30 or Cx26-mVenus, and others) the gap junctions mixed when included in the same gap junction Nexus structure.

We found that Cx26 and Cx30 gap junctions are significantly more mobile than Cx43. We also found that Cx26 is significantly more mobile when tagged by the monomerized superfolderGFP (msfGFP) variant

(V207K) than the non-monmerized superfolder (GFP 43.5+/-10% and 6+/-2% normalized FRAP at 30 seconds post-bleach for Cx26-msfGFP and Cx26-sfGFP, respectively). This effect was attenuated but still significant when the fluorescent protein tag is fused to the N-terminus of Cx26 instead of the C-terminus. The effects of the fluorescent protein tag were similar for Cx30. However, Cx43 displays very little or no mobility regardless of fluorescent protein type or site of fusion to a fluorescent protein.

We used several methods to quantitatively compare the mobility of gap junctions using data generated in FRAP experiments. We find that the unique morphology of the Nexus requires that results obtained through standard single focal plane FRAP experimentation be verified by 3D-timelapse imaging. These results have major implications for our understanding of the gap junction Nexus structure. Supported by the following grants 5T32NS007439-14, NS041282.

K63-linked poly-ubiquitination and phosphorylation: signals that regulate connexin43 gap junction turnover.

R.K. Andrews¹, M.M. Falk¹;

¹Biological Sciences, Lehigh University, Bethlehem, PA

Intercellular communication is a vital function for cellular homeostasis. Gap junctions (GJs) serve as a mechanism for cell-cell communication, physically coupling cells together and allowing small molecules to pass from cell to cell. Connexin (Cx) proteins are the transmembrane components of GJs. It is known that connexin 43 (Cx43) GJs are regulated via ubiquitination and phosphorylation. Ubiquitination is a post translational modification in which one or more 8.5 kDa ubiquitin (Ub) moieties are covalently attached to lysines on target proteins and is characterized by us and others on GJs and internalized GJ vesicles (annular GJs) (Rutz & Hulser 2001; Leithe & Rivedal 2004; Girão et al. 2009, Ribeiro-Rodrigues et al. 2014). Different types of ubiquitination can target proteins and protein complexes to cellular degradation pathways (e.g. K48-linked, proteasomal; K63-linked, clathrin-mediated endocytosis, endo-/lysosomal, autophagosomal). Phosphorylation of Cx43 has been shown to be a regulatory mechanism for Cx43 trafficking, GJ assembly, gating and GJ internalization and degradation (Lampe & Lau, 2004; Warn-Cramer & Lau, 2004; King & Lampe, 2005; Laird, 2005; Moreno, 2005; Solan & Lampe, 2005; 2007; 2009). These phosphorylation events lead to conformational changes within the C-terminus of Cx43 that may allow for regulatory protein binding. Little is known about what types of Ub modify Cx43 and how ubiquitination and phosphorylation coordinate to regulate GJ internalization and degradation. Using immunological and biochemical analyses we show that Cx43 is K63-polyubiquitinated in both GJs and annular GJs in cells expressing Cx43 endogenously (PAEC) and exogenously (HeLa, MDCK). Mutating specific lysines within the C-terminus of Cx43 leads to significant increases in total plasma membrane GJ number, half-life and phosphorylation, indicating GJ internalization impairment. Cx43 K to R mutants exhibit increases in several critical serine phosphorylations, indicating a prerequisite of both phosphorylation and K63-polyUb for internalization. We hypothesize that K63-linked polyubiquitination of Cx43 following phosphorylation is necessary for internalization and autophagic degradation of GJs.

P1448**Board Number: B897****Expression and Regulation of Connexins under “Inflammatory” state: Communication between Human Intestinal Epithelial Cells and Immune Cells.**S. Ghadban¹, M.E. El-Sabban²;¹Anatomy, Cell Biology and Physiological Sciences, American Univ Beirut, Beirut, Lebanon, ²American Univ Beirut, Beirut, Lebanon

Inflammatory bowel diseases (IBD) are related to functional impairment of intestinal epithelial cells (IECs) due to infiltration of the sub-mucosa by inflammatory cells. Three essential mechanisms may contribute to the induction of this state: (i) soluble mediators secreted by inflammatory cells, (ii) direct adhesion and signaling molecules expressed on the surface of immune cells and epithelial cells and (iii) cytoplasmic exchange of specific signals between the inflammatory cells and IECs via gap junction (GJ) channels. We explored the nature of the interaction between human IECs and macrophages (MΦ) in an in vitro model of IBD. We investigated the role of inflammatory cells in inducing IECs Matrix Metalloproteinases (MMPs) as a mechanism that results in breaching the sub-epithelial basement membrane and bringing inflammatory cells in close proximity with IECs. We then identified potential adhesion molecules and connexins (Cxs) involved in intercellular communication and studied the effect of inflammatory mediators on connexins expression at the transcriptional, protein, cellular localization, and functional levels. IECs and MΦ express Cx26, Cx43, and Cx45; however, Cx32 was only expressed in IECs. Connexin 26 and Cx43 expression and MMPs enzymatic activity were significantly up regulated in IECs under inflammatory conditions, which re-sulted in enhanced functional IECs-MΦ intercellular communication. We propose that the combination of paracrine and hetero-cellular communication between IECs and MΦs play a pivotal role in the regulation of epithelial cell function by establishing junctional complexes between inflammatory cells and IECs that might stabilize leakiness of intestinal epithelial barrier function.

P1449**Board Number: B898****Signals and Mechanisms Regulating Endocytosis Across the Connexin Protein Family.**C.G. Fisher¹, M.M. Falk¹;¹Biological Sciences, Lehigh University, Bethlehem, PA

Gap junctions are clusters of channels that directly connect the cytoplasm of apposing cells and permit the passage of hydrophilic molecules less than approximately 1.5kD in size. The channels are comprised of proteins called connexins (Cxs) which are four-pass transmembrane spanning proteins with their N- and C-termini residing in the cytoplasm. Twenty-one connexins exist in the human genome and are

expressed tissue specifically. In terms of controlling cell-cell communication, recent research has shown that the regulated endocytosis of gap junctions is as important for their function as the ability of cells to open and close existing channels; and that mis-regulated gap junction endocytosis can cause disease. Thus it is crucial to understand how and under what conditions cells use endocytosis to remove gap junctions from the plasma membrane. Previous work has shown that Connexin43 (Cx43), the most commonly expressed Cx, utilizes the clathrin-mediated-endocytosis (CME) pathway, mediated by the clathrin adaptor AP-2, to internalize gap junctions (Piehl et al. 2007, Gumpert et al. 2008, Fong et al. 2013). AP-2 interacts with Cx43 via motifs called tyrosine based sorting signals of which two appear and are used in the Cx43 C-terminus (Fong et al. 2013). In addition, Cx43 is ubiquitinated in a K63-linked pattern, and this ubiquitination is also important for endocytosis (Ribeiro-Rodrigues et al. 2014; Kells and Falk, unpublished). Cx43 is the only Cx whose endocytic mechanism has been studied in detail. Whether the clathrin-mediated internalization mechanism is common or unique throughout the Cx protein family remains to be investigated. It is feasible to speculate that other Cxs utilize other endocytosis strategies or do not undergo endocytosis on their own at all.

We conducted sequence analyses across all Cx subtypes to search for predicted endocytic motifs, that either exhibit known tyrosine (Y-X-X-Φ), or di-leucine (D/E-x-x-x-L-L/I) based sorting signals (Bonifacino & Traub 2003). Using the BLAST search tool we were able to group Cxs into 4 categories, either exhibiting different combinations of the above described canonical sorting signals, or not. Cx family members that do not display canonical endocytic motifs (such as Cx26), may be internalized using an ubiquitin, CLASP- (not AP-2) based pathway. Preliminary studies on Cx26 GJs indicate that they can undergo endocytosis, that they are ubiquitinated, and that they may use an alternative CLASP for endocytosis. Additional functional studies will further examine the role of clathrin and ubiquitin in Cx26 endocytosis and will characterize the endocytosis mechanisms and protein components that may be utilized by other representative Cx family members.

Connexin43 phosphorylation by PKC and MAPK signals gap junction internalization.

W. Nimlamool¹, M.M. Falk¹;

¹Biological Sciences, Lehigh University, Bethlehem, PA

Gap junctions (GJs) are specialized domains in the plasma membrane that consist of clusters of channels that allow direct intercellular communication between neighboring cells. These channels permit ions and small molecules to be transferred from cell-to-cell. Gap junction-mediated intercellular communication (GJIC) is crucial for normal cell function, including coordination of development, tissue homeostasis, growth and differentiation. Moreover, aberrant function of GJs and reduction of cell-cell coupling via GJs has been associated with many pathological conditions, including neuropathies, hearing loss, cataracts, craniofacial anomalies and cancer. GJs exhibit a complex modus of assembly and degradation to maintain balanced intercellular communication. Several growth factors as well as

natural inflammatory mediators, including vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), thrombin and endothelin have been reported to disrupt cell-cell junctions and to abolish GJIC. VEGF directly stimulates VEGF-receptor tyrosine kinases on endothelial cell surfaces. Exposing primary porcine pulmonary artery endothelial cells (PAECs) to VEGF for 15 minutes resulted in a rapid and almost complete loss of connexin43 (Cx43) GJs at cell-cell appositions and a concomitant increase in cytoplasmic, vesicular Cx43. After prolonged incubation periods (60 minutes), Cx43 GJs reformed and intracellular Cx43 restored to levels observed before treatment. These dynamic internalization and relocation events correlated with efficient inhibition of GJIC, up to 3.8-fold increased phosphorylation of Cx43 serine residues 255, 262, 279/282, and 368, and depended on clathrin-mediated endocytosis. Phosphorylation of serines 255, 262, 279/282 was mediated by MAPK, while serine 368-phosphorylation was mediated by PKC. Pharmacological inhibition of both signaling pathways significantly reduced Cx43 phosphorylation and GJ internalization. Together, our results indicate that growth factors, such as VEGF activate a hierarchical kinase program -including MAPK and PKC- that induces GJ internalization via phosphorylation of well-known regulatory amino acid residues located in the Cx43 C-terminal tail.

A novel Panx1-Crmp2 interaction impacts Panx1 surface expression in neural cells.

L.E. Wicki-Stordeur¹, A.K. Boyce¹, M.S. Kim¹, L.A. Swayne¹;

¹Division of Medical Sciences, University of Victoria, Victoria, BC

Pannexins are four-pass transmembrane proteins that oligomerize to form large-pore channels permeable to ions and metabolites, such as adenosine triphosphate (ATP), of up to 1 kDa. We previously demonstrated that Pannexin 1 (Panx1) promotes neural cell proliferation, at least in part through release of ATP and downstream purinergic receptor signaling. Moreover, we found that Panx1 promotes neural cell migration and inhibits neuronal differentiation. In fact, Panx1 levels are significantly reduced upon neuronal differentiation, and pharmacological block of Panx1 causes dramatic neurite outgrowth. To determine the specific molecular players mediating these roles for Panx1 in neural cells, we performed an unbiased proteomics screen for protein interaction partners using immunoprecipitation coupled to liquid chromatography and tandem mass spectrometry (LC-MS/MS). Here we present data validating and exploring the functional aspects of a specific Panx1-protein interaction with Collapsin Response Mediator Protein 2 (Crmp2). Crmp2 is specifically enriched in the nervous system where it acts as a microtubule binding protein and regulator of growth cone dynamics and neuronal differentiation. We demonstrate that Panx1 and Crmp2 interact both *in vitro*, and *in vivo* in developing and mature neurons. Further, Panx1 preferentially associates with Crmp2 that is un-phosphorylated at the Rho-kinase site, and this interaction appears to be important for Panx1 plasma membrane expression. Finally, using a competitive peptide strategy we find that interfering with the Panx1-Crmp2 interaction alters neural cell behaviors. Overall, we present several novel findings that transform and expand our current understanding of the cellular role of Panx1 in the brain.

P1452**Board Number: B901****Stimulus-evoked internalization of Pannexin 1 channels.**A.K. Boyce¹, L.E. Wicki-Stordeur¹, R.T. Prager¹, M.S. Kim¹, P.C. Nahirney¹, L.A. Swayne¹;¹Division of Medical Sciences, University of Victoria, Victoria, BC

Pannexin 1 (Panx1) is a large pore ion and metabolite permeable channel that is capable of permeating molecules up to 1kDa in size (including ATP). Panx1 has been linked to both neural cell proliferation in the healthy brain and neuronal death in pathological scenarios. To date, exploration of its function has been primarily restricted to its role at the plasma membrane; however, it also localizes to intracellular compartments. We therefore investigated whether the tight regulation of the cell surface versus intracellular Panx1 equilibrium is key for maintaining cell viability. Our first major objective was to definitively characterize the intracellular localization. Initially, confocal microscopy experiments suggested endosomal and nuclear membrane distribution. We confirmed nuclear membrane expression of Panx1 using subcellular fractionation and electron microscopy. We sought to elucidate the mechanism by which Panx1 localizes to these internal membranes because an increase in extracellular ATP causes Panx1 internalization. Interestingly, elevated extracellular ATP inhibits Panx1 activity and ATP is episodically released from neural cells under physiological conditions. Next, to explore retrograde trafficking, we transiently inhibited de novo protein synthesis (and therefore anterograde trafficking) then stimulated with ATP and other stimuli known to modulate Panx1 activity and/or cellular excitability. Using a combination of live and fixed cell confocal imaging, complemented with subcellular fractionation, we show striking evidence for ATP-induced internalization of Panx1 from the plasma membrane with concomitant increase in early endosome and nuclear membrane distribution. We provide additional evidence that the trafficking of Panx1 to the nuclear membranes is critical for cell survival. Our findings suggest that ATP-evoked Panx1 internalization occurs in physiological conditions and would increase in pathological conditions, when extracellular ATP is significantly elevated. ATP-evoked internalization of Panx1 to the nucleus provides an additional mechanism for Panx1 to modulate neural cell proliferation and viability.

P1453**Board Number: B902****Permeability properties of pannexin1 hemichannels activated by mechanical stress.**M. Subiabre¹, C. Puebla¹, A. Vargas¹, P. Fernandez¹, J.C. Saez^{1,2};¹Pontificia Universidad Catolica de Chile, Santiago, Chile, ²Instituto Milenio, CINV, Valparaiso, Valparaiso, Chile

Pannexins (Panx) constitute a protein family with three members (Panx1-3) with little homology to innexins and without homology to connexins. In vertebrates, they are ubiquitously expressed and play

critical roles in numerous physiological and pathological cell responses. Panx1 hemichannels are permeable to ions and small molecules but their permeability features remain controversial and require further characterization. Panx1 hemichannels can be activated via purinergic receptors or membrane stretching. Here, we characterized several features of Panx1 hemichannels. We used HeLa parental cells (HeLa-P) or HeLa cells transfected with Panx1. RT-PCR analyses revealed absence of Panx2 and Panx3. Hemichannels were activated by membrane stretching induced by falling drops of extracellular saline solution. The cell uptake of 4',6-diamidino-2-phenylindol (MW: 350, DAPI(+2)), ethidium (MW: 394, Etd(+)) bromide, propidium iodide (MW: 668, PI(+2)) or Evans blue (MW: 961, EB(-4)) was monitored in time-lapse experiments. Panx1 hemichannels were neither activated by extracellular divalent cations-free solution nor inhibited by La(3+). However, they were activated by mechanical stress and inhibited by carbenoxolone (5 μ M). The uptake showed a Michaelis-Menten behavior with characteristic K_m for each dye. HeLa-Panx1 cells did not present PI(2+) uptake and uptake of all dyes was absent in HeLa-P cells. Therefore, Panx1 hemichannels present low permeability to cationic molecules and are highly permeable to anionic molecules.

Complex Mechanisms Regulate the Gap Junction Coupling of Blood-Brain Barrier Endothelial Cells by Adenosine Receptor Stimulation.

A. Bader¹, D. Begandt¹, W. Bintig², A. Ngezahayo^{1,3};

¹Institute of Biophysics, Leibniz University Hannover, Hannover, Germany, ²Charité Universitätsmedizin Berlin, Berlin, Germany, ³Center for Systems Neuroscience Hannover, University of Veterinary Medicine Hannover, Hannover, Germany

The human cerebral microvascular endothelial cell line hCMEC/D3 is an accepted *in vitro* model of the endothelial cells of the blood-brain barrier (BBB). Recent data have shown that regulation of gap junction coupling in cerebral endothelial cells could be related to blood-brain barrier function. In our project, PCR experiments showed that the hCMEC/D3 cells expressed the adenosine receptor subtypes A₁, A_{2A} and A_{2B} as well as connexin37 (Cx37), Cx40, Cx43 and Cx45. The adenosine receptor agonist 2-phenylaminoadenosine (2-PAA) stimulated synthesis of cAMP in hCMEC/D3 cells, indicating that the receptor molecules were present in the cell membrane. Additionally, 2-PAA enhanced the gap junction coupling as shown by scrape loading/dye transfer experiments. The diffusion distance of Lucifer Yellow in hCMEC/D3 cells was increased from 66 μ m to 87 μ m by 5 μ M 2-PAA applied for 1 h. The increase achieved a maximum of 95 μ m after application of 20 μ M 2-PAA. The inhibitor of the A_{2B} adenosine receptor subtype, MRS1754 reduced the 2-PAA-related enhancement of the gap junction coupling back to control levels, whereas the inhibitor of the A_{2A} receptor subtype, SCH58261 could not significantly suppress the effect of 2-PAA on gap junction coupling. This indicates that the A_{2B} receptor subtype is predominantly involved in the regulation of gap junction coupling of the hCMEC/D3 cells. The inhibitor of the protein kinase A (PKA), Rp-cAMPS did not affect the 2-PAA-induced increase in gap junction

coupling while the activator of Epac, 8-pCPT-2'-O-Me-cAMP could not increase the gap junction coupling in the hCMEC/D3 cells. Interestingly, the 2-PAA-related enhancement of the gap junction coupling was significantly reduced if the drug was applied in absence of external Ca^{2+} or to cells preloaded with the Ca^{2+} chelator BAPTA. The results suggest that even if cAMP is produced by the stimulation of adenosine receptors in cerebral microvascular endothelial cells, the action on gap junction coupling does not only involve cAMP-activated proteins such as PKA or Epac but Ca^{2+} -dependent pathways are activated as well.

Distinct nano-scale organization of paired receptors at Natural Killer cell surfaces revealed by super-resolution microscopy.

A. Oszmiana¹, D. Williamson¹, S. Cordoba², D. Davis¹;

¹Manchester Collaborative Centre for Inflammation Research, University of Manchester, Manchester, United Kingdom, ²UCL Cancer Institute, University College London, London, United Kingdom

Human Natural Killer (NK) cells are regulated by a variety of germ-line encoded activating and inhibitory receptors. Broadly, activating receptors detect ligands that are expressed or up-regulated on cancerous or infected cells, while inhibitory receptors bind self-molecules to induce tolerance against healthy cells. Highly homologous pairs of activating and inhibitory receptors are also expressed on NK cells, including Killer Ig-like Receptors KIR2DL1 and KIR2DS1, which bind the same ligands, class I MHC proteins. With a view to understanding signal integration between these paired receptors, we used two super-resolution microscopy techniques - Ground State Depletion (GSD) and Stimulated Emission Depletion (STED) microscopy - to determine how KIR2DL1 and KIR2DS1 are organized on a nanometre-scale. Firstly, neither receptor was distributed randomly; both were observed to constitutively assemble in nanometre-scale clusters. $39 \pm 13\%$ of KIR2DS1 molecules were found in clusters, distributed at 3.5 ± 0.7 clusters/ μm^2 , while only $27 \pm 9\%$ of KIR2DL1 accumulated in clusters, at 8 ± 2 clusters/ μm^2 . Importantly, the activating receptor KIR2DS1 formed nano-clusters 2.4-fold larger (diameter 120 ± 13 nm) than its inhibitory counterpart KIR2DL1. The density of KIR2DS1 and KIR2DL1 within clusters was 7.5 and 4.5 fold greater than the average membrane density, respectively. Interestingly, clusters of KIR2DL1 and KIR2DS1 were significantly segregated from each other (with a negative Pearson's correlation coefficient). Thus, these data establish that paired NK cell receptors have a distinct nano-metre scale organisation at the cell surface which likely influences signalling; their segregation rules out models of signal integration which requires paired receptors to be juxtaposed to each other.

P1456**Board Number: B905****Triggering receptor expressed on myeloid cells1 (TREM-1) and innate immune responses to Plasmodium falciparum.**S. ADUKPO^{1,2}, P.G. KREMSNER², V.P. Thirumalaisamy²;¹IMMUNOLOGY, NOGUCHI MEMORIAL INSTITUTE FOR MEDICAL RESEARCH, ACCRA, Ghana, ²INSTITUTE FOR TROPICAL MEDICINE, UNIVERSITY OF TUEBINGEN, TUEBINGEN, Germany

Monocytes and Neutrophils mediate anti-malarial immune responses and release soluble factors including reactive oxygen species (ROS) that are toxic to the parasite. These inflammatory responses could be enhanced or dampened when certain receptors on immune cells are activated. Triggering receptor expressed on myeloid cells-1 (TREM-1) is a recently described trans-membrane and immune-regulatory receptor strongly expressed on neutrophils and in a subset of monocytes and macrophages. TREM-1 plays a central role in regulating innate immunity as it amplifies the inflammatory signals initiated by pathogen associated molecular pattern recognition receptors (PAMPs) such as Toll-like (TLR) and NACHT-LRRs. TREM-1 is of functional importance in a number of inflammatory diseases. Till-date, the involvement of TREM-1 in malaria pathogenesis is not investigated. We analyzed the effect of TREM-1 signaling on the responsiveness of Monocytes and Neutrophils to crude Plasmodium falciparum antigens and live parasites in the presence or absence of TREM-1 inhibitor. We co-incubated neutrophils and PBMCs with malaria antigens and subsequently measured ROS production over time by Chemiluminescence. Parasitaemia and parasite growth inhibition were also evaluated. Significant inhibition of ROS production was observed when TREM-1 was blocked. However no significant contribution to inhibition of P. falciparum growth was observed. In conclusion, TREM-1 was activated during interaction between Monocyte/Neutrophils and parasite but its activation does not seem to affect the growth of the P. falciparum in vitro.

P1457**Board Number: B906****Dysregulation of nectin-2 in the testicular cells: an explanation of cadmium-induced male infertility.**W. Lui¹, X. Zhang¹;¹School of Biological Sciences, University of Hong Kong, Hong Kong, Hong Kong

Nectin-2, a junction molecule, is found at the basal and apical ectoplasmic specializations (ES) for the formation of the blood-testis barrier (BTB) (constituted by tight junctions and basal ES) and Sertoli-spermatid adhesion. Loss of nectin-2 causes male infertility, suggesting nectin-2-based ES is crucial for spermatogenesis. Cadmium (Cd) has been known to induce severe testicular injury. Recent evidence has shown that the basal ES at the BTB and apical ES are the targets of Cd, suggesting that unique junction protein at the ES may explain why the testis is more susceptible than other tissues. Since nectin-2 is

expressed exclusively at the ES, it is highly possible that nectin-2 is the direct target of Cd. In this study, we investigate if nectin-2 is the target protein of Cd toxicity and the mechanism on how Cd down-regulates nectin-2 to achieve ES disruption. Our results revealed that Cd suppresses nectin-2 at transcriptional and post-translational levels. Inhibitor and shRNA knockdown have shown that Cd induces nectin-2 protein degradation via clathrin-dependent endocytosis. Immunofluorescence staining and endocytosis assays further confirmed that nectin-2 internalization is promoted upon Cd treatment. Besides, Cd directly represses nectin-2 transcription. EMSA and ChIP assays showed that Cd inhibits the binding of positive regulators to nectin-2 promoter. siRNA and overexpression analyses have demonstrated that Cd reduces the expression and binding affinity of positive regulators for transcription. Taken together, nectin-2 is the direct molecular target of Cd and its disruptive effects is mediated via direct repressing nectin-2 transcription and inducing endocytosis of nectin-2 for degradation.

High levels of glucose modulate tight junction-associated epithelial barrier function of renal tubular cell line: possible implication in diabetic nephropathy.

R.B. Oliveira¹, L.P. Canuto¹, B.M. Mongelli¹, C.B. Collares-Buzato¹;

¹Department of Biochemistry and Tissue Biology, University of Campinas (UNICAMP), Campinas - SP, Brazil

Type 2 diabetes mellitus (T2DM) is one of the most prevalent diseases worldwide. Diabetic nephropathy (DN) is a complication of diabetes and the mechanisms associated with the onset and progression of this disease is not fully understood. It has been shown that hyperglycemia is an independent factor to predict the development of DN in individuals with T2DM, however the mechanisms involved in kidney injuries associated with high plasma glucose levels remain unknown. In the present study, we investigated the in vitro effect of high levels of glucose (i.e. 180 or 360mg/dL) up to 24h upon epithelial barrier integrity of the kidney tubular cell line, MDCK. High levels of glucose (180 and 360 mg/dL) induced a tendency of decrease in transepithelial electrical resistance (TER) associated with subtle increase in epithelial paracellular permeability, as assessed by phenol red transepithelial flux, when compared to the control group (exposed to 100mg/dL glucose). Immunofluorescence analyses showed that glucose treatment induced a significant decrease in the tight junctional content of Claudin-1 as well as a significant increase in Claudin-2 and Occludin. The analyses of cell content of these junctional proteins by Western Blot corroborate the immunofluorescence data. Our data suggest that high levels of glucose induce changes in TJ structure in MDCK monolayers, suggesting a possible link between hyperglycemia-induced tubular epithelial barrier disruption and diabetic nephropathy. Financial support: FAPESP/Brazil (#2013/15767-0).

P1459**Board Number: B908****Towards identifying the mechanism by which Anillin localizes to cell-cell junctions and regulates junction integrity.**C.C. Reyes¹, A.L. Miller²;¹Program in Cellular and Molecular Biology, University of Michigan, Ann Arbor, MI, ²Department of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI

Anillin is a scaffolding protein that organizes and stabilizes actomyosin contractile rings and was previously thought to function primarily in cytokinesis. Using *Xenopus laevis* embryos as a model system to examine Anillin's role in the intact vertebrate epithelium, we recently identified a novel role for Anillin in regulating epithelial cell-cell junctions¹. We found that a population of Anillin surprisingly localizes to epithelial cell-cell junctions throughout the cell cycle where it plays a critical role in regulating cell-cell junction integrity. Both tight junctions and adherens junctions are disrupted when Anillin is knocked down, leading to abnormal intercellular spaces and increased permeability to fluorescent dextran. Anillin was known to interact with RhoA, F-actin, and Myosin II, all of which regulate cell-cell junction structure and function. Junctional F-actin and Myosin II accumulation are reduced when Anillin is knocked down and increased when Anillin is overexpressed. Additionally, increased dynamic "flares" of RhoA-GTP are observed at cell-cell junctions when Anillin is knocked down. We propose that Anillin is required for proper RhoA-GTP distribution at cell-cell junctions and for maintenance of a robust apical actomyosin belt, which are required for cell-cell junction integrity. Current work seeks to determine where Anillin localizes with respect to tight junctions and adherens junctions, how Anillin is targeted to cell-cell junctions, and which domains of Anillin are responsible for proper regulation of cell-cell junction structure and function.

Focal Adhesions and Invadosomes**P1460****Board Number: B909****Fetal Fibroblasts Exhibit Altered Mechanosensing Via Reduced Adhesion Formation and Force Production on Rigid Substrates.**A. Parekh¹, R. Jerrell¹;¹Department of Otolaryngology, Vanderbilt University Medical Center, Nashville, TN

In post-natal or "adult" dermal wound healing, fibroblasts mechanically sense ("mechanosense") rigidity and tension that develop in granulation tissue and differentiate into myofibroblasts. Myofibroblasts

generate large contractile forces that excessively contract and remodel the ECM resulting in scarring and fibrosis. In contrast, injured skin in the mammalian fetus heals scarlessly without myofibroblast involvement suggesting that smaller cellular forces contribute to regenerative repair. We have previously shown that populations of human dermal fetal fibroblasts significantly contract mechanically stressed type I collagen gels to a lesser extent than adult fibroblasts and exhibit less alpha-smooth muscle actin-rich stress fibers. These results suggest that fetal fibroblasts exhibit differential responses to matrix rigidity which normally induce myofibroblast differentiation in adult fibroblasts. Therefore, we hypothesized that fetal fibroblasts have intrinsically altered mechanosensing. Using polyacrylamide gels that mimic the different mechanical stages of wound healing that progressively induce myofibroblast differentiation, we tested whether a defect existed in focal adhesion maturation and contractile force generation in fetal fibroblasts in response to matrix rigidity. In comparison to adult fibroblasts, we found that initial adhesion formation and maturation in fetal fibroblasts after one hour is impaired on polyacrylamide gels that correspond to the rigidity of late stage granulation tissue. We also found a reduction in contractile forces exerted by fetal fibroblasts after overnight incubation on the same polyacrylamide gels. Therefore, our data suggest that fetal fibroblasts have altered mechanical responses to physiologic rigidities which may contribute to their lack of myofibroblast differentiation leading to scarless dermal healing.

Distribution of vinculin to lipid rafts is involved in sensing ECM stiffness.

A. Nagasato¹, H. Yamashita¹, M. Matsuo¹, K. Ueda^{2,3}, N. Kioka²;

¹Agriculture, Kyoto university, Kyoto, Japan, ²Agriculture, Kyoto University, Kyoto, Japan, ³iCeMS, Kyoto University, Kyoto, Japan

Extracellular matrix (ECM) is a key component of extracellular microenvironments, which are important for cell migration, proliferation and differentiation. In addition, ECM stiffness acts as a regulator of mesenchymal stem cell differentiation and lineage selection. Cells sense ECM stiffness through mesoscopic scale cell adhesion complexes, called focal adhesions (FAs). FAs consist of ECM receptors, integrins, which are connected to the ends of actin stress fibers through various cytoplasmic proteins, including talin and vinculin. Recently, our group has shown that interaction of vinculin with vinexin α , both of which are cytoplasmic FA proteins, play a critical role in sensing ECM stiffness and act as a mechanosensor in mouse embryonic fibroblasts (MEFs). Lipid rafts are membrane mesoscopic-domains where phosphatidylinositol 4,5-bisphosphate (PIP₂) and cholesterol are enriched. They have been implicated in diverse cellular processes including signal transduction. Here we investigated whether lipid rafts are involved in sensing ECM stiffness. First, we examined the distribution of vinculin to lipid rafts. Membrane fractions were extracted from WT MEFs and treated with 1% TritonX-100 at 4°C, followed by density-gradient ultracentrifugation. Certain part of vinculin and vinexin α were separated into the fractions containing flotillin, a raft maker protein. Furthermore, depletion of vinexin expression impaired distribution of vinculin to the raft fraction. Re-expression of vinexin α rescued the vinculin distribution,

indicating that vinculin α is necessary for vinculin distribution to the raft fraction. In addition, Mutation in the binding site for vinculin α also impaired the distribution of vinculin to the raft fraction, indicating that an interaction of vinculin with vinculin α is required for the distribution of vinculin to lipid rafts. Next we tested the effect of intracellular tension and ECM stiffness on the distribution of vinculin. Reducing intracellular tension by the treatment with blebbistatin, a myosin II inhibitor, decreased the distribution of vinculin to the raft fraction. Culturing on rigid ECM promoted the distribution of vinculin to the raft fraction compared to the culturing on soft ECM. These results suggest that intracellular tension and ECM stiffness are involved in the distribution of vinculin to lipid rafts. We previously reported that residence time of vinculin at FAs is important for sensing ECM stiffness. Thus we examined the effect of raft disruption on residence time of vinculin at FAs. Treatment with rafts-disrupting reagent (Methyl-beta-cyclodextrin) decreased the residence time of vinculin at FAs on rigid ECM. Taken together, these results suggest that distribution of vinculin to lipid rafts is involved in sensing ECM stiffness.

Fluctuation in Single Molecule Talin Stretching Correlates with Vinculin Binding in vivo.

X. Hu¹, F. Margadant²;

¹MechanoBiology Inst, Singapore, Singapore, ²MechanoBiology, Singapore, Singapore

Talin molecules in focal adhesions (FA) connect integrin to the actin network and recruit other FA proteins. They transmit and sense the forces between the extracellular matrix (ECM) and the cytoskeleton possibly by means of their cyclic stretching behavior in live cells. The stretching of an individual talin molecule exposes vinculin-binding sites on its rod domain and thereby welcomes the binding of vinculin which in consequence enhances the connection strength of the actin network to integrins. In a continuation of our previous study, employing multi-channel multi-molecule and single-molecule tracking techniques, we further explored the dynamic stretching behaviour of talin and its quantitative relationship to vinculin recruitment. Both the N terminus and C terminus of talin are cyclicly moving in a stretching event; the N terminus movement is due to the – possibly random - walk of integrin molecules and the C terminus movement is directly coupled to the actin flow. The talin stretching event correlates with vinculin recruitment both on the single molecule level and the photometry observation level. During a single talin dimer-stretching event in live cells, the method reported up to 12 vinculin molecules being recruited. With most of the vinculin binding events occurring in close proximity of the C terminus rather than the N terminus between the termini. In summary, the talin stretching recruitment events are correlated to the vinculin level in focal adhesions and multiple vinculins can bind to a single talin in the same cycle in live cells.

P1463**Board Number: B912****iPALM and FRET reveal the mechanism of vinculin activation and nano-scale spatial organization in focal adhesions.**L. Case¹, M. Baird², G. Shtengel³, S. Campbell⁴, H. Hess³, M.W. Davidson⁵, C. Waterman⁶;¹Cell Biology and Physiology Center, NHLBI/NIH, Bethesda, MD, ²Florida State University, Tallahassee, FL,³Janelia Farm, HHMI, Ashburn, VA, ⁴Biochemistry and Biophysics, UNC, Chapel Hill, NC, ⁵National High Magnetic Field Laboratory and Department of Biological Science, Florida State University, Tallahassee, FL, ⁶National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD

Focal adhesions (FAs) are multi-protein complexes that link the extracellular matrix (ECM) to the actin cytoskeleton to mediate cell adhesion, migration, mechanosensing and signaling. Previously, interferometric photoactivatable localization microscopy (“iPALM”), which uses single molecule localization to measure lateral position with ~20nm accuracy and interferometry to measure the axial position with ~10nm accuracy, revealed that FAs have a conserved laminar structure, with an integrin signaling layer (ISL) ~10-20 nm from the plasma membrane, an actin regulatory layer (ARL) ~100 nm from the membrane that extends into the stress fiber, and a force transduction layer (FTL) that spans the intervening space. However, it is unknown how the layered organization of proteins within focal adhesions contributes to the regulation of protein activity and function. Vinculin (Vcl) is a protein that undergoes a conformational change at focal adhesions to interact with multiple binding partners and regulate diverse cellular functions including protrusion, migration, mechanosensing and survival. Vcl has over 10 binding partners distributed throughout the FA including paxillin in the ISL, talin (Tln) in the FTL, and actin in the ARL. We hypothesized that the spatial compartmentalization of different binding partners into distinct FA layers contributes to Vcl activation, regulation and functional specificity at focal adhesions. To test this, we used point mutants to perturb specific protein interactions and assayed Vcl nanoscale localization and Vcl activation state at FAs. We used iPALM to image the 3D localization of vinculin molecules with nanometer accuracy as well as a FRET biosensor to assay vinculin conformational changes. By systematically perturbing specific protein interactions, we found that vinculin is recruited to the ISL in an inactive conformation by its interaction with paxillin. Subsequently, vinculin activation is mediated by talin and actin binding, and talin binding promotes vinculin association with the higher FTL and ARL. Active vinculin localizes ~10nm higher than inactive vinculin in FA. Vcl exhibits a gradient of low-to-high activation from the front-to-back of FA, and Vcl exhibits increased localization with the ARL in the back of FA. Finally, while Vcl is not required for the proper nanoscale localization of paxillin or actin, Vcl is required for Tln to be maintained in the maximally vertically extended conformation. By performing complimentary experiments with iPALM and FRET, we have been able to study the mechanism of vinculin activation on a structural level in a cellular setting. We propose that movement up the laminar FA structure facilitates Vcl activation and mechanical reinforcement of FA.

P1464**Board Number: B913****Role of Talin in Determining the Nanoscale Architecture of Focal Adhesions.**J. Liu¹, Y. Wang¹, W. Goh¹, H. Goh¹, M. Baird², M.W. Davidson³, P. Kanchanawong^{1,4};¹Mechanobiology Institute, Singapore, Singapore, ²Florida State University, Tallahassee, FL, ³National High Magnetic Field Laboratory and Department of Biological Science, Florida State University, Tallahassee, FL, ⁴National University of Singapore, Department of Biomedical Engineering, Singapore, Singapore

Focal adhesions (FAs) are integrin-based structures that mediate cell-extracellular matrix interactions, playing central roles in signaling, cell motility, and mechanotransduction. Although FAs has commonly been described and modeled as molecular machines, the interplay of ultrastructural, biophysical, and biochemical factors that underlie their multifunctional roles is still not well understood. Earlier, using superresolution microscopy we described the nanoscale architecture of FAs, in which several key proteins are stratified into nanoscale layers interposing between the integrin cytoplasmic tails and the actin cytoskeleton (Kanchanawong et al., Nature 2010). However, the molecular basis of how such nanoscale organization emerges remains poorly understood. Based on our prior observation that talin appears to be oriented in a polarized manner in FAs, with the N-terminus in the membrane-proximal zone and the C-terminus at the FA core/actin stress fiber interface, we hypothesize that talin may serve to regulate FA nanostructures. To test this, we constructed a series of talin analogues with lengths modified by partial deletions in the central rod domains, and performed superresolution imaging in conjunction with siRNA-mediated substitution of endogenous talin by such talin analogues. By probing the position of the N- or C- termini using fluorescent protein tags, we observed that the N-terminal position remains largely constant, while the C-terminal positions shifted downward in proportion to the molecular dimension, indicating that the talin analogues adopted an oriented organization similar to the full-length talin. Corresponding downshifts in the positions of the FA core/ actin stress fiber interface were also observed, suggesting that the FA core dimension may be controlled by the molecular dimension of the talin analogues. A lengthening modification by the insertion of a ~30-nm long FilaminaA segment resulted in the proportional upshifts of the C-terminal positions of the talin analogues in FAs, suggesting that talin modulates FA core dimension in a highly modular manner. Altogether, our results demonstrated how talin serves to determine the nanoscale architecture underlying the FA machinery through its molecular dimension, akin to a molecular ruler.

P1465**Board Number: B914****GEF-H1 controls focal adhesion signaling that regulates mesenchymal stem cell lineage commitment.**J. Kuo¹, I. Huang², C. Hsiao^{3,4}, J. Wu⁵, R. Shen⁶, C. Liu^{7,8}, Y. Wang^{9,10}, Y. Chen⁵, C. Huang⁵, J. Del Alamo¹¹, Z. Chang⁵, M. Tang¹², K. Focal adhesions (FAs) undergo maturation culminating in size and composition changes that modulate adhesion, cytoskeleton remodeling and differentiation. While it is well-recognized that stimuli for osteogenesis of mesenchymal stem cells (MSCs) drive FA maturation, actin organization, and stress-fiber polarization, the extent to which FA-mediated signals regulated by the FA protein composition specifies MSC commitment remains largely unknown. Here we demonstrate that, upon dexamethasone (osteogenic induction) treatment, guanine nucleotide exchange factor-H1 (GEF-H1) is significantly enriched in FAs. Perturbation of GEF-H1 inhibits FA formation, anisotropic stress-fiber orientation and MSC osteogenesis in an actomyosin contractility-independent manner. To determine the role of GEF-H1 in MSC osteogenesis, we explore the GEF-H1-modulated FA proteome that reveals non-muscle myosin-II heavy chain-B (NMIIB) as a target of GEF-H1 in FAs. Inhibition of targeting NMIIB into FAs suppresses FA formation, stress-fiber polarization, cell stiffness and osteogenic commitments in MSCs. Our data demonstrate FA signaling in specifying MSC commitment.

P1466**Board Number: B915****Autophagy regulates focal adhesion turnover in transformed cells.**C.M. Kenific¹, S. Stehbens², K. Woo¹, J. Ye¹, T. Wittmann³, J. Debnath¹;¹Department of Pathology, University of California, San Francisco, San Francisco, CA, ²QueenslandUniversity of Technology, Queensland, Australia, ³Department of Cell and Tissue Biology, University of

California, San Francisco, San Francisco, CA

Autophagy is a process of lysosomal-mediated degradation that has traditionally been viewed as a stress-adaptation pathway that promotes tumor cell survival. However, recent evidence suggests that

autophagy serves broader functions during cancer progression. Here, we demonstrate a new role for autophagy in regulating focal adhesion (FA) turnover in transformed cells.

Autophagy inhibition via RNAi-mediated depletion of essential autophagy regulators (ATGs) decreases single-cell migratory rate of cells in a wound healing assay, and wound edge cells have significantly enlarged FAs upon autophagy inhibition. Because FA assembly and disassembly, or turnover, regulates migratory rate we hypothesized that increased FA size was due to impaired FA turnover. Using spinning disk confocal (SDC) microscopy to image FA dynamics in live cells expressing Paxillin-mCherry, to mark FAs, we observed that ATG depletion decreased FA assembly and disassembly rates, while increasing FA lifetime, suggesting that stabilization of FAs upon autophagy inhibition impairs motility. To further analyze the relationship between autophagy and FAs, we determined if autophagosomes localize near FAs. Total internal reflection fluorescence microscopy of live cells revealed that autophagosomes, as marked by GFP-LC3, are found in proximity to FAs. Furthermore, SDC imaging showed that autophagosomes associate with dynamic FAs primarily during the disassembly phase of the turnover cycle.

Because autophagy is pathway of cellular degradation, these findings led us to hypothesize that autophagy facilitates FA disassembly by locally degrading FA components. To test this prediction, we focused on establishing if autophagy cargo receptors, which mediate selective autophagic degradation of cellular substrates by linking cargo to autophagosomes, modulate FA turnover. We found that similar to ATG depletion, knockdown of the cargo receptor NBR1 impairs FA turnover. Conversely, overexpression of NBR1 decreases FA lifetime, and GFP-NBR1 associates with dynamic FAs. These data suggest that NBR1-mediated selective autophagy controls FAs in transformed cells. We are now testing this model more rigorously using autophagy-defective mutants of NBR1.

In addition to regulating motility, cell-matrix adhesions also promote growth signals that drive metastatic colonization. Thus, enhanced cell-matrix adhesion due to increased FAs upon autophagy inhibition may support metastasis. Accordingly, ATG depletion in a polyoma middle T (PyMT) breast carcinoma cell line leads to enlarged FAs *in vitro* and enhanced pulmonary metastasis *in vivo*. We are now determining if increased cell-matrix adhesion is a mechanism by which autophagy inhibition potentiates metastasis and if NBR1 regulates metastasis of PyMT cells.

Differential Mechanisms of Matrix Degradation by Tumor Cells Versus Stromal Fibroblasts.

H. Cao¹, R. Eppinga^{1,2}, E.W. Krueger¹, J. Chen¹, G. Razidio², M.A. McNiven¹;

¹Mayo Clinic, Rochester, MN, ²BMB, Mayo Clinic, Rochester, MN

Metastatic invasion of tumors into peripheral tissues is known to rely upon protease-mediated degradation of the surrounding stroma. This remodeling process utilizes complex, actin-based,

specializations of the plasma membrane (PM) termed “invadopodia” that act to both sequester and release matrix metalloproteases. Two well-established components of invadopodia are the large membrane remodeling GTPase Dynamin 2 (Dyn 2), and oncogenic Src kinase. Here we report that cells of mesenchymal origin degrade substantial amounts of surrounding matrix by a mechanism, in part, independent of conventional invadopodia. Two distinct human, or rat, cultured fibroblast cell lines (HFs/RFs) or a pancreatic tumor stellate cell line (PSC) exhibit little to no matrix degradation when plated on fluorescent gelatin over a 24 hour period. Surprisingly, siRNA mediated knock-down of Dyn 2 in these cells induces a massive increase (3-4 fold) of substrate degradation. These degradative sites lack the punctate shape of conventional invadopodia but are instead spread along the cell base and are reticular and/or fibrous in character. In strong support of these findings, a tamoxifen activated knock-out of Dyn 2 in mouse embryonic fibroblasts also induces a marked increase (7-8 fold) in the degradation of matrix exhibited by these cells. Re-expression of wild type Dyn 2 or K44A GTPase defective mutant, actually reduces/eliminates matrix degradation to near normal levels. In strong contrast, siRNA knock down of Dyn 2, or expression of Dyn 2 K44A, in pancreatic adenocarcinoma cell lines (DanG, BxPC3) resulted in a near complete inhibition of canonical invadopodial-based degradation consistent with past findings. As matrix degradation in the mesenchymal cell lines appears to be induced by a reduction in Dyn 2 levels and exhibits a pattern distinct from conventional invadopodia, we tested a role for Src kinase in this novel process. While treatment of the pancreatic tumor cells with PP2 or SU6656 inhibitors markedly reduced invadopodia-based matrix degradation these had almost no effect on this process in the fibroblast cell lines. These findings provide evidence for a novel matrix remodeling process conducted by mesenchymal cells that is substantially more effective than conventional invadopodia, distinct in structural organization, and Dyn 2 and Src kinase independent.

Extracellular matrix compliance and Rho-family GTPase signaling guide plasticity of tumor cell invasion.

A.E. Sedgwick¹, J. Clancy¹, M. Balmert¹, H. Uwimpuweh¹, C. D'Souza-Schorey¹;

¹Biological Sciences, University of Notre Dame, Notre Dame, IN

Tumor cell invasion is a complex process that requires the molecular and physical adaptation of both the cell and its microenvironment. Increased MAPK signaling, small GTPase activation, cytoskeletal rearrangements, and the directed targeting of proteases to sites of extracellular matrix (ECM) degradation all accompany the process of tumor cell invasion. We have shown that nucleotide cycling on the ARF6 protein regulates the release of protease-loaded, plasma membrane-derived microvesicles from tumor cells into the microenvironment to promote ECM degradation. These shed vesicles are distinct from invadopodia, which are protrusions at the adherent surface of cells and mediate cell invasion. While the release of protease-loaded microvesicles potentially serves as a mechanism to bring about matrix degradation and also deposit paracrine information at distal locations creating paths of least resistance, invadopodia facilitate pericellular proteolysis of the ECM at the cell's invasive front and

appears to be linked to mesenchymal type tumor cell motility. We show that Rho GTPase signaling and the matrix microenvironment govern whether tumor cells produce invadopodia, or adopt an amoeboid phenotype and release microvesicles. The ability of tumor cells to switch between the aforementioned, qualitatively distinct modes of invasion may facilitate movement through different microenvironments. Understanding the interplay between these two invasive cell programs will provide new and important insights into the progression toward pathophysiological states.

Macrophage infiltration of the stroma in benign prostatic hyperplasia (BPH).

L.A. Gurski¹, L.E. Pascal¹, J.B. Nelson^{1,2}, J. Pilch³, Z. Wang^{1,2};

¹Urology, Univ Pittsburgh Med School, Pittsburgh, PA, ²University of Pittsburgh Cancer Institute, Pittsburgh, PA, ³Institute of Clinical Hemostaseology and Transfusion Medicine, Saarland University Medical Center, Homburg/Saar, Germany

Benign prostatic hyperplasia (BPH) has been previously characterized by inflammation and the increased presence of macrophages. Here, we seek to identify factors that mediate macrophage invasion in BPH. To test macrophage invasion *in vitro*, we embedded macrophage-differentiated THP-1 cells into a three-dimensional (3D) fibrin matrix and measured podosome formation. Using this model, we found that exogenous, but not endogenous, fibronectin was important for macrophage podosome formation. Supporting the clinical relevance of this mechanism, the prostatic stroma is rich in fibronectin and macrophages were found to co-localize with fibronectin in the stroma. Interestingly, a higher percentage of macrophages were found in the stroma of BPH prostate compared to matched normal prostate samples. Furthermore, conditioned medium from prostatic stromal cells promoted macrophage invasion in fibrin-fibronectin matrices. Together, these results suggest an important role for the stroma in promoting macrophage infiltration of BPH tissue. Ongoing work seeks to identify the mechanism by which stromal cells stimulate macrophage invasion.

Two distinct actin networks mediate traction oscillations to confer mechanosensitivity of focal adhesions.

Z. Wu¹, S.V. Plotnikov^{1,2}, C. Waterman¹, J. Liu¹;

¹National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD, ²Cell and Systems Biology, University of Toronto, Toronto, ON

Adherent cells actively sense the mechanical stiffness of their extracellular matrix (ECM) by exerting traction force through focal adhesions (FAs), which are integrin-based protein assemblies. Also, FAs control cell spreading, proliferation, survival, differentiation, and migration. FA-mediated

mechanosensation underlies cell durotaxis – the tendency of most cell types to migrate toward stiffer microenvironment. Strikingly, FA-mediated traction forces oscillate in time and space, and this oscillation governs durotaxis. The interactions underlying this intriguing spatio-temporal pattern of FA traction force are unknown, as are the contributions of these interactions to this mechanosensation. To address these questions, we established the first coherent, experimentally validated model of FA formation. The model integrated the spatiotemporal coordination between a branched actin network and stress fibers during FA growth. Our model predicted that retrograde flux of branched actin network contributed to a traction peak near the FA distal tip and that stress fiber-mediated actomyosin contractility generated a second traction peak near the FA center. Furthermore, a negative feedback loop involving formin-mediated stress fiber elongation and actomyosin contractility developed and resulted in oscillation of the center traction peak. This oscillation competed with the distal traction peak, and the competition underpinned oscillation of the FA traction maximum in time and space. More importantly, this negative feedback loop broadened the substrate stiffness range, over which the FAs could accurately adapt with traction force generation. Our findings shed light on the fundamental mechanism of FA mechanosensation and durotaxis.

Rigidity Signals Differentially Regulates Invadopodia Activity Through the ROCK Isoforms.

R. Jerrell¹, A. Parekh¹;

¹Department of Otolaryngology, Vanderbilt University Medical Center, Nashville, TN

Rho-associated kinase (ROCK) activity increases due to extracellular matrix (ECM) rigidity in the tumor microenvironment and drives cancer cell migration and invasion via actomyosin contractility. Invasion through cross-linked tissues is facilitated by actin-rich adhesive protrusions called invadopodia that proteolytically degrade the ECM. We have previously shown that ECM degradation by invadopodia is dependent on matrix rigidity and traction forces generated by non-muscle myosin II (NM II) suggesting that invadopodia activity is regulated by rigidity signals transmitted through cellular contractility. However, ROCK exists in two isoforms that may participate in other signaling pathways to regulate invadopodia activity independent of force generation. In particular, the ROCK substrate LIM kinase (LIMK) has been shown to regulate invadopodia activity to drive cancer cell invasion. Therefore, we hypothesized that rigidity signals induce differential ROCK activity to regulate invadopodia. Using siRNA to specifically inhibit each ROCK isoform, we investigated the contractile and invasive responses of an aggressive head and neck carcinoma cell line using polyacrylamide gels of different rigidities that span reported values for the mechanical properties of increasing grades of human tumor tissues. We found that only ROCK1 inhibition decreased traction forces while both ROCK1 and ROCK2 inhibition decreased ECM degradation. We also found that downstream ROCK signaling through both NM II and LIMK was dependent on matrix rigidity and regulated by ROCK1 and ROCK2, respectively. Therefore, our data suggest that matrix rigidity activates differential ROCK activity through two non-redundant signaling

pathways that converge to regulate invadopodia activity and may contribute to invasive behavior by cancer cells in response to the mechanical properties of the tumor microenvironment.

Laminin-derived peptide C16 regulates migration, invasion, invadopodia key molecules, and ROS generation in human prostate cancer cells.

R.G. Jaeger¹, L.C. Dos Santos¹, A.S. De Siqueira¹, T.M. Augusto^{2,3}, V.M. Freitas¹, H.F. Carvalho³;

¹Department of Cell and Developmental Biology, University of Sao Paulo, Institute of Biomedical Sciences, Sao Paulo SP, Brazil, ²Clinical Department, Faculty of Medicine of Jundiai, Jundiai SP, Brazil,

³Structural and Functional Biology Department, State University of Campinas, Campinas SP, Brazil

Prostate cancer is the second most frequently diagnosed cancer and sixth leading cause of cancer death in males. During tumor growth, neoplastic cells interact with the extracellular matrix (ECM) and this interaction influences tumor biology. Laminin is a molecule prominently expressed in ECM, and a key regulator of different tumors. Our Laboratory has demonstrated that peptides derived from laminin-111 cleavage are involved in migration, invasion and invadopodia formation in different tumor cell lines. Invadopodia are membrane protrusions made up by actin and actin-binding proteins. Invadopodia activity depends on expression of the proteins Tks4, Tks5, cortactin, MT1-MMP, as well as reactive oxygen species (ROS) generation. Here we analyzed the effect of C16, a laminin-derived peptide, on migration, invasion and invadopodia activity in human prostate cancer cells (DU145). Migration assays in chemotaxis chambers demonstrated that C16 increased migration activity of DU145 cells in a dose-dependent manner compared to cells grown on C16SX (scrambled peptide control). C16 also increased invasion of DU145 cells in a dose-dependent manner. We addressed signaling pathways related to C16 effects in tumor cells, and observed that the peptide stimulated Src phosphorylation. Migration and invasion are related to protease expression and invadopodia activity. Fluorescent substrate degradation assay showed that C16 increased invadopodia activity of DU145 cells. Immunoblot revealed that this peptide stimulated expression of key invadopodia molecules, such as Tks4, Tks5, cortactin and MT1-MMP. Reactive oxygen species (ROS) generation is also related with invadopodia formation. This prompted us to address whether C16 would induce ROS generation in DU145 cells. To detect ROS, control and treated cells were loaded with CellROX Deep Red kit. Quantitative fluorescence and flow cytometry showed that the peptide C16 increased ROS in DU145 cells. Our results strongly suggested that laminin peptide C16 regulates migration, invasion, invadopodia key molecules, and ROS generation in human prostate cancer cells (DU145). Support: FAPESP (2008/57103-8, 2009/17336-6, 2009/16150-6) and CNPq (304986/2009-7)

P1473**Board Number: B922****Mena localizes to invadopodia through interactions with specific targeting proteins to promote matrix degradation in breast carcinoma cells.**M.D. Weidmann¹, V.P. Sharma^{1,2}, J.S. Condeelis¹;¹Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ²Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY

Invadopodia, actin-polymerization driven protrusions of invasive carcinoma cells that focally secrete ECM-degrading proteases, are essential for tumor cell migration and intravasation in vivo during tumor cell dissemination from the primary tumor. Invadopodium formation involves the recruitment of a core complex of proteins including cortactin, cofilin, actin, N-WASP, and Tks5/FISH at the cell membrane. We have shown that cortactin phosphorylation at tyrosine residues, especially Y421, regulates the stability of this complex and promotes actin polymerization at invadopodium precursors. However, the mechanism by which cells regulate the cortactin phosphorylation-dephosphorylation cycle at invadopodia is unknown. Here we show that the invasion-specific Mena isoform, Mena^{INV}, is associated with a greater than 50 percent increase in phosphorylation of Y421-cortactin at invadopodia in human breast cancer cell lines after epidermal growth factor (EGF) stimulation. Little is known about the recruitment and localization of Mena isoforms to invadopodia, and we have found that Mena localizes to invadopodia before they begin degrading extracellular matrix (ECM). We show that Mena co-localizes at invadopodia with Riam, a scaffolding protein known to interact with Ena/VASP proteins similar to Mena, in a ring-distribution around invadopodia. We used acceptor-photobleaching FRET to show that Mena and Riam are in contact both at invadopodia and focal adhesions. We show that Mena initially localizes to the invadopodium core and later re-distributes to form a ring around the developing core complex, and that this pattern of localization is dependent on Riam and its closely-related family member Lamellipodin. Thus, Lamellipodin and Riam are involved in the recruitment of Mena to invadopodia, where Mena^{INV} specifically promotes invadopodium maturation by attenuating the dephosphorylation of cortactin at Y421. These results may explain the requirement for Mena^{INV} in invadopodium-dependent transendothelial migration during intravasation.

P1474**Board Number: B923****RhoG Negatively Regulates Invadopodia Formation.**S.M. Goicoechea¹, S. Awadia¹, A. Zynn¹, R. Garcia-Mata¹;¹Department of Biological Sciences, University of Toledo, Toledo, OH

Metastatic cells escape the tumor and enter the bloodstream by developing actin-rich membrane protrusions called invadopodia that degrade the extracellular matrix (ECM) to allow invasion of surrounding tissues. Even though many of the molecular components required for invadopodia formation have been identified, the signaling pathways that regulate these events are still poorly

understood. Invadopodia formation is controlled by the integrated activity of several members of the Rho family of GTPases, a family of proteins that regulates the actin cytoskeleton, but the molecular mechanisms that control their assembly are not known. Here we show that RhoG, a Rho GTPase related to Rac, functions as a negative regulator of invadopodia formation and functions during their disassembly, in a process that involves the exchange factor SGEF, paxillin and yet to be identified Rho-GAPs and effectors.

Our results show that silencing RhoG expression significantly increases the number of cells that form invadopodia in multiple breast cancer cell lines. In contrast, overexpression of RhoG inhibited the formation of invadopodia. Supporting these results, RhoG activity is significantly decreased during the formation of invadopodia. Silencing the expression of SGEF, a RhoG specific GEF, also increased the numbers of cells that formed invadopodia in a similar fashion than silencing RhoG. However, KD of other RhoG-GEFs, such as Ephexin 4 and PLEKHG6 did not affect the levels of invadopodia. These results suggest that SGEF functions to activate the pool of RhoG that negatively regulates the formation of invadopodia and that, for invadopodia to form, SGEF activity should be negatively regulated.

The molecular mechanisms by which RhoG regulates invadopodia formation are still under investigation, but we believe that paxillin phosphorylation is playing a role. Paxillin is a key component of invadopodia, and its phosphorylation plays a role in the disassembly of invadopodia. In RhoG KD cells, paxillin phosphorylation levels are significantly decreased, which suggests that the disassembly of invadopodia may be impaired in RhoG KD cells and would explain the increase in invadopodia number observed.

Microtubule acetylation regulates dynamics of KIF1C-powered vesicles and contact of microtubule plus ends with podosomes.

S. Linder¹, A. Castro-Castro², R. Bhuwania¹;

¹Inst. for Medical Microbiology, University Medical Center Eppendorf, Hamburg, Germany, ²Cell Biology, Institut Curie, Paris, France

Microtubule dynamics are important for a variety of key cellular functions such as intracellular trafficking, adjustment of the cell surface proteome, or adhesion structure turnover. In the current study, we investigate the effects of altered microtubule acetylation levels on the subcellular distribution of kinesins and actin cytoskeletal architecture in primary human macrophages. Microtubule acetylation was altered by overexpression or siRNA-induced depletion of the acetylase MEC-17, or by blocking alpha-tubulin deacetylation by addition of the inhibitor tubacin. We show that microtubule acetylation influences the subcellular distribution of vesicles associated with the kinesin KIF1C, as well as their directionality, velocity and run length. Moreover, tubulin acetylation alters the targeting frequency of microtubule plus ends on podosomes and influences the number of podosomes per cell and thus the matrix-degrading capacity of macrophages. Collectively, our results point to alpha-tubulin acetylation as

an important modification that impacts on kinesin vesicle dynamics, actin cytoskeletal architecture and cellular function of macrophages.

The heterodimer Kif3AC is a microtubule motor for polarized integrin trafficking and focal adhesion formation in migrating cells.

G.P. Nader¹, E.J. Ezratty¹, G.G. Gundersen¹;

¹Department of Pathology and Cell Biology, Columbia University, New York, NY

In migrating cells, microtubules (MTs) contribute to front-back polarity that is essential for directional migration of cells in a variety of environments. MTs are thought to provide the tracks for directional delivery of membrane precursors and actin regulators necessary for protrusion of the leading edge. MTs also regulate the turnover of focal adhesions (FAs) by stimulating integrin endocytosis and FA disassembly through an endocytic process. However, some key questions remain to be addressed: How is FA disassembly coupled with reassembly? Is there a particular cytoskeletal mechanism to ensure that there is a polarized trafficking of internalized integrins during cell migration? Are there specific MT motors involved in this trafficking? Here we developed a system to study FA turnover and integrin recycling based on the synchronous endocytosis of integrins during FA disassembly triggered by MT regrowth. Endocytosed integrin recycled back to the cell surface and FAs reformed 30 min after FA disassembly. Strikingly, FA reassembly occurred in a very biased fashion towards the cell periphery/leading edge, suggesting polarized endocytic trafficking underlies FA reassembly. Following FA disassembly, integrins localized to Rab5 endosomes and to the Rab11-endocytic recycling compartment. Rab11 knockdown blocked integrin return to the cell surface and FA reassembly, establishing that FA reassembly requires integrin recycling in this system. The Rab11-FIP5 (Rab11 family of interacting proteins) and kinesin II have been previously shown to be involved in endocytic recycling so we tested if the members of the kinesin II family were involved in the polarized trafficking of integrins from the recycling compartment. We found that Kif3A or Kif3C, but not Kif3B depletion blocked FA reassembly without interfering with FA disassembly. Consistently, microinjection of Kif3A-tail blocked FA reassembly. Moreover, Kif3A-depleted cells displayed smaller and fewer FAs and reduced velocity in directed migration assays. In agreement with the hypothesis that a microtubule-associated motor drives integrin recycling, Kif3A localized to the Rab11-endocytic recycling compartment and Kif3A knockdown blocked integrin return to the cell surface after FA disassembly. Our study establishes for the first time a direct link between FA disassembly and reassembly through an endocytic recycling pathway. Moreover, our results support a mechanism in which both integrin endocytosis and recycling occur toward the cell front, thus maintaining a spatially polarized distribution of cycling integrins. To the best of our knowledge, Kif3AC is the first kinesin to be implicated in the polarized transport of integrins to the leading edge of migrating cells.

p53 Protects Against MG132-Induced Apoptosis in a Cell State-Dependent Manner.

A. Legesse-Miller¹, J. Cheng¹;

¹Princeton University, Princeton, NJ

Since the approval of proteasome inhibitor, Bortezomib, for use in multiple myeloma in 2003, pharmacological proteasome inhibitors has been shown to be an important strategy for treating many types of cancer. While proteasome inhibitors induce apoptosis in certain rapidly proliferating cancer cells, some cells enters quiescence and survives. The mechanism by which quiescent cells become resistant to proteasome inhibitors is largely unknown. The tumor suppressor protein p53 plays an essential role in establishing and maintain quiescence in human cells. It also regulates several cell survival mechanisms, including cell cycle arrest, autophagy, and activation of reactive oxygen detoxifying enzymes. Here, we investigated the role of p53 in establishing resistance against proteasome inhibitors in quiescent cells. We found that MG132 (a know proteasome inhibitor) treatment induces the accumulation of p53 and its downstream target p21 more in quiescent cells than in proliferating primary human fibroblasts. shRNA mediated down-regulation of p53 sensitizes both proliferating and quiescent fibroblasts to MG132-mediated apoptosis and cell death, suggesting that p53 plays a protective role in all cell states. Additional experiments demonstrated that proliferating fibroblasts are susceptible to inhibition of cytoplasmic p53 activity, whereas quiescent fibroblasts are sensitive to inhibition of nuclear p53 activity. These findings suggest that p53 induces different protective mechanisms against MG132-mediated cell death, depending of the proliferative state of the cells. Autophagy, an alternative degradation pathway regulated by p53, is also induced in both cell states upon MG132 treatment. Identification of p53-mediated regulatory mechanisms that are activated in quiescent cells in response to proteasome inhibition may help to suggest strategies for improving the effectiveness of proteasome inhibitors in treating cancer.

Mule Ubiquitin Ligase Activity and the Tumor Suppressor ARF in Response to TNF.

C.K. Lee¹;

¹Division of Pulmonary and Critical Care, Northwestern University, Chicago, IL

Being a key mediator of inflammation, TNF is involved in many pulmonary diseases, including asthma, COPD, ALI, and ARDS. TNF-induced JNK activation, a MAPK pathway that most notably leads to apoptosis

and inflammation, is shown to be specifically regulated by the E3 ubiquitin ligase Mule, and its polyubiquitinated target Miz1. Miz1 is a well-studied transcriptional factor; however, its novel cytoplasmic function acts as a signal and pathway-spec modulator or regulator that selectively suppresses JNK activation. Its E3 ubiquitin ligase Mule is involved in various processes including transcriptional regulation, apoptosis, DNA replication, and DNA damage response and repair. Mule leads to Miz1 proteasomal degradation by catalyzing the K48-linked polyubiquitination of Miz1. Interestingly, tumor suppressor ARF has been described to directly interact and strongly inhibits Mule ubiquitin ligase activity. ARF is a critical component of tumor surveillance; it functions as a checkpoint to prevent unrestricted cellular proliferation in response to aberrant oncogenic signaling. The mechanism behind ARF-Mule regulation is not yet known, and no prior studies have indicated whether this regulation can be controlled by extracellular stimuli. Our result shows that ARF inhibits Mule E3 ligase activity in response to TNF stimulation, indicating that the interaction between ARF and Mule is altered in response to TNF. We further confirmed the ARF-Mule interaction weakens upon TNF stimulation and that the polyubiquitination status of Miz1 coordinates with the release of ARF. To examine the possible modification that may affect Mule E3 ligase activity, we detected Mule tyrosine phosphorylation in response to TNF; and this event is required for ARF-Mule dissociation and Mule ubiquitin ligase activity. Furthermore, evidence suggests an emerging protein kinase plays a role upstream of ARF and Mule. Here, we report that the ARF-Mule interaction is regulated upon TNF stimulation via posttranslational modification of Mule, thus contributing to Mule ubiquitin ligase activity in Miz1 polyubiquitination and JNK activation.

Ubiquitin-Specific Protease 5 is necessary for *Drosophila melanogaster* development.

G. Ristic¹, S.V. Todi¹;

¹Pharmacology, Wayne State Univ School of Medicine, Detroit, MI

Post-translational modification of proteins by the covalent attachment of ubiquitin (ubiquitination) plays an important role in numerous cellular pathways by altering protein function, location and stability. Ubiquitination is regulated by the actions of proteases known as deubiquitinating enzymes (DUBs). DUBs reverse protein ubiquitination and in turn regulate processes ranging from gene transcription to protein degradation. Ubiquitin-Specific Protease 5 (USP5) is a member of the ubiquitin-specific protease subclass of DUBs. The reported function of this protease is to hydrolyze unanchored (free) poly-ubiquitin chains and thereby recycle mono-ubiquitin for re-utilization. However, the physiological importance of USP5 *in vivo* is largely unclear. *Drosophila* USP5 is well conserved with its human counterpart. We show that, similar to its human orthologue, the fly USP5 hydrolyzes various types of ubiquitin-ubiquitin linkages rapidly *in vitro*. *In vivo* studies show that this DUB is developmentally required in the fruit fly: knockdown of USP5 throughout the fruit fly results in death during larval stages and this DUB is also physiologically important in glial and muscle cells, as well as in the fat body. At the biochemical level,

knockdown of USP5 causes an increase in poly-ubiquitin species without the depletion of mono-ubiquitin. In fact, expression of exogenous mono-ubiquitin does not suppress lethality caused by depleted USP5. Based on further data from genetic and biochemical assays, USP5 is required throughout fly development and may play a particularly important role in regulating general protein homeostasis.

The F-box protein FBXO25 plays a role in negative regulating of ELK-1 pathway in response to mitogens.

M.D. Gomes¹, F.R. Teixeira¹, A.O. Manfioli¹;

¹Faculty of Medicine of Ribeirao Preto, Sao Paulo University, Ribeirao Preto, Brazil

FBXO25 is one of the 69 known human F-box proteins that serve as specificity factors for a family of ubiquitin ligases composed of SKP1, Rbx1, Cullin1, and F-box protein (SCF1) that are involved in targeting proteins for degradation across the ubiquitin proteasome system. Recently, we applied an in chip ubiquitination screen using a human protein microarray to uncover putative substrates for the FBXO25 protein and we identified, the c-fos protooncogene regulator ELK-1 as endogenous substrate for SCF1(FBXO25) E3 ligase. Also by phospho-kinase array approach, we found that overexpression in HEK293 cells of FBXO25 suppressed ERK1/2 phosphorylation in response to PMA. These results show that FBXO25 plays a combined effect in inhibition of MEK-ERK1/2-ELK-1 activation in response to mitogens. Further work involves screening of kinase-phosphatase RNAi library to identify FBXO25 target proteins implicated in the hypophosphorylation of ERK1/2.

The regulation of mitochondrial homeostasis by MARCH5-mediated ubiquitination on acetylated Mfn1.

Y. Park¹, O.T. Nguyen¹, H. Cho¹;

¹Ajou University, Suwon, Korea

Mitochondrial dynamics and quality control have a central role in the maintenance of cellular integrity. Mitochondrial ubiquitin ligase membrane-associated RING-CH (MARCH5) regulates mitochondrial dynamics. Here, we show that mitochondrial adaptation to stress is driven by MARCH5-dependent quality control on acetylated Mfn1. Under mitochondrial stress conditions, levels of Mfn1 were elevated twofold and depletion of Mfn1 sensitized these cells to apoptotic death. Interestingly, overexpression of Mfn1 also promoted cell death in these cells, indicating that a fine tuning of Mfn1 levels is necessary for cell survival. MARCH5 binds Mfn1 and the MARCH5-dependent Mfn1 ubiquitylation was significantly elevated under mitochondrial stress conditions along with an increase in acetylated Mfn1. The

acetylation-deficient K491R mutant of Mfn1 showed weak interaction with MARCH5 as well as reduced ubiquitylation. Neither was observed in the acetylation mimetic K491Q mutant. In addition, MARCH5-knockout mouse embryonic fibroblast and MARCH5H43W-expressing HeLa cells lacking ubiquitin ligase activity experienced rapid cell death upon mitochondrial stress. Taken together, a fine balance of Mfn1 levels is maintained by MARCH5-mediated quality control on acetylated Mfn1, which is crucial for cell survival under mitochondria stress conditions.

Quantitative analysis of CRL function by single-molecule TIRF microscopy.

F. Lampert¹, M. Peter¹;

¹Institute of Biochemistry, ETH Zürich, Zuerich, Switzerland

Ubiquitin is a universal post-translational regulator of virtually all aspects of cellular function. Originally identified as a key part of the eukaryotic proteolytic system, ubiquitin-transfer to proteins is not inevitably a “kiss-of-death” signal but alternatively serves as a cue for ubiquitin-binding proteins (UBPs) that are integrated in numerous protein networks leading to complex subcellular rearrangements and differential signaling outputs. Ubiquitin conjugation to its target proteins involves the enzymatic activity of a myriad of E3 Ligase complexes. The most abundant E3 superfamily comprises the multi-subunit Cullin-RING ligases (CRLs). Unambiguous pairing of CRLs to their respective substrates has proven the key – and often rate limiting – step to fully understand the cellular role of these modular protein complexes. Technical difficulties to achieve this goal include short substrate residence times, rapid turnover of ubiquitinated targets and frequently low cellular abundance. To overcome these limitations we are pursuing a novel experimental route and adapt quantitative single molecule TIRF microscopy imaging to study CRL-substrate relationships. In particular, we aim to investigate novel CRL3 and CRL4 complexes required for cell cycle regulation, and exploit ultrasensitive detection of frequently transient and rare physiological E3 ligase–substrate encounters from cell extracts. A list of novel putative mitotic Cul4 substrate specific adaptors that emerged from in silico predictions and high-content RNAi screening previously conducted in our lab provides the biological foundation for this study. Plus, this single molecule imaging technique is accessible to recapitulate and quantitatively analyze general mechanistic aspects of dynamic E3 ligase function.

P1483**Board Number: B933****Arginyltransferase is critical for stress response and apoptosis and involved in cancer progression.**A. Kumar¹, M. Birnbaum¹, D.M. Patel¹, F. Zhu², Y. Guan², F. Zhang^{1,3};¹Molecular and Cellular Pharmacology, Univ Miami, Miami, FL, ²Department of Computational Medicine and Bioinformatics, Univ of Michigan, Ann Arbor, MI, ³Sylvester Comprehensive Cancer Center, Miami, FL

Arginyltransferase1 (Ate1) is an evolutionarily conserved enzyme that mediates posttranslational arginylation, which is the addition of an extra arginine to an existing peptide chain. The arginylation reaction changes the de facto primary sequence and surface charge of the target protein. It is known to lead to either ubiquitination and degradation, or functional modulation of the target. The in vivo activity of arginylation often increases during stressing conditions, such as heat shock, oxidative stress, or injury, all of which are known risk factors for cancers. However, as a posttranslational modification, arginylation is understudied and poorly understood. Currently, almost nothing is known about the role of arginylation or Ate1 in cancer or any other disease. Using multiple types of eukaryotic cells as test models, we found that knockout of Ate1 in cells leads to significantly reduced levels of apoptosis in the presence of stressing conditions. Conversely, over-expression of Ate1 leads to cell death. Therefore, our data indicate that arginylation is a pro-apoptotic factor. Intriguingly, we also found that the deletion of Ate1 gene in mammalian cells lead to a loss of contact inhibition and other cancer-like behaviors. Furthermore, a down-regulation of Ate1 leads to increased tolerance of reactive oxygen species (ROS) in prostate cancer cells, and that a lower level of Ate1 is linked to the metastasis of prostate cancer, where oxidative stress plays a major role in disease progression. Our data therefore uncover the novel role of Ate1 and arginylation as an regulator for stress response and apoptosis, with a potential involvement in the development of prostate cancers and other cancers.

P1484**Board Number: B934****Essential role of RecQL4 in checkpoint response to DNA damages in human cells.**S. Park¹, J. Im¹, Y. An¹, H. Choi¹, M. Hong¹, J. Lee¹;¹Dept of Biology Education, Seoul National University, Seoul, Korea

RecQL4 is a member of RecQ family helicase that plays important roles in maintaining genome integrity. Mutations in this gene are associated with Rothmund-Thomson Syndrome (RTS), which leads to developmental abnormalities, signs of premature aging, and high incidences of osteosarcoma. RecQL4 was shown to play multiple roles including the cellular response to DNA damage or oxidative stress, telomere maintenance, and DNA replication. RecQL4 comprises several domains. Distinct N-terminus of

RecQL4 showing limited homology to yeast Sld2 is essential for the initiation of DNA replication. While the function of helicase domain located in central part of RecQL4 is not well known, it appears to play important role in genome maintenance because most alternations of RecQL4 found in RTS patients are nonsense or frameshift mutations resulting in a truncated helicase domain. In this study, we examined the role of RecQL4 in checkpoint response to various DNA damages in human cells, and found that RecQL4 plays essential roles in checkpoint response. Essential roles of RecQL4 and its helicase activity in checkpoint responses will be discussed.

³Fondazione IRCCS Policlinico San Matteo, University of Pavia, Pavia, Italy, ⁴University of Torino, Torino, Italy

Primary light chain amyloidosis (AL) is the most common form of systemic amyloidosis. AL is caused by a plasma cell (PC) clone producing unstable light chains (LC), which deposit in target tissues as amyloid fibrils and cause fatal organ failure. The leading therapies adopted against AL imitate the regimens for multiple myeloma (MM), the prototypical PC malignancy, including the first-in-class proteasome inhibitor (PI) bortezomib, aiming at reducing the PC clone, to limit toxic LC production (1). The recently established high clinical response of AL to PIs, nearing 90% complete remission when associated with alkylators, raises the attractive possibility that AL PCs are intrinsically vulnerable to drugs that perturb protein homeostasis. However, the relative unavailability of primary samples and suitable disease models hampers the investigation of the biology of AL PCs. We hypothesized that the unstable amyloidogenic LC could impair protein homeostasis and be stressful to PCs, sensitizing these cells to PIs. If correct, understanding the underlying molecular bases may disclose new therapeutic targets against AL. To test our hypothesis, we characterized, for the first time, patient-derived AL cells biochemically, functionally, and morphologically. Patient-derived AL PCs showed exquisite, in vitro unprecedented vulnerability to proteasome inhibition. As a result, they were significantly more sensitive to bortezomib-induced apoptosis than primary MM cells, paradigmatic PI-sensitive cancer cells. However, AL and MM cells showed comparable proteasome activity and proteosynthetic workload, two key determinants of PI sensitivity in PCs (2). To gauge the bases of PI sensitivity, we analyzed primary AL PCs by electron microscopy (EM) and EM cytochemistry, and disclosed that AL PCs display more abundant endoplasmic reticulum (ER) than primary MM cells, and have perinuclear mitochondria, revealing remarkable cellular stress. In view of the established role of autophagy, a lysosomal recycling cellular strategy, in protein and mitochondrial homeostasis (3), and of our recent discovery of adaptive ER-phagy in PCs (4), our evidence raises the possibility that AL LC production results in cellular stress by challenging autophagy.

To establish cause-effect relationships, we exploited an AL patient-derived cell line (ALMC1), and engineered a PC line to express patient-derived amyloidogenic and non-amyloidogenic LCs through a doxycycline-inducible system, to investigate the direct, cell-intrinsic effects of AL LC expression. Our models confirm the presence of higher cellular stress in amyloidogenic LC expressing cells, resulting in perturbed ER and mitochondria homeostasis. Ongoing functional characterization of AL cells holds promise towards the identification of novel molecular targets in AL.

Prolyl Hydroxylation and Glycosylation of the SCF-E3 Ubiquitin Ligase Complex Is Important for Protozoan Growth and Development at Physiological Oxygen Levels.

K. Rahman¹, P. Zhao², L. Wells², I.J. Blader³, C. West¹;

¹Biochemistry and Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, ²Complex Carbohydrate Research Center, University of Georgia, Athens, GA, ³Microbiology and Immunology, University at Buffalo, Buffalo, NY

Toxoplasma gondii is an obligate intracellular protozoan parasite that can proliferate in warm-blooded animal cells residing at 0.5-21% O₂, but the mechanism of adaptation is unknown. Previous studies showed that *Toxoplasma* depends on a cytoplasmic prolyl 4-hydroxylase (TgPhyA), which hydroxylates Skp1, an adaptor subunit of SCF (Skp1/Cullin-1/F-box protein)-class of E3 ubiquitin ligases, for optimal proliferation especially at low O₂. Disruption of Skp1 hydroxylation reduces its apparent Mr by approximately 1 kDa based on Western blotting which suggests hydroxylation-dependent additional modifications of Skp1 in wild-type parasites. We now provide tandem mass spectrometry evidence that TgSkp1 hydroxyproline is modified by a branched pentasaccharide. Contributions of two predicted cytoplasmic glycosyltransferases (TgGnt1 and TgPgtA) in TgSkp1 modification were confirmed by gel shift analysis and mass spectrometry of TgSkp1 from the disruption strains. Furthermore, the glycosyltransferase knockout strains exhibited reduced growth in fibroblast monolayers similar to those of TgPhyA-KO strains, suggesting that glycosylation may mediate the role of prolyl hydroxylation for optimal growth. Detection of substantial levels of the unmodified TgSkp1 peptide in Skp1 proteomic analyses of all strains implicate TgPhyA activity as rate limiting for TgSkp1 modification. Proteomic interactome studies revealed that the SCF complex exists in *Toxoplasma* and suggest that TgSkp1 hydroxylation and glycosylation regulates the abundance of assembled complexes. Finally, the Skp1 modification pathway is conserved with that of the social amoeba *Dictyostelium discoideum* but not in metazoans. Thus, as documented in *Dictyostelium*, hydroxylation-dependent glycosylation of TgSkp1 may be important for E3 SCF ubiquitin-ligase assembly and activity as the parasite senses changes in O₂-

availability. Moreover, our data indicate that TgPhyA O₂-sensing is a protist-specific mechanism suggesting that it may be a novel drug target.

Molecular mechanisms of hnRNPA1 and hnRNPA2 misfolding and toxicity.

A.F. Ford¹, L. Guo¹, E.A. Scarborough^{1,2}, J. Shorter¹;

¹Department of Biochemistry and Biophysics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, ²Department of Biochemistry, University of Washington, Seattle, WA

Missense mutations in heterogeneous ribonucleoproteins A1 and A2 (hnRNPA1-D262V and hnRNPA2-D290V) are strongly associated with inclusion body myopathy (IBM) with frontotemporal dementia (FTD), Paget's disease of bone (PDB), and amyotrophic lateral sclerosis (ALS)— a complex disorder known as multisystem proteinopathy (MSP). Thus, hnRNPA1 and hnRNPA2 join the ranks of RNA-binding proteins with “prion-like domains” (PrLDs) that are implicated in human neurodegenerative diseases. The mechanism by which they cause pathology in MSP is unknown. Both mutations occur within PrLDs and are predicted to enhance the prionogenicity of these proteins. In vitro experiments confirm that the wild-type proteins form self-seeding fibrils, and this process is accelerated in the mutated variants. I have established a yeast model that recapitulates the protein toxicity and mislocalization seen in disease. I have demonstrated that both hnRNPs require an intact RNA recognition motif (RRM) for toxicity, and that disruption of RNA-binding via missense mutations suppresses the toxicity of both proteins. The data suggest that, in the cytoplasm, both proteins must form aggregates to cause toxicity, but aggregate formation is not necessarily toxic.

Characterization of the Intracellular Behavior of COL4A5 and Clarification of Molecular Mechanism of Alport Syndrome.

K. Omachi¹, M. Kamura¹, K. Teramoto¹, R. Fukuda¹, M. Suico¹, T. Shuto¹, H. Kai¹;

¹Molecular Medicine, Kumamoto Univ Sch Pharm, Kumamoto, Japan

Alport syndrome (AS) is caused by mutation in COL4A3, COL4A4 or COL4A5, components of glomerular basement membrane (GBM). COL4A3/4/5 are secreted as heterotrimer. Restoring the normal COL4A3/4/5 network in the GBM is important for AS therapy; hence the need to investigate intracellular behavior of mutant COL4A5 such as degradation, heterotrimer formation and secretion. However, understanding COL4A3/4/5 regulation is poor due to a lack of cellular model for AS. Here, we establish AS cellular model and clarify the difference in degradation mechanism between wild type and mutant

COL4A5 proteins. We cloned and constructed human COL4A3/4/5 expression plasmids. These plasmids were transfected in HEK293 cells. We extracted whole cell lysates and checked the proteins' expression by western blotting. We made mutant COL4A5 plasmids by site-directed mutagenesis. We are now investigating whether wild type and mutant COL4A5 are degraded by proteasome or lysosome by treating transfected cells with inhibitors. COL4A5 protein stability is also checked by chase experiments. We constructed COL4A3/4/5 expression plasmids and detected these proteins' expression. Some mutant COL4A5 plasmids were successfully constructed. Now, we are investigating the difference in degradation mechanism between wild type and COL4A5 mutants. We made a novel AS cellular model, which expresses human COL4A3/4/5 proteins. This model is an important tool to investigate AS phenotype in molecular level such as protein stability, degradation mechanism, and heterotrimer formation of wild type or mutant COL4A5. Using this cellular model, we may be able to clarify the intracellular behavior of some mutant COL4A5, which could help to establish mutation-dependent personalized medicine.

The ribosome-associated complex antagonizes prion formation in yeast.

A. Amor¹, D. Castanzo², D. Selechnik³, A. van Ooy³, D.M. Cameron³;

¹Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, ²Department of Molecular and Cellular Biology, University of California, Berkeley, Berkeley, CA, ³Biology Department, Ursinus College, Collegeville, PA

The number of known fungal proteins capable of switching between alternative stable conformations is steadily increasing, suggesting that a prion-like mechanism may be broadly utilized as a means to propagate altered cellular states. To gain insight into the mechanisms by which cells regulate prion formation and toxicity we examined the role of the yeast ribosome-associated complex (RAC) in modulating both the formation of the *[PSI⁺]* prion – an alternative conformer of Sup35 protein – and the toxicity of aggregation-prone polypeptides. The Hsp40 RAC chaperone Zuo1 anchors the RAC to ribosomes and stimulates the ATPase activity of the Hsp70 chaperone Ssb. We found that cells lacking Zuo1 are sensitive to over-expression of some aggregation-prone proteins, including the Sup35 prion domain, suggesting that co-translational protein misfolding increases in $\Delta zuo1$ strains. Consistent with this finding, $\Delta zuo1$ cells exhibit higher frequencies of spontaneous and induced prion formation. Cells expressing mutant forms of Zuo1 lacking either a C-terminal charged region required for ribosome association, or the J-domain responsible for Ssb ATPase stimulation, exhibit similarly high frequencies of prion formation. Our findings are consistent with a role for the RAC in chaperoning nascent Sup35 to regulate folding of the N-terminal prion domain as it emerges from the ribosome.

P1490**Board Number: B940****Calreticulin gene expression is regulated by sumoylation in XBP-1-dependent mode in *Caenorhabditis elegans*.**Y. Lim¹, D. Lee², K. Kalichamy³, S. Hong¹, M. Michalak², J. Ahnn³, D. Kim¹, S. Lee⁴;¹Life Science, GIST, Gwangju, Korea, ²Biochemistry, University of Alberta, Edmonton, AB, ³Hanyang Univ, Seoul, Korea, ⁴BK21Plus BDR Team, Hanyang Univ, Seoul, Korea

Excessive accumulation of unfolded proteins in the endoplasmic reticulum (ER) lumen causes ER stress, which induces a set of genes, including those encoding ER-resident chaperones, to relieve the detrimental effects and recover homeostasis. Calreticulin is a chaperone that facilitates protein folding in the ER lumen, and its gene expression is induced by ER stress in *C. elegans*. Sumoylation conjugates small ubiquitin-like modifier (SUMO) proteins with target proteins to regulate a variety of biological processes, such as protein stability, nuclear transport, DNA binding, and gene expression. In this study, we showed that *C. elegans* X-box-binding protein 1 (Ce-XBP-1), an ER stress response transcription factor, interacts with the SUMO-conjugating enzyme UBC-9 and a SUMOylation target. Our results indicated that abolishing sumoylation enhanced calreticulin expression in an XBP-1-dependent manner, and the resulting increase in calreticulin counteracted ER stress. Finally, RNAi against *ubc-9* mainly affected the expression of genes associated with ER functions, such as lipid and organic acid metabolism. Our results suggest that sumoylation plays a regulatory role in ER function by controlling the expression of genes required for ER homeostasis in *C. elegans*.

P1491**Board Number: B941****The San1 and Ubr1 pathways in the quality control cytosolic protein folding.**R. Prasad¹, D.T. Ng^{2,3};¹Temasek Life Sciences Laboratory, Singapore, Singapore, ²Biological Sciences, National University of Singapore, Singapore, Singapore, ³Temasek Life Sciences Laboratory, Singapore, Singapore

Misfolded proteins in the cytosol are detected and degraded by the ubiquitin proteasome system through quality control pathways defined by specific E3 ubiquitin ligases. Although these pathways apparently work together as a comprehensive system to monitor the folding of most, if not all, cytosolic proteins, their respective contributions remain unknown. In budding yeast, two pathways have been established based around the E3 ligases San1 and Ubr1. San1 is a nuclear localized enzyme so its cytosolic substrates must traffic into the nucleus for ubiquitination and degradation. The localization of Ubr1 is unclear but some of its known folded substrates are nuclear suggesting that at least a fraction of Ubr1 functions in the nucleus. To bridge existing gaps and approach a unifying model of cytosolic protein quality control (CytoQC), the San1 and Ubr1 pathways were studied in detail. Interestingly, the chaperone requirements for both pathways are similar suggesting that the mechanisms upstream to

ubiquitination are the shared. These and new data on the relationship between the two pathways will be presented.

Role of Mouse Heat Shock Transcription Factor Isoforms in Zinc Ion Stress Pathways.

J.S. Saint-Juste¹, N.J. Bachman¹;

¹Biology Department, SUNY Oneonta, Oneonta, NY

The ability to handle low levels of environmental stressors is a key adaptive capacity of living things. Heat shock transcription factor 1 (HSF1) is the main regulator of stress pathways in response to heat, peroxide, and heavy metals such as cadmium and zinc ion. The goal of this project was to identify levels of zinc ions that would induce a stress response, then test whether Hsf1 isoform messenger RNAs vary in response to zinc treatment. Growth bioassays were carried out by treating NIH 3T3 cells in separate wells with different concentrations of zinc sulfate (0-640 μ M); surviving cells were identified using luminescence. Once appropriate treatment conditions were established, total RNA was isolated from treated and untreated cells, and complementary DNA was synthesized. To demonstrate that zinc induces the expression of heat shock protein (hsp) target genes, real-time RT-PCR (Taqman) assays were carried out. When cells are treated with 160 μ M zinc sulfate for 90 min, three hsp genes were activated (hsp70.1, 140-fold; hsp25, 8800-fold, and clusterin, 2-fold) compared to controls. To compare levels of expression of Hsf1 isoforms, we used specific primer sets to amplify the individual isoforms (Hsf1 alpha, beta, gamma, or delta) using PCR. The PCR products were analyzed by agarose gel electrophoresis. The levels of HSF1 alpha remain about the same in the presence and absence of zinc. Levels of Hsf1 delta and/or Hsf1 gamma may be down regulated by up to 50%. Levels of Hsf1 beta may be slightly upregulated in the presence of zinc. To further quantitate changes in Hsf1 isoform expression during zinc stress, we are developing isoform specific SYBR green assays. These experiments have established conditions for studying the role of heat shock factor 1 in metal stress response pathways in mouse cells. This work was supported by NIH NIGMS grant R15 GM096231 and Diversity Supplement.

Tagged HSF1 Gamma as a Tool for Tracking Heat Shock Components in Mouse Cells.

A. Marmet¹, J. Fielhaber¹, N.J. Bachman¹;

¹Biology Department, SUNY Oneonta, Oneonta, NY

Organisms must survive a variety of stressful conditions, including sudden temperature increases that damage important cellular structures and interfere with essential functions. Proteins activated in

response to elevated temperatures are called heat shock proteins (hsps). Heat shock proteins bind to misfolded proteins to repair them, promoting survival. The main regulator of genes for hsps is called Heat Shock Transcription Factor 1 (HSF1). Humans, mice, and other vertebrates express four different types of HSF1, called isoforms, which differ structurally in the presence or absence of either of two short regions of 28 and 22 amino acids. We have constructed sets of plasmids, which enable the individual mouse HSF1 isoforms to be expressed in tissue culture cells, with or without an activating deletion. Each set contains specific protein tags [either FLAG or HA] with one set tagged at the beginning (N-FLAG or N-HA) and another set tagged at the end (C-FLAG or C-HA) for each tag. The production of the tagged proteins was detected after transient transfection of NIH 3T3 cells via Western analysis. Three of the four sets are complete or mostly complete as confirmed by binding of HA or FLAG primary antibodies and later reprobing with HSF1 primary antibodies. The confirmed sets of plasmid constructs comprise highly specific tools for investigating HSF1 function in mouse cells. We are investigating the subcellular localization and hsp70.1 target gene activation of HSF1 isoform Gamma (δ) and Gamma Delta ($\delta\Delta$) using N-FLAG, C-HA, and C-terminal green fluorescent protein tagged versions. Based on immunofluorescence, in the absence of heat shock, CHA-tagged HSF δ is mainly present in the nucleus of cells. In contrast, CHA-tagged HSF $\delta\Delta$ is majorly present in the cytoplasm. In the presence of heat shock, CHA-tagged HSF δ is distributed more in the cytoplasm of a cell than in the nucleus. CHA-tagged HSF $\delta\Delta$ is entirely located in the cytoplasm when heat shock is present. This work was supported by a student-initiated research grant from SUNY Oneonta to A. M. and NIH NIGMS grant R15 GM096231 to N. J. B.

Defining a metazoan protein disaggregase for ALS disease proteins.

L. Guo¹, H. Wang¹, N. Singh¹, J. Shorter¹;

¹Department of Biochemistry and Biophysics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA

Amyotrophic lateral sclerosis (ALS, also called Lou Gehrig's disease) is a debilitating, fatal neurodegenerative disease that is characterized by a severe and selective devastation of upper and lower motor neurons, progressive muscle weakness, paralysis, and death. Recently, ALS-linked mutations have been uncovered in several RNA-binding proteins with prion-like domains. Ordinarily, these proteins are localized to the nucleus. However, in ALS, mutations in different domains of these proteins lead to mislocalization of the proteins to the cytoplasm and formation of cytoplasmic inclusions in degenerating motor neurons. In the current study, we discovered that a nuclear import factor can function as a molecular chaperone to prevent the aggregation of these proteins by recognizing signal sequences in these RNA-binding proteins. Our results indicate that this nuclear import factor effectively inhibits the aggregation of WT disease proteins in vitro. The effectiveness of this nuclear import factor against disease protein aggregation is modulated by its interaction with the signal sequences. We show in our study that its activity is slightly impaired in disease mutants that have mutation in the signal sequence and is severely impaired in disease mutants that lack the signal sequences. We also

demonstrated in this study that this nuclear import factor is effective against aggregates that have different morphologies. Moreover, this nuclear import factor is shown to be able to reverse the aggregation of a subset of ALS disease proteins. Our results show that it has the potential to be developed as a general protein disaggregase for proteins bearing a signal sequence.

Using Tetracycline-Repression to Determine the Role of the J-protein Swa2 in [URE3] Prion Propagation.

M.E. Rockman¹, E.M. Troisi¹, E.E. Oliver¹, J.K. Hines¹;

¹Chemistry, Lafayette College, Easton, PA

Many neurodegenerative diseases, such as Alzheimer's and Parkinson's disease, are associated with an insoluble protein conformation called amyloid. Investigating prions in the baker's yeast *Saccharomyces cerevisiae* provides insight into amyloid biology. A specific set of chaperone proteins in yeast (Sis1, Ssa1, and Hsp104) has been shown to be essential for prion propagation. Further, some prions have additional chaperone requirements, indicating that the role of chaperone proteins in prion propagation is heterogeneous. Unpublished studies from our laboratory have demonstrated that the J-protein Swa2 is required for propagation of the prion [URE3] and gene dissection analysis has revealed the minimum domain requirements of Swa2 necessary for successful [URE3] propagation. However, whereas gene dissection analysis reveals requirements, reducing Swa2 expression *in vivo* should provide mechanistic information about the specific function of Swa2 in prion propagation. As expected, our initial repression experiments demonstrated that aggregates of [URE3] are cured upon addition of drug and subsequent decrease in Swa2 expression, further confirming that Swa2 protein expression is necessary for [URE3]. Surprisingly, these experiments also revealed curing in cultures without added doxycycline. Upon further investigation, it was determined that the tetracycline-repressible promoter significantly overexpresses Swa2, resulting in curing of [URE3] by generic J-protein overexpression. We subsequently optimized the experimental conditions and drug dosage to initiate experiments with Swa2 expression near wild-type levels. Using this optimized tetracycline-repression method which stabilizes [URE3], Swa2 expression can be fully repressed after approximately twelve generations upon supplementation with additional drug. While a colony color phenotype allows the measurement of curing kinetics, we are employing a Ure2-GFP chimera that will allow us to monitor changes in location and morphology of the biological aggregates *in vivo*. We are also optimizing a Semi Denaturing Detergent Agarose Gel Electrophoresis (SDD-AGE) protocol to monitor changes in amyloid polymer size and supplement the data gathered from GFP studies. We anticipate that this approach, in combination with homology studies, will expand upon our understanding of both molecular chaperone functions and amyloid biology.

P1496**Board Number: B946****Structural homology analyses of the tetratricopeptide repeat region of the yeast auxlin homolog Swa2 reveal considerable structural conservation with human HOP1.**E.E. Oliver¹, M.E. Rockman¹, J.K. Hines¹;¹Chemistry, Lafayette College, Easton, PA

Previous results from our laboratory assert that the yeast Hsp40 chaperone protein Swa2 is essential for the propagation of the prion [URE3] in a yeast population. Two regions of the protein are both necessary and sufficient to maintain [URE3] in these populations: the J-domain and the tetratricopeptide repeat (TPR) region. The J-domain is characteristic of all Hsp40 proteins and is known to interact in a complex with Hsp70, strongly suggesting that Swa2 acts in conjunction with Hsp70 in [URE3] propagation. However, the function of the TPR domain in Swa2 is undetermined. TPR domains typically act as docking platforms for a variety of protein complexes. As such we propose that the Swa2 TPR domain either participates in a bipartite interaction with Hsp70, analogous to the C-terminal domains of other yeast Hsp40s, or that the TPR domain mediates the formation of a ternary complex with another undetermined protein in [URE3] propagation. Pair-wise sequence alignments of the Swa2 TPR region to the TPR1 and TPR2A domains of the human HOP1 protein, which interact with human Hsp70 and Hsp90 proteins respectively, showed significant residue identity indicating a conservation of overall tertiary structure between all three domains. Although the Swa2 TPR region is more similar to TPR1 than TPR2A, residues which are likely to mediate protein-protein interactions had yet to be identified and characterized. To do this, we analyzed the crystal structures of the TPR1 and TPR2A domains co-crystallized with peptide ligands in conjunction with our sequence alignments. Our analyses uncovered a high degree of sequence similarities in key charged residues that likely form the two-carboxylate clamp, strongly suggesting that Swa2's TPR region will bind the canonical EEVD motif found on in yeast Hsp70 and Hsp90, and many other proteins. The analyses also suggested that Swa2 may specifically recognize the C-terminal dicarboxylate of the C-terminal aspartate, indicating that Swa2's in vivo binding partner likely possess a C-terminal EEVD motif. The capacity to form hydrophobic interactions that determine specificity between Hsp70 and Hsp90 was clearly evident but no conclusion about specificity between these two proteins can be currently drawn. However, this analysis has identified candidate residues for mutagenesis to test potential interactions with yeast Hsp70 and Hsp90. We expect that understanding the function of the Swa2 TPR domain will provide new insight into both J-protein function and the complex mechanisms of prion propagation.

P1497**Board Number: B947****Yeast prions and lipid profiles: protein-only inheritance and control of membrane lipid composition.**Q.H. Bui¹, J. Sherma¹, B. Fried², J.K. Hines¹;¹Chemistry, Lafayette College, Easton, PA, ²Biology, Lafayette College, Easton, PA

A central characteristic of all prions is that they are self-templating: once formed, the prion aggregate recruits additional monomeric protein into the growing fiber. Yeast prions of the species *Saccharomyces cerevisiae* stand as an example of the inheritance of complex traits based solely on the acquisition of a cytoplasmic protein aggregate as they confer distinctive phenotypes to the cells which harbor them, creating heterogeneity within an otherwise clonal cell population. These phenotypes typically arise from a loss-of-function of the prion protein which is unable to perform its normal cellular function while sequestered in prion amyloid aggregates. For example, the prion [PSI⁺], formed by the protein Sup35, broadly affects the proteome of yeast cells that harbor it by causing widespread nonsense suppression due to the sequestration of Sup35, a ribosomal translation termination factor. The physiological consequences of prion formation are largely undetermined given the recent discovery of most yeast prions within only the past five years. To begin to address this issue, we initiated a direct investigation into the potential control that yeast prions exert over fungal lipid content. Following a total lipid extraction, we utilized silica gel HPTLC (high performance thin-layer chromatography) to conduct pairwise quantifications of the relative levels of free sterols, free fatty acids, steryl esters, squalene, phosphatidylethanolamine, phosphatidylcholine, and phosphatidylserine in otherwise clonal [PSI⁺]-infected and [PSI⁺]-cured ([psi⁻]) cells. Preliminary analyses with n≥4 replicates have revealed differences (p

P1498**Board Number: B948****A potential role of the 'Anti-prion J-protein 1' (Apj1) in the curing of the prion [PSI⁺] by Hsp104 overexpression.**M.T. Astor¹, Z.A. Sporn¹, J.K. Hines¹;¹Chemistry, Lafayette College, Easton, PA

The prions of *Saccharomyces cerevisiae* are heritable aggregates of misfolded yeast proteins. Yeast prions are incorporated into daughter cells through the fragmentation of these aggregates by molecular chaperone proteins, including J-proteins, Hsp70s, and Hsp104. Interestingly, previous studies have shown that the overexpression of Hsp104 cures only the prion [PSI⁺]. By studying the genetic interactions between J-proteins and Hsp104, we aim to better understand how the action of multiple chaperones results in the curing of only this specific and otherwise highly stable prion. In order to clarify the role of J-proteins, we asked whether any of the other 12 J-proteins located in the *S. cerevisiae*

cytosol are also necessary for Hsp104-induced [PSI⁺] curing. We also investigated whether prion amyloid structure (variant identity) affects experimental outcomes. In order to do this, we first demonstrated that either of two weak [PSI⁺] variants, Sc37 and VL, can be maintained in the absence of each J-protein other than Sis1 using mating experiments. Subsequently, curing of weak [PSI⁺] by Hsp104 overexpression was examined, and [PSI⁺] was cured in all strains, demonstrating that no J-protein other than Sis1 is necessary for the curing of weak [PSI⁺] by overexpression of Hsp104. This analysis was next repeated using a strong [PSI⁺] variant, STR. In this case, previous studies have already shown that deletion of these individual J-proteins does not affect [PSI⁺]STR propagation, allowing us to again examine curing by Hsp104 overexpression in each deletion strain. [PSI⁺]STR was cured upon Hsp104 overexpression in all J-protein deletion strains, however we noted exceptional resistance to Hsp104 mediated curing in the strain lacking Apj1 (originally named: Anti-Yeast Prion J-protein 1) specifically. Apj1 has been implicated in prion biology several times; often acting similarly to Ydj1 in prion biology. Here we find a novel genetic interaction for Apj1 and prions that is distinct from Ydj1. Additional experiments at the level of domains will allow further characterization of a potential role for Apj1 in Hsp104-mediated [PSI⁺] curing and may help to explain the prion-specificity of this curing mechanism.

P1499

Board Number: B949

Domain and homology studies of the J-protein Sis1 in the curing of [PSI⁺] by overexpression of Hsp104.

Z.A. Sporn¹, M.T. Astor¹, J.K. Hines¹;

¹Chemistry, Lafayette College, Easton, PA

The purpose of this investigation was to examine the yeast cytoplasmic Hsp40 protein Sis1 and its homologs with regard to their role in the curing of the [PSI⁺] prion due to overexpression of Hsp104. Yeast prion propagation requires the chaperone proteins Sis1, Ssa1, and Hsp104. Interestingly, when Hsp104 is overexpressed the [PSI⁺] prion is lost, or “cured”, from the population in a poorly understood but Sis1-dependent manner. The mechanism of [PSI⁺] curing by Hsp104 overabundance is currently the subject of significant debate in literature. We recently reported that the human homolog of Sis1, Hdj1, was capable of substituting for Sis1 in the propagation of strong but not weak [PSI⁺] variants. Here, we have extended that investigation to explore the potential of both Hdj1 and the *Drosophila melanogaster* homolog Droj1 to substitute for Sis1 in the curing of [PSI⁺] by Hsp104 overexpression. In addition, we also considered the potential effects of yeast genetic background and controlled for polymorphisms by utilizing two distinct yeast strain backgrounds commonly used in yeast prion investigations. We found that like Hdj1, Droj1 only substitutes for Sis1 in the propagation of strong variants; two weak variants, Sc37 and VL, were lost when Droj1 was expressed as the sole Sis1 homolog whereas two strong variants, Sc4 and VH, were maintained without any distinct phenotype in both yeast genetic backgrounds tested. Upon transformation with a plasmid overexpressing Hsp104, we found that both strong variants were maintained, again in both backgrounds, indicating that Droj1 is incapable of substituting for Sis1 in Hsp104-mediated curing. Hdj1 behaved similarly to Droj1 except that, surprisingly, the variant Sc4 was

cured, but only in the 74D-694 background, indicating that while Hdj1 is clearly deficient in replacing Sis1 in this mechanism, the combination of a specific yeast genetic background and prion variant alters the experimental outcome. Notably, the finding that the same variant was stable when Droj1 was present instead of Hdj1 indicates that Hdj1 has a gain of function in that genetic background, rather than an alternative model in which the curing mechanism simply becomes Hsp40-independent. Finally, because we found differences due to both yeast genetic background and prion variant identity, we also conducted an additional investigation of the Sis1-domain requirements for Hsp104-mediated [PSI⁺] curing, expanding upon another prior investigation by extending the analysis to multiple [PSI⁺] variants and genetic backgrounds. In accordance with our most recent published investigation, we found drastic differences in the requirement for Sis1 in Hsp104-mediated [PSI⁺] curing between weak and strong [PSI⁺] variants.

Glycobiological aspects of cellular stress responses.

K. Kozak¹, J. Lanteigne¹, A.V. Timoshenko¹;

¹Biology, Western University, London, ON

Mammalian cells adaptively respond to exogenous stressors through a number of conservative signaling pathways that activate specific transcription factors leading to the upregulation of genes required for either cell survival or programmed cell death. A novel conceptual paradigm has recently emerged suggesting the contribution of glycocalyx remodeling to maintain cell homeostasis. It was hypothesized that stress-dependent changes in the expression of cell surface glycans to endogenous lectins (glycan-binding proteins) represents a distinctive level of glycobiological regulation of cellular functions. To test this hypothesis, we used a human promyelocytic leukemia cell line HL-60 as a model and examined the effects of three different stress stimuli, mimicking oxidative stress (0.01 mM menadione), hypoxia (0.1 mM cobalt chloride), and endoplasmic reticulum stress (0.001 mg/mL tunicamycin), on the cell adhesion to immobilized plant lectins with different glycan-binding specificities, as well as examining the expression of eleven galectin genes (LGALS 1, 2, 3, 4, 7, 8, 9, 10, 12, 13, and 14). Suspension culture of HL-60 cells was maintained in Iscove's modified DMEM supplemented with 10% FBS and then exposed for 24h to the stress drugs, rinsed with PBS, and used either directly for cell adhesion assay or for total RNA extraction, cDNA synthesis, and conventional PCR. Glycoprofiling of HL-60 cells revealed a strong adhesion of untreated cells to immobilized lectins from *Canavalia ensiformis*, *Sambucus nigra*, and *Ricinus communis* while the adhesion to fibronectin and lectins from *Arachis hypogaea*, *Dolichos biflorus*, *Glycine max*, *Triticum vulgare*, and *Ulex europaeus* was relatively weak. All three stress treatments were found to increase significantly the adhesion to *Triticum vulgare* agglutinin; in addition menadione significantly increased adhesion to *Sambucus nigra* agglutinin. Stress-induced changes in the expression of galectin genes were more diverse allowing us to classify them tentatively in three categories: upregulated (3, 10, and 12), downregulated (1 and 9), and constitutive (stable expression of 8 and 14 as well as not detectable 2, 4, 7, and 13) galectins. Although this classification of galectins was

not uniform between different stress treatments, it provides a new starting point to recognize the complexity of galectin networks in cells. As such, it is not surprising that our preliminary bioinformatics analysis revealed non-overlapping diversity in putative transcription factors and miRNAs regulating the expression of galectins. Collectively, our results provide a strong support to the conceptual idea that differential expression of specific glycans and galectins can serve as a molecular signature of cellular stress responses.

Oncogene de-addiction from Hsp90 induces senescence-like phenotype in malignant and metastatic tumor cells.

A.V. Kanugovi¹, S.S. Amere¹;

¹CSIR-Centre for Cellular and Molecular Biology, Hyderabad, India

Bypassing senescence in normal cells is being achieved by activation of multiple signal transduction pathways. We studied how Hsp90 favours oncogene addiction using primary, malignant and metastatic tumor cells. Between the wild type and mutant Raf, mutant Raf induced senescence in primary cells and malignant tumor cells, but enhanced proliferation in metastatic cells. However, inhibition of Hsp90 induced cell death in metastatic cells suggesting that oncogene addiction requires Hsp90. With increased Raf expression, we observed an increase in active Hsp90. Examining the interaction between different forms of Raf with deletion constructs of Hsp90 revealed that the highly charged middle region of Hsp90a, called the “hinge region” is responsible for the Raf interaction and stabilization. Interestingly, the constitutive form of Hsp90, the Hsp90b is found to play no role in the oncogene addiction. Further, Hsp90 has more affinity towards the mutant Raf over the wild type Raf. In contrast to the previous reports that Hsp90 interacts with the kinase clients through a kinase-kinase interaction domain, for the first time we demonstrate that the Hsp90 kinase interacting domain is indispensable for Raf interaction. Promoting “proliferative crisis” by overexpressing mutant forms of Raf in tumor cells had survival advantage, due to active Hsp90. However, Raf expression in primary cells lacking active Hsp90 resulted in senescence. We also demonstrated that Raf induced senescence requires intact DNA damage response (DDR) and functional p53. Pre-sensitizing these cells to Hsp90 inhibition enhanced senescence. Our findings indicate adaptive roles of Hsp90 to oncogene addiction, and a new perspective of using Hsp90 inhibitors to promote senescence.

P1502**Board Number: B1002****Sigma-1 Receptor Deficiency Hinders p35 Degradation and Causes Impaired Neuronal Circuitry.**S.A. Tsai¹, M.J. Pokrass¹, T. Su¹;¹NIDA, NIH, Baltimore, MD

Cyclin-dependent kinase (cdk5) is a serine/threonine directed kinase that performs signaling roles in neuronal survival, migration, synaptogenesis, and axon guidance. Cdk5 activity is dependent on its activator, p35, which is a short-lived ($t_{1/2} = 20$ min.) neuronal-specific peptide that is anchored to the plasma membrane (PM) via an N-terminal myristoylation motif. Dysregulation of cdk5 has long been implicated in the pathophysiology of neurodegenerative disease because it causes abnormal hyperphosphorylation of cytoskeletal proteins such as tau and neurofilament, which ultimately leads to the emergence of neurofibrillary tangles. Thus, p35 is a tightly regulated protein that undergoes rapid proteasomal degradation; however, neurotoxic insults promote p35 conversion to p25. p25 also activates cdk5, though it possesses a longer half-life and is no longer anchored to the PM, allowing atypical phosphorylation by cdk5. The sigma-1 receptor (Sig-1R) is an endoplasmic reticulum (ER) molecular chaperone that is implicated in several diseases of the central nervous system such as Alzheimer's disease, drug addiction, and depression. Neuroimaging studies have revealed that brains of Alzheimer's and Parkinson's patients are deficient in Sig-1R expression; however, the specific role of the Sig-1R in neurodegeneration is still unclear. This study examined the role of Sig-1Rs in the regulation of p35. We found that Sig-1R siRNA (siSig-1R) treated neurons exhibit greater basal levels of p35 expression and that this increase is likely due to a decreased degradation rate of p35. siSig-1R neurons also display shorter axonal length and disoriented axonal projection. Treatment with myristate restored axonal elongation in the Sig-1R KO neurons, although myristate itself may promote axonal growth. Furthermore, we show that myristic acid competes with the Sig-1R agonist (+)-pentazocine for Sig-1R binding. Taken together, these findings indicate that Sig-1Rs mediate the myristoylation of p35, thereby regulating the degradation of p35, which, in turn modulates cdk5 activity. This property of the Sig-1R appears important to the structural and functional maintenance of the axon.

P1503**Board Number: B1003****Subcellular fractionation analysis of the extraction of ubiquitinated polytopic substrates during ER-associated degradation.**K. Nakatsukasa¹, T. Kamura¹;¹Division of Biological Science, Nagoya University, Nagoya, Japan

During ER-associated degradation (ERAD), misfolded polytopic membrane proteins are ubiquitinated and retrotranslocated to the cytosol for proteasomal degradation. The mechanisms underlying the

recognition and ubiquitination of polytopic substrates have been well-documented; however, the events associated with the post-ubiquitination step of polytopic substrates remain largely unknown. To better define the localization and physical properties of ubiquitinated polytopic substrates during ERAD, we performed subcellular fractionation analyses of ubiquitinated Ste6p (star), a 12 transmembrane domain-containing ERAD substrate. Consistent with previous studies, the extraction of ubiquitinated Ste6p* from the ER membrane was dependent on Cdc48p/p97. Ubx2p, which recruits Cdc48p/p97 to the ER, facilitated the extraction of Ste6p (star). By contrast, the downstream components of Cdc48p/p97, including Rad23p/Dsk2p, and the proteolytic activity of the proteasome were dispensable for the extraction. Lipid droplet formation was not required for the degradation of Ste6p (star). Sedimentation and flotation assays showed that ubiquitinated Ste6p* in the cytosol was free from membranes and most likely resides in a protein complex. Our results suggest that the solubility of polytopic substrates in the cytosol is maintained by proteinous factors. The fractionation assays developed in the present study provide a means to further dissect the ill-defined post-ubiquitination step during ERAD of polytopic substrates.

Identification of three different structures of human alpha synuclein relevant to Parkinson disease.

W.K. Lim¹, J.H. Cho¹, H.J. Shin²;

¹Department of Molecular Biology, Pusan National Univ, Busan, Korea, ²Division of Energy and Bioengineering, Dongseo University, Busan, Korea

Alpha synuclein (aSyn) is the major component of Lewy bodies and Lewy Neurites which are pathological markers for synucleinopathy including Parkinson's disease. The physiological structure of aSyn has been controversial from natively unfolded structure(s) to a stable helical tetrameric structure. It has been known that aSyn could also exist as membrane bound forms, dimer/oligomer, and amorphous/amyloid aggregates. Here we examined various structures of aSyn polypeptide formed under varied conditions. The resultant structures were analyzed mainly by deuterium hydrogen exchange mass spectrometry, which has been proved to be excellent in analyzing many metastable and amorphous protein structures. All deuterium-labeled aSyn was prepared by incubating aSyn in 100% deuterium oxide at 45°C for 30 min. The deuterated aSyn was incubated in H₂O buffer under the varied conditions, and their structures were evaluated by deuterium to hydrogen exchange mass spectrometer with highly efficient online protease HPLC system. More than 100 peptides covering whole 140 residues were successfully obtained. N-terminal and NAC domains of aSyn could form three different conformations with different exchange rate; low, medium, high protection values. The structure with low protection seems to be similar to (pre)molten globule-like structure. The structure with high protection resembles a highly organized structure like helical dimer or tetramer. On the other hand, the structure with medium stability may be metastable under the condition examined, because it is only partially detected between two other structures. For all three structures, C-terminal domain (~100~140) of aSyn shows little protection values

close to those of corresponding peptides, indicating that it exists as random disordered structure. It is suggested that aSyn could be converted via this metastable intermediate structure from unfolded to (pre)molten globule to highly organized structures.

Inhibition of ER Ca²⁺ release or the p38 SAPK inhibits UPR signaling and apoptosis activation during moderate ER stress.

T.A. Johnson¹, A.G. Scholl¹, Z.G. Coffman¹, T.L. Vandergon¹, J.L. Brewster¹;

¹Natural Science Division, Pepperdine Univ, Malibu, CA

When unfolded proteins accumulate in the endoplasmic reticulum (ER), stress signaling pathways collectively called the Unfolded Protein Response (UPR) are induced. Modeling of ER stress in cultured cells is often performed with high doses of poisons that arrest essential functions within the ER. In examining the potential implications of chronic ER stress signaling in organismal models, a modest ER stress would be anticipated as clinically appropriate. In this study, the ER was challenged with a 50-fold range of tunicamycin, an inhibitor of N-linked glycosylation. Tunicamycin induced cellular apoptosis and stress signaling over a range of concentrations from 20 nM to 1000 nM. Increasing doses of tunicamycin resulted in similar increases in activation of signaling from the ER-localized IRE1 transmembrane protein, expression of UPR transcriptional targets, and activation of the p38 stress activated protein kinase. High doses of tunicamycin were shown to cause an elevation in cytosolic Ca²⁺, while modest doses showed no significant changes in cytosolic Ca²⁺ levels. Interestingly, inhibition of Ca²⁺ release from the inositol trisphosphate receptor was found to inhibit ER stress signaling and apoptosis only at modest doses of ER stress (20-40 nM). During moderate ER stress, p38 inhibition was sufficient to inhibit UPR-based increases of GRP78 expression and the activation of cellular apoptosis. This work supports a model in which moderate ER stress uses Ca²⁺ release and p38 signaling as a central component of both UPR activation and a subsequent ER stress-induced apoptosis.

Suramin Inhibits Hsp104 ATPase and Disaggregase Activity.

M. Torrente¹, L.M. Castellano¹, J. Shorter²;

¹Biochemistry and Biophysics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²Department of Biochemistry and Biophysics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA

Hsp104 is a hexameric AAA+ protein that utilizes energy from ATP hydrolysis to dissolve disordered protein aggregates as well as amyloid fibers. Interestingly, Hsp104 orthologues are found in all kingdoms of life except animals. Thus, Hsp104 could represent an interesting drug target. Specific inhibition of

Hsp104 activity might antagonize non-metazoan parasites that depend on a potent heat shock response, while producing little or no side effects to the host. However, no small molecule inhibitors of Hsp104 are known except guanidinium chloride. Here, we screen over 16,000 small molecules and identify 16 novel inhibitors of Hsp104 ATPase activity. Excluding compounds that inhibited Hsp104 activity by non-specific colloidal effects, we defined Suramin as an inhibitor of Hsp104 ATPase activity. Suramin is a polysulphonated naphthylurea and is used as an antiprotozoal drug for African Trypanosomiasis. Suramin also interfered with Hsp104 disaggregase, unfoldase, and translocase activities, and the inhibitory effect of Suramin was not rescued by Hsp70 and Hsp40. Suramin does not disrupt Hsp104 hexamers and does not effectively inhibit ClpB, the *E. coli* homolog of Hsp104, establishing yet another key difference between Hsp104 and ClpB behavior. Intriguingly, a potentiated Hsp104 variant, Hsp104A503V, is more sensitive to Suramin than wild-type Hsp104. By contrast, Hsp104 variants bearing inactivating sensor-1 mutations in nucleotide-binding domain (NBD) 1 or 2 are more resistant to Suramin. Thus, Suramin depends upon ATPase events at both NBDs to exert its maximal effect. Suramin could develop into an important mechanistic probe to study Hsp104 structure and function.

The molecular chaperone Hsp70 binds to and stabilizes Nod2, an important protein involved in Crohn's disease: Identifying a small molecule stabilizer.

V. Mohanan¹, C. Grimes¹;

¹Biological Sciences, University of Delaware, Newark, DE

Microbes are detected by the pathogen-associated molecular patterns (PAMPs) through specific host pattern recognition receptors (PRR). Nucleotide binding oligomerization domain-containing protein 2 (Nod2) is an intracellular PRR that recognizes fragments of bacterial cell wall. Nod2 is important to human biology, as when it is mutated it loses the ability to respond properly to bacterial cell wall fragments, as observed in Crohn's disease. In order to determine the mechanisms of misactivation in the Nod2 Crohn's mutants, we developed a cell based system to screen for protein-protein interactors of Nod2. We identified heat shock protein 70 (Hsp70) as a protein interactor of both wild-type and Crohn's mutant Nod2. Hsp70 has previously been linked with inflammation, especially in the regulation of anti-inflammatory molecules. Induced Hsp70 expression in cells increased Nod2 response to bacterial cell wall fragments. In addition, a Hsp70 inhibitor, KNK437, was capable of decreasing a Nod2 mediated NF- κ B activation in response to bacterial cell wall stimulation. We found Hsp70 to regulate Nod2's half-life, as increasing the Hsp70 level in cells increased Nod2's half-life, and down-regulating Hsp70 decreased Nod2's half-life. The expression level of the Crohn's associated Nod2 variants were less compared to wild-type. The over-expression of Hsp70 significantly increased Nod2 levels as well as the signaling capacity of the mutants. Thus our study shows that restoring the stability of the Nod2 Crohn's mutants is sufficient for rescuing the ability of these mutations to signal the presence of a bacterial cell wall ligand. Further, we have identified the minimal region of Hsp70 that facilitates the interaction with

Nod2. Studies are currently under way to identify a pharmacoperones that can potentially stabilize the Crohn's associated Nod2 variants.

²Institute of Molecular Life Sciences, University of Zürich, Zurich, Switzerland, ³FOM Institute AMOLF,

Amsterdam, Netherlands, ⁴Department of Molecular, Cellular, and Developmental Biology, University of Colorado, Boulder, CO

The cytoplasm is generally seen as a passive, viscoelastic material that is enclosed by the cell membrane and with characteristics that are defined by the nature and the density of its content. A recent essay discussed evidence suggesting that the cytoplasm should not be seen as a simple fluid but rather as a poroelastic material with a fluid and a solid phase [1]. Similarly, it was hypothesized in another context that liquid phase separation may be a fundamental principle of cytoplasm organization [2]. Both publications imply the possibility that cells can actively regulate the physical properties of their cytoplasm, even locally, which would provide a novel way to contribute to mesoscale organization of the cell. Yet, good experimental evidence or even molecular mechanisms for such control of cytoplasmic states have not been found. Here we show that such active control of cytoplasm viscosity occurs. We present a novel state of cytoplasmic organization, in which the cytoplasm transitions from fluid-like to solid-like. We therefore term this phenomenon cytoplasmic freezing. The frozen state is characterized by the fact that the diffusive motion of observable structures in the cytoplasm is completely restricted and that optical tweezers can no longer move lipid granules. In addition, cell wall removal does not result in the loss of cylindrical cell shape as occurs in normal cells. The frozen state occurs in fission yeast cells in advanced glucose starvation and rapidly reverses upon glucose addition. The dramatic immobilization of all structures suggests the formation of a fine polymer network. The primary candidates for the formation of such a network would be proteins known to form filament networks like actin, microtubules or septins, but based on our single particle tracking, optical tweezers, fluorescence microscopy, and electron microscopy data, we discard all of them.

P1509**Board Number: B1010****Computing cytoplasmic flows during pronuclear migration and spindle positioning in C-elegans embryo.**E. Nazockdast¹, D. Needleman², M. Shelley¹;¹Courant Institute, New York University, New York, NY, ²School of Engineering and Applied Sciences, Harvard University, Cambridge, MA

We investigate theoretically models of pronuclear migration and spindle positioning in single cell *Caenorhabditis elegans* embryos using new and highly efficient numerical techniques. These methods fully resolve the long-ranged hydrodynamic interactions, mediated by the cytoplasm, between microtubules and with other cytoskeletal objects, and account for microtubule flexibility and dynamic instability. To do this, many-body fluid-structure interactions are computed using a highly efficient and scalable fast multipole method for the Stokes equations of viscous flow, which allows simulating thousands of fibers. Different types of molecular motors can be incorporated into our framework. We explore pronuclear migration and spindle positioning in single cell *Caenorhabditis elegans* embryos using two previously proposed positioning mechanisms: cytoplasmic pulling upon MTs and MTs pushing upon cortex. While our simulations show proper positioning occurs in both models, their associated cytoplasmic flows are fundamentally different. This suggests that cytoplasmic flow visualization during pronuclear migration and spindle positioning could differentiate between different proposed mechanisms. We also investigate the consequences of varying catastrophe and rescue rates, microtubule rigidity, and the shape of embryo.

P1510**Board Number: B1011****The nucleus is an intracellular propagator of actomyosin forces in NIH 3T3 fibroblasts.**S. Alam¹, D. Lovett², K.J. Roux³, R.B. Dickinson², T.P. Lele²;¹Chemical Engineering, Univ Florida, Gainesville, FL, ²Chemical Engineering, University of Florida, Gainesville, FL, ³Children's Health Research Center, Sanford Research, Sioux Falls, SD

How the migrating cell positions its nucleus is not understood. Previous studies with engineered lamellipodia suggested that the nucleus is pulled forward by anterior actomyosin contraction in crawling fibroblasts. Here we show that the nucleus deforms due to the formation of local protrusions proximal to the nuclear surface. The deformation relaxed on collapse of the local protrusion, and required actomyosin activity and an intact LINC complex. Femtosecond laser ablation of lateral stress fibers that run parallel to the side of the nucleus and appear to be touching did not result in a lateral expansion of the nucleus, arguing against a mechanism in which the protrusions pull on compressive fibers and allow the nucleus to locally expand. Instead, we propose that actomyosin contraction in the protrusion pulls

on the nuclear surface to move it. Consistent with this mechanism, we found that the nuclear position closely coincided with the point of maximum tension in the cell (quantified from traction force microscopy), whereas it lagged behind it by several microns in LINC complex disrupted cells. To further challenge the hypothesis that the nucleus transmits tension from the anterior to the posterior of a migrating cell, we detached the trailing edge with a micropipette and quantified the drop in the traction stress in the anterior region of the cell. The drop in the traction stress at the front was significantly larger in normal cells as compared to LINC complex disrupted cells. Collectively, these results are consistent with a model in which nuclear position in migrating fibroblasts is determined by a tug-of-war between anterior and posterior actomyosin pulling forces.

Super-resolution imaging reveals structural determinants underlying genetic polymorphisms that influence cellular plasticity and disease susceptibility.

X. Liu¹, P. Xia², J. Zhou¹, D. Wang³, W. Wang³, C. Jin³, X. Yao⁴;

¹Physiology, Morehouse School of Medicine, Atlanta, GA, ²Cellular Dynamics, University of Science of Technology of China, Hefei, China, ³Univ Sch Technol-China, Hefei, China, ⁴Cellular Dynamics, University of Science Technology of China, Hefei, China

Visualization of specific molecules and their interactions in real time and space is essential to delineate how cellular dynamics and signaling circuit are orchestrated. Spatial regulation of conformational dynamics and structural plasticity of protein interactions is required to rewire signaling circuitry in response to extracellular cues. Genome-wide analyses indicate that genetic variations such as polymorphisms account for the cellular plasticity difference among individuals. Our early genome-wide analyses of single nucleotide polymorphisms (SNPs) with potential influence on protein phosphorylation characteristics in human suggest that these SNPs may result in signal rewiring due to alteration of protein-protein interactions such as dimerization (Mol Cell Proteomics. 2010. 9, 623-34). Here we introduce a method for optically imaging intracellular protein interactions at nanometer spatial resolution in live cells using photoactivatable complementary fluorescent (PACF) proteins. Subsets of complementary fluorescent protein molecules were activated, localized, and then bleached followed by the assembly of super-resolution images from aggregate position of sum interactive molecules. Using microtubule plus-end hub protein EB1, we have established proof-of-concept and revealed previously uncharacterized EB1 structural determinant in tracking microtubule plus-ends. A combination of PACF with PhosSNP, a database we established for predicting SNPs that influence phosphorylation-elicited signaling rewiring enables us to visualize the mechanism of action underlying PhosSNP-elicited cellular plasticity changes. Thus, PACF provides a unique approach to visualize structural determinants underlying SNP-rewired spatial dynamics of protein-protein interactions at single molecule scale.

P1512**Board Number: B1013****From intracellular signaling to collective behavior: Understanding the dynamical origins of collective cAMP oscillations in *Dictyostelium discoideum*.**A. Sgro¹, D. Schwab¹, J. Noorbakhsh², P. Mehta², T. Gregor¹;¹Physics and Lewis-Sigler Institute, Princeton University, Princeton, NJ, ²Physics, Boston University, Boston, MA

Collective behaviors are a common feature of a diverse range of biological systems, from flocking birds and schooling fish to swarming bacterial colonies and embryonic morphogenesis. Such population-level behaviors in cellular collectives are controlled by complex biochemical signaling networks that reside within individual cells to coordinate cell-cell communication. One of the most striking examples of these behaviors is the cAMP-coordinated transition from an independent, single-celled state to a multicellular aggregate in the eukaryotic social amoebae *Dictyostelium discoideum*. However, describing how these population-level collective behaviors arise from intracellular signaling network dynamics is challenging. Even in well-studied model systems many of the dynamics of underlying signaling networks remain uncharacterized, complicating efforts to build a predictive model that takes into account each network component and interaction. Physical systems have taught us that collective behaviors do not depend on all the details of the system and that in regimes with behavioral changes only a few types of behaviors exist. Using these principles, we have condensed the amoeba's complex signaling network dynamics into a simple two-variable phenomenological model. We have confirmed our model's success at capturing these dynamics through quantitative experimental measurements, using microfluidics to control the extracellular environment and a FRET reporter for intracellular cAMP to monitor cellular responses. By using the single-cell model as a building block for a multicellular model, we are able to predict and experimentally verify novel population-level behaviors. Together, our model and experiments demonstrate that stochasticity is a key player both in the initiation and the ongoing coordination of collective behaviors, allowing cells to communicate in noisy extracellular environments. Our results lay the groundwork for using these types of models to identify common principles of how cellular collective cellular behaviors arise in nature.

P1513**Board Number: B1014****Mechanochemistry of persistent plasmid movement.**L. Hu¹, J. Liu¹;¹National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD

The segregation of DNA prior to cell division is essential to the faithful inheritance of the genetic materials. In many bacteria, the segregation of the low-copy-number plasmids involves an active partition system composed of ParA ATPase and DNA-binding ParB protein, which stimulates the hydrolysis activity of ParA. Both in vivo and in vitro experiments have shown that the ParA/ParB system

can drive persistent movement in a directed fashion, just like a processive motor protein. However, the underlying mechanism remains unknown. We have developed the first theoretical model on ParA/ParB-mediated motility. We establish that the coupling between the ParA/ParB biochemistry and its mechanical action works as a robust engine. It powers the directed movement of plasmids, buffering against diffusive motion. Our work thus sheds light on a new emergent phenomenon, in which elaborate mechanochemical couplings of non-motor proteins can work collectively to propel cargos to designated locations, an ingenious way shaped by evolution to cope with the lack of a processive motor protein in bacteria.

Mechanistic and Structural Insight into Protein Liquid Droplets Formed by the DEAD-Box Helicase LAF-1.

S. Elbaum¹, Y. Kim², S. Myong^{2,3}, C. Brangwynne⁴;

¹Princeton University, Princeton, NJ, ²Bioengineering, University of Illinois, Urbana-Champaign, Urbana, IL, ³Univ Illinois, Urbana, IL, ⁴Chemical and Biological Engineering, Princeton University, Princeton, NJ

Phase transitions into liquid and hydrogel states have emerged as playing critical roles in cellular organization, including the regulation of RNA/protein assemblies, and their dysregulation in disease. However, the underlying molecular mechanisms remain poorly understood. Here, we show that LAF-1, a DEAD-box RNA helicase associated with P granules in the *C. elegans* germline, can phase separate into liquid droplets in-vitro, at near physiological (low μM) concentrations. LAF-1 droplet formation is driven by its N-terminal RGG domain, which is predicted to be disordered. We map the phase diagram of LAF-1, demonstrating that salt concentration finely tunes droplet propensity. Furthermore, we use microrheology and FRAP to reveal the local viscoelastic properties and molecular dynamics of droplets as a function of salt and time. These findings provide mechanistic and structural insight into the phase transition-driven assembly of liquid-like intracellular organelles.

MOLECULAR BIOPHYSICAL CHARACTERIZATION OF Krr1p-ssDNA COMPLEX.

A.M. Rodriguez Nassif¹, B. Pastrana-Rios¹;

¹Chemistry, Univ Puerto Rico-Mayaguez, Mayaguez, PR

Many syndromes are specifically related to defects in interactions between proteins and DNA. The study of the interaction between Krr1 with DNA will improve our understanding of fragile X syndrome and provide the basis to have the knowledge of regulatory functions within the nucleus. We studied the GXXGloop within the Krr1 KH domain specifically K159RRQRLIGPKGSTLKALELLTNCW182 (Krr1p) using Circular Dichroism (CD), Fourier transform Infrared Spectroscopy (FT-IR), and Two Dimensional Infrared

Spectroscopy (2DIR) to establish the secondary structure composition and molecular behavior of the Krr1p upon thermal denaturation. Krr1p was observed to have both α -helical and random coil components. In addition, the thermal transition temperature (T_m) was determined. We then proceeded to study the Krr1p-ssDNA interaction using CD and FT-IR which resulted the destabilization of Krr1p within the complex as the temperature increased above 40°C. More importantly the molecular dynamic of the complex will be discussed.

Microscopic (FLIM) analysis of NADH state changes during cell cycle progression in cancer cells.

C. Goul¹, M. Murata², M.A. Digman^{1,2}, S. Rafelski¹;

¹Developmental and Cell Biology, University California-Irvine, Irvine, CA, ²Biomedical Engineering, University California-Irvine, Irvine, CA

Cancers exhibit high metabolic activity via the “Warburg effect”, the shift to a high rate of glycolysis followed by lactic acid fermentation in the cytosol, rather than a low glycolytic rate followed by pyruvate oxidation. This increased glycolytic state causes a corresponding increase in cytosolic free NADH production. Increased NADH production in cancer cells is also the result of a heightened metabolic demand due to rapid cell division. Thus, NADH levels are indicative of cancer cell metabolic state. Specifically, a higher free/bound NADH ratio represents higher glycolytic activity, whereas a lower free/bound NADH ratio represents higher mitochondrial respiration. Without knowledge of NADH state (free or bound), NADH levels cannot be effectively studied. However, little is known about NADH state or distribution in cancer cells. Phasor-Fluorescence Lifetime Imaging Microscopy (Phasor-FLIM) is a useful tool to study NADH state and distribution, but NADH state and distribution are variable from cell to cell. NADH state analysis at different cell-cycle stages will allow for more specific and detailed comparisons between cancer cells. Here, Phasor-FLIM is used to quantify changes in NADH state and distribution during cell cycle progression. Different cancer cell lines, including Mb231 and U2OS, are used. Cancer cells in their flat, adherent interphase stage exhibit a low free/bound NADH ratio. During their rounded mitotic stage, cancer cells transition to a high free/bound NADH ratio and then return to a low free/bound NADH ratio as they divide. Therefore, striking change in NADH state during part of mitosis is observed. This suggests that cancer cells are at a high mitochondrial respiratory state in other stages but exhibit a spike in glycolysis during mitosis, returning to their original state by the time of division. The mitotic stages at which the spike occurs will be determined using mitosis specific fluorescent markers, and measurements will be compared to those in noncancerous cells.

P1517**Board Number: B1018****Getting in shape: mechanics of the extracellular matrix and *Drosophila* follicle geometry.**I. Heemskerk¹, S. Streichan¹;¹Kavli Institute for Theoretical Physics, Univ California-Santa Barbara, Santa Barbara, CA

During morphogenesis, genetics and mechanics determine tissue shape by controlling growth, movement, and shape change of cells. This involves forces that can be exerted within cells by regulation of the cytoskeleton, or externally by the extracellular matrix. The *Drosophila* follicle develops from round to asymmetrically elongated. We hypothesize that the basal membrane, which becomes organized during elongation, exerts the dominant forces required for this shape change. To guide our intuition and refine this idea, we formulate a mathematical model for follicle mechanics. Testing this requires organ scale or in toto data. Few analysis tools for effectively analyzing in toto image data are available. We present ImSAnE, a general software tool for quantitative analysis on curved tissue surfaces. We use it to quantify follicle geometry, infer tension anisotropies in the follicle epithelium, and measure the structure of the basement membrane. We then test our model against these data.

P1518**Board Number: B1019****Limitations of the limiting-pool mechanism for controlling the size of biological structures in cells.**L. Mohapatra¹, T. Lagny², J. Kondev¹;¹Department of Physics, Brandeis University, Waltham, MA, ²Institut Curie, Paris, France

Cells contain a number of micron-scale structures whose physiological functions are related to their size. Examples include mitotic spindles, cilia, and actin cables. Each of these structures is characterized by a narrow size distribution and they are composed of molecular building blocks that diffuse in the cytoplasm. A key question in cell biology is how the size of these structures is maintained in light of constant turnover of their molecular components. A related question is how different sized structures can coexist in the same cytoplasm while making use of the same building blocks. The role of the finite pool of building blocks in the control of size has received considerable attention as it offers a simple mechanism of size regulation: the size of the structure grows until the pool of available building blocks is depleted. Using theory and simulations, we study the limiting-pool mechanism of size control. We consider a simple model where a structure grows from a nucleating center by addition of diffusible building blocks which can also dissociate. The number of building blocks in the cell is fixed. While the growth rate is proportional to the free monomer concentration, we assume the dissociation rate to be constant. When we consider a single structure, we find that the distribution of sizes in steady state is peaked around a mean value and therefore the limiting pool of components provides a size-regulation

mechanism. Surprisingly, if there are two identical nucleating centers we find that the total mass of the two generated structures reaches a stable value, however their individual sizes are characterized by large fluctuations. When considering two competing nucleating centers with different rates of assembly, the one with the higher rate wins and produces a structure of a well-defined size, while the other structure does not form. Our theoretical study illustrates the limitations of the limiting-pool mechanism of size control and highlights the importance of additional mechanisms that are required if the cell is to generate multiple structures of a well-defined size using a common pool of building blocks.

Investigation of the electrical properties of doped melanin.

E. Mirizio^{1,2}, S. Rajasimhan¹, H. Li³, B. Qian³, M.F. Kiani³, F. Ren³, S.A. Baranowitz¹;

¹EpiTek, Medford, NJ, ²College of Biomedical Engineering, Drexel University, Philadelphia, PA, ³College of Engineering, Temple University, Philadelphia, PA

Melanin is a multifunctional pigment found in many species of animals. Its best understood function is the absorption of UV radiation in the human skin. Although the synthesis pathways of melanin are known, the final molecular structure of natural melanin remains controversial. It has been observed that the melanin molecules have the ability to incorporate water and metallic ions into their structure, thereby affecting behavior. Melanin has been reported to have thermoelectric, piezoelectric, and semiconducting properties in addition to its known biological functions.

This study focuses on the change in electrical resistance of melanin with the addition of several dopants. The melanin was extracted from a natural source, *Sepia officinalis* (cuttlefish) ink, centrifuged at 2900G, and sealed into glass samples with copper leads on both ends. The melanin was tested with several dopants: copper sulfate, zinc sulfate, ferrous sulfate, calcium chloride, lithium chloride, clay, and silicified cellulose. The dopants were added to the extracted melanin by heating the 50:50 mixtures of melanin and dopant for four hours with constant stirring. The excess dopant was then centrifuged out and the doped melanin was made into samples, each containing approximately 2 grams of the mixture. A multimeter was used to measure resistance over a period of 10 minutes.

Compared to the control (undoped) melanin, the only dopant that showed a substantial decrease in resistance was copper sulfate, having a decrease in resistance of about one order of magnitude. Additional testing has shown that increased external temperature during testing also decreases the resistance of the samples. This study indicates that the addition of the copper sulfate can significantly decrease the resistance of natural melanin. This may enhance its potential for use in electrical applications.

P1520**Board Number: B1021****Evaluation of temperature dependent electrical properties for hydrated natural melanins.**H. Li¹, E. Mirizio^{2,3}, S. Rajasimhan², B. Qian¹, S. Baranowitz², M.F. Kiani⁴, F. Ren⁴;¹Mechanical Engineering, Temple University, Philadelphia, PA, ²EpiTek, Medford, NJ, ³College of Biomedical Engineering, Drexel University, Philadelphia, PA, ⁴College of Engineering, Temple University, Philadelphia, PA

Melanins are widespread pigments found in cells called melanophores or melanocytes. Though known primarily for their ability to absorb ultraviolet light, melanins have a variety of interesting physical and electrical properties including photoconductivity, piezoelectricity, and thermoelectricity. These less studied properties may be related to some important biological functions. For example, thermoelectricity could be utilized to achieve cooling as a result of electrical current induced heat pumping.

Many studies on the thermoelectric properties of melanins were performed in the lyophilized (dehydrated) state, which is very different from the physiological state in which melanins exist in vivo. Since the electrical properties of melanins are strongly affected by their hydration level, this study examined melanins in their naturally hydrated states. Sepia melanin was centrifuged, washed, and then placed in sealed capsules. Polarization, electrical conductivity, heat induced voltage change, and thermal conductivity were measured.

Our results showed that natural melanins in their hydrated states exhibited natural polarization, which saturated over time. When subject to heating, voltage across the sample changed as a function of temperature difference. Both increasing and decreasing trends were observed, and further studies are desired to reveal the underlying mechanisms of the heat-induced voltage change. Nevertheless, based on our preliminary study, we suspect that the temperature dependent electrical properties are related to the pyroelectric phenomena of melanins where the polarization is a function of the temperature.

Results of the current study not only provide information on the thermal electrical properties of melanins, which are the basic pigment molecules of melanocytes, but also provide a general methodology to study the electrochemical behavior of pigments of many types that may be essential to key cellular processes.

Engineered Cell Penetrating Peptides for Stem Cell Biology Control.

G. Jin¹, F. Ghasemi Tahrir¹, W. Ma¹, W.H. Suh¹;

¹Bioengineering, Temple University, Philadelphia, PA

Cell Penetrating Peptides (CPPs) are utilized in various molecular delivery applications. CPPs actively transport into mammalian cells across the plasma membrane barrier. CPPs are commonly derived from proteins such as the HIV-1 transcriptional activator and the murine vascular endothelial cadherin. The lengths of CPPs generally range from 30-50 amino acids and can lead to preparative challenges. In this presentation, we will introduce a newly engineered short cell penetrating peptide (herein PepB; Due to patent filing issues we are not able to disclose the PepB sequence at this time) as an enabling platform technology. We have currently reduced the CPP sequence to PepB (<10mer). We have tested the PepB sequence to deliver bioactive molecules to mammalian cells and they have increased the mode of action inside stem cells when repeat sequences were utilized. Experimentally, PepB molecules were cultured with human embryonic kidney, lung cancer and neural stem cells and tested over multiple days to assess toxicity and biological activity (e.g., neuronal differentiation). Cellular uptake propensities were modulated based on PepB's covalent attachment to select small molecules. In order to more precisely define PepB's cell penetrating properties, we conducted live-cell imaging and confirmed that PepB-incorporating synthetic agents can enter cells and label them for multiple months in vitro.

Silencing the transcriptional repressor ZCT1 alters alkaloid biosynthesis in hairy root cultures of *Catharanthus roseus*/.

N.F. Rizvi¹, E.J. Cram², C. Lee-Parsons³;

¹Department of Chemical Engineering, Northeastern University, Boston, MA, ²Biology, Northeastern University, Boston, MA, ³Chemical Engineering; Chemistry and Chemical Biology, Northeastern University, Boston, MA

The medicinal plant, *Catharanthus roseus*, is the source of pharmaceutically valuable anticancer alkaloids, vincristine (VCR) and vinblastine (VBL). These alkaloids are produced only in *C. roseus* and at extremely low levels (0.0002 wt%). Due to their low levels, the isolation of these compounds is both laborious and costly, ranging from \$4 to \$60 million/kg. Despite these barriers, these alkaloids have been effectively used to treat cancer for over 50 years.

The biosynthesis of VCR and VBL is not entirely known but involves at least 35 intermediates and 30 enzymes. In an effort to increase VCR and VBL, key enzymes in the *C. roseus* biosynthetic pathway have

been overexpressed but this strategy has proven unsuccessful since the enzymatic bottleneck is shifted downstream. However, transcription factors regulate *multiple* genes in the pathway and therefore engineering their expression may potentially increase the overall flux through the network and lead to increased production of the desired compounds.

Here, we study key transcription factors involved in regulating multiple alkaloid biosynthetic enzymes. Since ZCT1 (Zinc finger *Catharanthus* transcription factor) is a known repressor of alkaloid biosynthetic enzymes, we established stable *C. roseus* hairy root cultures with estrogen-inducible *Zct1*-silencing through RNA interference (RNAi). The results of silencing this key repressor and implications in alkaloid biosynthesis in *C. roseus* were studied. Levels of *Zct1* decrease with estradiol treatment, and importantly, *Zct1* induction with plant hormone methyl jasmonate is overcome by estradiol silencing. *Zct1*-silencing also leads to an increase in specific metabolites including new metabolites not observed in the wild-type hairy root cultures. These changes in metabolites may potentially be correlated with changes in the regulation of downstream alkaloid biosynthetic genes.

Francisco, San Francisco, CA, ⁶Center for Systems and Synthetic Biology, University of California, San

Francisco, San Francisco, CA

There is growing interest in using extracellular matrix supported 3D organoid cultures to model cell-cell and cell-matrix interactions. Compared to 2D cultures, these organoid models are better in-vitro representations of disease and more faithfully recapitulate in-vivo phenotypes such as gene expression patterns, toxicology profiles and cell signaling. However, current 3D culture methods are limited in their ability to rapidly and reproducibly generate heterotypic assemblies of controlled size and shape, particularly when using primary cells. DNA-programmed assembly is one approach for controlling cell-cell or cell-surface adhesion without the need to genetically modify cells. We report a new strategy utilizing stepwise assembly of fatty acid modified oligonucleotides to label the phospholipid membrane of cells with single stranded DNA. This DNA is subsequently used as a reactive handle to control adhesion by specific duplex formation. Here we demonstrate proof of concept experiments for this strategy and robust DNA labeling of several primary cell samples. In addition, we use this labeling strategy in conjunction with a capping strand and microwells to rapidly synthesize aggregates of cells in desired sizes and shapes beyond simple spheroids. We demonstrate that these aggregates can be

transferred to extracellular matrix for further culture and study. We anticipate that simplifying the synthesis of microtissues will increase the accessibility of 3D organoid cultures as model systems.

Differential signaling through the EGFR pathway drives distinct collective cell behaviors in epithelial tissues.

A.K. Paulson¹, C. Krishnamurthy², J.S. Liu², Z.J. Gartner^{2,3};

¹Biomedical Sciences, University of California, San Francisco, San Francisco, CA, ²Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, ³Center for Systems and Synthetic Biology, University of California, San Francisco, San Francisco, CA

Emergent properties of tissues arise from the collective behavior of their constituent cells. These coordinated behaviors are believed to result in part from controlled or stochastic cell-to-cell variation in signaling and play important roles in development, homeostasis and disease processes such as invasion and metastasis. We previously demonstrated that heterogeneous expression of oncogenic Ras among mammary epithelial cells was sufficient to elicit multiple and distinct collective behaviors. Along with normal morphogenesis, behaviors observed in these tissues included cell extrusions, collective cell migration, and single hypermotile cells. Interestingly, emergent behaviors occurred with very low frequency when all cells of the tissue expressed similar levels of oncogenic Ras and depended on signals propagated through EGFR, Ras/MAPK, and PI3K. However, it is unknown how heterogeneous groups of cells decode these signals to make a collective behavioral decision. We used siRNA to target these key signaling pathways in high- and low-Ras expressing cells in order to determine whether some or all cells in a group require these signals to promote each emergent behavior. We find that in general, elevated pathway activation is required in a single 'leader' cell within the group for cell extrusion and collective cell migration behaviors. However, a counterintuitive requirement for signaling in the 'follower' cells also exists, and this regulates the shift between one emergent behavior and another. Indeed, some loss-of-function perturbations in the 'follower' cells actually accentuated emergent behaviors within the tissue. These studies imply that therapeutics delivered to a heterogeneous tumor environment could lead to unexpected enhancement of malignant behaviors.

P1525**Board Number: B1026****Development of a Novel, Physiologically and Anatomically Realistic *in vitro* Pediatric Blood Brain Barrier on a Chip.**S.P. Deosarkar¹, B. Augelli², B. Prabhakarandian³, B. Krynska², M.F. Kiani⁴;¹Department of Mechanical Engineering, Temple University (PA), Philadelphia, PA, ²Department of Neurology and Shriners Hospitals Pediatric Research Center, Temple University, Philadelphia, PA,³Biomedical Technology, CFD Research Corporation, Huntsville, AL, ⁴College of Engineering, Temple University, Philadelphia, PA

Blood brain barrier (BBB) is a physical and functional barrier that protects and regulates the brain parenchyma. Thus, a dysfunctional BBB can lead to various neurological disorders. Pediatric and adult BBB exhibit significant differences in its structure and function. In the immature brain, major risk factors of brain damage such as inflammation and/or hypoxia/ischemia have been shown to result in increased BBB permeability and are involved in the development of diseases such as cerebral palsy and traumatic brain injury. However, the biological mechanisms underlying the pathological changes of blood-brain barrier permeability in children are still largely unknown. This is primarily because of the ethical difficulties of conducting experiments in children and the lack of good experimental models of pediatric BBB. Thus, the objective of this study was to develop a physiologically realistic *in vitro* pediatric BBB model on a chip (B³C) that could be used to study the biological mechanisms of pediatric BBB function and/or dysfunction. We fabricated a B³C using an optically clear, oxygen permeable polymer, polydimethylsiloxane (PDMS) on a glass slide with vascular (apical) and tissue (basolateral) compartments. We isolated rat brain endothelial cells (RBECs) from rat pups. RBECs were cultured in the vascular compartment of the device under static or flow conditions in the presence or absence of astrocyte conditioned media (ACM). The barrier formation by RBECs in B³C was assessed by immunofluorescence staining of RBECs for tight junction molecules [e.g. zonula occludens-1 (ZO-1)] and by measuring transendothelial electrical resistance (TEER) and permeability of fluorescently tagged molecules of different sizes (e.g. sodium fluorescein and FITC-Dextrans of different molecular sizes) across the barrier formed by RBEC. Fluorescence microscopy was used to analyze the permeability of fluorescently tagged molecules across the *in vitro* BBB in our B³C model. We observed significant differences in the permeability of different sized molecules (e.g. sodium fluorescein and FITC-Dextrans of different molecular sizes). Additionally, we observed that RBEC exhibited more uniform tight junction formation when cultured under flow conditions in B³C compared to static conditions. Thus, in this study, we have developed a first realistic pediatric BBB model (B³C) using RBECs from rat pups which could serve as an *in vitro* model system for studying BBB function in pediatric neurological diseases as well as for testing novel therapies for these diseases.

P1526**Board Number: B1027****Contractility mediated wound closure in mesenchymal 3D microtissues.**J. Eyckmans^{1,2}, M.S. Sakar³, V. Shenoy⁴, D. Eberli⁵, B. Nelson³, C.S. Chen^{1,2};

¹Biomedical Engineering, Boston University, Boston, MA, ²Wyss Institute for Biologically Inspired Engineering, Harvard University, Boston, MA, ³Institute of Robotics and Intelligent Systems, ETH Zurich, Zurich, Switzerland, ⁴Dept of Material Science and Engineering, University of Pennsylvania, Philadelphia, United States, ⁵Laboratory for Urologic Tissue Engineering and Stem Cell Therapy, University Hospital Zurich, Zurich, Switzerland

Wound healing after injury is a highly dynamic process requiring migration and proliferation of multiple cell types. Many insights on the cellular interactions and signaling networks underlying wound healing are based on healing of scratches in monolayers of epithelial cells in 2D culture systems or wounds in *Drosophila* embryos. In contrast, how fibroblasts participate in wound healing is less well understood. Unlike epithelial cells lining surfaces and lumen *in vivo*, fibroblasts are ensconced in fibrous ECM and therefore don't display apical-basal polarity. Hence, the influx of cells into the site of injured ECM, the closure of the wound, and the subsequent ECM stiffening are all components of the process that are not captured by planar *in vitro* models for wound healing. To overcome this limitation, we present in this work a novel wound healing model to evaluate healing of microsurgically-induced wounds in an engineered 3D microtissue of fibroblasts embedded in a type I collagen matrix. Using our microfabricated tissue gauge technology (1), we generated arrays of 3D microtissues suspended between flexible cantilevers that simultaneously constrain the microtissues and report microtissue contractility in real-time. After compaction, microtissues were damaged with a microsurgical knife mounted to a microrobotic manipulation platform. Depending on the size of the incision (longitudinal axis: 100 to 300 μm), the wound closed within 12 to 24h. Gap closure was associated with progressively increasing microtissue contractility concomitant with directed migration of the cells towards filling of the defect. While phosphorylated myosin was detected with immunohistochemistry during closure, no purse string was observed. Using pharmacologic reagents, we found that the mechanisms for closure in this 3D model were distinct from those involved in healing of traditional 2D scratch wounds. Both increased and decreased Rho signaling reduced healing rates in 3D, but had no effect in the 2D scratch assay. In contrast, Cdc42 or Rac1 inhibitors did not impact 3D closure but prevented wound closure in 2D. We will present additional findings elucidating and further validating the mechanisms involved in driving wound healing in this model. These studies introduce a new model for studying wound, and highlight important mechanistic differences between gap closure by fibroblasts embedded in 3D matrix versus adherent to a planar surface.

Effects of exogenous retinoic acid on regenerating intestines from sea cucumbers in organ culture.

S.A. Bello-Melo¹, J.E. García-Arrarás¹;

¹Department of Biology, University of Puerto Rico, Rio Piedras Campus, San Juan, PR

The study of the mechanisms that allow the spontaneous regeneration of lost complex organs in simpler organisms might provide clues on how to stimulate organ regeneration in humans. The sea cucumber *Holothuria glaberrima* exhibits the extraordinary capacity to regenerate its gastrointestinal tract in less than four weeks after induced evisceration. Previously, our group has shown that some components of the retinoic acid (RA) signaling pathway, homologous to the chordate counterparts, are expressed during intestinal regeneration in sea cucumbers. However, the role of the RA signaling pathway during regeneration in sea cucumbers is still poorly understood. Here, we investigated the effects of exogenous retinoic acid (RA) during the intestinal regeneration of sea cucumbers using an *in vitro* approach. Regenerating gut rudiments were dissected from sea cucumbers at 7 days post-evisceration (dpe) and cultured for 60 h in modified L-15 cell culture medium containing RA at different doses (100, 50, 25, or 2.5 μ M). Gut rudiments incubated with DMSO were used as a control group. BrdU (50 μ M) was added to the culture medium for the last 24 h of culture to evaluate the effect of RA on cell proliferation. Subsequently, the intestines were processed according to the immunocytochemical techniques previously used in our lab. The size of the regenerating gut rudiment, the percentage of the proliferating cells, and the presence of muscle fibers or spindle-like structures (a measure of muscle dedifferentiation as cell condense their myofilaments) in the regenerating gut rudiment and adjacent mesentery were evaluated in tissue sections using fluorescence microscopy and the software Image J. We observed an increased gut rudiment's size in the tissues treated with the highest doses of RA (100 and 50 μ M) compared with those treated with the lowest doses of RA (25 and 2.5 μ M) and the control. In contrast, the percentage of dividing cells decreased with the RA treatment in a dose-dependent manner, from 15% for the control group (DMSO) to 5% in the group treated with RA 100 μ M. Unexpectedly, short muscle fibers were observed in the mesothelium of the regenerating gut rudiments treated with RA and in the control group. However, the fibers were more abundant in tissues treated with RA 2.5 μ M. At 7 dpe muscle fibers are not normally observed in the gut rudiment since they disappear at early regenerative stages and reform later on during regeneration. Taken together, these results suggest that the exogenous RA may accelerate the intestinal regeneration in sea cucumbers. The molecular mechanisms by which RA affects the intestinal regeneration will be explored in future experiments.

P1528**Board Number: B1030****c-Jun N Terminal Kinase (JNK) is required for archenteron invagination in the developing sea urchin embryo.**J. Long¹, M.T. Peeler¹;¹Biology, Susquehanna Univ, Selinsgrove, PA

The cellular events of gastrulation have been well characterized in sea urchins; however the underlying molecular mechanisms have not been well studied. This study seeks to understand the role of c-Jun N-terminal kinase (JNK), a component of the planar cell polarity pathway in the development of sea urchins. JNK has been shown to be required for embryonic development in other species, particularly in mediating cell migration. Adenosine triphosphate competitive JNK inhibitor SP600125 was used to characterize JNK's role in sea urchin embryos. We determined that loss of JNK function specifically disrupts invagination of the archenteron but not other cellular movements. Embryos treated with 2uM SP600125 developed normal vegetal plates but did not invaginate to form an archenteron. Other notable embryonic cell movements, specifically skeletogenic mesenchyme ingression, were not affected with treatment. Despite lacking a visible archenteron, cells at the vegetal plate expressed molecular markers for endoderm differentiation, such as alkaline phosphatase staining. These results suggest that JNK is required for invagination and morphogenesis of the archenteron but not for differentiation of endoderm, pigment, or skeletogenic mesenchyme cells, during sea urchin gastrulation.

P1529**Board Number: B1031****A force balance explains local and global cell movements during early zebrafish development.**J. Chai¹, A.L. Hamilton², C.D. Buckley¹, M. Krieg², I.H. Riedel-Kruse³, A.R. Dunn¹;¹Chemical Engineering, Stanford University, Stanford, CA, ²Molecular and Cellular Physiology, Stanford University, Stanford, CA, ³Bioengineering, Stanford University, Stanford, CA

Biological tissues undergo radical changes in shape during development, growth, and repair. Little is known about how 100-1000s of cells generate these intricately choreographed transformations. Here we examine the origins of collective cell movement during early zebrafish development, a powerful model system for addressing this topic. The first morphogenetic movement in zebrafish is epiboly, in which the blastoderm spreads uniformly across the yolk and converges at the vegetal pole. In this study, we show that tension within the actin band, a dense mesh of actin and myosin that assembles near the blastoderm margin, coordinates blastoderm migration on both the organismal and cellular length scales. We find that gentle mechanical deformation of the developing embryo causes shape-dependent alterations in blastoderm migration. In addition, we observe realignment of the anterior-posterior (AP) axis away from the animal-vegetal axis toward the new long axis of the embryo. Chemical disruption of

the actin band restores uniform blastoderm migration, eliminates AP axis reorientation, and increases cellular disorder at the blastoderm margin. An analytical model and resulting simulation based upon forces generated by the actin band recapitulates the experimental observations. Taken together, our findings suggest that a relatively simple physical mechanism, in this case tension generated by the actin band, can lead to long-range coordination of cell movements that would be difficult to achieve by biochemical signaling alone. Further, we show that AP axis specification, a fundamental step in the development of all embryos, is exquisitely sensitive to mechanical cues. These observations support the possibility that mechanical forces may play a ubiquitous role in

Development of the Zebrafish Pronephros: Cellular and Genetic Analysis of Nephron Tubulogenesis and Segment Patterning.

G. Gerlach¹, R.A. Wingert²;

¹Biological Sciences, University of Notre Dame, Notre Dame, IN, ²Department of Biological Sciences, University of Notre Dame, Notre Dame, IN

Chronic kidney disease (CKD) affects 300 million people worldwide, representing the 12th leading cause of death. Understanding how nephrons, the simplest functional unit of the kidney, develop can lend insight into the processes that go awry during disease. The zebrafish pronephros provides an excellent *in vivo* system to study the mechanisms of vertebrate nephrogenesis. When and how renal progenitors in the zebrafish embryo undergo tubulogenesis to form nephrons is poorly understood, but is known to involve a mesenchymal to epithelial transition (MET) and the acquisition of polarity. We determined the precise timing of these events in pronephros tubulogenesis. As the ternary polarity complex is an essential regulator of epithelial cell polarity across tissues, we performed gene knockdown studies to assess the roles of the related factors atypical protein kinase C iota and zeta (*prkci*, *prkcζ*). We found that *prkci* and *prkcζ* serve partially redundant functions to establish pronephros tubule epithelium polarity. Further, the loss of *prkci* or the combined knockdown of *prkci/ζ* disrupted proximal tubule morphogenesis and podocyte migration due to cardiac defects that prevented normal fluid flow to the kidney. Surprisingly, tubule cells in *prkci/ζ* morphants displayed ectopic expression of the transcription factor *pax2a* and the podocyte-associated genes *wt1a*, *wt1b*, and *podxl*, suggesting that *prkci/ζ* are needed to maintain renal epithelial identity. Knockdown of genes essential for cardiac contractility and vascular flow to the kidney, such as *tnnt2a*, or elimination of pronephros fluid output through knockdown of the intraflagellar transport gene *ift88*, was not associated with ectopic pronephros gene expression, thus suggesting a unique role for *prkci/ζ* in maintaining tubule epithelial identity separate from the consequence of disruptions to renal fluid flow. Interestingly, knockdown of *pax2a*, but not *wt1a*, was sufficient to rescue ectopic tubule gene expression in *prkci/ζ* morphants. These data suggest a model in which the redundant activities of *prkci* and *prkcζ* are essential to establish tubule epithelial polarity and also serve to maintain proper epithelial cell type identity in the tubule by inhibiting *pax2a* expression. Intriguingly, segment patterning of the pronephros was initially intact in *prkci/ζ* morphant

embryos suggesting the overarching MET and nephron patterning processes occur independent of one another. To better understand the conserved segmentation process of the nephron a forward genetic screen was performed. From our screen candidate mutations that disrupt the epithelial segments of the pronephros have been identified. These studies provide a valuable foundation for further analysis of MET during nephrogenesis, and have implications for understanding the pathways that affect nephron epithelial cells during kidney disease and regeneration.

Genetic Analysis and Characterization of the Novel Zebrafish Podocyte Mutant *zeppelin*.

P.T. Kroeger Jr¹, R. Miceli¹, M. McKernan¹, A. Fox¹, R. Bounds¹, J. Cihlar¹, R. Thummel², I. Leshchiner³, A.J. Davidson⁴, W. Goessling³, R.A. Wingert¹;

¹Department of Biological Sciences, University of Notre Dame, Notre Dame, IN, ²Department of Anatomy and Cell Biology, Wayne State Univ, Detroit, MI, ³Department of Medicine, Brigham and Women's Hospital, Boston, MA, ⁴Department of Molecular Medicine and Pathology, The University of Auckland, Auckland, New Zealand

The zebrafish pronephros is highly conserved with higher vertebrates, including mammals, thus making it an excellent model to study kidney formation. The nephron, or functional unit of the kidney, modifies the blood to excrete metabolic waste using a blood filter with specialized epithelial cells known as podocytes. Knowledge about podocyte development is highly relevant to the treatment and prevention of kidney disease, as podocyte injury leads to progressive scarring and nephron atrophy culminating with end stage renal failure, however the pathways that specify the podocyte lineage remain poorly understood. Through an edema based F3 forward genetic screen, we isolated *zeppelin* (*zep*), which displays edema at 5 days post fertilization and forms severely reduced podocytes as assayed by *in situ* hybridization with markers such as *wt1a*, *wt1b*, *lhx1a*, and *nephrin*. *zep* mutant embryos are unaffected by retinoic acid (RA) treatment, indicating that RA acts upstream or in an unrelated pathway with that of *zep*. Interestingly, the interrenal gland of *zep* mutants is increased in size. Preliminary cell death and proliferation assays in *zep* mutants did not show any alterations from wildtypes, suggesting the possibility of a cell fate switch between the podocyte and interrenal lineages. To determine the genetic lesion responsible for *zep*, we utilized a combinatorial strategy of whole genome sequencing (WGS) and meiotic mapping. These techniques narrowed the region to a small interval on chromosome 15, and candidate genes were knocked down with morpholinos (MO). Three independent MOs designed against *breast cancer 2, early onset* (*brca2*) phenocopied *zep*, recapitulating both the unique late edema phenotype, as well as the vast reduction of podocytes. This suggests, for the first time, that *brca2* is essential for renal development. Taken together, these findings provide novel insights into the genetic regulatory networks that control podocyte formation in the vertebrate kidney

P1532**Board Number: B1034****NADPH oxidase activity is required for axonal development in zebrafish.**C.J. Weaver¹, Y.F. Leung¹, D.M. Suter¹;¹Department of Biological Sciences, Purdue University, West Lafayette, IN

Nicotinamide adenine dinucleotide phosphate (NADPH) oxidases produce bursts of reactive oxygen species (ROS). Long thought to be involved exclusively in host defense, NADPH oxidase-derived ROS are now appreciated as critical signaling intermediates in a growing number of cell signaling pathways. However, their role in axonal growth and guidance has not been extensively studied. The zebrafish (*Danio rerio*), because of excellent live-imaging capability and well-developed molecular genetics, is an extremely powerful model system for studying axonal development *in vivo*. Our current study is the first to detail the expression of the known zebrafish NADPH oxidase (Nox) isoforms, Nox1, Nox2, Nox5 and Duox during development. Using quantitative PCR, we show that all Nox isoforms are expressed during the first two days of development. Our results indicate that expression levels differ greatly among Nox isoforms and over time. We used *in situ* hybridization to investigate Nox isoform expression in the brain, retina, and spinal cord. In support of the qPCR results, we detected expression of all four Nox isoforms in all brain tissues. Surprisingly, individual Nox isoforms are not tissue specific, but expressed broadly throughout the brain and spinal cord. We next investigated the functional significance of NADPH oxidases in axonal growth and guidance by applying two broad-spectrum Nox inhibitors, VAS2870 and Celastrol, during critical periods of axonal development. Both the anterior commissure and the optic nerve showed diminished axonal growth and the formation of mistargeted axons when NADPH oxidases were inhibited. This demonstrates that despite broad expression, inhibition of NADPH oxidases only interferes with the development of specific axons. In order to explore the function of individual Nox isoforms during axonal development, we have used a CRISPR/Cas9-based method to generate the first specific loss-of-function mutants for Nox1, Nox2, Nox5 and Duox in zebrafish. Upon the completion of genetic and phenotypic analysis, we will assess axonal growth and guidance in each mutant line. This study is the first to demonstrate an *in vivo* role for NADPH oxidase-derived ROS in axonal development.

P1533**Board Number: B1035****Oriented cell divisions during collective cell migration in *Drosophila*.**L.K. Lewellyn¹, V. Sun², S. Horne-Badovinac²;¹Biological Sciences, Butler University, Indianapolis, IN, ²MGCB, University of Chicago, Chicago, IL

Morphogenesis is a highly dynamic process that is critical to determine the final shape of an organ. We use *Drosophila* egg development as a highly tractable model system to study morphogenesis. Each fly egg develops from a multicellular, organ-like structure called an egg chamber. The egg chamber is composed of a central germ cell cluster surrounded by a layer of epithelial cells, called the follicle cells. As it grows during the 14 developmental stages of oogenesis, the egg chamber elongates preferentially

along the anterior-posterior (A-P) axis to generate an elliptical egg. During the early stages of egg chamber elongation, the follicle cells undergo a collective migration around the circumference of the egg chamber, resulting in a global tissue-level rotation. Collective follicle cell migration leads to the remodeling of the underlying basement membrane, which is thought to create a molecular corselet that promotes preferential growth of the egg chamber along the A-P axis. Through stage 6 of oogenesis, the follicle cells are undergoing both collective migration and mitosis. Because oriented cell divisions contribute to tissue elongation in other contexts, we asked whether oriented follicle cell divisions contribute to egg chamber elongation. Measuring the division angle of mitotic follicle cells demonstrated that there is an increasing bias in the orientation of division, such that as the egg chamber develops, follicle cells preferentially divide closer to the A-P axis. At the end of stage 6, the follicle cells stop dividing and switch to endocycling; however, collective migration continues through stage 8. If we prolong mitoses into these later migratory stages, we observe a significant increase in elongation of the egg chamber. Further, blocking follicle cell migration disrupts the bias in the division angle, suggesting that collective migration provides a cue to orient the dividing cells along the A-P axis. Therefore, our work suggests that there is a bias in the orientation of divisions in the developing egg chamber, and that the ability of cells to collectively migrate correlates with this progressive bias.

Cell cycle arrest is required for cell invasive behavior.

D.Q. Matus¹, L.L. Lohmer², L.C. Kelley², D.R. Sherwood³;

¹Biochemistry and Cell Biology, Stony Brook University, Stony Brook, NY, ²Biology, Duke University, Durham, NC, ³Biology Department, Duke University, Durham, NC

Despite its critical role in development, tissue homeostasis and cancer, the molecular mechanisms that drive cell invasive behavior are poorly understood. We are utilizing *Caenorhabditis elegans* anchor cell (AC) invasion as an *in vivo* model to identify transcription factors required to confer an invasive phenotype. Through a large-scale RNAi screen we have identified cell cycle arrest as a new transcriptionally-mediated feature of the invasion program. The conserved nuclear hormone receptor, *nhr-67/tlx* maintains the AC in a G1 arrested state through upregulation of *cki-1* (p27/KIP1) expression. Depletion of *nhr-67* creates non-invasive, mitotic ACs that fail to generate invadopodia or express matrix metalloproteinases (MMPs). Induced AC-specific expression of *cki-1* in *nhr-67* mutants restored G1 arrest, invadopodia formation, pro-invasive gene expression and rescued invasion. Together, our data indicates the requirement for a genetic program that links cell cycle arrest to the differentiation of the invasive phenotype and provide a possible explanation for the paradoxical observation that many metastatic cancers are non-proliferative.

P1535**Board Number: B1037****Non-muscle myosin regulates *C. elegans* epidermal morphogenesis.**K. Mastronardi¹, D. Wernike¹, Y. Chen¹, A.J. Piekny¹;¹Department of Biology, Concordia University, Montreal, QC

Tissue formation requires coordinated cell migration and shape changes, and is essential for the development of metazoans. However, it is challenging to study in complex organisms. We study epidermal morphogenesis in *C. elegans*, which is an excellent model due to its simplicity and amenability to microscopy, genetics and transgenic tools. Furthermore, the underlying processes that govern migration and cell shape changes are highly conserved among metazoans. We are interested in ventral enclosure, when the ventral epidermal cells migrate over underlying neuronal precursor cells, the neuroblasts, in order to encase the embryo in a single layer of epidermis. This process is initiated by the migration and adhesion of two pairs of anterior leading epidermal cells, followed by the migration and adhesion of eight pairs of posterior pocket epidermal cells. Previous studies showed that migration of the ventral epidermal cells requires the formation of F-actin-rich protrusions, and genes that mediate their formation are essential for ventral enclosure. However, non-muscle myosin has not been studied in this process, even though it is a key regulator of cell migration and shape change in other organisms. Furthermore, it is not clear how the underlying neuroblasts contribute to ventral enclosure; they likely secrete chemical cues that regulate migration of the ventral epidermal cells, but also could provide mechanical cues.

We found that the Rho GEF Ect2 (*ect-2* in *C. elegans*) is required for ventral enclosure. In *ect-2* mutant embryos, migration of the ventral epidermal cells and neuroblasts are strongly delayed. RhoA is also required for ventral enclosure, and both RhoA and ECT-2 are expressed in epidermal cells and neuroblasts. Since RhoA regulates Rho kinase to mediate non-muscle myosin contractility for migration in other organisms, we propose that myosin also regulates ventral epidermal cell migration for ventral enclosure. In support of this hypothesis, we found that GFP-tagged non-muscle myosin localizes to foci that organize into a supra-cellular ring-like structure around the ventral pocket cells during ventral enclosure. Surprisingly, these foci come from both epidermal cells and neuroblasts, and we found that the number and intensity of foci in both cell types are reduced in embryos mutant for *ect-2* or Rho kinase. We are currently examining the tissue-specific contribution of non-muscle myosin during ventral enclosure. These studies should shed light on the interplay between tissues during embryonic development.

P1536**Board Number: B1038****NAD⁺ Deficiency Triggers Changes in Metabolic Energy Pathways Affecting Gonad Development in *C. elegans*.**M.R. McReynolds¹, W. Wang¹, M. Shu¹, W. Hanna-Rose²;¹Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA, ²Pennsylvania State University, University Park, PA

NAD⁺ is an essential co-enzyme necessary for electron transport in many metabolic reactions, such as the citric acid cycle, glycolysis and the regeneration of ATP from ADP. NAD⁺ functions as a substrate for several enzymes known as NAD⁺ consumers (e.g. sirtuins and PARPs) that regulate key biological processes. Due to the emerging importance of cellular NAD⁺ metabolism, the goal of our research is to understand how NAD⁺ homeostasis is maintained. Our lab recently discovered that NAD⁺ insufficiency leads to delayed development of the gonad in *C. elegans*. Using Global Metabolomic Profiling, we discovered that our *pnc-1* mutants experienced glycolytic blockage where glyceraldehyde-3-phosphate (G3P) levels are up and 3-phosphoglycerate (3-PGA) levels are down. However, the level of pyruvate is inconsistent with the notable trends of G3P and 3-PGA. Restoring glycolysis, by feeding 3-PGA and phosphoenolpyruvic acid (PEP) metabolites, rescued this gonad delay phenotype in our *pnc-1* mutants. Although we noticed glycolytic blockage, we had evidence that pyruvate levels and mitochondrial functions were not changed in our *pnc-1* mutants indicating that the TCA cycle was not affected by NAD⁺ insufficiency. This led us to the question that if glucose is not being converted to pyruvate, then how are the levels and functions of pyruvate unchanged? Therefore, we hypothesized that excessive use of amino acids as an energy source compensates for insufficient glycolysis flux in *pnc-1* mutants. We performed targeted metabolomics and measured the levels of alanine and cysteine. Our results revealed that both alanine and cysteine show a 2-fold increase in our *pnc-1* mutants. We also observed an up-regulation of aminotransferase mRNA expression of important enzymes involved in amino acid catabolism. We are currently measuring the flux of isotope labeled glucose, alanine and cysteine to pyruvate in both N2 and *pnc-1* animals. If the turnover rate of alanine and/or cysteine is higher in our *pnc-1* mutants, then this data supports our hypothesis. Whereas, if the turnover rate of glucose is lower in our *pnc-1* animals, then this data supports the notion that glycolytic blockage is occurring due to NAD⁺ insufficiency. We interpret these data as evidence that excessive amino acid use as an energy source is compensating for glycolysis flux in *pnc-1* mutants.

P1537**Board Number: B1039****Hindsight regulates photoreceptor axon targeting through transcriptional control of jitterbug/Filamin and multiple genes involved in actin regulation and axon targeting in *Drosophila*.**

P. Olguin¹, C. Oliva², M. Maureira¹, J. Canovas², C. Molina-Fernandez¹, E. Lopez², J. Sierralta²;
¹Human Genetics, ICBM, Universidad de Chile, Santiago, Chile, ²Physiology and Biophysics, ICBM, Universidad de Chile, Santiago, Chile

The establishment of well-defined synaptic connections during development is a key step in the maturation of the nervous system of vertebrates and invertebrates. Previously, by using a microarray analysis, we have shown that the transcription factor Hindsight (HNT) controls the expression of a group of genes involved in axon guidance and actin regulation.

However, it remains unclear how HNT controls the expression of these genes and how they function to regulate axon targeting.

To tackle these questions, first we performed loss of function (LOF) analysis, which confirmed the role of *otk/PTK7* in photoreceptor axon targeting and uncovered Tiggrin, an integrin ligand, and *Jbug/Filamin*, a conserved actin-binding protein, as new factors that participate of photoreceptor axon targeting. Since HNT LOF results in diminished expression of *jbug/Filamin* and *otk* we hypothesized that HNT acts directly through them to regulate axon targeting. To test this idea, we overexpressed *jbug/Filamin* in a HNT mutant background to verify whether the phenotype is rescued. Our data indicates that HNT acts partially through *jbug/Filamin* to regulate axon targeting.

Finally, to confirm our previous bioinformatic data on the transcription regulation of *jbug/Filamin*, we performed a promoter analysis *in silico* and by using Chromatin Immunoprecipitation and EMSA. Our data showed that HNT binds directly to a new consensus motif, suggesting that HNT regulates directly and positively the expression of *jbug/Filamin*.

Our work sheds light into the understanding of how transcription factors coordinate the expression of a group of genes involved in actin regulation and axon targeting in order to achieve the correct connectivity pattern in the nervous system. Further studies will be required to clarify the mechanism by which these genes regulate axon targeting.

P1538**Board Number: B1040****Blocking EGF signaling in perineurial glia during *Drosophila* metamorphosis leads to aberrant nerve branching patterns.**J.J. Fernandes¹, M. Siefert¹;¹Miami Univ, Oxford, OH

The pattern of larval abdominal nerves in *Drosophila* is reorganized during metamorphosis to generate a new adult pattern. This involves fusion of 5 sets of posterior abdominal nerves into a single terminal nerve trunk (TNT), which defasciculates in the body wall to innervate muscle targets. Each nerve is surrounded by three glial layers and this study aims to examine a role for the most external layer in bringing about nerve fusion. Using a layer specific Gal4 driver line, a dominant negative form of the EGF receptor (DN DER) was targeted to the perineurial layer, and was expressed during the 4 day period of metamorphosis. In the adults that emerged, the number of glial cells were examined using the anti-repo antibody, in addition to the pattern of nerves (visualized with anti- HRP). The number of repo-positive nuclei in experimental animals along the TNT just as it emerges from the abdominal ganglion was reduced by half (controls: 32.4 ± 3.2 ; experimental: 16 ± 0.8 ; $n=8$ for both groups; P

P1539**Board Number: B1041****Sac1 selectively regulates trafficking of adhesion molecules in the developing *Drosophila* eye.**L. Del Bel^{1,2}, R. Wilk¹, G. Polevoy², J. Burgess^{1,2}, J.A. Brill²;¹Molecular Genetics, University of Toronto, Toronto, ON, ²Cell Biology Program, Hospital for Sick Children, Toronto, ON

Phosphatidylinositol phosphates (PIPs) are membrane lipids that regulate many cellular events. They can act as signaling molecules, organelle identifiers and recruiters of effector proteins. Phosphatidylinositol (PI) 4-phosphate (PI4P) is the most abundant cellular PIP. PI4P is present on most membranes in the cell; however, it is enriched at the Golgi, where it recruits effectors of intracellular trafficking. PI4P-regulating enzymes have been well studied in yeast and cultured cells, yet little is known about their specific roles in animal development. In *Drosophila melanogaster*, three PI 4-kinases are responsible for generating PI4P, whereas a single phosphatase, Sac1, keeps PI4P levels in check. By generating *Drosophila* mutants, we discovered that proper regulation of PI4P by Sac1 is critical for eye development. Flies bearing a temperature-sensitive (ts) allele of *sac1* exhibit an eye pigmentation defect, as well as a rough eye phenotype due to defects in pigment cell morphogenesis.

During early pupal eye development (24-30hr after puparium formation, APF) we find that the Neph1 homolog Roughest, a transmembrane protein required for ommatidial patterning and pigment cell specification, is normally enriched at the plasma membrane. However, this enrichment is not observed

in *sac1^{ts}* mutants. As a result, *sac1^{ts}* mutants exhibit irregular, multi-layered interommatidial cells (pigment cell precursors), as well as disorganized bristles. Interestingly, Roughest's paralog Kirre, reaches the plasma membrane as expected, suggesting that Roughest regulation and trafficking alone is sensitive to alterations in PI4P. At later stages of pupal eye development (42hr APF), we find that interommatidial cells in *sac1^{ts}* mutants exhibit ER stress, as monitored by increased Xbp1 splicing. These cells also accumulate Myospheroid (β -integrin) and Notch, in addition to Roughest and Kirre. Our results demonstrate that proper regulation of PI4P by Sac1 is critical for trafficking of adhesion proteins and for maintaining ER homeostasis during *Drosophila* eye development.

Regulatory Role of miR-124 in Early Development.

S. Suarez¹, J.L. Song²;

¹Biology, University of Delaware, Newark, DE, ²Biological Sciences, University of Delaware, Newark, DE

microRNAs (miRNAs) play a crucial role in cell differentiation. The brain-specific miR-124 is highly conserved in both invertebrates and vertebrates. We propose to use the purple sea urchin, *Strongylocentrotus purpuratus*, to examine the function of miR-124. The Delta/Notch is a conserved signaling pathway that regulates neural differentiation and it also activates GCM that is critical for the specification of mesodermally-derived pigment cells. We bioinformatically identified Notch and GCM to contain potential miR-124 binding sites. We hypothesize that miR-124 regulates the Delta/Notch signaling pathway important for neurogenesis and mesodermal specification. Using luciferase reporter constructs and site-directed mutagenesis, we will test the direct regulation of miR-124 of Notch. Dose-dependent miR-124 loss-of-function induced phenotypes include a significantly larger midgut width, abnormal cell sizes, and cell clumps at the gastrula stage (48 hours post fertilization). This study elucidates the function of miR-124 by identifying its direct gene targets and contributes to our understanding of neural development and mesodermal specification in the early embryo.

Microtubule-dependent apical restriction of recycling endosomes sustains adherens junctions during morphogenesis of the *Drosophila* tracheal system.

V. Brodu¹, P. Le Droguen², S. Claret¹, A. Guichet¹;

¹Institut Jacques Monod, Paris, France, ²Cell and Developmental, University of Dundee, Dundee, United Kingdom

Epithelium remodelling is an essential mechanism for organogenesis during which cells change shape and positions while maintaining contact with each other. Adherens junctions (AJs) mediate stable cohesion between cells but must be actively reorganised to allow morphogenesis. Vesicle trafficking and

the microtubule (MT) cytoskeleton contribute to regulating AJ plasticity but their cross relationship remains elusive. We carried out a detailed analysis of the role of MTs in cell remodelling during the formation of the embryonic respiratory organ of *Drosophila*. The so called tracheal system is a very well characterised multicellular organ composed of highly ramified epithelial branches. We induced MT depolymerisation specifically in tracheal cells, and found that MTs are essential during a specific time frame corresponding to tracheal cell elongation that drives branch outgrowth. In the absence of MTs, tracheal cells over-elongated ultimately leading to branch breaks. We established through 3D quantifications that MTs are critical to sustain E-Cadherin and Par-3 levels at AJs. Furthermore, maintaining E-Cadherin/Par-3 levels at the apical domain requires de novo synthesis rather than internalisation and recycling from and to the apical plasma membrane. However, we showed that the apical targeting of E-Cadherin and Par-3 requires the functional recycling endosome, suggesting an intermediate role for this compartment in sorting de novo synthesized E-Cadherin to the plasma membrane. Our results further demonstrated that, in tracheal cells, the observed apical enrichment of the recycling endosome is dependent on the MT motor Dynein, and essential for its function. We revealed that E-Cad distribution in tracheal cells, undergoing 3D remodelling through collective cell migration, is more sensitive to MT depolymerisation and to the function of the recycling endosome than the overlying 2D ectodermal cells. Altogether, our results uncover an MT-Dynein-dependent apical restriction of recycling endosomes that controls adhesion by sustaining Par-3 and E-Cadherin levels at AJs during organ formation.

Twist signaling and intercellular coupling coordinate pulsed and ratcheted apical contractions during tissue folding.

S. Xie¹, A.C. Martin²;

¹Computational and Systems Biology PhD Program, Massachusetts Institute of Technology, Cambridge, MA, ²Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA

For multicellular tissues to change shape, dynamic cell shape changes must be coordinated across the tissue to give rise to the correct pattern of forces and geometries that will restructure tissue architecture. A ubiquitous mechanism responsible for cell shape change is actin-myosin contraction, in which the molecular motor myosin contracts cortical networks of filamentous actin (F-actin) to generate tensile force. In a wide variety of developmental contexts, actin-myosin contractions occur in discrete force generating events, called pulses, in which myosin cyclically contracts an F-actin meshwork. A well-studied example is apical constriction during *Drosophila* ventral furrow formation, in which collective apical constriction causes epithelial folding and cell invagination. In this system, cycles of rapid constriction are stabilized through a proposed ratchet mechanism that is dependent on high levels of the transcription factor Twist. To investigate how these two modes of contractility, pulse and ratchet, are spatiotemporally coordinated through signaling or intercellular coupling, we developed a computational approach that systematically identifies contractile events as well as makes quantitative

measurements of their location, timing, and ratchet engagement. We find that Twist signaling in ventral furrow cells promote the transition from unratcheted, weak, and lower-frequency pulses to ratcheted, stronger, and higher-frequency pulses. We also show that pulses are spatially coordinated; both cell-autonomous and non cell-autonomous factors influence ratchet engagement. Ratcheting is associated with persistent myosin structures within a cell as well as enrichment in having pulses co-occur in next-neighbor cells. In addition, neighboring ratcheted pulses act cooperatively to constrict the cells' apical areas. Our findings show that coordinated force generation arises from the interplay between a global signaling program and intercellular coupling between individual cells of the epithelium.

Macroglobulin complement related (Mcr) and Thioester protein 3 (Tep3) demonstrate a requirement for thioester-containing proteins in *Drosophila* development.

S.M. Hall¹, R.E. Ward¹;

¹Molecular Biosciences, University of Kansas, Lawrence, KS

Thioester-containing proteins (TEPs) are conserved among vertebrates and invertebrates and include the complement and macroglobulin families of proteins. TEP proteins have been studied for their role in innate immunity and have been found to aid in the phagocytosis of pathogens. Our lab recently characterized one of the six *Drosophila* TEP genes, *Macroglobulin complement related (Mcr)*, as having an essential developmental role in the establishment and maintenance of the epithelial septate junction, the invertebrate barrier junction that is functionally analogous to the vertebrate tight junction. Interestingly, a recent examination of the vertebrate TEP gene, *CD109*, also suggested a developmental requirement, indicating that this protein family may have roles in essential developmental processes in addition to innate immunity. Our lab is investigating if this dual role is specific to *Mcr* and *CD109* or is a conserved feature of additional TEP genes. To examine this question, we conducted a lethal phase analysis and found that four of the six *Drosophila* TEP genes contribute to one or more developmental processes. *Thioester protein 3 (Tep3)* encodes a protein with a signal sequence, a potential integrin binding site, and a complete macroglobulin domain. Mutations in *Tep3* result in an extended lethal phase with a variety of terminal phenotypes, including persistent salivary glands. Autophagy dependent programmed cell death is required for the destruction of larval salivary glands during metamorphosis and requires the engulfment receptor Draper. The localization of Draper in salivary glands requires *Tep3*, suggesting a role for *Tep3* in developmental autophagy.

P1544**Board Number: B1046****ROCK organizes ratcheted apical constriction in a folding epithelium by continuously stabilizing apical myosin.**J.S. Coravos¹, A.C. Martin¹;¹Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA

Apical constriction transforms epithelial cells from a columnar to a wedge or cone shape, which can result in bending and folding of epithelial sheets during organogenesis. Apical constriction in many systems, including *Drosophila* gastrulation, occurs through pulses of rapid contraction, with reduced apical area being maintained between pulses. These dynamics suggest that apical constriction requires a ratchet-like component. A proposed mechanism for ratcheted constriction is that Rho-associated coiled-coil kinase (ROCK) not only elicits contractile pulses through dynamic myosin phosphorylation, but also subsequently stabilizes an apical actomyosin meshwork that restrains apical area against opposing stresses. This model is difficult to test because genetic inactivation of ROCK or early inhibitor injection prevents all apical myosin accumulation. Here, we present a novel approach in which we can image an embryo while simultaneously injecting it with an inhibitor. By giving us both precise temporal control of the perturbation, and observations of the immediate response, this approach allows us to probe the requirement of ROCK in stabilizing cell shape after constriction has initiated. We find that ROCK inhibition leads to immediate relaxation of apical area and loss of apical actin and myosin organization. This result suggests that continuous ROCK activity organizes the molecular ratchet through maintenance of actin and myosin in the apical domain of apically constricting cells.

P1545**Board Number: B1047****Regulation of adherens junction stability by intracellular pH dynamics.**B.K. Grillo-Hill¹, M. Esquivel¹, K.A. White¹, D.L. Barber¹;¹Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA

Changes in intracellular pH (pHi) are linked to several developmental processes, however the role of pHi dynamics in cell differentiation and epithelial plasticity remains unexplored. We found that increased pHi is necessary for the differentiation program of epithelial-mesenchymal transition (EMT). With EMT of human lung alveolar and mouse mammary epithelial cells induced by TGF- β , we found that pHi increased ~ 0.3 units and we found increased activity of the plasma membrane Na⁺-H⁺ exchanger NHE1, a major regulator of pHi homeostasis. NHE1 shRNA specifically prevents increased pHi and blocks EMT, including dissolution of adherens junctions, actin stress fiber formation and transcriptional reprogramming. We also found that increasing pHi in the absence of TGF- β was sufficient to decrease β -catenin levels at adherens junctions. To test a role for β -catenin in pH-dependent dissolution of adherens junctions, we investigated genetic interactions in *Drosophila*. We found that retinal overexpression of *Dnhe2*, the ortholog of NHE1, increases pHi and disrupts cell architecture, manifested

as a “rough eye” phenotype. Overexpression of *armadillo* (*arm*, ortholog of β -catenin) suppresses this phenotype, while RNAi knockdown of *arm* enhances it. These data suggest that β -catenin may be a pH sensor with decreased stability at higher pH. β -catenin degradation is predominantly mediated by GSK3- β phosphorylation of Ser33 and Ser37, which promotes recognition and degradation by the ubiquitin-proteasome pathway. We predicted His36, located between Ser33/37 might function in pH sensing with a neutral His36 at higher pH decreasing stability and a protonated His36 at lower pH increasing stability. Although His36 is evolutionarily conserved, its functional significance has not been reported. However, the COSMIC database indicates a recurring β -catenin-H36R mutation in distinct cancers, which generally have increased pH_i. We predicted that a substitution with a positive charge would prevent pH-regulated β -catenin degradation. We confirmed this prediction by showing that overexpression of *armH47R* (analogous to human H36R) but not *armH47A* or *armWT* phenocopies the gain-of-function *armT52A* that is nonphosphorylatable and resistant to degradation. We are currently testing whether charged His36 at lower pH increases β -catenin stability by electrostatically interfering with Ser33/37 phosphorylation or E3 ubiquitin ligase binding. Our data indicate the new finding of pH sensing by β -catenin, with decreased stability at higher pH_i, and reveal a novel mechanism for remodeling of cell-cell junctions by dynamic changes in pH_i. Additionally, many cancers have increased pH_i, suggesting that oncogenic roles for β -catenin may also be regulated by pH_i.

Cell Intercalation in *Drosophila* Germ-Band Extension Is Controlled Through Local Regulation of Junction Sliding.

T.E. Vanderleest¹, A. Motlong¹, C. Jewett¹, Y. Xie¹, J.T. Blankenship¹, D. Loerke¹;

¹Univ Denver, Denver, CO

The elongation of the central body axis is a fundamental morphogenetic process in embryogenesis and organogenesis. One widely studied example of this process is germ-band extension (GBE) in *Drosophila*, where the germ-band epithelium elongates along the anterior-posterior (AP) axis while simultaneously narrowing in the dorsal-ventral (DV) direction. This process is driven by cell intercalation, where a junction between AP neighbors fully contracts to a common vertex, which in turn resolves directionally through the formation of a new junction between DV neighbors. In *Drosophila* GBE, the symmetry-breaking cues for intercalation are provided by a system of planar polarized localization of acto-myosin and adhesion proteins, which are concentrated at AP or DV junctions, respectively. Based on the requirement for myosin and on measurement of the line tension of these junctions in laser dissection experiments, the current mechanistic model holds that shortening of AP junctions is caused by an increase in AP line tension mediated by the contraction of apically enriched actomyosin superstructures. Physically, this line tension model predicts that (1) contraction of AP junctions should occur through mechanically coupled inward motion of junction vertices, and that (2) contraction should be initiated from the apical end. Using a Matlab-based suite for automated computational image analysis, we have tracked junction remodeling during GBE with high spatial and temporal resolution. We found no

evidence that vertex motion during GBE junction remodeling is mechanically coupled, but that vertices undergo independent and reversible step-like motion. In addition, instead of systematic propagation from the apical to the basal end, we found that remodeling events - including contractions of AP junctions - are initiated both apically and basolaterally. Based on these results, we suggest that junction remodeling is *not* directly driven by apical line tension anisotropy; rather, junction remodeling is the result of directional local sliding motion of individual vertices, which is driven by a pool of actomyosin that operates on the entire length of the apical-basal axis, and that regulates adhesion and/or membrane traffic events through a mechanism based on locally confined and anisotropic contraction.

A maternal-zygotic module stabilizes F-actin to promote robust morphogenesis.

L. Zheng¹, H. Xu¹, L.A. Sepúlveda¹, L.C. Rhonald², O. Lichtarge², I. Golding^{1,3,4}, A.M. Sokac¹;

¹Verna and Marrs McLean Department of Biochemistry and Molecular Biology, Baylor College of Medicine, Houston, TX, ²Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, ³Center for Theoretical Biological Physics, Rice University, Houston, TX, ⁴Center for the Physics of Living Cells, University of Illinois at Urbana-Champaign, Urbana, IL

Robustness is a property built into biological systems to ensure that the outcome of an event is reliable even when inputs, like gene dosage and environment, vary. During development, robustness safeguards embryos against mistakes that underlie structural and functional birth defects. Yet, our knowledge of how robustness is achieved during mechanical events like embryonic morphogenesis is very limited.

Here we show that the tissue-building event of *Drosophila* cellularization is made robust by mechanisms targeting F-actin. We find that F-actin levels are significantly reduced in cellularizing embryos upon high temperature perturbation. This F-actin reduction leads to failures in cellularization and embryos that do not hatch. Using a genetic strategy, we identified two novel members of the Vinculin/ α -Catenin Superfamily that work together to reinforce F-actin against such perturbations (Zheng et al., 2013). We find that zygotically-expressed *serendipity- α* (*sry- α*) and maternally-loaded *spitting image* (*spt*) are paralogs that share an overlapping, actin-stabilizing activity during cellularization. *spt* alone is sufficient for cellularization at optimal conditions, but both *spt* plus *sry- α* are required at high temperature and when the actin cytoskeleton is genetically compromised by a reduced dose of the actin accessory protein Profilin.

Strikingly, we find that *Sry- α* and *Spt* expression is precisely controlled, and that there is crosstalk between them. Specifically, *Spt* provides pre-cellularization functions that *Sry- α* cannot provide; and expressing elevated levels of *Spt* alone is not an option because it induces gain-of-function phenotypes. In addition, reducing maternal *spt* dosage triggers a compensatory up-regulation of zygotic *sry- α* transcription.

We suggest that *Sry- α* and *Spt* represent a robustness-promoting module for cellularization: Cross-talk between maternal *spt* and zygotic *sry- α* demonstrates that “paralog interactions” can span between maternal and zygotic genomes to promote robustness. In addition, we show for the first time that specific cytoskeletal-based mechanisms promote robust morphogenesis. Since all morphogenesis depends on cytoskeletal remodeling, in embryos and adults, robustness-promoting mechanisms aimed at F-actin could be effective at all life stages.

Myosin II regulation and activity provide spatial and temporal control of the forces that shape tissues.

K.E. Kasza¹, D.L. Farrell¹, J.A. Zallen²;

¹Developmental Biology Program, Sloan-Kettering Institute, New York, NY, ²Developmental Biology, Sloan-Kettering Inst/HHMI, New York, NY

During development, the forces generated by actomyosin contractility are controlled in space and time to shape simple epithelia into tissues with complex form and structure. Myosin II regulation and force generation have been extensively studied *in vitro*, but how these molecular properties are translated to longer lengthscales to achieve the patterns of forces that shape tissues is poorly understood. In the *Drosophila* embryo, planar polarized patterns of myosin activity promote oriented cell rearrangements that rapidly elongate the body axis from head to tail. To gain insight into how tissue elongation arises from molecular-level myosin activity, we generated a collection of transgenic lines expressing myosin II variants with altered molecular properties, including variants that disrupt regulatory phosphorylation or alter the speed at which myosin translocates actin filaments. We are using quantitative live imaging, FRAP, and laser ablation to analyze myosin dynamics and activity during tissue elongation. We find that both classes of myosin variants disrupt elongation, but have distinct effects at the molecular and cellular levels. First, we manipulated myosin regulatory light chain (RLC) phosphorylation, which promotes the assembly of inactive myosin monomers into active contractile filaments. These phosphovariants reveal that regulated myosin phosphorylation influences both the level and the spatiotemporal pattern of myosin activity. In embryos expressing phosphomimetic, constitutively active RLC, myosin is more stably associated with the cell cortex and cells rearrange faster and participate in more higher-order collective rearrangements. In embryos expressing unphosphorylatable, inactive RLC, myosin turns over faster at the cortex and there are fewer, slower cell rearrangements. Strikingly, myosin planar polarity and mechanical anisotropy are reduced in embryos expressing either phosphovariant, associated with poorly oriented cell rearrangements and less efficient tissue elongation, indicating that regulated myosin phosphorylation is essential for controlling the spatiotemporal patterns of myosin activity in this tissue. In addition, we manipulated the myosin motor domain to produce variants predicted to alter the speed at which myosin translocates actin filaments. Like constitutively active myosin, motor variants predicted to slow myosin translocation are more stably associated with the cortex, but produce distinct myosin localization patterns, cell behaviors, and tissue elongation phenotypes. These quantitative live imaging

studies provide insight into how specific features of myosin activity at the molecular level give rise to the spatially and temporally regulated forces that shape tissues.

Tight apposition and multiple cell-cell contacts mediate myoblast fusion in *Drosophila*.

N. Dhanyasi^{1,2,3}, E. Shimoni⁴, V. Shinder⁴, K. Vijayraghavan², B. Shilo¹, E.D. Schejter¹;

¹Department of Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel, ²Genetics and Development, National Centre for Biological Sciences, Bangalore, India, ³Manipal University, Manipal, India, ⁴Chemical research support, Weizmann Institute of Science, Rehovot, Israel

Myoblast fusion is an essential process underlying development, growth and regeneration of muscles in multicellular organisms. Our work focuses on an ultra-structural description of the fusion process during formation of the indirect flight muscles (IFMs) of *Drosophila*. These large muscles, which display a variety of structural features analogous to those of vertebrate muscles, are generated through fusion of numerous myoblasts with prominent myotube templates, making them an attractive subject for study of myoblast fusion in an experimental system amenable to genetic investigation. In order to study fusion between IFM myotubes and myoblasts, we have employed a novel tissue preparation protocol, which allows for high-quality preservation and visualization of cell membranes, and a variety of transmission electron-microscopy (TEM) techniques (FIB/SEM, single section TEM and STEM tomography). Using these methods, we have identified a series of distinct steps in the IFM myoblast fusion process, mediated, as genetic analysis suggests, by different cellular machineries. Cell-adhesion elements are essential for an initial association between the myoblasts and myotubes, bringing them in close (~25nm) proximity to each other. Myoblasts then flatten their surface and move even closer (~10nm) to the myotubes, a transition that is associated with formation of multiple point-like contact sites between the two cell types. Components of the Arp2/3 branched-actin polymerization machinery, established mediators of myoblast fusion in *Drosophila*, as well as the MARVEL-domain transmembrane protein Singlet-bar, are required for these events. The myotube-myoblast contact sites, which form along long stretches of the apposed membranes, and are not associated with membrane protrusions, give rise to multiple nascent fusion pores, which perforate the cell membranes. The pores grow in size, leading to cell membrane breakdown and completion of the fusion process.

P1550**Board Number: B1052****Mechanical forces drive vertex resolution during *Drosophila* axis elongation.**J. Yu¹, R. Fernandez-Gonzalez^{1,2,3};¹Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, ²Department of Cell and Systems Biology, University of Toronto, Toronto, ON, ³Developmental and Stem Cell Biology Program, The Hospital for Sick Children, Toronto, ON

Convergent extension, a conserved process in which a tissue elongates along one axis and narrows along a second orthogonal axis, is necessary for kidney tubule, limb bud, and neural tube elongation. In the *Drosophila* embryo, the elongation of the anterior-posterior body axis is driven by convergent extension largely mediated by cell intercalation. During intercalation, cell interfaces parallel to the dorsal-ventral axis of the animal contract, forming transient vertices where four or more cells meet. These multicellular vertices are resolved through the assembly of new cell interfaces parallel to the anterior-posterior axis of the animal. Currently, the mechanisms behind new interface assembly during vertex resolution are poorly understood.

Vertex resolution is accompanied by the accumulation of actin at the resolving interface, and mechanical tension can promote actin polymerization. To determine if new cell interfaces during axis elongation sustain mechanical tension, we used laser ablation to sever newly-forming interfaces. The velocity of retraction of the tricellular vertices on either side of the ablation site is proportional to the tension sustained by the severed interface. Using particle tracking velocimetry to quantify recoil velocity, we found that new cell interfaces resulting from vertex resolution sustained 32% greater mechanical tension than older, more stable interfaces with a similar orientation. To determine if mechanical tension is sufficient to increase the rate of new interface assembly, we applied ectopic tension parallel to the direction of interface resolution using laser nanosurgery, and we found that the elongation rate of new interfaces increased 1.81-fold when compared to control embryos. Together, these data suggest that mechanical forces oriented along the anterior-posterior axis of the animal drive vertex resolution during axis elongation in *Drosophila*. We previously showed that intercalating cells undergo pulsatile contractions of their apical surfaces, and that the amplitude of these contractions is greater along the anterior-posterior axis of the embryo. Using quantitative image analysis, we have found that new interfaces resulting from vertex resolution do not elongate in a continuous manner; rather, elongation occurs in pulses. We are currently investigating whether pulses of new edge elongation are correlated with pulses of apical constriction in the cells anterior and posterior to the new interface. Characterizing the mechanical signals behind axis elongation will be crucial in understanding the cellular and molecular mechanisms of animal development, as well as the causes of birth defects such as spina bifida and limb malformations.

P1551**Board Number: B1053****Compensatory branching morphogenesis of stalk cells in the *Drosophila* trachea.**D. Francis¹, A. Ghabrial¹;¹Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA

Tubes are essential for nutrient transport and gas exchange in multicellular eukaryotes, but how connections between different tube types are maintained over time is unknown. In the *Drosophila* tracheal system, mutations in oak gall (*okg*) and conjoined (*cnj*) confer identical defects, including late onset blockage near the terminal cell (TC)-stalk cell (SC) junction, and ectopic extension of autocellular, seamed tubes into the TC. We determined that *okg* and *cnj* encode the E and G subunits of the vacuolar ATPase (vATPase), and showed that both V0 and V1 domains are required for TC morphogenesis. Remarkably, the ectopic seamed tubes running along vATPase-deficient TCs belonged to the neighboring SCs. All vATPase-deficient tracheal cells had reduced apical domains, and TCs displayed mislocalized apical proteins. Further, TCs mutant for apical polarity genes, *par6* or *aPKC*, had ectopic seamed tubes. We thus identify a novel mechanism of compensatory branching in which SCs extend autocellular tubes into neighboring TCs with undersized apical domains.

Stem Cells and Pluripotency**P1552****Board Number: B1054****Molecular ties between the cell cycle and differentiation in embryonic stem cells.**V. Li¹, M.W. Kirschner^{1,2};¹Department of Systems Biology, Harvard Medical School, Boston, MA, ²Systems Biology, Harvard Medical School, Boston, MA

Attainment of the differentiated state during the final stages of somatic cell differentiation is closely tied to cell cycle progression. Much less is known about the role of the cell cycle at very early stages of embryonic development. Here we show that molecular pathways involving the cell cycle can be engineered to strongly affect embryonic stem cell differentiation at early stages in vitro. Strategies based on perturbing these pathways can shorten the rate and simplify the lineage path of ES differentiation. These results make it likely that pathways involving cell proliferation intersect at various points with pathways that regulate cell lineages in embryos and demonstrate that this knowledge can be used profitably to guide the path and effectiveness of cell differentiation of pluripotent cells.

P1553**Board Number: B1055****The influence of glucose concentration on the pluripotency of mouse embryonic stem cells.**C. Yoneda¹, K. Hayakawa¹, M. Hirosawa¹, S. . Tanaka¹, K. Shiota¹;¹Dep. of Anim. Res. Sci., The University of Tokyo, Tokyo, Japan

Cells can sense their nutritional status and adapt to various circumstances. Information regarding the glucose concentration can be transmitted to the nucleus through the O-GlcNAcylation of various molecules, which is catalyzed by O-linked N-acetylglucosamine transferase (OGT). Pluripotent cells including ES cells and iPS cells were established and maintained in a medium with relatively high glucose content (25 mM), whereas other cell types were cultured in lower glucose concentrations (~5 mM). To understand why the pluripotent stem cells favor hyperglycemic conditions, we studied the influence of low and high glucose concentrations on the growth, differentiation and expression of pluripotency-related genes and epigenetic regulators in mouse ES cells (mESCs). The mESCs cultured in 1, 5, and 25 mM glucose did not show a significant difference in their proliferation. Analysis of the gene-expression profiles of pluripotency markers revealed that the culture with 1 mM and 5 mM glucose for 4 days showed decreased *Dppa3* expression and unaltered expression of *Nanog*, *Klf4*, *Oct4*, *Sall4*, *Dppa2*, *Dppa4*, and *Zfp42*. This suggested that mESCs could harbor a set of glucose-sensitive genes. Considering the fact that *Dppa3* is involved in pluripotency and that it is the master gene for germ cell differentiation, we investigated the effects of low glucose concentrations on the pluripotency of mESCs by studying embryoid body (EB) formation. The shape and size of EBs were similar among the mESCs pre-cultured with low and high levels of glucose for 4 days. Intriguingly, the expression of the marker genes for the endoderm (*Gata4*, *Gata6*), mesoderm (*Kdr*), ectoderm (*Nog*) and germ cells (*Dppa3* and *Blimp1*) was reduced in mESCs pre-cultured in a low-glucose medium. We conclude that cells sense the glucose concentration in the surrounding environment and alter the expression of a specific set of genes that are involved in pluripotency or differentiation. We analyzed the expression of epigenetic factors to explore the mechanism of glucose concentration-dependent regulation of gene expression in mESCs and found an increase in OGT expression and O-GlcNAcylation in mESCs cultured in a low-glucose medium. Furthermore, we also observed an increase in the expression of *Ezh2* and *Suz12*, the components of the polycomb repressive complex 2, which catalyzes the trimethylation of lysine 27 of histone H3. In summary, mESCs require hyperglycemic conditions to maintain pluripotency. The glucose concentration sensed during the undifferentiated state is retained as a "glucose memory" that affects the differentiation capacity of mESCs, through alterations in the expression of epigenetic factors and the process of O-GlcNAcylation.

P1554**Board Number: B1056****Zebrafish intestinal stem cells are located at the base of the inter-villus pocket between villi ridges and populate both sides of the flanking ridges.**S. Tavakoli¹, P.T. Matsudaira¹;¹Mechanobiology Institute, National University of Singapore, Singapore, Singapore

In contrast to the stereotypic villus-crypt organization of the bird and mammalian intestine, the zebrafish intestinal epithelium is folded into villar ridges and crypts are absent. Previous studies have shown the dividing cells are located at the base of the villus ridge while cell death occurs at or near the villus tip. This simple organization suggests that intestinal stem cells (ISCs) maintain the villus epithelium along a base-to-tip axis. We tested the dynamics of zebrafish intestinal epithelium renewal by label retention assay, creation of mosaic intestinal tissues and finally lineage tracing. We examined the intestinal stem mammals' cell markers candidate in zebrafish. The promoters of *prmt1* and *Irig1* genes, as the most reliable intestinal stem cell markers in zebrafish, were used to express CreER^{T2} in the generated transgenic lines. Activating the CreER^{T2} at desired time helps to trace the Cre mediated recombination in tissue. Our result suggests that renewal of the zebrafish epithelium is similar to birds and mice with the newly divided cells at the base of the inter-villus pocket, which complete their translocation to the ridge. Furthermore, similar recombination pattern of the inter-villus pocket flanking sides of the villi ridges, demonstrates the bilateral migration of newly reproduced cells toward the flanking ridges. In another words, intestinal stem cells are located at the inter-villus pocket between villi ridges and populate facing ridges. Therefore, the facing ridges share the stem cells at the base and show similar expression pattern. In contrast, two sides of a ridge may show different expression pattern as originate from different stem cells.

P1555**Board Number: B1057****The neurofilament-derived peptide NFL-TBS.40-63 targets neural stem cells but does not affect their microtubule network.**J. Eyer¹, C. Lepinoux-Chambaud²;¹INSERM, Angers, France, ²Université d'Angers, Angers, France

Neural stem cells (NSC) are characterized by their capacity to self-renew, form neurospheres in culture, proliferate, and generate neurons, astrocytes and oligodendrocytes (multipotency). These characteristics provide new therapeutic strategies for the treatment of neurodegenerative disorders or malignant glioma.

We previously showed that a peptide corresponding to the tubulin-binding sequence located on the neurofilament light chain (NFL-TBS.40-63), alone or linked to nanoparticles, is able to target glioblastoma cells in vitro and in vivo. The selective and massive uptake of this peptide by glioblastoma

cells occurs through endocytic pathways and is related to their high proliferative state, whereas a low level of internalization occurs for slow proliferative healthy cells (astrocytes, oligodendrocytes or neurons). Moreover, while the peptide is able to disrupt the microtubule network of glioblastoma cells and inhibit their proliferation, it has no major effect on the microtubule network from healthy cells. Finally, when injected in rats bearing glioblastoma, the peptide reduces tumour development (Bocquet et al., 2009 J. Neurosci. 29, 11043-11054; Berges et al., 2012 Mol. Ther. 20, 1367-1377; Balzeau et al., 2013 Biomaterials 34, 3381-3389; Lepinoux-Chambaud & Eyer, 2013 Int J Pharm. 454, 738-747).

Here, we show that this peptide is able to translocate passively in neural stem cells in vitro and in vivo. The microtubules of these cells show no detectable alteration by the peptide. Moreover, the in vitro formation of neurospheres and the cell viability are not affected by the peptide. However, the NSC capacity to self-renew is reduced with the peptide and is associated with an increase of adherent cells and a decrease of NSC proliferation. Finally, when injected in the cerebrospinal fluid of rats the peptide targets adult neural stem cells in vivo without major detectable cytotoxicity. These results indicate that this peptide represents a new molecular tool to target neural stem cells in order to develop new strategies for regenerative medicine and treatment of brain tumors. This peptide also allows the manipulation of the cytoskeleton of these neural stem cells and to investigate the consequences of such manipulations.

The Wnt signaling and cytoskeletal regulator APC2 controls stem cell niche size and architecture.

S.L. Oliver¹, B.M. McCartney¹;

¹Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

Stem cell behavior is controlled by the cellular neighborhood, or niche, in which stem cells reside. Niche function relies on specific tissue architecture and cell-cell signaling to maintain tissue homeostasis. Signaling within the niche is well studied. However, regulation of niche architecture is not well understood. Here we report that the Wnt signaling and cytoskeletal regulator, Adenomatous polyposis coli (APC2) is required for proper niche size and architecture in the germarium. 5-7 Cap cells (Cpc), a central component of the female germline stem cell niche, reside at the anterior tip of the germarium and are essential for maintaining stem cells in the niche. Loss of APC2 results in an increased number of Cpc, and their displacement away from the anterior tip. Interestingly, there does not appear to be a direct relationship between the increase in Cpc number and the defect in Cpc position. In addition, APC2 null mutants exhibit an increased number of germline stem cells (GSCs) that may result from increased Cpc number. Preliminary data using a separation of function allele of APC2 suggest that Cpc number is

regulated by Wnt signaling, while Cpc position requires the actin regulation function of APC2. In the syncytial embryo, APC2 regulates cortical actin through a collaboration with the formin Diaphanous. We are currently testing the hypothesis that this collaboration regulates Cpc position. Consistent with our hypothesis, selective reduction of the actin organizers Spectrin and Kelch in Cpcs results in Cpc displacement, and Spectrin is mislocalized in APC2 mutants. These results suggest that the assembly and organization of cortical actin is required for proper Cpc position. Taken together, our data suggest that APC2 plays a dual role in the stem cell niche. APC2 regulates niche size by restricting Cpc number through negative regulation of Wnt signaling, and controls Cpc position within the germarium through the regulation of cortical actin.

Lack of arginylation causes stem cells' inability to maintain pluripotency, leading to abnormalities during embryogenesis.

S. Kurosaka¹, N.A. Leu², A.S. Kashina³;

¹University of Hiroshima, Hiroshima, Japan, ²Animal Biology, University of Pennsylvania, Philadelphia, PA, ³Department of Animal Biology School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA

Mice lacking arginyltransferase Ate1 die during embryogenesis with severe malformations in the heart, including thin myocardium, septation and outflow tract defects. The mechanisms of these malformations have been unknown and cannot be recapitulated in any conditional model with Ate1 knockout in heart-forming cell lineages, suggesting that these defects may originate prior to lineage specification. To investigate this possibility we have first attempted to generate Ate1 knockout stem cells, but failed to do so on multiple attempts, suggesting that these cells may have viability issues in culture or other reasons that preclude them from being generated. We next used primary embryonic fibroblasts derived from E12.5 wild type and Ate1 knockout embryos to generate induced pluripotent stem (iPS) cells by transfecting them with an expression cassette containing combination of reprogramming factors known to induce pluripotency (Oct4, Sox2, and Klf4). This approach was successful in yielding multiple Ate1 knockout iPS lines. These lines could maintain pluripotency in culture, however they showed a decrease in the intracellular level of several other pluripotent markers compared to the control. Moreover, removal of the expression cassette resulted in their inability to maintain pluripotency and induced their spontaneous differentiation into cardiomyocytes over the course of several days. Chimeras generated from these iPS cells died in development with prominent malformations and morphogenic defects. These data suggest that Ate1 is required to maintain normal intracellular levels of pluripotency factors in embryonic stem cells during early embryogenesis. We propose that cardiovascular malformations seen in Ate1 knockout embryos result from premature differentiation of cardiac progenitors into non-proliferating cardiomyocytes, which can occur before the progenitors can expand sufficiently to ensure normal cell numbers in the developing myocardium and

septae. This effect is likely universal and may affect other tissues and organs that do not have a chance to develop due to the timing of Ate1 knockout embryonic lethality.

Corneal epithelial stem cells are essential for maintaining homeostasis at the ocular surface. However, conclusive markers for corneal epithelial stem cells have not yet been defined. Our previous studies have demonstrated that rabbit limbal epithelial side population (rLE-SP) cells exhibit stem cell-like phenotypes including the enhanced expression of somatic stem cell markers that were commonly observed in other tissues. However, the unestablished database of rabbit genome sequences and the lack of available antibodies for rabbit antigens have made further characterization of rLE-SP cells difficult. Here, we show the gene expression profiles of both rLE-SP and rLE-non SP cells through RNA sequencing in which reads are mapped to both rabbit-derived sequences in the public database and the contigs that were created by de novo assembly. Firstly, we compared gene expression levels between rLE-SP and rLE-non SP cells, and confirmed that this gene expression analysis enables to recapitulate our previous results: rLE-SP cells showed higher gene expression of stem cell markers such as ATP-binding cassette sub-family G (*Abcg2*), polycomb complex protein BMI-1 (*Bmi1*), and *Nestin* than rLE-non SP cells. In addition, genes that were upregulated more than 5-fold in rLE-SP cells were identified using RNA sequencing, and five of these genes were selected for further analysis: ATP-binding cassette sub-family B (*Abcb1*), *vascular cell adhesion protein1 (Vcam1)*, Vimentin (*Vim*), *CD34*, and *Kit*. The differential expression of all of these genes was validated using real-time polymerase chain reaction. Expression of *Abcb1* has been detected in embryonic stem cells, induced pluripotent stem cells, and cancer stem cells. In addition, *CD34*, *Vcam1*, and *Kit* are known as somatic stem or progenitor cell markers. These findings support the hypothesis that immature cells are enriched in the rLE-SP cell fraction. On the other hand, expression of *Vim* has also been detected in endothelial, fibroblast, muscle, and mesenchymal cells. In addition, both *Vcam1* and *CD34* are also expressed in activated endothelial cells as well as mesenchymal stem cells. These findings indicate that rLE-SP cells have an endothelial and/or mesenchymal cell-like phenotypes rather than epithelial cells. In the present study, we have established a comprehensive gene expression analysis of rLE-SP cells using RNA sequencing, and the results suggest that rLE-SP cells have stem cell-like phenotypes. Specifically, we found that rLE-SP cells have an endothelial and/or mesenchymal cell-like phenotypes, which may imply a novel character and/or population of corneal epithelial stem cells.

P1559**Board Number: B1061****Analysis of gene expression in developing C2C12: changes in the proteome, titin and galectin-1.**S. Rashid¹, L. Gallagher², R. Giles¹, G.R. Walker¹;¹Biological Sciences, Youngstown State Univ, Youngstown, OH, ²School of Medicine, Trinity College Dublin, Dublin, Ireland

Myogenesis is a tightly regulated process resulting in unique structures called myotubes or myofibers, which compose skeletal muscle. Myotubes are multi-nucleated fibers containing a functional unit composed of cytoskeletal proteins called the sarcomere. The specific arrangement of these proteins in the sarcomere works to contract and relax muscles; literature suggests these proteins may even serve more than just a structural role but act as a scaffold for cell signaling, titin being of particular interest. During embryonic and post-embryonic development, fluctuations in expression of growth factors throughout the program account for the dramatic structural changes from cell to mature muscle fiber. In order to assess the dynamics of protein expression throughout myogenesis, we conducted a time course study using the mouse myoblast cell line C2C12, in which cells were allowed to differentiate, and insoluble protein fractions were collected at seven time points. The insoluble protein fraction accounts for cytoskeletal proteins, involved in the dramatic remodeling of cells. In order to discover influence of growth factors on protein expression, a similar time course was conducted with the of adding back to the cultures of growth factor (serum) at specific time points after induction of myogenesis. The cells were allowed to differentiate through the time course and the insoluble-protein fractions were collected. Analysis of protein expression during myogenesis shows significant changes in the insoluble proteome, Quantitative PCR shows an increase in titin expression and a transitory increase in galectin-1 expression.

P1560**Board Number: B1062****The Effects of Allogeneic Platelet Releasate Preparations on the Growth and Gene Expression of Human Adipose Derived Stem Cells.**M. McLaughlin¹, P. Gagnet¹, R. Yeager¹, S. Kapp¹, E. Cunningham¹, K. Guski¹, D. Kuebler¹;¹Biology, Franciscan University, Steubenville, OH

The administration of human adipose derived stem cells (ASC) represents a promising regenerative based therapy for joint injuries given the ability of these cells to undergo chondrogenic differentiation *in vitro*. These cells can be easily isolated from liposuction-derived adipose tissue and cultured under a variety of conditions to produce sufficient numbers of cells for treatment. Because different culture conditions are likely to have an effect on the physiology and therapeutic potential of these cells, we examined the effect of culturing ASCs in media supplemented with 10% allogeneic platelet releasate

(PR) as compared to standard 10% FBS supplemented media. PR was prepared from four patients using the Harvest SmartPrep® system followed by thrombin activation of the platelets. In every case, ASCs grown in media supplemented with PR proliferated much faster both during passage 0 (P0) and passage 1 (P1). The P1 cells in PR had an average doubling time of 27.1 ± 1.3 hours as opposed to 48.7 ± 5.7 hours in 10% FBS. In addition, the PR supplemented cells were smaller and more spindly in shape. The cells grown in PR retained the ability to differentiate along osteogenic, adipogenic and chondrogenic lineages and they retained expression of mesenchymal stem cell surface markers CD73 and CD90. In addition to assessing growth and differentiation potential, we also examined the effect that culturing the cells in 10% PR had on gene expression as compared to 10% FBS. We found that PR exposed ASCs displayed elevated expression of BMP-4 (5.7 ± 0.97 fold increase) and BMP-2 (4.7 ± 1.3 fold increase), both of which are implicated in cartilage development. The gene expression patterns of TGF-beta and VEGF were not significantly changed by PR exposure while decreased levels of gene expression were found in the cases of PDGF-B (4.0 ± 1.4 fold decrease) and FGF-2 (33 ± 9.0 fold decrease), two growth factors that are found at high levels in PR. These changes in gene expression were consistent across all four PR samples. In conclusion, the use of allogeneic PR to culture ASCs consistently leads to both an increased cell yield and a defined gene expression profile that may be beneficial for the treatment of joint injuries.

Mouse Parthenote Stem Cell Genome Editing Using CRISPR/CAS9.

R.M. Meijer¹, J. Lawitts², V. Dinopoulou¹, M. Kearnan¹, A.A. Kiessling¹;

¹Bedford Research Foundation, Somerville, MA, ²Beth Israel Deaconess Medical Center, Boston, MA

Mouse parthenote stem cells are derived from unfertilized, activated mouse eggs, that can be either diploid or haploid. Genome editing at the time of activation therefore has the theoretical potential to give rise to uniformly modified chromosomes, leading to stem cell lines fully enriched for the gene modification of interest.

To test this possibility, we have designed a CRISPR/Cas9/signal RNA strategy to inactivate the CCR5 gene, an important co-receptor for HIV infection. B6C3 f1 mouse oocytes at the zygote stage were activated in a calcium/protein free medium supplemented with Strontium chloride and cytochalasin then micro-injected with an RNA transcript encoding Cas9 plus a signal RNA targeting a naturally occurring deletion in CCR5 known to inactivate CCR5 protein. Two of 19 micro-injected zygotes developed to the blastocyst stage, with one stable stem cell line derived from the inner cell mass of a hatched blastocyst cultured with standard stem cell culture protocol. At approximately 100,000 cells, half were analyzed for CCR5 gene mutations by sub-cloning and sequencing PCR products.

Twenty five percent of the clones exhibited CCR5 deletions at the sgRNA locus, indicating that one of 4 chromosomes was genome edited either at the late zygote or early two-cell stage. Interestingly, a DNA

construct of CCR5 sequences flanking a GFP reporter gene was not incorporated into the CCR5 region targeted by the sgRNA, but an homologous region of CCR2 was incorporated.

That 5% of microinjected parthenote zygotes gave rise to a stable cell line (now at passage 5) is an encouraging result. The 25% mutated DNA suggests either one blastomere at the four cell stage was homozygous for the CCR5 deletion, or two blastomeres at the four cell stage were heterozygous for the CCR5 deletion. Studies are in progress to distinguish between these two possibilities.

These results support the hypothesis that CRISPR/CAS genome editing of parthenotes at the haploid zygote stage may be a highly efficient system for deriving uniformly genetically modified stem cell lines, and significantly facilitate biological studies of early embryo development.

c-MET Regulates Myoblast Motility and Myocyte Fusion during Adult Skeletal Muscle Regeneration.

M.T. Webster¹, C. Fan¹;

¹Embryology, Carnegie Institution for Science, Baltimore, MD

Adult muscle stem cells, satellite cells (SCs), endow skeletal muscle with tremendous regenerative capacity. Upon injury, SCs activate, proliferate, and migrate as myoblasts to the injury site where they become myocytes that fuse to form new muscle. How migration is regulated, though, remains largely unknown. Additionally, how migration and fusion, which both require dynamic rearrangement of the cytoskeleton, might be related is not well understood. c-MET, a receptor tyrosine kinase, is required for myogenic precursor cell migration into the limb for muscle development during embryogenesis. Using a genetic system to eliminate c-MET function specifically in adult mouse SCs, we found that c-MET was required for muscle regeneration in response to acute muscle injury. c-MET mutant myoblasts were defective in lamellipodia formation, had shorter ranges of migration, and migrated slower compared to control myoblasts. Surprisingly, c-MET was also required for efficient myocyte fusion, implicating c-MET in dual functions of regulating myoblast migration and myocyte fusion.

Role of Hazara virus infection in aquaporin expression and cell migration.

A. Molinas¹, A. Holm¹, K. Magnusson¹, V.M. Loitto¹, A. Mirazimi¹, E. Vikström¹;

¹Medical Microbiology, Dept. of Clinical and Experimental Medicine, Linköping University, Linköping, Sweden

Crimean-Congo hemorrhagic fever virus (CCHFV) is a human lethal pathogen which belongs to the *Bunyaviridae* family and causes Crimean-Congo hemorrhagic fever (CCHF), a severe disease characterized by hemorrhages, fever, muscle pain and other serious symptoms, and high mortality rates. CCHF may be transmitted to humans by the bite of ticks of the *Hyalomma* genus, which are present in many areas of Asia, Africa, Europe and the Middle East, and also by contact with blood or body fluids of infected livestock or humans. To date, there are some studies focusing on CCHFV-host cell interaction, the mechanisms of entry and release from cells and the replication cycle, but little is known about CCHFV effects on expression of aquaporins (AQPs) and cell migration.

Our aim was therefore to investigate how virus replication affects expression and distribution of AQPs and cell migration. Specifically, the role of AQP6 in cell migration is unknown, and it is further distinguished from other AQPs by exhibiting a strictly intracellular localization. Since the handling of CCHFV requires high containment biosafety level 4 laboratory facilities, we used Hazara virus as a model to study CCHFV. Using the wound healing assay, we investigated the effects of the virus on the migration of human epithelial intestinal Caco-2 cells. Moreover, we explored the effects of the virus on the expression of AQPs, through transfection of C3H10T1/2 mouse embryonic fibroblasts with AQP6.

We demonstrated for the first time that Hazara virus can inhibit epithelial sheet migration of Caco-2 cells and that the effects depend on the time of the infection and the virus concentration. Furthermore, we observed that AQP6 expression was reduced and cellular distribution was altered upon infection with Hazara virus. Finally, we developed a cellular assay that allows dynamic visualization of AQP6 in live cells over time and we propose a model of how virus infections affect epithelial sheet migration.

P1564**Board Number: B1067****Phosphorylation of HPV-16 E2 at serine 243 enables binding to Brd4 and mitotic chromosomes.**S. Chen¹;¹National Taiwan University, Taipei, Taiwan

The replication cycle of papillomaviruses is coupled to the differentiation program of the infected host keratinocytes. Infection is initiated when viruses enter the basal epithelial cells, where the viral genomes replicate to a low copy number and are maintained as extra-chromosomal episomes that replicate in synchrony with the host DNA. The papillomavirus E2 protein is involved in the maintenance of persistent infection and known to bind either to cellular factors or directly to mitotic chromosomes in order to partition the viral genome into the daughter cells. However, how the HPV-16 E2 protein acts to facilitate partitioning of the viral genome remains unclear. In this study, we found that serine 243 of HPV-16 E2, located in the hinge region, is crucial for chromosome binding during mitosis. Bromodomain protein 4 (Brd4) has been identified as a cellular binding target through which the E2 protein of bovine papillomavirus type 1 (BPV-1) tethers the viral genome to mitotic chromosomes. Mutation analysis showed that, when the residue serine 243 was substituted by glutamic acid or aspartic acid, whose negative charges mimic the effect of constitutive phosphorylation, the protein still can interact with Brd4 and colocalize with Brd4 in condensed metaphase and anaphase chromosomes. However, substitution by the polar uncharged residues asparagine or glutamine abrogated Brd4 and mitotic chromosome binding. Moreover, following treatment with the inhibitor JQ1 to release Brd4 from the chromosomes, Brd4 and E2 formed punctate foci separate from the chromosomes, further supporting the hypothesis that the association of the HPV-16 E2 protein with the chromosomes is Brd4-dependent. In addition, the S243A E2 protein has a shorter half-life than the wild type, indicating that phosphorylation of the HPV-16 E2 protein at serine 243 also increases its half-life. Thus, phosphorylation of serine 243 in the hinge region of HPV-16 E2 is essential for interaction with Brd4 and required for host chromosome binding.

P1565**Board Number: B1068****Dissecting the role of parafusin-related protein1 and calcineurin in Ca²⁺ signaling of *Toxoplasma gondii*.**S. Saha¹, B. Coleman¹, C. Chen¹, M. Gubbels¹;¹Biology, Boston College, Chestnut Hill, MA

Like any eukaryotic organism, Ca²⁺ signaling has been demonstrated to play pivotal roles in different cellular processes of the obligate intracellular apicomplexan parasite *Toxoplasma gondii*. In recent years several players of the Ca²⁺ signaling pathway have been mapped with critical roles in host cell invasion

and egress. Here we extend on this work by evaluating the functions of a putative phosphoglucomutase, parafusin-related protein 1 (PRP1), and the widely conserved Ca^{2+} dependent protein phosphatase calcineurin (CaN), which both have been associated with Ca^{2+} -dependent exocytosis (microneme secretion). Using fluorescent protein tagged constructs, we demonstrated the sub-cellular localization of the two proteins in live parasites. PRP1 localizes at the rhoptries (a Ca^{2+} independent secretory organelle) and inner membrane complex (IMC; cortical membrane cytoskeleton) in intracellular parasites while losing the IMC association in extracellular forms. CaN has cytoplasmic presence in intracellular parasites while in extracellular ones it colocalizes at both the apical and basal end with calmodulin. Direct knockout of PRP1 shows that the protein is non-essential. However, CaN is essential and its absence drastically reduces host cell attachment, but surprisingly microneme secretion is not affected. In conclusion, the roles of PRP1 and CaN are different than anticipated. Our current work aims to further our understanding of the exact role of CaN and PRP1 in *Toxoplasma* and where they fit in the overall Ca^{2+} signaling pathway in this highly successful group of pathogens.

Effects of Quorum Sensing Signaling of *Pseudomonas aeruginosa* on Water Homeostasis in Human Primary Macrophages.

A. Holm¹, K. Magnusson¹, E. Vikström¹;

¹Medical Microbiology, Dept. of Clinical and Experimental Medicine, Linköping University, Linköping, Sweden

The opportunistic Gram negative bacteria *Pseudomonas aeruginosa* cause chronic urinary tract, pulmonary and wound infections. They utilize the small molecule-based communication system called quorum sensing (QS) to regulate transcription of virulence genes and biofilm formation. The aim of the present study was to assess if QS signaling affects the cellular ability to phagocytose and the specific role of water homeostasis in this regard. The N-3-oxo-dodecanoyl-homoserine lactone (3O-C₁₂-HSL) and N-buturyl-homoserine lactone (C₄-HSL) are two important QS molecules that also affect human cells. Studying the effects of these QS molecules on human blood-derived macrophages we observed a stimulatory effect on phagocytosis of *P. aeruginosa* PAO1 wt compared to the QS-mutant lasI⁻/rhlI⁻ strain. During phagocytosis the plasma membrane needs to be highly dynamic to allow changes in cell shape and migration. Aquaporins (AQPs) are water channels situated in cellular membranes, regulating water homeostasis and cell volume. Moreover, they have been shown to play a pivotal role in cell migration and membrane protrusion formation providing a means for the plasma membrane to separate from the cytoskeleton allowing actin elongation into the water filled space to stabilize the protrusion. AQP9 is the main aquaporin in human immune cells. Using live cell microscopy we observed a cell-area change in 3O-C₁₂-HSL stimulated macrophages. Furthermore mRNA and protein analyses revealed a dose-dependent increase in the AQP9 expression. After infection of *P. aeruginosa* PAO1 both the expression and cellular distribution of AQP9 were affected. Thus, with high resolution imaging we found an evenly smooth distribution and high intensity of AQP9 in the wild type but not in the lasI⁻/rhlI⁻

infected cells. All together, studying the inter-kingdom interaction between *P. aeruginosa* and human immune cells can elicit an array of eukaryotic responses both at the transcriptional and cellular structure levels strengthening the importance of water homeostasis and thus a role of AQP_s in infection and inflammation.

Mucosa-associated *E. coli* as an IBD exposome prolongs epithelial NF- κ B activation via macrophage inhibitory cytokine 1.

B. Song¹, Y. Moon²;

¹Department of Biomedical Sciences, BB21 Project, Pusan National University School of Medicine, Yangsan, Korea, ²Department of Biomedical Sciences, Pusan National University School of Medicine, Yangsan, Korea

Commensal bacterial community shifts in the pathogenic colonic environment and chronic colonization of mucosa-associated *Escherichia coli* (MAEC) has been linked to chronic colonic inflammatory diseases. Enteropathogenic *Escherichia coli* (EPEC) is one of commonly identified MAEC in inflammatory bowel disease patients. The aim of this study is to address the contribution of MAEC colonization to human inflammatory signals such as nuclear factor kappa B (NF- κ B). The present study was conducted to investigate the prolonged epithelial responses to persistent EPEC infection via NF- κ B activation. EPEC infection led to sustained activation of NF- κ B signal in mouse intestinal epithelial cells in vivo and in vitro, which was positively associated with a type III secretion system, whereas early NF- κ B is regulated. Moreover, prolonged NF- κ B activation was found to be a part of macrophage inhibitory cytokine 1 (MIC-1)-mediated signaling activation, a novel link between NF- κ B signaling and infection-associated epithelial stress. Functionally, both EPEC-induced MIC-1 and NF- κ B signaling mediated epithelial survival by enhancing the expression of cyclin D1, a target of NF- κ B. In summary, the results of the present study suggest that MIC-1 serves as a mediator of prolonged NF- κ B activation, which is critical in maintaining gut epithelial integrity in response to EPEC-induced injuries (This work was supported by the Basic Science Research Program through the National Research Foundation of Korea, funded by Ministry of Education, Science and Technology Grant 2012R1A1A2005837, and a grant from the Korean Health Technology Research and Development Project, Ministry of Health and Welfare, Republic of Korea (HI13C0259)).

P1568**Board Number: B1071****The E3 ubiquitin ligase MABP negatively regulates the MAVS-mediated innate immune response.**Y. Yoo¹, H. Cho², Y. Park²;¹Ajou University, SuWon, Korea, ²Ajou University, Suwon, Korea

Mitochondrial antiviral signaling (MAVS) is an essential adaptor protein in innate RIG-I-like receptor signaling pathways and tightly regulated to ensure a rapid response to pathogens and to limit host immunopathology. Mitochondria act as a crucial platform for MAVS activation and inhibition of MAVS is also essential to limit excessive harmful immune response; however, how these signaling pathways are integrated at the mitochondria remains unclear. Here, we report that MABP is a negative regulator of MAVS. MABP deficiency in bone marrow-derived macrophages, Raw 264.7 and THP-1 resulted in increased type I interferon production and a marked reduction in viral replication of influenza A and vesicular stomatitis virus (VSV). MABP-deficient mice exhibited reduced susceptibility and enhanced survival following VSV infection. MABP binds to MAVS upon viral infection, promoting proteasome-mediated degradation of MAVS via Lys48-linked polyubiquitination of Lys7 and Lys500 residues of MAVS. Together, these findings identify MABP as a novel regulator of host antiviral immunity that ensures timely degradation of activated MAVS.

P1569**Board Number: B1072****Anti-chaperone activity of human α -defensin HNP1 against bacterial toxins.**E. Kudryashova¹, R. Quintyn¹, S.M. Seveau², W. Lu³, V. Wysocki¹, D.S. Kudryashov^{1,4};¹The Department of Chemistry and Biochemistry, The Ohio State University, Columbus, OH,²Microbiology, The Ohio State University, Columbus, OH, ³The Department of Chemistry andBiochemistry, University of Maryland, Baltimore, MD, ⁴Molecular and Cellular Developmental Biology Program, The Ohio State University, Columbus, OH

Defensins are short cationic, amphiphilic, cysteine-rich peptides that constitute the front line immune defense against various pathogens. In addition to exerting direct antibacterial activities, defensins inactivate several classes of unrelated bacterial exotoxins. To date, no coherent mechanism has been proposed that would explain defensins' enigmatic efficiency towards various toxins. We show that binding of α -defensin HNP1 to affected bacterial toxins causes their local unfolding, potentiates their thermal melting and precipitation, exposes new regions for proteolysis, and increases susceptibility to collisional quenchers, without causing similar effects on tested mammalian structural and enzymatic proteins. We propose that protein susceptibility to inactivation by defensins is contingent to their thermolability and conformational plasticity and that the defensin-induced unfolding is a key element in the general mechanism of toxin inactivation by human α -defensins.

P1570**Board Number: B1073****Chemical Biology to probe the molecular mechanisms of innate immune activation.**C.L. Grimes¹, J. Melnyk¹;¹Chemistry and Biochemistry, University of Delaware, Newark, DE

The innate immune system is charged with a tremendous task: it must deal with bacterial threats and the trillion of commensal bacteria that occupy the human body. In order to deal with this bacterial load, the innate immune system uses over twenty innate immune receptors to work in concert with each other to generate a proper immune response. However, when one of these receptors is broken, tremendous consequences can ensue. This is the case in Crohn's Disease; the receptor, Nod2 is mutated and is not able to properly respond to bacteria. Recently our laboratory has developed in vitro assays to measure the binding between Nod2 and its ligand, fragments of bacterial cell wall. We have shown that in vitro Nod2 binds to muramyl dipeptide with nanomolar affinity. However, this interaction has not been shown to occur in vivo. In order to determine if Nod2 interacts with this bacterial cell wall ligand in a cellular context, we have used synthetic organic chemistry to build bacterial cell wall fragments that contain a photo-activatable cross linker. We will describe the synthesis and biological activity of these derivatives. In addition, we will describe the biological targets that these cross-linking derivatives identified in preliminary experiments. It is our hope that by the development of the proper probes, we can use our background in chemical biology to understand the molecular recognition motifs used by nature to sense bacterial cell wall fragments.

P1571**Board Number: B1074****Ribosomal Inactivation Disrupts Gut Innate Immunity and Barrier Integrity in *Caenorhabditis elegans* through p38/MAPK Signaling Pathway.**J. PARK¹, Y. Moon²;¹Department of Biomedical Sciences, BB21 project, Pusan National University School of Medicine, Yangsan, Korea, ²Department of Biomedical Sciences, Pusan National University School of Medicine, Yangsan, Korea

Ribosomal inactivation has been known as one of exogenous etiological factors of experimental or human inflammatory bowel disease (IBD). Mechanistically, ribosomal inactivation triggers pro-inflammatory responses which may mediate the disruption of epithelial barrier and subsequently allows translocation of luminal bacteria as the crucial inflammatory agent. To provide these mechanistic evidences of the gut barrier-based pathogenesis of environmental IBD, we used gut exposure model in *Caenorhabditis elegans* since the nematode living in soil has a simple innate defense system with gut epithelial barrier

against luminal antigens including commensal bacteria. Based on our observation that *C. elegans* under the mucosal stress by ribosomal inactivation showed shorter life span than the control group, the molecular mechanism was addressed in association with gut barrier integrity. In term of gut bacteria, mucosal ribosomal inactivation increased gut load of ingested bacteria and p38/MAPK deficiency allowed more microbial exposure in the gut, indicating the protective roles of p38-linked gut defense. Moreover, various lysozymes, the crucial innate immune mediators, were also interfered by ribosomal inactivation, which contributed to more bacterial exposure to the nematode gut lumen. The ribosomal inactivation-disrupted gut integrity was also confirmed by barrier staining and monitoring of microbial translocation into the sub-epithelial parts of gut in *C. elegans*. All of these events were highly dependent on the p38/MAPK signaling pathway. Taken together, mucosal ribosomal inactivation disturbed innate immunity in the intestinal barrier of *C. elegans*, which led to more microbial infection and subsequently shorter lifespan. The present model can be associated with the mucosal disorder under ribosome-inactivating stress, a potent environmental trigger of human IBD (This work was supported by the Basic Science Research Program through the National Research Foundation of Korea, funded by Ministry of Education, Science and Technology Grant 2012R1A1A2005837, and a grant from the Korean Health Technology Research and Development Project, Ministry of Health and Welfare, Republic of Korea (HI13C0259)).

Dictyostelium discoideum TirA mediates signaling in response to bacterial prey.

M.L. Snyder¹, M. Fink¹, M. Weichseldorfer¹, T. White¹, M. Berlett¹, K. Stephens¹, E. Shaw¹, A. Zapf¹;

¹Biological Sciences, Towson Univ, Towson, MD

Cells of the innate immune system use pattern recognition receptors (PRRs) to detect conserved molecular motifs on a wide variety of microbial pathogens. The best characterized PRRs are the Toll-like receptors (TLRs), which utilize toll/interleukin-1 receptor (TIR) domains to initiate signaling responses. Among the signaling pathways activated downstream of mammalian TLRs are NF- κ B, caspase and MAPK-mediated pathways, as well as the generation of reactive oxygen species (ROS). The social amoeba *Dictyostelium discoideum* phagocytizes bacteria for nutritional purposes. While its genome does not encode for full-length TLRs, the model organism does express several TIR domain-containing proteins, including *D. discoideum* TirA, which previously has been shown to play a role in the growth of *D. discoideum* in the presence of Gram-negative bacteria. Furthermore addition of lipopolysaccharide (LPS), a component of the Gram-negative cell wall has been shown to enhance *D. discoideum*'s bactericidal activities in a TirA- and ERK-dependent manner. While *D. discoideum* does not encode for NF- κ B or caspases, exposure of *D. discoideum* to bacteria does result in the activation of MAPK-ERK signaling pathways as well as the generation of ROS. Here we find that both ERK phosphorylation, as well the generation of ROS, are reduced in TirA-deficient cells as compared with WT cells in response to Gram-negative, but not Gram-positive bacteria. In contrast, ERK phosphorylation in response to folic acid does not appear to be greatly affected by the absence of TirA. We are currently investigating the

role of additional signaling molecules in the response of *D. discoideum* to Gram-negative bacteria. In addition to these procedures we are also attempting to solve the structure of *D. discoideum* TIR domains through the use of X-ray crystallography. By obtaining this structural information new insights into the conserved mechanisms of TIR domain signaling in may be revealed.

Board Number: B1076

Altered N-Glycan profile play important roles on growth and morphogenesis of *Paracoccidioides brasiliensis* and on the biological activities of yeast proteins.

F.B. Almeida¹, M.C. Roque-Barreira¹;

¹Molecular and Cellular Biology, University of Sao Paulo, Ribeirao Preto, Brazil

The fungus *Paracoccidioides brasiliensis* is a human pathogen that causes paracoccidioidomycosis, the most prevalent systemic mycosis in Latin America. The cell wall of *P. brasiliensis* is a network of glycoproteins and polysaccharides, such as chitin and glucan, performing several functions. N-linked glycans are involved in glycoprotein folding, intracellular transport, secretion, and protection from proteolytic degradation. We investigated the influence of tunicamycin (TM)-mediated inhibition of N-linked glycosylation on N-acetyl- β -D-glucosaminidase (NAGase), α - and β -(1,3)-glucanases and on α -(1,4)-amylase in *P. brasiliensis* yeast and mycelium cells. The underglycosylated yeasts were smaller than their fully glycosylated counterparts and exhibited a drastic reduction of cell budding, reflecting impairment of growth and morphogenesis by TM treatment. The intracellular distribution in TM-treated yeasts of the *P. brasiliensis* glycoprotein paracoccin was investigated using highly specific antibodies. Paracoccin was observed to accumulate at intracellular locations, far from the yeast wall. Paracoccin demonstrated lower NAGase activity when underglycosylated, although no difference was detected between the pH and temperature optimums of the two forms. Murine macrophages stimulated with underglycosylated yeast proteins produced significantly lower levels of TNF- α and NO. Moreover, incubation with TM did not alter α - and β -(1,3)-glucanase activity in yeast and mycelium cell extracts. In contrast, NAGase and α -(1,4)-amylase activity was significantly reduced in underglycosylated yeast and mycelium extracts after exposure to TM. In spite of its importance for fungal growth and morphogenesis, N-glycosylation was not required for glucanase activities. This is surprising because these activities are directed to wall components that are crucial for fungal morphogenesis. On the other hand, N-glycans were essential for α -(1,4)-amylase activity involved in the production of malto-oligosaccharides that act as primer molecules for the biosynthesis of α -(1,3)-glucan. Our results suggest that reduced fungal NAGase and α -(1,4)-amylase activity affects cell wall composition and may account for the impaired growth of underglycosylated yeast and mycelium cells. Taken together, the impaired growth and morphogenesis of tunicamycin-treated yeasts and the decreased biological activities of underglycosylated fungal components suggest that N-glycans play important roles in *P. brasiliensis* yeast biology.

P1574**Board Number: B1077****Proteome analysis reveals differential expression of proteins in macrophages J774A.1 infected with *Leishmania amazonensis*.**J.C. Buitrago-Gutiérrez^{1,2}, S.S. Novoa-Herrán¹, R.A. Rodríguez-Castro¹, M.Y. Sánchez-Gómez¹, M. Camacho^{2,3};¹Química, Universidad Nacional de Colombia, Bogotá D.C., Colombia, ²Centro Internacional de Física, Bogotá D.C., Colombia, ³Biología, Universidad Nacional de Colombia, Bogotá D.C., Colombia

The phenomena described by our group that characterizes the impact of *Leishmania* infection on the electrical properties of infected macrophages, the decrease in the level of Kir2.1 expression in *Leishmania amazonensis* infected macrophages, revealed that the protein profile is different compared to non-infected macrophages and prompted us to study this in more detail. The macrophage-like cell line J774A.1, *L. amazonensis* promastigotes as well as infected macrophages were culture in vitro and harvested by centrifugation to obtain total protein extracts in RIPA buffer. The protein concentration was determined by densitometry and protein separated in 1D and 2D electrophoresis (2DE). Proteins were focused in equilibrated IPG-strips of 7cm pH linear (Bio-Rad) within a range between 3 to 10, and then separated in 10% SDS-PAGE gels which were stained with colloidal Coomassie Brilliant Blue G-250, before documentation in VersaDoc™ imaging system (Bio-Rad) for image analysis with Melanie 7.0 software (Swiss Institute of Bioinformatics). The initial gels show that most of the spots detected for non-infected and infected macrophage total extracts were in the pH range 5 to 8. Thus, this pH range was chosen for the 2DE reference maps. The analysis showed high reproducibility in terms of spot number, relative position and intensity between gel replicas of a particular treatment (e.i non-infected). Approximately 205 and 178 spots were detected for non-infected and infected macrophage total extracts, respectively. In order to find protein expression differences between samples, the statistical test ANOVA was used and spots with p-values below 0.5 were selected. Statistically significant differences in the expression level of the spots was found in 58% of the cases. These differences are related in a greater proportion to unique expression in any of the two classes: 34.2% to non-infected and 16.9% to infected macrophages. Quantitative changes in the expression level of shared spots was also found where in 2.6% of them the expression level was higher in non-infected, while 4% of the spots the expression level decreased in non-infected macrophages. This is the first study in which the differential expression of protein level from macrophages J774A.1 infected with *Leishmania amazonensis* is achieved using two-dimensional electrophoresis and revealing differential expression of proteins attributable to infection.

P1575**Board Number: B1078****Ralstonia solanacearum provokes gene expression changes in Arabidopsis roots and targets different regions of the plant cell.**R.M. Mitra¹, A. Duncan¹, W. Truman², J. Lu¹, R. Chen¹, D. Mishkind¹, E. Matsuda¹, J. Glazebrook², F. Katagiri²;¹Biology Department, Carleton College, Northfield, MN, ²Plant Biology Department, Carleton College, Northfield, MN

Bacterial wilt, caused by *Ralstonia solanacearum*, is one of the most devastating diseases of plants worldwide affecting hundreds of plant species including crops such as potato and tomato. *R. solanacearum* can persist in moist soils and invades roots via wounds or sites of lateral root emergence, which provide access to the xylem tissue. In the xylem, the pathogen multiplies to high densities, inhibiting water flow and causing the entire plant to wilt.

In order to evade detection and repel plant defenses, phytopathogenic bacteria often introduce a suite of effector proteins directly into the plant cell using a type III secretion system. Approximately 95 type III effectors have been identified across members of the *Ralstonia* species complex, 32 of which are found in nearly all of the sequenced strains. Approximately half of these conserved effectors are not present in other bacterial pathogens, suggesting that *R. solanacearum* targets novel pathways in the plant.

We are using two approaches for studying the *Ralstonia*-plant interaction. First, we are characterizing the localization of conserved *R. solanacearum* effector proteins in planta with the goal of identifying plant targets that may play important roles in plant defense. Second, we are examining the plant transcriptional response to bacterial inoculation, as plants have evolved molecular mechanisms to recognize the presence or activity of specific bacterial effector proteins, and activate plant defense pathways. We have identified a group of genes that are differentially expressed in roots in response to *R. solanacearum* but not in leaves in response to root inoculation. Several of these genes are also responsive to the plant hormones auxin and cytokinin, methyl jasmonate and abscisic acid suggesting a role for these hormones in bacterial wilt disease. Together, these studies should provide information about the interface between the bacterial and plant cell during bacterial wilt disease.

Epithelial IKK β signaling activates esophageal inflammation and angiogenesis via GM-CSF.

M. Tetreault¹, B. Sackey¹, D. Weinblatt¹, J.P. Katz¹;

¹GI/Medicine, University of Pennsylvania, Philadelphia, PA

Background: Deregulation of IKK β and/or NF κ B activities is associated with different inflammatory diseases and with various forms of cancer, including reflux esophagitis. **Objective:** To delineate the role of epithelial IKK β signaling in the modulation of the esophageal microenvironment. **Methods:** The *ED-L2* promoter of Epstein-Barr virus was used to drive *Cre* expression, producing overexpression of constitutively active IKK β (IKK β ca) in mouse esophageal epithelial cells but not inflammatory cells or surrounding stroma. Human esophageal keratinocytes with overexpression of constitutively active IKK β and their conditioned media were used for *in vitro* studies of gene regulation, tube formation, and endothelial cell migration. **Results:** *ED-L2/Cre;Rosa26-SFL-IKK β ca (L2/IKK β ca)* mice had alterations not only in esophageal epithelia but also in the surrounding microenvironment. At 1 month of age, *L2/IKK β ca* mice had mild hyperplasia. By 1.5 month of age, esophageal epithelia of *L2/IKK β ca* mice became irregular with the presence of a CD45 positive inflammatory infiltrate. Furthermore, we observed increased microvessel density in *L2/IKK β ca* mice at 1.5 and 3 months of age. To identify the pro-angiogenic factors expressed by esophageal epithelial cells in response to IKK β activation, we performed mouse PCR arrays on epithelial scrapings from 1 month-old *L2/IKK β ca* mice. We identified Granulocyte-macrophage colony-stimulating factor (GM-CSF) as a critical inducer of angiogenesis. *L2/IKK β ca* mice had a 7-fold increase in *GM-CSF* expression. Human esophageal keratinocytes with overexpression of constitutively active IKK β had increased GM-CSF mRNA expression and protein secretion. The expression and secretion of GM-CSF was critical for angiogenesis as neutralization of GM-CSF impaired endothelial functions *in vitro*, including HUVEC cell migration and tube formation. We are currently examining the effects of a GM-CSF blocking antibody *in vivo*. **Conclusions:** Constitutive activation of IKK β in esophageal epithelial cells results in early changes in inflammation and the esophageal microvasculature via GM-CSF.

P1577**Board Number: B1081****Establishment of two novel portal myofibroblast RGF and RGF-N2 cell lines from rat liver and functional characterization.**M. Fausther^{1,2}, J.R. Goree^{1,2}, E.G. Lavoie^{1,2}, J.A. Dranoff^{1,2};¹Internal Medicine, University of Arkansas Medical Sciences, Little Rock, AR, ²Research Service, Central Arkansas Veterans Administration Health Center, Little Rock, AR

Background and Rationale: Activated portal fibroblasts, along activated hepatic stellate cells, are increasingly recognized as major sources of scar-forming myofibroblasts during hepatic fibrosis, particularly in cholestatic liver injury settings. However, in contrast to well-characterized hepatic stellate cells, portal fibroblasts are understudied and remain poorly defined. Additionally, isolation of rodent portal fibroblasts for extensive functional studies remains technically challenging due to low cell numbers, reduced viability, variable purity, and limited growth capacity. To remediate this issue, two polyclonal cell lines, RGF and RGF-N2, were established from primary portal fibroblasts isolated from adult rat livers, and subjected to culture activation and subsequent SV40-mediated immortalization. Particularly, Ntpdase2/Cd39L1-sorted primary rat portal fibroblasts were used to generate the RGF-N2 cell line. **Main results:** First, gene screening indicates that primary (non-immortalized) culture-activated portal fibroblasts and both immortalized RGF and RGF-N2 cells are positive for myofibroblast markers such as, alpha smooth-muscle actin, type I collagen, tissue inhibitor of metalloproteinases 1, Ntpdase2, Cd73, and “portal fibroblast”-specific elastin, while negative for “hepatic stellate cell”-specific desmin and Irat, as determined by RT-PCR. Expression of alpha smooth-muscle actin, elastin, SV40 large antigen, Ntpdase2 and Cd73 proteins was confirmed in both RGF and RGF-N2 cell lines by immunofluorescence. Moreover, RGF and RGF-N2 cells are negative for “hepatocyte”-specific albumin and “macrophage”-specific F4/80 markers, although positive for “cholangiocyte/bile duct cell”-specific cytokeratin marker, as determined by RT-PCR. Absence of cytokeratin expression was established by immunoblot. Second, preliminary transfection assays using GFP expression vector and Fugene reagent show that DNA transfer is achievable in RGF and RGF-N2 cells. Lastly, the proliferation rate of immortalized Mz-Cha-1 cholangiocytes is decreased during co-culture with RGF and RGF-N2 cells in a bromodeoxyuridine uptake assay, a feature that has been also described for primary culture-activated portal fibroblasts.

Conclusion: Immortalized rat portal myofibroblast RGF and RGF-N2 cell lines express markers typical of myofibroblasts deriving from activated portal fibroblasts, are suitable for DNA transfection, and can inhibit bile ductular proliferation. Both RGF and RGF-N2 cell lines represent novel and useful in vitro cellular models for the functional studies of portal (myo)fibroblasts and their contribution to the progression of liver fibrosis.

P1578**Board Number: B1082****Determination of signature microRNAs in experimental liver fibrosis by miRnome profiling of circulating exosomes.**L. Chen¹, R. Chen¹, D.R. Brigstock^{1,2};¹Center for Clinical and Translational Research, Nationwide Children's Hospital, Columbus, OH,²Department of Surgery, The Ohio State University, Columbus, OH

Background: Hepatic fibrosis is a serious pathology that compromises normal hepatic structure and function and is a harbinger of cirrhosis, hepatocarcinoma, and end-stage liver disease. Current methods of fibrosis assessment are limiting and do not allow progression or resolution to be accurately determined. Since a major goal it to establish non-invasive protocols that are amenable to longitudinal analysis in the dsame individuals, we have analyzed the miR content of circulating exosomes to identify potential fibrosis markers. Exosomes are membranous nanovesicles that arise by inward budding of multivesicular bodies and are released extracellularly when these multivesicular bodies fuse internally with the plasma membrane; thereafter exosomes traverse the intercellular spaces and may be taken up by neighboring cells. Exosomes contain a complex mixture of miRs, mRNAs and proteins that is a fingerprint of their producer cells, offering the opportunity to establish signature molecular profiles in health and disease.

Methods: Serum exosomes were isolated (PureExo Exosome Isolation Kits) from the circulation of mice after 1 or 5 weeks of treatment with CCl₄, or from oil-treated controls, with liver injury/fibrosis confirmed histologically. Exosomal RNA from 1ml of pooled serum (5 mice; 200µl/mouse) was profiled using a mouse miRnome miR PCR Array, allowing analysis of the 940 best characterized miRs in the mouse miRnome. Differentially expressed miRs were confirmed and/or further evaluated by qRT-PCR of exosomal RNA independently obtained at 1-, 4- or 5-weeks of CCl₄ administration (n=5).

Results: Microarray analysis revealed that, as compared to their respective oil controls, there were significant alterations in the expression of numerous miRs after either 1- or 5-wks of CCl₄ treatment. After 5 weeks of CCl₄ treatment, miR-7a, -21, -22, -24, -34a, -155, or -195 were all upregulated and miR-27a, -192, -214, or -377 were all downregulated and mirrored the respective changes in hepatic expression that has been previously reported for each of these miRs. Additionally, upregulation of exosomal miR-26b or -122 and down-regulation of miR-9 or -196b were noted as consistent changes that highlighted these additionalmiRs as potentially novel fibrosis markers that have not previously been identified in earlier studies. Many of these miRs exhibited individually distinct patterns of expression during fibrosis progression highlighting their potential utility for assessment of different fibrotic stages.

Conclusions: Dynamic changes occur in the miR content of circulating exosomes during experimental hepatic fibrosis showing that fibrosis progression and severity is amenable to minimally-invasive assessment through determination of signature exosomal miRs.

P1579**Board Number: B1083****Role of p217 and p290 in activation of INS-R on salivary glands of diabetic mice.**R.E. da Silva¹, R.O. Netto¹, M.J. de Barros¹, T.M. Augusto^{2,3}, L.A. Peroni¹, E.J. Caldeira¹;¹Morphology and Basic Pathology, Faculty of Medicine of Jundiaí, Jundiaí, Brazil, ²Clinical Department, Faculty of Medicine of Jundiaí, Jundiaí SP, Brazil, ³Structural and Functional Biology Department, State University of Campinas, Campinas SP, Brazil

Various studies have suggested that the glutamic acid decarboxylase (GAD) and its proteins play a critical role in type 1 diabetes. However, questions remain about the total efficacy of this therapy. The objective of this study was analyzed the activity of peptides p217 and p290 of GAD, in the possible re-establishment of salivary organs of diabetic mice. A total of 21 mice were divided in 3 series: I: formed by 7 Balb/C (control mice); II: formed by 7 diabetic NOD mice; and III: with 7 diabetic NOD mice. The group III received the peptide p290 associated to p217 (200µg diluted in 100µl of Incomplete Freund's Adjuvant). The animals (I and II) were subjected to intraperitoneal injections of saline solution and in all groups, the glucose levels were observed during the twenty-one days and salivary gland specimens were obtained for the fluorescence microscopy analysis of INS-R (Ethical Process Number: 304/11). Peptide therapy promoted reduction in glucose levels and the re-establishment of insulin receptors (INS-R) in both salivary organs. The peptide vaccine, especially when combined the p217 and p290, brought a major interaction between insulin and receptors. Thereby, this therapy contributed to the glucose balance and activated the α -subunits of insulin receptors, showing the regression of damage in the salivary organs. Support: FAPESP #2012/18012-2, CAPES, CNPq, and NAPED/FMJ.

P1580**Board Number: B1084****Human placenta-derived mesenchymal stem cell promote hepatic regeneration on BDL-injured rat hepatic failure model via dual function of phosphatase of regenerating liver-1.**J. Choi¹, S. Lim^{1,2}, J. Park³, I. Oh⁴, G. Kim¹;¹Dept. of Biomedical Science, CHA University, Seoul, Korea, ²Dept. of Biomedical Science, Cha University, Seoul, Korea, ³Dept. of Biomedical Sciences and Pharmacology, Seoul National University College of Medicine, Seoul, Korea, ⁴Catholic High Performance Cell Therapy Center, The Catholic University of Korea, Seoul, Korea

Hepatic failure is the inability of the liver to perform its normal function as well as irreversible severe disease. Placenta-derived mesenchymal stem cells (PD-MSCs) have been introduced as an attractive cells comparing to other MSCs. We previously reported that therapeutic effect of PD-MSCs on CCl₄-injured early cirrhosis rat model. However, it is still controversy the effect of PD-MSCs depend on animal models. Therefore, the objectives of this study were to analyze the effect of PD-MSCs on hepatic failure

by bile duct ligation (BDL), which is representative late stage of hepatic diseases. The survival ratio in a group with PD-MSCs transplantation and proliferation activities of hepatocyte isolated from rat models were significantly enhanced comparing to sham group. Otherwise, rat model engrafted PD-MSCs reduced the hepatic fibrosis compared with BDL until 2 weeks. PD-MSCs transplantation show anti-apoptotic effect via increasing Bcl2 and decreasing Bax and cleaved PARP expressions. Taken together, PD-MSCs transplantation could be enhanced liver regeneration in severe hepatic failure model through anti-fibrotic and anti-apoptotic effects. Therefore, the findings provide fundamental background for understanding of PD-MSCs effect in hepatic diseases as well as support to application of cell therapy using PD-MSCs.

HIV-1 Antiretroviral, Efavirenz Stimulates Cathepsin Protease Activity in Macrophages: Implications for HIV-associated Atherosclerosis.

K.M. Porter¹, K.N. Burch², M.O. Platt¹;

¹Biomedical Engineering, Georgia Tech/Emory Univ, Atlanta, GA, ²Project ENGAGES, Georgia Tech, Atlanta, GA

Approximately 1.2 million individuals in the United States are living with HIV. Antiretrovirals (ARV) effectively manage viral loads, both preventing progression to AIDS and enhancing patient survival. However, reports indicate that people with HIV exhibit an increased risk for developing atherosclerosis, a form a cardiovascular disease characterized by lipid and macrophage-filled plaque formation and arterial remodeling. Recent research implicates ARVs in the development of atherosclerosis, as efavirenz correlates with endothelial dysfunction and elevations in low-density lipoprotein. Yet, the mechanisms underlying this association are not completely understood. In preliminary studies, we found that AZT increased cysteine cathepsin activity in arteries in a mouse model. These cathepsins are potent proteases, known to promote vessel remodeling via collagen and elastin degradation. Therefore, we hypothesize that efavirenz contributes to atherosclerotic vascular remodeling by increasing cathepsin protease activity. To test this, we exposed Thp-1 monocytes or monocyte-derived macrophages to efavirenz (25 μ M) for 24 hours. Cells were then collected and analyzed for cathepsin protein and active enzyme by immunoblot and multiplex cathepsin zymography, respectively. Our results demonstrate that efavirenz exposure causes a 50% decrease in monocyte levels of active cathepsins (n=6; p<0.05), which was reflected by significant reductions in their ability to degrade elastin (n=4, p<0.05). Efavirenz also reduces cathepsin mRNA and protein expression, but increases the levels of cystatin C, the extracellular protein cathepsin inhibitor. Conversely, in monocyte-derived macrophages, efavirenz exposure induced 2-fold increases in cathepsins V, S, and L expression and activity (n=6; p<0.05). Moreover, western blot analyses indicate that efavirenz-induced alterations in monocyte and macrophage cathepsin activity are mediated by JNK signaling. Overall, our findings demonstrate that efavirenz increases macrophage-

derived cathepsin activity. These efavirenz-induced elevations in cathepsin degradation may promote vessel remodeling and accelerate atherosclerosis development and progression.

Stress reticulocytes, CD 36 and CD 49d in SSFA2 homozygous sickle cell black patients followed in Abidjan, Côte d'Ivoire.

D. SAWADOGO¹, V. YAPO², M. SANGARE¹, E. ADJAMBRI¹, H. KASSI³;

¹Hematology, Pharmacy University Felix Houphouet Boigny, Abidjan 08, Ivory Coast, ²Cellular Biology, Pharmacy University Felix Houphouet Boigny, Abidjan, Ivory Coast, ³Central Laboratory, University Hospital of Yopougon, Abidjan, Ivory Coast

The complex physiopathology of sickle cell disease involves many factors, among them adhesion molecules such as the $\alpha 4\beta 1$ integrin or CD 49d and CD36. These antigens are found on immature reticulocytes or stress reticulocytes. We investigated whether there were links between the clinical manifestations and the presence of stress reticulocytes and the expression of CD 36 and CD 49d. We evaluated 60 SSFA2 homozygous sickle cell in patients (30 in painful crisis and 30 in steady state) with complete blood count, the presence of total reticulocytes, total stress reticulocytes, and CD 36 and CD49d antigens with immunophenotyping by flow cytometry. Out of the 308, 845/uL reticulocytes, 48.2% and 42.5% expressed respectively CD 36 and CD 49d. In over 90% of patients, stress reticulocytes were found. The presence or absence of complications, or of moderate or severe clinical manifestations, was not correlated with the expression of CD36 and CD 49d. From a clinical point of view, there was no difference between subjects expressing or not the CD 36. Even if the level of stress reticulocytes, CD 49d + and CD 36 + reticulocytes were high, the clinical status was not correlated with the expression of adhesion molecules.

Investigation of the Interactions between Antimalarial and Antiretroviral drugs.

S. Saeed¹, M. Eraifej², J. Porter-Kelley³, F.O. Akinbo⁴, G. Mayer¹;

¹Biology, Manhattan College, Riverdale, NY, ²Manhattan College, Riverdale, NY, ³Department of Life Sciences, Winston-Salem State University, Winston Salem, NC, ⁴University of Benin, Benin City, Nigeria

Malaria and AIDS are two infectious diseases that are prevalent in sub-Saharan Africa due to geographic overlap. Malaria, caused by the protozoan parasite *Plasmodium*, is transmitted to humans by the female *Anopheles* mosquito. The Human Immunodeficiency Virus (HIV), which can lead to AIDS, is a retrovirus that damages the immune system by destroying CD4 T-cells. It is transmitted both parentally and sexually. Previous research in our laboratory has shown that co-infected patients in Benin City, Nigeria taking both antiretroviral and antimalarial drugs, still had *Plasmodium* present in their bloodstream. We

have demonstrated that *P. falciparum* was the only species present in these patients at a 28.7% prevalence. We have also shown a lack of correlation between the levels of CD4 T-cells and *Plasmodium* in these patients suggesting no interaction between HIV and *Plasmodium*. Therefore, we hypothesized that antiretroviral drugs are inhibiting the antimalarial drugs. This was tested by performing a 3H-hypoxanthine incorporation assay in the presence of antimalarial and antiretroviral drugs, used individually and in combination. We found that the antimalarial drugs, sulfadoxine and lumefantrine, were inhibited by the antiretroviral drugs, zidovudine, lamivudine, and stavudine, respectively. We also found that stavudine had the most inhibitory effects on all of the antimalarial drugs, except for artemisinin.

²Institute of Advanced Biomedical Engineering and Science, Tokyo Women's Medical University, Tokyo, Japan, ³Department of Integrative Bioscience and Biomedical Engineering, Waseda university, Tokyo,

Japan

Hematopoietic stem cells (HSCs) can generate blood cells throughout the lifespan of an organism owing to their self-renewal and multi-differentiation properties. However, the underlying mechanism for the maintenance of stemness of HSCs remains unclear. Hence, to clarify this mechanism, we focus on the transcription factors (TFs) that are specifically expressed in HSCs, and examine whether these TFs are involved with the maintenance of the undifferentiated state of HSCs. First, we performed RNA-seq of mouse HSCs (CD150+, CD34⁻, c-Kit+, Sca-1+, and Lineage marker⁻ cells), hematopoietic progenitor cells (HPCs; CD34+ c-Kit+, Sca-1+, and Lineage marker⁻ cells), and cultured HSCs. Thereby, we extracted 11 HSC-specific transcription factors (11 HSTFs) that seem to have the potential for the involvement with maintaining stemness of HSCs. Therefore, to determine whether these factors actually affect the undifferentiated state of HSCs/ HPCs, we prepared 11 of retroviral vectors for the transfection of each HSTF, and analyzed HPCs transduced with the cocktail of these retroviral vectors. These HPCs retained their proliferative activity for 32 days in vitro, and cells with c-Kit+, Sca-1+, lineage marker⁻ (KSL) phenotype, which is a cell surface lineage marker pattern specific to HSCs/HPCs, were constantly observed during long-term culture. In contrast, HPCs transduced with the control retroviral vector exhibited significantly decreased proliferation at approximately 14 days after the culture, resulting in the impossible passage at approximately 20 days. In addition, the transduction of the 11 HSTFs not only contributed to the maintenance of KSL phenotype in HPCs, but also allowed some c-Kit+, Sca-1⁻, lineage marker⁻ cells, which are regarded to be more differentiated than KSL cells, to gain the KSL phenotype again. In contrast, this phenomenon was never observed in c-Kit+, Sca-1⁻, lineage marker⁻ cells transduced with the control retroviral vector. Furthermore, KSL cells induced from c-Kit+,

Sca-1-, lineage marker— cells by 11 HSTFs-transduction also retained not only proliferation activity but also KSL phenotype during long-term culture. These results indicate that these 11 transcription factors, individually or in combination, contribute to the maintenance of the undifferentiated state of HPCs, thus suggesting that these factors are involved in the maintenance of stemness of HSCs. Therefore, we have now filtered the transcription factors that actually induced these observed phenomena, and have simultaneously examined whether the factors affect stemness of HSCs.

Pseudomonas aeruginosa induces the production and release of a cytotoxic factor from pulmonary endothelial cells.

R.D. Balczon¹, A. Morrow¹, B. Edmonds¹, L. Cauthen¹, D. Frank², T. Stevens¹;

¹Univ South Alabama, Mobile, AL, ²Medical College of Wisconsin, Milwaukee, WI

Pseudomonas aeruginosa infection causes pneumonia that can progress to sepsis and acute respiratory distress syndrome. Patients who survive the initial infection oftentimes succumb to *Pseudomonas* months later, secondary to progressive end organ dysfunction that occurs after the bacteria have been killed. These data suggest that a toxic substance is produced during the infection process that contributes to progressive demise. We have tested this possibility in vitro using cultured rat primary microvascular endothelial cells (PMVECs) and pulmonary artery endothelial cells (PAECs). *P. aeruginosa* uses a type III secretion system to inject various exoenzymes into cells during infection processes. PMVECs were infected with *P. aeruginosa* and media were collected, filter sterilized, and then added to naïve PAECs and PMVECs. The inoculated cells died within 12-24 hrs following addition of the media. The importance of infection of the endothelial cells was demonstrated when the PcrV strain, a type of *Pseudomonas* that lacks a functional type III secretion system, was used. PAECs treated with media collected from PMVECs that had been inoculated with PcrV bacteria survived. Similar results were obtained in a Matrigel vessel formation assay. Cells treated with medium collected from *P. aeruginosa* infected cells failed to form vessels while control cultures formed numerous vessels. The substance released from infected PMVECs resists DNase and RNase digestion, and is resistant to boiling. The substance can be precipitated from culture supernatants using 50% ammonium sulfate. RNA analyses determined that PMVECs express various known and suspected pathologic proteins including prion protein, tau, alpha synuclein, and amyloid precursor protein, and immunoblot analyses have demonstrated that several of these proteins are released from PMVECs during *Pseudomonas* infection. Studies are in progress to identify the cytotoxic substance released from PMVECs following infection with *P. aeruginosa* and to establish possible roles for this substance in clinical outcomes.

P1586**Board Number: B1090****Endothelial to Mesenchymal Transition (EndoMT) leads to a loss of normal endothelial cell function and may contribute to the development of pulmonary arterial hypertension.**R.B. Good¹, A. Gilbane¹, S. Trinder¹, C. Denton¹, G. Coghlan², D. Abraham¹, A.M. Holmes¹;¹Rheumatology and Connective Tissue Diseases, UCL- Royal Free hospital, UCL - Royal Free Campus, Rowland Hill St, United Kingdom, ²Royal Free Hospital NHS Foundation Trust, National Pulmonary Hypertension Service, London, United States**Background**

Endothelial cells form a biological exclusion barrier actively regulating the exchange of macromolecules, solutes and cells, between the blood and the surrounding tissues. Expansion of vascular mesenchymal cells and endothelial dysfunction are cardinal features that contribute to vascular remodelling in pulmonary arterial hypertension PAH. Recent studies suggest that as well as resident mesenchymal cells, endothelial cells can undergo endothelial-mesenchymal transition (EndoMT) and acquire a mesenchymal phenotype, which can contribute to the expansion of mesenchymal cell populations. Here we sought to assess the capacity of pulmonary artery endothelial cells to undergo EndoMT and assess the cellular effects and determine the prevalence of EndoMT in the pulmonary vasculature of PAH patients and pre-clinical models of PAH.

Methods

EndoMT was induced in human PAECs *in vitro* by exposure to TNF α , IL-1 β and TGF β in combination. Western blotting and immunofluorescence was used to quantify EndoMT: CD31, vWF, occludin, VE-cadherin, α SMA, calponin and collagen type 1 expression. Levels of pro-inflammatory secretion was quantified by MSD arrays on conditioned PAEC, EndoMT and HC and SSc-PAH fibroblast media. The capacity of EndoMT monolayers and mixed cultures comprising 1:10 EndoMT:PAECs cells to form exclusion barriers was assessed using trans-well permeability FITC-albumin assays. Using lung tissue from PAH and healthy control (HC) donors, and from the hypoxia/SU5416 pre-clinical murine model of PAH, the presence of EndoMT was assessed by immunofluorescence based on co-expression of vWF and α SMA.

Results

PAECs treated with TNF α , IL-1 β and TGF β exhibited significant morphological changes, loss of endothelial markers and gained expression of mesenchymal markers by day 6. There was a significant (P<0.01) 5-fold increase in permeability compared to PAECs alone. Consistent with this, EndoMT cells co-cultured with PAECs in a ratio of 1:10 led to 2.5-fold significant (P>0.05) increase in permeability. Assessment of pre-clinical models and clinical material from PAH patients for EndoMT demonstrated co-localisation of vWF and α SMA in \leq 5% of pulmonary arteries.

Conclusion

We demonstrate that EndoMT is present in patients and pre-clinical models of PAH. Induction of EndoMT *in vitro* leads to a loss of normal PAEC morphology and an enhanced secretion of pro-inflammatory chemokines. Furthermore EndoMT cells failed to form integral biological barriers and contributed to enhanced permeability of PAEC barriers. Collectively our data suggests that EndoMT may contribute to the loss of normal endothelium function and the development of PAH.

Angiotensin II AT1 receptors blockers reduce cholesterol deposition in AGE-LDL induced foam cells via reverse cholesterol transport pathway.

M. Mori¹, M. Hikosaka¹, K. Suda¹, R. Motohashi¹, K. Imai¹, S. Kikuchi¹, M. Takahashi¹;

¹Cellbiological pathology, Chiba Institute of Science, Chiba, Japan

[Objective] AGE(Advanced Glycation Endproduct)-LDL, may be formed in DM (Diabetes mellitus) patients, reduces cholesterol export from the foam cell and enhances foam cell apoptosis. To elucidate the intracellular cholesterol traffic of foam cells, the relationship among AGE-LDL, FC-related foam cell apoptosis were investigated. HDL, potent molecule cholesterol uptake from atherosclerotic lesions, strongly associated with ABC transporter function of foam cells. To confirm disfunction of reverse cholesterol transport in AGE-LDL induced foam cells can be improved by **vascular statins** and **ARB** (telmisartan, losartan, irbesartan) treatment. **[Method]** Foam cells were prepared by J774 cells incubating with various human modified LDL for 24-72hr, then cultured up to 3-6 days in the presence of LPDS +/- HDL and ARB or statin. PC-FC complex and Apoptotic cells were detected by immunofluorescent microscopy using specific monoclonal antibodies or FITC-AnnexinV. FC rich lipid droplet can be detected by Filipin staining. **[Results & Discussion]** PC-FC Complex specifically recognized by atheroma specific monoclonal antibody (ASH1a/256C), induced in foam cells by Acetylated LDL(AcLDL), is corresponding to foam cell apoptosis via FC(free cholesterol)-rich lipid droplet formation. AGE-LDL is also inducing foam cells expressing FC-rich lipid droplets and PC-FC Complex, however, accumulation rate is very slow. HDL enhances FC reverse transport result in foam cell survive in AcLDL induced foam cells, whereas, HDL defects the FC-removing activity in AGE-LDL induced one. Vascular statin molecules (Simvastatin, Atrovastatin) had a potent activity of inducing ABC transporter and its translocation, avoid foam cell death and reduce FC-rich lipid droplet formation in AGE-LDL induced foam cells. HDL treatment might be affected cellular nCEase activity leading to cellular FC increase, in resulting foam cells expressed a little amount of FC-rich lipid droplets, PC-FC Complex. AGE-LDL and its metabolates may reflect on cellular FC transport including ABC transporters translocation. ARB was well known as PPAR ligand and its activity can be associated fatty acid metabolism. In ARB treated AGE-LDL induced foam cells, it was observed reducement of FC-rich lipid droplet formation, amount of lipid droplets and foam cell apoptosis. Telmisartan and irbesartan strongly reduce FC-rich lipid droplets in both AcLDL and AGE-LDL induced foam cell, however, losartan act only AGE-LDL induced foam cells, but no significant difference in AcLDL induced cells. These significantly relationship in AGE-LDL induced foam

cells, among the cellular FC increase, PC-FC complex formation, and foam cell apoptosis may reflect to development of atherosclerosis in DM patients. Contact me by; mmori@cis.ac.jp

Hydroxychloroquine Binding Sites of Human Erythrocytes.

M. Nakagawa¹, K. Sugawara², H. Wakui¹, W. Nunomura^{1,3};

¹Life Sci Div, Akita Univ, Akita, Japan, ²Grad Sch Med Sci, Akita Univ, Akita, Japan, ³Ctr Engin Sci, Akita Univ, Akita, Japan

Although hydroxychloroquine (HCQ) is used to use in the treatment of malaria, arthritis, and lupus for many years, the precise mechanism of their action remains unclear. In the present study, we investigated HCQ binding proteins in human erythrocyte membrane by using HCQ coupling Sepharose column chromatography. We prepared erythrocyte ghosts from healthy human blood removed white blood cells by cellulose column chromatography. The ghosts were dissolved in 50 mM Tris-HCl buffer, pH7.4 containing 0.15 M NaCl, 1 mM 2ME, 1 mM EDTA and 0.1% NP-40 (Buffer A). HCQ was coupled with epoxy activated Sepharose (HCQ-Sepharose). The erythrocyte membrane skeletal proteins, Band 3 (anion exchanger 1, AE1), spectrin, ankyrin, 80kDa protein 4.1R and protein 4.2 were eluted by 20 mM HCQ in Buffer A from HCQ-Sepharose. These proteins did not bind to plain Sepharose. NHE (Na⁺/H⁺ exchanger) 1 and CD47 did not bind to HCQ-Sepharose. Inside-out-vesicles (IOV) depleted of all peripheral proteins (pH11-IOV) and trypsin-digested pH11-IOV (T-pH11-IOV) were prepared according to methods previously described (Biochem. J. (2010) **432**:407-416). Band 3 in the IOVs and pH11-IOV bound to HCQ-Sepharose but not in T-pH11-IOV. Recombinant cytoplasmic N-terminal 43kDa domain of Band 3 bound to HCQ-Sepharose was eluted with 40 mM HCQ. These results indicate that the HCQ binding site of erythrocyte membrane is N-terminal cytoplasmic domain of Band 3 in human erythrocytes. Activity of lactate dehydrogenase (LD) is inhibited by chloroquine (JA Read et al. J. Biol. Chem. (1999) **274**:10213-10218). Activity of LD in the erythrocytes incubated with HCQ was decreased ~60% compared with non-treatment. That of cells treated with DIDS (4,4'-diisothiocyano-2,2'-stilbenedisulfonic acid) being Band 3 inhibitor following HCQ incubated was not changed. These results indicate that although major HCQ binding protein is Band 3 in human erythrocyte membrane, HCQ may not permeate thorough the Band 3. Finally, we investigated the effect of HCQ on the Band 3 activity. The activity was measured by the methods using dipoclinic acid and TbCl₂ described by Tu and Xu (Bioscience Reports (1994) **14**:159-169). The Band 3 activity of the HCQ treated ghost was ~20% reduced compared with none treatment. Taken together, HCQ binds to cytoplasmic N-terminal domain of Band 3 and reduces its activity in human erythrocytes.

Hepatic DNA deposition and sensing: a new feature of drug-induced liver injury.

P.E. Marques¹, A.G. Oliveira¹, R.V. Pereira¹, B.A. David¹, L.F. Gomides¹, D.A. Pires¹, M.M. Antunes¹, J.T. Novaes¹, M.M. Teixeira¹, D.S. Mansur², G.B. Menezes³;

¹Morphology, Federal University of Minas Gerais, Belo Horizonte, Brazil, ²Immunobiology, Federal University of Santa Catarina, Santa Catarina, Brazil, ³Federal University of Minas Gerais, Belo Horizonte, Brazil

Drug-induced liver injury (DILI) is an important cause of acute liver failure with limited therapeutic options. During DILI, necrosis and release of intracellular contents such as self-DNA may amplify liver inflammation and injury. Therefore, we aimed to determine whether DNA released from damaged hepatocytes accumulates within the necrotic liver and the impact of its recognition by the immune system. Treatment with different hepatotoxic drugs (paracetamol and thioacetamide, 20 and 70mM, respectively) caused DNA release to hepatocyte cytoplasm, which occurred in parallel with cell death *in vitro* (50% reduction in MTT metabolism). Administration of these drugs *in vivo* (600mg/kg) caused severe liver injury, shown by histology and increased serum transaminase levels (control = 43.5±7.6; paracetamol-treated = 3736±378.2). Surprisingly, using confocal intravital microscopy, we observed massive DNA deposition in liver necrotic areas (19% of total area), together with an intravascular DNA coating (25% of total area). In addition, liver injury led to a directional migration of neutrophils to DNA-rich areas, where they exhibited an active patrolling behavior. Analysis by flow cytometry showed that emigrated neutrophils expressed the DNA receptor TLR9 in their surface during injury, and these cells sensed and reacted to extracellular DNA by activating the transcription factor NF-κB (15-fold increase) and up-regulating the chemokine receptor CXCR2 (120-fold increase), measured by real-time PCR. DNA removal by intravenous injection of DNASE1 (1000 units; 6/6hours) or blockage of TLR9 receptor-mediated sensing (E6446; 100mg/kg) significantly reduced hepatic cytokine production (TNFα and CXCL1 levels; 80% and 50% respectively), liver neutrophil recruitment (50% inhibition) and hepatotoxicity (transaminase levels: DNASE-treated = 1489±288.3; TLR9 blocker-treated = 637±139) even if given 6 hours after the toxic challenge. Likewise, adoptive transfer of wild-type neutrophils to TLR9^{-/-} mice reversed the hepatoprotective phenotype otherwise observed in TLR9 absence. Conclusion: Hepatic DNA accumulation is a novel feature of DILI pathogenesis and blockage of DNA accumulation or recognition by the immune system may consist in a promising therapeutic option. Financial Support: CAPES, CNPq, FAPEMIG

P1590**Board Number: B101****Visual evidence for the direct interaction between MDA5 and IPS-1 proteins.**K. Deguchi¹, A. Yoshida¹, J.L. Gilmore¹, R. Yamaue^{1,2}, H. Kato^{1,2}, T. Fujita^{1,2}, K. Takeyasu¹;¹Graduate School of Biostudies, Kyoto University, Kyoto, Japan, ²Institute for Virus Research, Kyoto University, Kyoto, Japan

The front line of defense of a host cell against pathogenic invasion is the innate immune system. In the cytoplasm, several sensor proteins, including RIG-I-like receptors (RLRs), function against viral invasion. They recognize invading viral RNAs and, via the following several steps, produce type I interferons (IFNs) and IFN-inducible antiviral proteins. MDA5, one of the RLRs, is believed to be activated by binding specifically to long (>2000 base pairs) double-stranded RNAs (dsRNAs). The activated MDA5 is then assumed to interact with IPS-1 (also referred as MAVS/VISA/Cardif), a downstream factor localized on the outer mitochondrial membrane. At present, the molecular mechanism of the RNA—MDA5—IPS-1 signaling cascade has not been clarified. Here we established a method of investigating the protein-dsRNA/protein-protein interactions with a combination of biochemistry, molecular biology, and atomic force microscopy (AFM). The results obtained are:

Multiple MDA5 molecules bind to dsRNA, forming fiber-like structures on it.

MDA5 consists of three domains (C-terminal domain, helicase domain, and two CARDs), which can be recognized individually by AFM, and exists in an equilibrium between open and closed conformations.

In a mutant form of MDA5 (which constitutively activates the IFN pathway), the equilibrium is shifted to the closed form, suggesting that the closed form is active.

After ATP-hydrolysis of the fiber-like structures, the closed form of wild-type MDA5 is released, consistent with the idea that the closed form is active.

The constitutively active MDA5 mutant, many of whose molecules are closed, induces significantly more *in vitro* aggregation of IPS-1 than the wild type MDA5. The volume of such aggregate is 100~ times as large as that of a single molecule of IPS-1. This provides direct evidence that the closed MDA5 is active and that the activated MDA5 interacts directly with IPS-1.

From these results, we propose a new model of the RNA—MDA5—IPS-1 signaling cascade. The open MDA5 recognizes viral dsRNA by binding to it and forming fibrous structures. This process is accelerated by binding to ATP. The MDA5 molecules on dsRNA release themselves from it after ATPase-hydrolysis, and then interact with IPS-1 on the outer membrane of mitochondria.

P1591**Board Number: B102****Efficient neuron reconstruction with NeuTu.**R. Pearcy¹, D. Hunt², D. Jin³, N. Spruston²;¹University of Richmond, Richmond, VA, ²Janelia Research Campus, Ashburn, VA, ³Pennsylvania State University, State College, PA

Neurons have a broad range of morphologies that directly impact cellular function. Analyzing morphology can help discern the possible functions of specific cell-types and the mechanisms behind how cells process synaptic inputs, as well as helping to create accurate computational models of neurons. To study morphology, it is crucial to reconstruct neurons in an accurate and efficient manner. NeuTu is a novel software tool that has been recently developed with the goal of reducing the time and effort required for neuron tracing and reconstruction compared to the previously used manual methods. NeuTu processes tiles of bright-field image z-stacks of neurons and uses a semi-automatic tracing method to reconstruct neurites with accurate shapes and diameters. The neurites are represented in SWC format in a 3D viewer and are also displayed in the stack image for direct comparisons to the neurites they represent. The user interface is designed to facilitate manual inspection and correction of the reconstructed neuron to enhance reconstruction accuracy. The SWC output can then be analyzed to determine morphological differences between cells and to create computational models that enable the study of dendritic integration. As an open-source software tool, NeuTu will be used to create a database of reconstructed neurons that can be edited by individuals to improve the quality of the reconstructions and will give researchers access to high quality data on many different types of neurons.

P1592**Board Number: B103****MultiOmyxTM* immunocytochemistry reveals heterogeneous biomarker expression in human ESC and iPSC.**B. Davis¹, A. Larriera¹, M. Rothney¹, E. Kovacs¹, M. Gerdes¹;¹General Electric, Niskayuna, NY

Stem cells hold considerable promise for regenerative medicine, however, questions regarding the equivalency or homogeneity of different cell lines constantly arise, and this is exacerbated when iPSC lines are produced from somatic cells. It is well known that individual cell lines have a bias toward certain lineages through default differentiation pathways, and that cultures frequently undergo spontaneous differentiation. Monitoring the phenotype of the cells is complex, as no single marker defines the pluripotent state or lineage fate during directed differentiation. Likewise, directed differentiation protocols fail to fully induce all cells, with efficiencies of conversion to the desired phenotype being as low as 10% leading to heterogeneous mixtures of cells that ultimately need separation prior to applications in regenerative medicine such as transplantation. To address the heterogeneous nature of stem cell cultures and differentiated phenotypes, our team has applied

MultiOmyx™* immunocytochemistry to characterize these dynamic processes in human ESC and iPSC cultures in the pluripotent state as well as ES cultures undergoing directed differentiation to hepatocyte lineages. This approach allows sequential staining of the samples with intervening inactivation of dye conjugated primary antibodies and re-imaging on the same areas of the sample. We have successfully demonstrated 12 or more markers per sample and identified patterns of biomarker expression using algorithms developed for in situ single cell analysis within the colonies. For studies on ES and iPSC cells, traditional markers for pluripotency were examined including Sox2, SSEA-1, Nanog, Oct4, and ABCG2, revealing heterogeneous patterns of cellular localization within colonies undergoing phenotypic drift. In a separate study, efficacy of hepatocyte differentiation from the ES state was assessed by staining cultures for SOX17, FOXA2, OCT4, SOX2, BRACHYURY, Nestin and AFP, allowing process efficiency to be monitored. Use of MultiOmyx™* technology can characterize subpopulations within cultures, providing additional spatial and temporal details lost in conventional flow cytometry and immunocytochemistry methods.

Stimulated emission depletion (STED) microscopy reveals a sub-diffraction, 9-fold symmetric domain containing Cby1, Ahi1, and Ofd1 at the centriole-cilium interface.

C. Comerci¹, Y.L. Lee², T. Stearns^{3,4}, W.E. Moerner⁵;

¹Biophysics, Stanford University, Stanford, CA, ²Biology, Stanford University, Stanford, CA, ³Department of Biology, Stanford University, Stanford, CA, ⁴Department of Genetics, Stanford School of Medicine, Stanford, CA, ⁵Chemistry, Stanford University, Stanford, CA

Mutations and deletions of certain centriolar proteins result in a family of related syndromes called ciliopathies. For instance, deletion of the protein Cby1 results in cystic kidneys, a common ciliopathy phenotype. The centrioles' small size (~200 x 500 nm) is near the diffraction limit of light microscopy (~250 nm), making it difficult to precisely localize centriolar proteins, to determine their location with respect to other centriole proteins, and thus to build a molecular understanding of the detailed architecture of the centriole. We used stimulated emission depletion (STED) immunofluorescence microscopy with a FWHM resolution of 60 nm to image five centriolar proteins in multiciliated mouse tracheal epithelial cells (MTECs): Ahi1, Cby1, Ofd1, Sdccag8, and Tmem237 and find 9-fold symmetric structures. By calculating the radial intensity profile, the average radial positions of the five proteins were determined to better than 2 nm precision. This analysis revealed that Cby1 localizes near the distal centriole protein Ofd1 and the transition zone component Ahi1. Our work establishes a ring-shaped domain between the distal end of the centriole and the base of the cilium containing Cby1, Ahi1, and Ofd1.

P1594**Board Number: B105****Molecular Counting by Photobleaching in Protein Complexes with Many Subunits: Best Practices and Application to the Cellulose Synthesis Complex.**Y. Chen^{1,2}, N.C. Deffenbaugh¹, C.T. Anderson^{2,3}, W.O. Hancock^{1,4};¹Department of Biomedical Engineering, Pennsylvania State University, University Park, PA, ²Cell and Developmental Biology, Pennsylvania State University, University Park, PA, ³Department of Biology, Pennsylvania State University, University Park, PA, ⁴Interdisciplinary Graduate Degree Program in Bioengineering, Pennsylvania State University, University Park, PA

The constituents of large multi-subunit protein complexes dictate their functions in cells, but determining their precise molecular makeup *in vivo* is challenging. One example of such a complex is the cellulose synthesis complex (CSC), which in plants synthesizes cellulose, the most abundant biopolymer on Earth. In growing plant cells, CSCs exist in the plasma membrane as six-lobed rosettes that contain at least three different cellulose synthase (CESA) isoforms, but the number and stoichiometry of CESAs in each CSC is unknown. To begin to address this question, we performed quantitative photobleaching of GFP-tagged AtCESA3-containing particles in living *Arabidopsis thaliana* cells using variable-angle epifluorescence microscopy and developed a set of information-based step-detection procedures to estimate the numbers of GFP molecules in each particle. The step detection algorithms account for changes in signal variance due to changing numbers of fluorophores, and the subsequent analysis avoids common problems associated with fitting multiple Gaussian functions to binned histogram data. The analysis indicates that at least ten GFP-AtCESA3 molecules can exist in each particle. These procedures can be applied to photobleaching data for any protein complex with large numbers of fluorescently tagged subunits, providing a new analytical tool with which to probe complex composition and stoichiometry.

P1595**Board Number: B106****The use of time-lapse ptychography to measure angiogenesis assay dynamics.**R. Suman¹, K. Langley², K. Riches³, K.E. Porter³, P. O'Toole¹;¹University of York, York, England, ²Phasefocus, Sheffield, United Kingdom, ³University of Leeds, Leeds, United Kingdom

Endothelial cells (EC) play an important role in the formation of new blood vessels through angiogenesis. This functional capacity is conventionally analysed using angiogenesis assays whereby EC are plated onto a Matrigel substrate where they form tubes. The number of tubes formed are then analysed at fixed time points, e.g. 12 hours after seeding the cells. Using this fixed point method it is possible to identify treatments or disease states that modulate angiogenic capacity. Here we demonstrate the use of a ptychographic microscope (Phasefocus VL21) to study the dynamics of the angiogenesis/tube

forming assay through time lapse microscopy, negating the need for a fixed point assay that may miss key events and thus not reveal the whole biological dynamics of the tube formation process.

Ptychography is a novel imaging modality that produces high contrast label-free images of living cells. The technique reconstructs an image from overlapping diffraction patterns using an iterative algorithm (Maiden et al., 2010), generating both amplitude and phase data from the sample to report on quantitative changes in the refractive index (RI) and thickness of the specimen.

Large fields of view (2.4mm x 2.4mm, pixel size = 0.653 μ m) of human primary EC plated on Matrigel were imaged on the Phasefocus VL21 microscope every 10 minutes for periods up to one week. Quantitative parameters of the angiogenesis assay such as tube number, tube area and tube wall width were measured over time. With the availability of this temporal information we were able to identify dynamic changes in tube assembly and/or degradation. For example we were able to differentiate between tubes that failed to form and those that formed and subsequently broke down. This temporal data is not available using a fixed point assay where only the reduction in tube number would be evident.

In summary, we believe that this technique could form a new assay that provides additional information and reveal previously unavailable biological data to enable a more detailed understanding of the underlying mechanisms behind angiogenesis.

Multicolor correlative light and electron microscopy of single molecules: A case study of acetylcholine receptor localization at the mouse neuromuscular junction.

I.V. Roeder¹, M. Pfannmoeller², C. Dietrich³, J. Fuchs⁴, C. Wojek⁴, R.R. Schroeder¹;

¹Cryo Electron Microscopy, Universitaet Heidelberg, Heidelberg, Germany, ²EMAT, Antwerp, Belgium,

³Carl Zeiss AG, Jena, Germany, ⁴Carl Zeiss Microscopy GmbH, Oberkochen, Germany

With state-of-the-art on-section immuno-labeling proteins exposed to the surface of ultrathin sections can be labeled. However, using this technique not all existing epitopes are detected and resulting micrographs have to be evaluated carefully. To validate the on-section immuno-labeling of acetylcholine receptors (AChR) of the mouse neuromuscular junction (NMJ) on ultrathin sections and to study the AChR distribution we used a combination of different light and electron microscopic techniques. For registration of multi-modal images we established a fiducial-based workflow resulting in a robust and precise correlation better than 20 nm. By labeling AChR using fluorescent quantum dots (QDs) that can be detected in both imaging modes we are able to correlate single-molecular signals from both microscopes. First, the diaphragm muscle was explanted and AChR were labeled with α -bungarotoxin, a snake venom, conjugated to Alexa Fluor 555 (AF555). Subsequently the tissue was high pressure frozen, freeze substituted and embedded in Lowicryl resin. The AF555 fluorescence was preserved during this procedure giving the opportunity to study the whole resulting block using confocal laser scanning

microscopy to locate the structure of interest within the huge sample volume. Second, ultrathin sections were made and deposited either on indium tin oxide coated cover slips or on carbon coated grids with a formvar-film. The first type of samples enables subsequent super-resolution fluorescence light microscopy (FLM) based on multi-emitter localization microscopy and scanning electron microscopy. Analysis of a set of subsequent sections enables a three-dimensional representation of the preserved AF555 fluorescence which can be registered to the corresponding electron micrographs. Thereby the AChR distribution can be investigated in relation to the NMJ ultrastructure. The second type of samples is used for conventional FLM and for analytical scanning transmission electron microscopy (STEM). Additionally to the preserved AF555 fluorescence at AChR, receptors are labeled on-section using immuno-labeling with primary antibodies against a receptor subunit and secondary antibodies conjugated with two different QDs. QD fluorescence can be detected and distinguished in the FLM and using a novel workflow for the analytical STEM, particles can be separated according to their specific spectral features. By this means the distribution of multi-colored single molecules can be studied in light and subsequently in electron microscopy and resulting signals can be correlated. Combining these methods allows studying particular details by detection of single molecules within large volumes. As our workflows are modular they can be readily applied to other biological questions.

Shs1 is required for an organized septin higher order structure in vivo.

M. McQuilken¹, S. Abrahamsson², S. Mehta³, G. Harris³, A. Verma³, R. Oldenbourg³, A.S. Gladfelter¹;

¹Biological Sciences, Dartmouth College, Hanover, NH, ²Rockefeller University, New York, NY, ³Cellular Dynamics, Marine Biological Laboratory, Woods Hole, MA

Septins are conserved filament-forming proteins that act in cytokinesis, membrane remodeling, cell polarization, and migration. They closely associate with membranes and can act as diffusion barriers to restrict the diffusion of proteins within membranes. Although septin function is critical for diverse cell events, it is not well understood how they assemble *in vivo* or how they are remodeled throughout the cell cycle. GFP can be excited by and emit linear polarized light and linking GFP in a constrained manner to an endogenous septin enables analysis of septin organization *in vivo* by polarization microscopy. Polarized fluorescence analysis has previously suggested that septins filaments are paired in higher order structures, and that organized septin filaments undergo a coordinated 90° reorientation during cytokinesis *in vivo*. We developed a Multifocus Polarization Microscope (MF-PolScope) to evaluate septin organization in 3D through time to capture the assembly and rearrangement of higher-order septin structures, and analyze mutant yeast strains with abnormally organized septins. This method allows simultaneous detection of 9 focal planes at a single instant so as to analyze the degree of coordination of events in different areas of the cell and assess if filaments in mutant strains are likely paired. MF-PolScope imaging has led to the identification of septin interactors important for distinct aspects of the assembly, stability, and rearrangement of septins. One interactor necessary for ordered assembly of septin higher order structures is the septin, Shs1. The septin structure is disordered in *shs1*

mutant cells in a manner consistent with the absence of paired septin filaments. Our work demonstrates the power of this new imaging approach to assess dynamic rearrangements of the cytoskeleton in whole, live cells.

Nanoscale Analysis of Clathrin Coated Pit Formation using dSTORM.

M. Lehmann¹, J. Schöneberg², A. Ullrich², Y. Posor³, G. Lichtner², V. Haucke³, F. Noe², J. Schmoranzner¹;

¹Biochemistry, Free University Berlin/Leibniz Inst. f. Mol. Pharmacology, Berlin, Germany,

²Computational Molecular Biology, Freie Universität Berlin, Berlin, Germany, ³Leibniz Inst. f. Mol. Pharmacology, Berlin, Germany

Clathrin mediated endocytosis (CME) is one of the major mechanisms of how cells retrieve membrane proteins and growth factors from the cell surface. CME depends on phosphoinositides (PIs) that regulate the recruitment and precise nanoscale organization of endocytic proteins (i.e. BAR proteins, PI-kinases, coat proteins). While initial stages of CME depend on PI(4,5)P₂ recent data have identified a crucial role for PI(3,4)P₂ in late steps of CME preceding dynamin-mediated fission (Posor et al. , 2013). The precise spatiotemporal organization of CME components is critical for the successful formation of clathrin coated pits (CCPs) that are diffraction limited structures of about 150 nm diameter. Here we use direct Stochastic Optical Reconstruction Microscopy (dSTORM) to investigate the nanoscale localization of the coat protein clathrin, the PI(3) kinase PI(3)KC2 α , the dynamin-associated PX-BAR domain protein sorting nexin 9 (SNX9) and the GTPase dynamin during CME. We observe distinct nanoscale distributions of these CME components in late stage CCPs. While clathrin and PI(3)KC2 α localize to the coat, dynamin is at the neck and SNX9 in an intermediate zone between coat and neck. Using live-cell imaging and electron microscopy we show that depleting SNX9 leads to lack of dynamin bursts at the end of CME and to the accumulation of U-shaped pits. Our data, supported by mathematical modeling, shows that PI(3,4)P₂ dependent recruitment of SNX9 to the neck-coat transition zone is necessary for successful CCP constriction and CME.

P1599**Board Number: B110****Nanoscale segregation of branched F-actin nucleation and elongation determines dendritic spine shape.**G. Giannone¹, A. Chazeau², A. Mehidi¹, D. Nair¹, J. Gautier³, C. Leduc⁴, F. Kage⁵, O. Thoumine¹, K. Rottner⁶, D. Choquet¹, A. Gautreau⁷, J. Sibarita⁸;¹Interdisciplinary Institute for NeuroScience, CNRS/Univ Bordeaux, Bordeaux, France, ²Utrecht University, Utrecht, Netherlands, ³Ecole Normal Supérieur, Paris, France, ⁴Institut Pasteur, Paris, France, ⁵Division of Molecular Cell Biology, Technical University Braunschweig, Braunschweig, Germany, ⁶University of Bonn, Bonn, Germany, ⁷CNRS, Gif-sur-Yvette, France, ⁸Institut Magendie - Univ Bordeaux2, Bordeaux, France

Actin dynamics drive morphological remodeling of neuronal dendritic spines and changes in synaptic transmission. Yet, the spatiotemporal coordination of actin regulators in spines is unknown. Using single protein tracking and super-resolution imaging we revealed the nanoscale organization and dynamics of branched F-actin regulators in spines. Branched F-actin nucleation occurs at the PSD vicinity, while elongation occurs at the tip of finger-like protrusions. This spatial segregation differs from lamellipodia where both branched F-actin nucleation and elongation occur at protrusion tips. The PSD is a persistent confinement zone for IRSp53 and WAVE complex, activator of the Arp2/3 complex. In contrast, filament elongators like VASP and formin-like protein-2 move outwards from the PSD with protrusion tips. Accordingly, Arp2/3 branch points are immobile and surround the PSD. Arp2/3 and Rac1 GTPase converge to the PSD, respectively, by cytosolic and membrane free-diffusion. Enhanced Rac1 activation and Shank3 over-expression, both associated with spine enlargement, induce delocalization of WAVE from the PSD. Thus the specific localization of branched F-actin regulators in spines might be reorganized during changes in synaptic activity to regulate spine structural plasticity.

P1600**Board Number: B111****Novel spectral imaging and analysis to unravel the organelle interactome.**A.M. Valm¹, S. Cohen¹, W.R. Legant², M.W. Davidson³, E. Betzig², J. Lippincott-Schwartz^{4,5};¹Cell Biology and Metabolism Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD, ²HHMI/Janelia Farm Research Campus, Ashburn, VA, ³National High Magnetic Field Laboratory and Department of Biological Science, Florida State University, Tallahassee, FL, ⁴Physiology Course at Marine Biological Laboratory, Woods Hole, MA, ⁵Cell Biology and Metabolism Program, NICHD, NIH, Bethesda, MD

The organization of the eukaryotic cell into membrane-bound compartments allows for regulation of cellular processes. However, the morphodynamic activities of spatially distinct organelles must be coordinated so that cellular processes can be carried out. Inter-organelle membrane contacts have emerged as key sites for exchange of metabolites and signaling molecules, as well as playing roles in

organelle division and maturation. Much progress has been made recently in elucidating the functions of pairwise organelle interactions, including the interaction between mitochondria and the endoplasmic reticulum (ER). However, it is likely that important cellular activities are coordinated between three or more organelles over time. For example, lipid droplets have been shown to interact with multiple organelles, including the ER, mitochondria, peroxisomes and the endocytic system, presumably in order to facilitate exchange of lipids in response to changing metabolic needs. A systems-level understanding of the dynamic organelle interactions within eukaryotic cells, i.e., the organelle interactome, remains unattained due to the inability to label and distinguish more than a few different fluorescent proteins in a single sample. Here, we present a novel cell labeling, image acquisition and analysis approach to study the spatial distribution of multiple organelles within single eukaryotic cells. Cells are transfected with multiple fluorescent fusion proteins targeted to various organelles or with organelle-specific fluorescent chemical dyes to label 6 or more different subcellular compartments. Live-cell, time-lapse images are acquired of labeled cells using commercially available imaging systems, then linear unmixing algorithms are applied to the recorded image data to deconvolve spectrally overlapping fluorophores. A computational image analysis procedure is then used to track the observed inter-organelle contacts through time. We further adapted a lattice light sheet imaging system for spectral imaging by introducing multiple laser lines coupled with fast acousto-optical beam splitting to record spectral images in the excitation regime. We developed a novel excitation-side unmixing algorithm and applied it to the recorded data to reconstruct full isotropic three dimensional time lapse images of live cells labeled with 6 different organelle markers. We imaged cells that simultaneously express fluorescent fusion protein markers for peroxisomes, lysosomes, mitochondria, the ER and the Golgi apparatus, as well as a vital chemical stain to label lipid droplets. We applied our organelle interactome analysis to test the hypothesis that there are subpopulations of lipid droplets within mammalian cells that differ in their organelle interactions.

Learning to count: Calculating receptor densities on membranes from super resolution images.

K. Raghunathan¹, A. Ahsan¹, U.S. Allam¹, M. Nyati¹, D. Ray¹, S.L. Veatch²;

¹University of Michigan, Ann Arbor, MI, ²Biophysics, University of Michigan, Ann Arbor, MI

Quantifying the number of labeled biomolecules from super resolution images is difficult due to artifacts from both over-counting and under-counting. We use over-counting artifacts in super-resolution images to calculate receptor density in cells. This method takes advantage of the observation that the magnitude of self-clustering due to over-counting is inversely proportional to the density of the labeled protein, as long as the labeled protein is sampled randomly. Pair autocorrelation functions calculated from over-counted fluorescence images are correlated ($g(r) > 1$) at radii on the order of the resolution limit of the measurement. We also demonstrate the effectiveness of this technique by using single-color STORM imaging to estimate EGFR density under different conditions. This method faithfully

recapitulated previously reported numbers for EGFR per cell in MCF-7 cell line. Furthermore, the absolute density of EGFR in different cell lines measured using this method agreed with relative densities determined using quantitative Western blots. We have further extended this method to quantitate interactions between labeled proteins in single cells by using two-color super resolution imaging. Cross correlation between two color channels have been used earlier in various studies as a measure of the strength of interaction between labeled proteins. Here, we combine cross correlation measurements with the protein densities calculated from autocorrelation functions to determine the number of interacting proteins in a single cell. We illustrate how this method complements existing biochemical techniques by investigating how the interaction of EGFR with the heat shock protein, HSP90 or E3 ubiquitination enzyme, Smurf2 affects its stability. Upon EGF stimulation, the density of Smurf2 on membrane increased while that of EGFR decreased. siRNA knockdown of Smurf2 increased EGFR degradation from the membrane upon EGF treatment, suggesting that Smurf2 stabilized activated EGFR. In support of this, we observed increased the interaction between EGFR and Smurf2 upon EGF stimulation. These results along with our previous work on HSP90-EGFR interaction show that the stability of EGFR in the plasma membrane is enforced by toggling its interaction of EGFR with these two proteins. Monomeric EGFR is stabilized through its interaction with HSP90, while in its activated state, it gets stabilized through monoubiquitination through interaction with Smurf2. Super-resolution methods have been used successfully to dissect several biological problems and our method of determining protein densities will extend the application of super-resolution to complement western blots and co-immunoprecipitation techniques that have traditionally been used to study biochemical pathways.

Lattice light sheet microscopy: imaging molecules, cells, and embryos at high spatiotemporal resolution.

W.R. Legant¹, B. Chen², K. Wang¹, L. Shao¹, E. Betzig¹;

¹HHMI/Janelia Farm Research Campus, Ashburn, VA, ²Research Center for Applied Sciences, Academia Sinica, Taipei, Taiwan

By definition, living specimens are animate. Therefore, a full understanding of dynamic biological systems will only be obtained by observing them with enough 4D spatio-temporal resolution and for a sufficient duration, to capture the phenomena of interest. Unfortunately, conventional widefield or confocal microscopes are either too slow, lack the spatial resolution, or induce too much photodamage to meet these requirements. To address these limitations, we have developed a new approach for sub-cellular light-sheet microscopy capable of imaging fast three-dimensional (3D) dynamic processes *in vivo* at signal to noise levels typically obtained only in total internal reflection fluorescence (TIRF) illumination. By utilizing 2D optical lattices, we generate a thin (~400 nm full width half maximum) plane of light coincident with the focus of a high NA detection objective. Using this technique, we demonstrate substantial advantages in speed, sensitivity and reduced phototoxicity compared to conventional point scanning and spinning disc confocal microscopes as well as light-sheet microscopes

utilizing single Gaussian or Bessel beams. We leverage these advantages to image samples ranging over three orders of magnitude in length scale from single molecules to whole embryos. Specific examples to be presented include: 3D single molecule tracking of fluorescently tagged transcription factors in densely labeled embryonic stem cell spheroids, 3D imaging and quantification of microtubule growth phases and organelle dynamics throughout the course of cell division, rapid 3D imaging of Tetrahymena motility at over 3 volumes per second, and 3D protein localization throughout the course of dorsal closure in Drosophila embryos. By combining lattice light sheet microscopy with novel fluorescent probes, we will also demonstrate 3D super-resolution localization microscopy with unprecedentedly rich detail over large fields of view and in thick 3D samples such as dividing cells and small embryos.

²Affinity Proteomics, Science for Life Laboratory, KTH - Royal Institute of Technology, Stockholm, Sweden

Mapping proteins to subcellular compartments is key for understanding their function and interactions, and further, the complex machinery of eukaryotic cells. Despite vast research, much is still unknown regarding the spatial organization and biological processes of many proteins.

The Subcellular Protein Atlas aims to systematically localize the entire human proteome on a subcellular level, using an antibody-based approach as part of the Human Protein Atlas project. In order to find suitable samples expressing the target protein, the panel of cell lines has been expanded and RNA-seq is used to cherry pick the best cell line for each protein (1). More than 10.000 human proteins have been localized and validation methods applied include gene silencing using siRNA for antibody binding and protein localization (2), fluorescently tagged proteins (3) and paired antibodies targeting the same protein.

Our results indicate that there exist distinct organelle proteomes that are common for cell lines, with a strong correlation to protein function. Also, our results suggest that approximately 50% of all proteins localize to multiple compartment, whereas 5-10% show a cell cycle dependent expression pattern (4). In addition, in order to localize the full human proteome, our data imply that cells of different origin will need to be used, pointing towards cells with hematopoietical or neurological functions in complement to adherent epithelial cells. We have thus optimized our high-throughput protocols to enable characterization of cells in suspension, stem cells and differentiated neurons.

Here we discuss the importance of spatial proteomics and present the content and results of the Subcellular Protein Atlas. We also discuss the path to successfully analyze the full human proteome on a subcellular level.

Superparamagnetic nanoparticles (SPMNPs) are appealing for use in organelle isolation strategies. Yet, this potential remains largely unexplored because thus far research has focused on either physicochemical design or on their application in micron-sized beads. For their use in life sciences, the biocompatibility of SPMNPs goes beyond their chemical composition and shape, and features like their size and more importantly their surface properties are becoming more important to exploit extra- and intracellular interactions. Here we introduce thermal decomposition to manufacture iron oxide based SPMNPs (Ø10nm) and demonstrate how different surface functionalizations can lead to different types of cellular interactions. Cationic aminolipid-coated SPMNPs reside surprisingly strong at the outer cell surface. In contrast, anionic dimercaptosuccinic acid-coated SPMNPs are efficiently internalized and accumulate in a time-dependent manner in endosomal and lysosomal populations. These features allowed us to establish a standardized magnetic isolation procedure to selectively isolate plasma membranes and intracellular late endosomes/lysosomes with high yields and purities as consolidated by biochemical and ultrastructural analyses. Subsequent quantitative and qualitative proteome analysis

underpins the overall high enrichment for hydrophobic (membrane) proteins as well as plasma membrane and lysosomal constituents in the respective purified fractions. This nano based technology provides therefore a breakthrough in the field of subcellular 'omics' as it allows the identification of subtle alterations in the biomolecular composition of different SPMNP-isolated compartments that would be otherwise not detected in total cell or tissue analysis.

Developing Mitochondrial Enrichment for Targeted Analysis (META) to Study Phosphorylation Kinetics.

M. Ryoo^{1,2}, O. Harding³, M.A. Tangrea¹, R. Weigert³, A. Shitara³, J.C. Hanson¹, A. Rosenberg¹, N. Porat-Shliom³, Y. Chen¹;

¹NCI, NIH, Bethesda, MD, ²Duke University, Durham, NC, ³NIDCR, NIH, Bethesda, MD

Mitochondria are a dynamic organelle whose localization, morphology and function are subjected to precise regulation. It is known mitochondria activity differs vastly in different tissues. Investigating the post-translational modifications of mitochondrial proteins is crucial to understand mitochondria activity under both physiological and pathological conditions. The main challenge in this kind of studies is the fact that the isolation procedures used to prepare purified/enriched mitochondria severely affects post-translational modifications by triggering, for example, massive dephosphorylation and proteolysis. To overcome this issue, we developed Mitochondria Enrichment for Targeted Analysis (META), a streamlined workflow to study changes in protein phosphorylation profile in mitochondria isolated from mouse salivary glands. This two-step approach includes mitochondrial enrichment with minimal tissue disruption and analysis via targeted mass spectrometry using a library of putative phosphorylation sites in mitochondrial proteins. For sample preparation, cryofixation and subsequent sectioning were performed to preserve mouse salivary glands. We probed mitochondria in the prepared tissue samples with mitochondria-specific antibody anti-TOM20 and applied expression-based microdissection (xMD) to isolate mitochondria from the tissue onto polymer films. The films containing dissected mitochondria were then subjected to DAPI staining and Scanning Electron Microscopy (SEM) to visually verify the exclusion of nuclei and presence of mitochondria. The efficiency of microdissection was assessed to be 45.91% by comparing the segmented images of the tissue before and after xMD. Following protein extraction we evaluated the extent of mitochondrial protein enrichment by immunoblot assay and found cytochrom C to beta-actin ratio to be 152% higher compared to the manual microdissection controls. In order to systematically study the dynamic changes of phosphorylation in response to stimuli in mitochondrial proteins using targeted mass spectrometry, putative phosphorylation sites of mitochondrial proteins were predicted *in silico* and compiled into a library, where a total of 231 proteins and 42,966 possible M/Z peak changes are listed. In summary, our results show that META is a powerful tool for mitochondria enrichment from tissue and guiding subsequent proteomics profiling. Moreover, this workflow can also be applied to study protein dynamics in mitochondria in other tissue types as well as to characterize protein dynamics in other organelles.

P1606**Board Number: B117****ENGINEERED CONTROL OF PROTEIN TYROSINE PHOSPHATASE ACTIVITY IN LIVING CELLS.**J.E. Brinks Klomp¹, V. Huyot², A.V. Karginov¹;¹Pharmacology, University of Illinois - Chicago, Chicago, IL, ²Pharmacology, University of Illinois at Chicago, Chicago, IL

We describe here a new broadly applicable approach to activate the catalytic function of specific protein phosphatases in living cells. Insertion of an engineered allosteric switch, the iFKBP domain, at a structurally conserved position within the catalytic domain makes the modified phosphatase inactive. Treatment with rapamycin triggers interaction with a small FKBP-rapamycin-binding domain (FRB) and restores the activity of the phosphatase. The method utilizes genetically encoded and membrane permeable reagents providing tight temporal control of phosphatase activity. Based on the structural similarity of catalytic domains this method should be applicable to many tyrosine phosphatases. We have already developed rapamycin-regulated (RapR) analogs of Shp2, PTP-PEST and PTP1B. Using PTP-PEST as an example we demonstrate that amino acid sequence alignment provides sufficient information for generation of new RapR-phosphatases. Through conjugation of FRB to a desired protein, we are able to restrict phosphatase activation to interaction with a specific downstream target, and to specific subcellular locations. This approach opens new opportunities for interrogation of phosphatase-mediated signaling pathways.

P1607**Board Number: B118****Insertion of LOV and engineered domains to control kinases, Rho GTPases and GEFs with light or small molecules.**O. Dagliyan¹, P. Chu², M. Tarnawski³, M. Shobair¹, D. Shirvanyants¹, I. Schlichting³, N. Dokholyan¹, K.M. Hahn²;¹Department of Biochemistry and Biophysics, University of North Carolina, Chapel Hill, NC, ²Department of Pharmacology, University of North Carolina, Chapel Hill, NC, ³Department of Biomolecular Mechanisms, Max Planck Institute for Medical Research, Heidelberg, Germany

For many cellular behaviors, it is essential that signaling is precisely coordinated in space and time. Such spatiotemporal dynamics can only be fully understood using tools that examine and manipulate protein behavior in intact living cells. Here we report the insertion of engineered domains to inhibit kinases, GTPases and guanine exchange factors (GEFs) with light, and activate GEFs with small molecules. Previously, we developed an approach in which a ligand-controlled engineered domain was inserted into the surface loops of kinases, where it exerted allosteric control of kinase activity. Kinases were rendered catalytically inactive until rapamycin analogs rescued activity. By building switchable Src family kinase

isoforms, including RapR Src, Fyn, and Lyn, we were able to demonstrate different roles and localization for each isoform at specific stages of polarization. Here, we show the approach can be applied to a different protein family, Rho GEFs, which are activators of small GTPases. Molecular dynamics and other approaches indicated allosteric interactions between active sites and distant residues, guiding insertion of an engineered “RapR domain” into Vav2 and intersectin, conferring rapamycin-induced activation. By inserting the light sensitive LOV domain, we produce GEFs, GTPases and kinases inhibited by light. We will describe ongoing studies focused on protein interactions mediating different stages of cell polarization.

A statistical framework to analyze molecule colocalization.

T. Lagache¹, N. Sauvonnnet¹, L. Danglot², J. Olivo-Marin¹;

¹Cell Biology and Infection, Institut Pasteur, Paris, France, ²Membrane Traffic in Health and Disease, INSERM ERL U950, UMR 7592, Institut Jacques Monod, CNRS, Univ Paris Diderot, Paris Cedex 13, France

The quantitative analysis of molecule interactions in bioimaging is key for understanding the molecular orchestration of cellular processes and is generally achieved through the study of the spatial colocalization between different populations of molecules.

Most colocalization methods are based on pixel overlap between the previously denoised signal that is emitted from two (or more) different fluorescent labels, and use a global image correlation such as Pearson's or Manders' coefficients. These data, however, cannot be linked to physical parameters such as the real percentage of colocalizing molecules or the average colocalization distance. In addition, randomly distributed molecules can partially overlap, and it is hard to measure the statistical significance of the computed correlation indices. Here, we present a novel statistical method to analyze molecule colocalization that is based on the automatic detection of molecule fluorescent spots, followed by their representation as Point Processes and the statistical analysis of their spatial distribution. This allows to :

1. Test robustly and rapidly whether two molecule distributions colocalize in space, thanks to a closed-form analysis with no need for simulations;
2. Measure statistically the real percentage of colocalizing molecules and the interaction mean distance. Using our method and Total Internal Reflexion Fluorescence (TIRF) microscopy, we first analyse the spatial colocalization between different endocytic cargos and cellular molecules at the cell membrane. Moreover, by coupling our statistical method to single-particle tracking techniques, we propose an automated framework to study the dynamical interactions of molecules and the endocytosis orchestration.

P1609**Board Number: B120****A new variant of BioID to identify protein-protein associations in live cells.**D. Kim¹, S.C. Jensen¹, K. Noble², R.H. Anderson¹, B. KC¹, K. Motamedchaboki³, K.J. Roux¹;¹Children's Health Research Center, Sanford Research, Sioux Falls, SD, ²Department of Biology, Florida State University, Tallahassee, FL, ³Sanford-Burnham Medical Research Institute, La Jolla, CA

Identification of protein-protein interactions is frequently a critical facet to the process of biological discovery. To address technical barriers to monitoring protein-protein associations in living cells we developed proximity-dependent biotin identification (BioID). This method is based on the cellular expression of a promiscuous biotin ligase fused to a protein of interest, thus generating biotinylation of endogenous proteins in a proximity-dependent manner. These biotinylated proteins can be identified by mass-spectrometry following biotin-affinity capture. Although BioID has rapidly become an established method to monitor protein interactions, there remain limitations in its application. One constraint results from the size of the promiscuous biotin ligase used for BioID, which is approximately 35kDa. We have found that certain integral membrane proteins are unable to target appropriately when fused to BioID. To overcome this limitation, we have developed a substantially smaller promiscuous biotin ligase called BioID-2 (approximately 27 kDa). BioID-2 permitted appropriate targeting of fusion proteins that were improperly targeted with BioID. We applied both BioID and BioID-2 to LaA, a major constituent of the nuclear lamina and detected similar candidates thus revealing that BioID-2 is functionally comparable to BioID. Comparative studies of BioID and BioID-2, both in vivo and in vitro, reveal differences in enzyme properties that may indicate preferential applications for each variant. Collectively, these studies expand the capabilities of the BioID method.

P1610**Board Number: B121****Probing the nuclear pore complex with BioID.**D. Kim¹, B. KC¹, K. Motamedchaboki², V. Doye³, K.J. Roux¹;¹Children's Health Research Center, Sanford Research, Sioux Falls, SD, ²Sanford-Burnham Medical Research Institute, La Jolla, CA, ³Inst Jacques Monod-UMR 7592 CNRS-Univ Paris Diderot, Paris Cedex 13, France

Proximity-dependent biotinylation (BioID) is a method to identify protein associations that occur in living cells. Fusion of a promiscuous biotin ligase to a bait protein for cellular expression enables covalent biotin labeling, selective isolation, and identification of proteins proximate to the bait. This effectively generates a history of protein associations that occurred during a defined labeling period in live cells. We have used BioID to study the human nuclear pore complex (NPC), a large macromolecular assembly. BioID was applied to constituents of the Nup107-160 complex and the Nup93 complex, two conserved NPC subcomplexes. A strikingly different set of NPC constituents was detected depending on the position of the BioID-fusion proteins within the NPC. By applying BioID to multiple constituents located

throughout the extremely stable Nup107-160 subcomplex we have refined our understanding of this highly conserved subcomplex, in part by demonstrating a direct interaction of Nup85 with Nup43. And by using the extremely stable Nup107-160 structure as a molecular ruler we have defined the practical labeling radius of BioID, thus enabling a more rational use of the method and interpretation of results. Furthermore, we have extended these studies to include characterization of a BioID enzyme variant. These studies further our understanding of human NPC organization and demonstrate that BioID is a valuable tool to explore the constituency and organization of large protein assemblies in living cells.

Localized light-induced protein dimerization in living cells using a photocaged dimerizer.

E.R. Ballister¹, C. Aonbangkhen², A.M. Mayo¹, M.A. Lampson¹, D.M. Chenoweth²;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA, ²Chemistry, University of Pennsylvania, Philadelphia, PA

Regulated protein localization is critical for many cellular processes. We present a new technique to rapidly and reversibly control protein localization in living human cells with subcellular spatial resolution using a cell permeable, photoactivatable chemical inducer of dimerization. This novel dimerizer consists of a Halotag ligand linked to a photocaged derivative of trimethoprim (TMP). The Halotag ligand covalently binds to Halotag fusion proteins, which serve as anchor domains for protein relocation experiments. Photocaged TMP remains inert until illuminated with ~400 nm light, at which point the unmasked TMP non-covalently binds *E. coli* dihydrofolate reductase (EcDHFR), thereby dimerizing EcDHFR and Halotag fusion proteins. Using this system, we demonstrate light-induced recruitment of a cytosolic protein to individual centromeres, kinetochores, mitochondria, and centrosomes in living human cells. Several systems for light-induced dimerization utilizing naturally light-sensitive proteins have been developed, but none of these systems have been successfully applied at centromeres or kinetochores, complex chromatin structures which are crucial for cell division. Although the photochemical uncaging reaction is irreversible, dimerization can be reversed by addition of free TMP. This work represents a new strategy for controlling protein localization with light using a modular photocaged dimerizer covalently pre-localized to an anchoring protein. This technique should be readily and widely applicable at a variety of cellular locations to address a range of biological questions.

P1612**Board Number: B123****Fluorescence-based, live-cell assessment of ER stress.**M. Liljevald¹, D. Swahn¹, U. Andersson¹, V.M. Loitto²;¹Drug Safety and Metabolism, AstraZeneca RD, Molndal, Sweden, ²Medical Microbiology, Dept. of Clinical and Experimental Medicine, Linköping University, Linköping, Sweden

Cell-based, *in vitro* alternatives to toxicity testing are very much needed to reduce the number of laboratory animals. We are working on setting up a set of cellular assays composed of cell- and organelle-specific analyses, such as mitochondria, membrane integrity, cell cycle, and endoplasmic reticulum. An important part of this battery of assays is assessing cellular stress, more specifically the unfolded protein response. As an initial effort we are currently testing the IRE1a/XBP1 pathway for which we have designed novel fluorescent probes. For this purpose, we have made probes that are FRET-based and probes that have stress-inducible onset of fluorescence. With both conventional expression plasmids as well as lentivirally generated stable cell clones, we are currently validating the novel probes. In initial experiments using HepG2 cells, we have found that probes assessing IRE1a activation of the XBP1 pathway accurately and dose-dependently reflect exposure to known ER stress inducers such as Tunicamycin and Brefeldin A and other compounds that are associated with liver toxicity in the clinic. Using the fluorescence-inducing XBP1-probe, cells treated with 2 μ M Tunicamycin or 50 nM Brefeldin A for 24h shows 10-15 times increased fluorescence compared to controls. We have also identified compounds that inhibit ER-stress responses and may act as molecular chaperones, which could be of potential therapeutic benefit in several diseases where ER stress plays important role such as NASH and diabetes. Our long-term goal is to reduce the number of animals needed for ranking novel drug candidates and to reliably predict possible adverse effects.

P1613**Board Number: B124****A Novel Fluorophore-Based Imaging Method Is Useful for Studying the Substrate Specificity of Gut Hydrolases in *Caenorhabditis elegans*.**S. Dube¹, H. Dube¹, N.B. Green^{1,2}, R.J. Johnson², J.R. Kowalski¹;¹Biological Sciences, Butler University, Indianapolis, IN, ²Chemistry, Butler University, Indianapolis, IN

Traditionally, the expression and localization of proteins has been studied *in vivo* by fluorescent tagging. The first such experiments with green fluorescent protein (GFP) were conducted in *Caenorhabditis elegans*, as these transparent roundworms are amenable to genetic manipulation and fluorescence microscopy. With one fluorescent tag per protein, however, this method cannot quantify subtle changes in protein levels, such as those due to the action of regulatory mechanisms. Our goal was to develop a more sensitive *in vivo* method to amplify the fluorescent signal and allow for rapid, cell type-specific quantification of small changes in protein abundance. We chose to focus on neuronal proteins since their abundance and activity are tightly regulated and because *C. elegans* shares conservation of

neuronal proteins and nervous system structure with humans. We made use of an enzyme-activated fluorescence system recently developed by Tian *et al.* (2012), in which they synthesized an ester-masked version of fluorescein, the fluorescence of which could be activated in a cell-specific manner by the orthologous esterase, porcine liver esterase (PLE), when expressed in cultured mammalian cells. We attempted to apply this method *in vivo* by delivering ester-masked fluorophores to *C. elegans* with neuronal expression of PLE. Since fluorophore delivery is hindered by the cuticle, a proteinaceous covering around the worms, we synthesized two ester-masked fluorescein derivatives with hydrophobic tails of either 12 or 18 carbons in length to aid uptake into the plasma membranes of externally exposed sensory neurons. We confirmed *in vitro* activation of these masked fluorophores by purified recombinant PLE. We also created transgenic *C. elegans* strains with neuron-specific PLE expression, which we verified by RT-PCR and Western blot. Though we have not seen neuronal activation of our ester-masked fluorophores in the transgenic worms, we have observed fluorescence activation in gut granules of both wild-type and PLE-expressing animals. Thus, we now believe this esterase-ester-masked fluorophore system will be useful for identifying and characterizing the substrate specificities of gut hydrolases in *C. elegans*, an underexplored area of research in this otherwise well-characterized animal. We are currently delivering masked fluorescein derivatives to various mutant strains to determine the identity and specificity of these digestive enzymes.

Real-Time Observation of Lipid-Protein Interactions in Crude Cell Lysates with Single-Molecule Resolution.

E. Arauz¹, V. Aggarwal², A. Jain², T. Ha^{2,3}, J. Chen¹;

¹Department of Cell and Developmental Biology, University of Illinois at Urbana-C, Urbana, IL, ²Institute for Genomic Biology, Center for Biophysics and Computational Biology, Urbana, IL, ³Department of Physics and Howard Hughes Medical Institute, University of Illinois at Urbana-C, Urbana, IL

Lipid-protein interactions play key roles in signal transduction. Obtaining mechanistic insights of these interactions is obligatory for a better understanding of biological processes. Here we have extended a single-molecule pull-down assay (SiMPull) to probe lipid-protein interactions in crude cell lysates. Single-molecule data analysis is performed to quantitatively describe the assembly of lipid-binding domains on their target lipids. Importantly, this assay is applicable to full-length proteins expressed in crude cell lysates, as shown for the protein kinase AKT which binds specifically to the lipid PI(3,4,5)P₃. Our results demonstrate proof-of-principle for the application of this new assay to investigating protein-lipid second messenger interactions at high resolution in whole cell lysates, eliminating the need of harsh and lengthy procedures employed in biochemical purification.

P1615**Board Number: B126****A sentinel protein assay for the simultaneous quantification of cellular processes.**M. Soste¹, R. Hrabakova¹, S. Wanka², A. Melnik¹, P. Boersema¹, C. von Mering², P. Picotti¹;¹Institute of Biochemistry, ETH Zürich, Zurich, Switzerland, ²Institute of Molecular Life Sciences, University of Zürich, Zurich, Switzerland

Here we introduce a novel proteomic screening approach that provides a system-wide, quantitative snapshot of the activity status of a variety of cellular processes, simultaneously. The approach is based on the concept of sentinel proteins. Sentinels are biological markers whose change in abundance characterizes the activation state of a given pathway or functional module in a cell. Sentinels are proteins, phosphorylation sites or protein degradation products that have been previously validated and are commonly assayed in molecular biology laboratories, typically one at a time by traditional antibody-based techniques. For example, sentinels include: specific phosphorylation events in the activation loop of MAP kinases as markers for signalling along different MAPK branches; or induction of the protein Atg8 (LC3 in mammals) as a marker for the activation of the autophagic response. By combining previous biochemical knowledge and computational prediction, we selected a set of 309 sentinels to probe the physiology of *S. cerevisiae* cells. We assembled an information-rich targeted proteomic fingerprint assay based on selected reaction monitoring-mass spectrometry (SRM-MS) that measures the complete sentinel set at high-throughput (1 hour per sample), and reports on the activation state of 188 biological processes. To validate the approach, we applied it to a set of eight well-characterized environmental perturbations of yeast physiology. We show that it recapitulates many known responses and enables the identification of novel cellular events, thereby demonstrating that the sentinel approach could be used to analyse the cellular responses to a large set of uncharacterized perturbations, such as a collection of drugs.

Our current interest is in applying the approach to characterize at high-throughput the modulation of cytotoxicity induced by the aggregation-prone protein, alpha-synuclein. Using yeast as a model system, cytotoxicity induced by alpha-synuclein has been shown to be dose- and time-dependent yet can be modulated by the co-overexpression of ~100 different protective genes. We are using the sentinel assay to decipher the effects of these mostly uncharacterized genetic modulators of toxicity. By screening the activity status of biological processes in yeast rescued by these modulators, we should be able to identify effectors of the rescue. The findings of this study should highlight the processes most crucial to rescue from alpha-synuclein toxicity and provide targets for follow-up in higher models.

P1616**Board Number: B127****Near Infrared (NIR) Reversible Total Protein Staining as an Alternative Loading Control Method for Quantitative Fluorescent Western Blotting.**R. Skopp¹, S. Day², T. Urlacher², N. Padhye²;¹LI-COR Inc., Lincoln, NE, ²LI-COR Biosciences, Lincoln, NE

In Western blotting, a suitable internal protein loading control is essential for accurate and quantitative comparisons of various sample types. Selecting a proper loading control is critical to ensure reliable evaluation of protein amounts across various samples, to reduce errors introduced by sampling irregularities and uneven protein transfer across a membrane. Traditionally, housekeeping genes such as tubulin, actin and GAPDH have been used to normalize protein loading as they were thought to be expressed at consistent levels across nearly all tissue types and experimental conditions. However, recent studies have found that the expression and therefore protein concentration of housekeeping genes may fluctuate depending on expression conditions and treatments. Unbiased detection of all proteins in each sample lane would provide a more versatile and robust method for normalizing protein loading amounts in Western Blots. Traditional methods of normalization using total protein analysis require samples to be run in parallel where one set is stained using visible stains; the other set is used for immunodetection. Visible protein stains such as Ponceau S, Amido Black and Coomassie blue have several limitations including long incubations, difficult preparation and irreversible protein staining; they also lack the sensitivity required for normalization. Here we present a simple, rapid, sensitive and reversible method for staining total protein on a membrane using Direct Blue 71 (DB 71). The stain provides visual confirmation of transfer of proteins to an immobilizing membrane. Further, the fluorescence signal can be used to quantify the amount of protein in individual lanes or bands. After quantitation, the stain can be removed from the membrane without interference or disruption of downstream processing by Western blot. For quantitative Western analysis, a correlation between the results and the protein amounts in samples must be established. DB 71 staining exhibits sensitive linear response from 1 to 40 μg of cell lysate, with r^2 values of 0.97. The normalization of proteins in stimulated and unstimulated cell lysates using DB 71 total protein staining was comparable to normalization using housekeeping genes (Erk and Actin). Thus, DB 71 staining can be used as a robust alternative loading control method for NIR quantitative fluorescent Western blotting with advantages which include ease of use, wide linear range, quantitative accuracy, reversibility and compatibility with immunodetection.

P1617**Board Number: B128****Large-scale analysis of the evolutionary history of phosphorylation motifs.**S. Okuda¹, H. Yoshizaki²;¹Niigata University, Niigata, Japan, ²Kanazawa Medical University, Kanazawa, Japan

Protein phosphorylation is catalyzed by kinases and is involved in the regulation of a wide range of processes. The phosphosites in protein sequence motifs determine the types of kinases involved. The development of phosphoproteomics has allowed the identification of huge numbers of phosphosites. Employing the known phosphosite data enabled us to develop a novel method detecting protein phosphorylation related to important cellular functions. Known phosphosites retrieved from the large-scale database were mapped to the human genome and the peripheral regions including the phosphosites were extracted. Subsequently, we clustered the sequences by the homology and created our original phosphomotifs. To trace the evolutionary transition of the three amino acid residues, serine, threonine, and tyrosine, of the phosphosites, we performed a comparative genome analysis and investigated the conservations from yeast to human. We observed that several phosphomotifs identified by our method were frequently acquired at a certain point in an evolutionary scenario. We also showed that the motifs present in specific species functioned in an additional network that interacted directly with the core signaling network conserved from yeast to humans. Our method may facilitate the efficient extraction of novel phosphomotifs with physiological functions, thereby contributing greatly to the analysis of complex phosphorylation signaling cascades. Our study suggests that the phosphorylation networks acquired during evolution have added signaling network modules to the core signaling networks.

P1618**Board Number: B129****Comprehensive Phenotyping and Functional Profiling of the Immune System with Single Cell Resolution using Mass Cytometry.**M. Poulin¹, M. Konrad¹, S. Han¹, L. Chokhani¹, T. George¹, P. Delucchi¹;¹Fluidigm Sciences Inc., South San Francisco, CA

Understanding the heterogeneity inherent to normal and diseased tissue requires multi-parametric analysis with single-cell resolution. Mass cytometry is a powerful new single-cell proteomics platform that enables analysis of at least 30 proteins per cell simultaneously, and at high cellular acquisition rate, without the requirement for compensation. Antibodies directed against protein targets are labeled with isotopically pure rare earth metals and quantified by inductively coupled plasma mass spectrometry (ICP-MS). Single cell analysis of the proteome by mass cytometry enables rich phenotypic sub-categorization of cells and reveals, within these populations, different functional states defined by cell activation status, cell cycle progression and effector protein expression. In this study, panels of both human- and mouse-specific metal conjugated antibodies against surface markers were used to

phenotype all of the major immune cell subsets. These surface panels were then systematically combined with complementary antibody panels designed to characterize cell cycle status, signaling activity, or effector cytokine expression in each of the identified immune cell subsets. We demonstrate that mass cytometry enables an unprecedented ability to resolve the functional profile of the entire immune cell compartment.

Near Infrared Chemifluorescent Detection for Enhanced Western Blot Sensitivity.

V. Boveia¹, Y. Wang¹, S. Day¹, T. Urlacher¹, N. Padhye¹;

¹LI-COR Biosciences, Lincoln, NE

Detection of low-abundance proteins in a complex mixture is a key requirement for biotechnology research. Here we describe a method for highly sensitive protein detection on Western blots using a horse radish peroxidase (HRP) substrate with excitation and emission at near infrared wavelengths. Film detection of HRP mediated reactions has long been the standard for Western blot detection. Digital imaging has slowly supplanted film detection due to increasing film and hazardous waste expenses, but some targets are only detectable using film with high sensitivity chemiluminescent substrates. Detection of HRP reactions in the NIR has several advantages over chemiluminescent detection, such as extending the dynamic range compared to film by using digital imaging. The chemifluorescent reaction produces a stable fluorescent signal detected at 700nm which can be quantified to determine the linear range. We demonstrate up to 8-fold improved sensitivity with NIR chemifluorescent detection of a low-abundance phosphorylated protein and hormone receptor compared to the highest sensitivity chemiluminescent substrate. The low relative abundance of many proteins within a given mixture and the limited quantity of precious sample make sensitive detection of target proteins highly desirable in Western blotting. We expect other protein detection methods such as ELISAs and protein arrays will also benefit from improved sensitivity.

Accurate absolute quantitation of endogenous protein using Simple Western.

P. Piatti¹, A.W. Tu¹, I. Kazakova¹, F. Ramirez¹, A. Boge¹;

¹ProteinSimple, San Jose, CA

Why do researchers use Western blots? Since the technique was developed thirty years ago it's been a trusted method for confirming the presence or absence of a protein but lacks the quantitative rigor for accurate measurement of the amount of protein present. The process requires many steps which each introduce variability. While portions of the technique have been automated to improve consistency,

there hasn't been a major leap in the technology to propel this method of protein analysis from qualitative to quantitative.

Simple Western is the modern evolution of traditional immunoassay techniques. Wes, the latest addition to the Simple Western platform, is an easy to use, fully automated system that removes the variability seen with traditional Westerns for more reproducible results run to run and between users. Researchers can now identify their protein and achieve reliable quantitation of their target proteins quickly and with very little sample.

To demonstrate the ability of Wes to accurately quantitate protein, we ran spiked GST-tagged AKT1 to act as a standard curve into Jurkat cell lysate. The samples were run on both Wes and a traditional Western blot and when the two methods were compared, Wes not only reduced the hands on time from 120 to 30 minutes and time to results from 2 days to 3 hours, but the reproducibility of the data (9.4%CV vs. 34.5%CV) provides a higher degree of confidence in the accuracy of the reported concentration of endogenous AKT1. Why do researchers use Western blots? P1621**Board Number: B132****Loss-of-Function Genetic Screens to Find Genes Regulating Cell Responses and Identify Potential Drug Targets.**P. Diehl¹, D. Tedesco¹, K. Bonneau¹, M. Makhanov¹, D. Deng¹, K. Hyder¹, P. Sun², A.A. Chenchik¹;¹Cellecta, Inc., Mountain View, CA, ²The Scripps Research Institute, La Jolla, CA

Loss-of-function genetic screens using RNAi provide one of the few ways to identify genes essential for growth. With cultured cells and complex pools of viral-based shRNA expression libraries with constrained representation, these sort of screens can be efficiently and cost-effectively run on a genome-wide basis to identify genes essential for viability in the presence or absence of a compound or other factor. However, despite strong interest to use similar broad genetic screens with *in vivo* xenograft models to find genes essential for tumor growth, cell growth variability and low take rates create significant challenges in adapting the methodology to these systems. To address these challenges, we have designed novel pooled shRNA libraries that contain a unique barcode feature that enables assessment of each clonal cell population with a screen responds. This clonal tracking provides a more robust analysis of how each shRNA affects cellular growth within the tumor which significantly improves the reliability of the results from pooled shRNA genetic screens of xenografts.

Actin and Actin-Associated Proteins 3**P1622****Board Number: B134****Structural polymorphism of actin detected by intramolecular FRET *in vivo* and *in vitro*.**T. Noguchi¹, M. Okazaki¹, S. Kijima^{1,2,3}, M. Morimatsu⁴, A. . Nagasaki², Y. Iwadate⁵, T. Yanagida^{6,7}, T. Uyeda^{2,3};¹Dept. of Chem. Sci. and Eng., Miyakonojo Nat. Coll. of Tech., Miyakonojo, Miyazaki, Japan, ²Biomed. Res. Inst., Natl Inst Adv Indust Sci Technol, Tsukuba, Ibaraki, Japan, ³Grad. Sch. Sci., Univ. of Tsukuba, Tsukuba, Ibaraki, Japan, ⁴Chemical Engineering, Stanford University, Stanford, CA, ⁵Yamaguchi Univ., Yamaguchi, Yamaguchi, Japan, ⁶Osaka Univ, Suita, Osaka, Japan, ⁷QBiC, RIKEN, Suita, Osaka, Japan

Actin plays a variety of important roles in eukaryotic cells, and these functions depend on interactions with many actin-binding proteins (ABPs). Meanwhile, microscopic and biochemical studies suggested that actin takes multiple conformational states. This polymorphism of actin structure has been speculated to affect interactions with ABPs. However, such polymorphism of actin has not been detected in cells, and its physiological relevance is unclear.

To understand the effects of ABPs on actin structure, we developed actin with an intramolecular FRET probe, of which the two major domains (the small domain and large domain) were labeled with two

fluorescence dyes. The actin with the FRET probe was copolymerized with unlabeled actin, and the co-filaments were immobilized on a glass surface by the avidin-biotin system. Single-molecule observation of the actin protomer with the FRET probe in co-filaments revealed that actin subunits take at least two distinct structural states. Furthermore, addition of skeletal heavy meromyosin (HMM) and ATP changed the distribution of the actin structures. We also prepared G146V mutant actin with the FRET probe, since G146V mutant actin showed severe motility defect with skeletal HMM (Noguchi et al., 2012). Interestingly, the distribution of structures of the G146V actin protomer with the FRET probe was different from that of the control, suggesting that the motor activity of skeletal HMM needs optimal conformational changes of actin. Next, the actin with the FRET probe was introduced into PtK2 cells using our laboratory-built electroporator optimized for adherent cells, and were observed by confocal microscopy. The FRET ratio (intensities of acceptor/donor) in PtK2 cells differed locally, indicating that actin structure in cells is also variable. We speculate that such polymorphism of actin *in vivo* is correlated with subcellular localization of ABPs. We previously showed that myosin and cofilin each binds to actin filaments cooperatively *in vitro*. The two cooperative bindings are mutually exclusive, and we speculated that myosin and cofilin each stabilizes different conformations of actin filaments, and prefers to bind to the filaments with the tailored conformation (Kijima et al., submitted). We suggest that the polymorphism of actin we observed *in vivo* is correlated with differential affinities for various ABPs, and play important roles in subcellular localization of the ABPs.

Structural basis of Arp2/3 Complex Inactivation revealed by single particle EM.

O. Sokolova¹, B.L. Goode², C. Ydenberg³, A. Chemeris¹, A. Gautreau⁴, M. Gandhi³, V. David⁴;

¹Moscow M.V.Lomonosov University, Moscow, Russia, ²Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA, ³Brandeis University, Waltham, MA,

⁴CNRS, Gif-sur-Yvette, France

Actin nucleation is one of the key control points in cellular regulation of actin cytoskeleton dynamics. The Arp2/3 complex is an evolutionarily conserved nucleator that binds to the side of an existing actin filament and induces polymerization of a new daughter filament at a 70 degree angle. In many organisms, this 'branched nucleation' activity of Arp2/3 complex is essential for cell motility, endocytosis, and intracellular transport of specific organelles and vesicles. While the biochemical mechanisms leading to activation of the Arp2/3 complex by WASP and WAVE are beginning to be understood in some detail, what is comparatively less clear is how densely branched networks of filaments are subsequently 'pruned' or debranched during phases of rapid actin network turnover and remodeling *in vivo*. Further, there remains a limited understanding of how the many different ligands of Arp2/3 complex affect its conformation and activity. Here, we have used single particle electron microscopy to determine the 3D structures of Arp2/3 complex bound to two recently-identified ligands/regulators, Arpin (1) and GMF (Dang et al., 2013). We found that Arp2/3 complex bound to Arpin adopted an 'open' inactive conformation, and since the binding site on Arp2/3 complex for Arpin

overlaps with the VCA-binding site (Xu et al., 2012), this suggests a specific mechanism of nucleation inhibition. On the other hand, we found that GMF-bound Arp2/3 complex adopted two novel and distinct conformations, possibly reflecting the occupancy of two separate GMF-binding sites on Arp2/3 complex, as proposed (Ydenberg et al., 2013). Additionally, GMF and Coronin together were more effective in shifting Arp2/3 complex to the inactive conformation, and in blocking nucleation activity, demonstrating that multiple ligands can work in concert to govern Arp2/3 conformation and activity.

¹Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, ²Department of Molecular, Cellular and Developmental Biology, Yale University School of Medicine, New Haven, CT, ³Department of Molecular Biophysics and Biochemistry, Yale University School of Medicine, New Haven, CT,

⁴Department of Cell Biology, Yale University School of Medicine, New Haven, CT

Actin filament nucleation and branching by the actin-related protein (Arp) 2/3 complex play key roles in cell migration, endocytosis and cytokinesis. The ubiquitous Arp2/3 complex consists of seven subunits, two of which, Arp2 and Arp3, are structurally similar to actin. The crystal structure of the inactive state of the Arp2/3 complex suggests that a ~30 Å movement of Arp2 towards Arp3 is required for the activation of Arp2/3 complex. Together with actin filaments, the VCA motifs at the C-terminus of nucleation promoting factors (NPFs) are thought to activate and drive Arp2/3 complex conformational changes that are necessary for the branch formation at the side of a pre-existing actin filament. However, how actin filaments and VCA motifs activate Arp2/3 complex is currently unclear, mainly due to the lack of detailed biochemical and structural characterization of conformational changes occurring in Arp2/3 complex activation pathway. Here, we used fluorescence spectroscopy to study interactions of Arp2/3 complex with VCA and actin filaments. We labeled specific sites on Arp2, Arp3, ARPC1 and ARPC3 with fluorescent dyes (FIAsH and Alexa568) either singly or in pairs and studied the effects of VCA and actin filament binding on fluorescence intensity. First, we observed changes in fluorescence intensity in singly labeled Arp2/3 complex. VCA binding to Arp2/3 complex increased the fluorescence intensities of Arp2-FIAsH, Arp3-Alexa568, and ARPC3-FIAsH constructs indicating that this ligand changes the environment of the fluorophores. Intensity changes, directly or through conformational changes, suggest VCA binding sites near the C-terminus of Arp2 and the interface of ARPC3 and Arp3. The

locations on Arp3 and ARPC3 are consistent with previous interpretations of NMR, crystal structures and chemical crosslinking data. The effect of VCA on the fluorescence intensity of Arp2-Flash suggests that C might bind to Arp2 in a similar way, as proposed by Boczkowska et al. and Padrick et al. Second, we observed binding of VCA and/or actin filaments to double-labeled constructs Arp2-Flash/Arp3-Alexa568 and ARPC1-Flash/ARPC3-Alexa568 changed the emission intensity profile of the fluorophores consistent with Förster resonance energy transfer (FRET) efficiency changes induced by each ligand. Our results suggest a model in which VCA and actin filaments contribute distinctly to Arp2/3 complex structural changes

Differential requirement of Arp2/3 complex subunits for actin polymerization during *Listeria* cell invasion and actin comet tail formation ***Listeria* is a bacterial pathogen that subverts mammalian signals.**

A. Kuhbacher¹, M. Emmenlauer², P. Rämö², C. Dehio², P. Cossart¹, J. Pizarro-Cerda¹;

¹Cell Biology and Infection, UIBC Pasteur Institute, INSERM U604, INRA USC2020, Paris, France, ²Focal Area Infection Biology, Biozentrum, University of Basel, Basel, Switzerland

Listeria is a bacterial pathogen that subverts mammalian signaling cascades to infect diverse host tissues. Entry within non-polarized epithelial cells is mainly triggered by interaction between the bacterial protein InlB and the cellular receptor Met, leading to plasma membrane and cytoskeletal rearrangements dependent on the actin nucleator complex Arp2/3. The bacterial protein ActA also activates the Arp2/3 complex for actin-based motility and cell-to-cell spread. Applying a genome-wide siRNA screen for host factors involved in *Listeria* infection, we established that not all subunits of the Arp2/3 complex are equally required for bacterial entry and actin tail formation: while only the subunits Arp2, Arp3, p21, p34 and p41 are required for entry (p16 and p20 are dispensable for this step), all the subunits except p16 are necessary for actin tail formation. Our data highlight that different biological processes may use alternative Arp2/3 complexes.

Interactions with Actin Monomers, Actin Filaments and Arp2/3 Complex Define the Roles of WASP Family Proteins and Cortactin in Coordinately Regulating Branched Actin Networks.

L.A. Helgeson¹, J.G. Prendergast¹, A.R. Wagner¹, M. Rodnick-Smith¹, B.J. Nolen¹;

¹Institute of Molecular Biology, University of Oregon, Eugene, OR

Arp2/3 complex is an important actin filament nucleator that creates branched actin filament networks required for formation of lamellipodia and endocytic actin structures. Cellular assembly of branched

actin networks frequently requires multiple Arp2/3 complex activators, or nucleation promoting factors (NPFs). We recently presented a mechanism by which cortactin, a weak NPF, can displace a more potent NPF, N-WASP, from nascent branch junctions to synergistically accelerate nucleation rates. The distinct roles of these NPFs in branching nucleation are surprising given their similarities. We biochemically dissected these two classes of NPFs to determine how their Arp2/3 complex and actin interacting segments modulate their influences on branched actin networks. We find that the Arp2/3 complex-interacting N-terminal acidic sequence (NtA) of cortactin has structural features distinct from WASP acidic regions (A) that are required for synergy between the two NPFs. Our mutational analysis shows that differences between NtA and A do not explain the weak intrinsic NPF activity of cortactin, but instead that cortactin is a weak NPF because it cannot recruit actin monomers to Arp2/3 complex. We use TIRF microscopy to show that cortactin bundles branched actin filaments using actin filament binding repeats within a single cortactin molecule, but that N-WASP antagonizes cortactin-mediated bundling. Finally, we demonstrate that multiple WASP family proteins synergistically activate Arp2/3 complex and determine the biochemical requirements in WASP proteins for synergy. Our data indicate that synergy between WASP proteins and cortactin may play a general role in assembling diverse actin-based structures, including lamellipodia, podosomes, and endocytic actin networks.

New insights on the regulation of Las17 during endocytosis.

D. Feliciano¹, T. Tolsma¹, K. Farrell¹, L. Barry¹, S.M. Di Pietro¹;

¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

During endocytosis, remodeling of the plasma membrane requires a repertoire of endocytic regulatory proteins working in concert to achieve cargo accumulation and vesicle internalization. Clathrin-mediated endocytosis (CME) is a fundamental pathway conserved from yeast to humans that proceeds by forming a clathrin coat at the plasma membrane followed by the recruitment of proteins that promote membrane curvature, actin polymerization, and scission. The Wiskott-aldrich syndrome protein (WASp) and its homologues play a main role in activation of the Arp2/3 complex and actin nucleation in CME. Regulation of WASp family members can be achieved in different ways including phosphorylation-dephosphorylation cycles, autoinhibition, and assembly in to stable complexes where the capacity for promoting actin polymerization is blocked. In budding yeast, Las17 (WASp) is associated in a large and biochemically stable complex with the clathrin adaptor Sla1 (intersectin-1) that we have termed SLAC. Sla1 binds to sequences overlapping a newly identified G-actin binding site in Las17, thus blocking G-actin binding and inhibiting Las17 activity. It has been shown that Bzz1 (syndapin), an F-BAR containing protein, can relieve Sla1 inhibition on Las17 in vitro. Here we present new findings for SLAC complex regulation by Bzz1 and describe a Las17 novel G-actin binding motif (LGM) dependent on a group of arginine residues. We used a combination of biochemical analyses, pyrene-actin polymerization assays, and live cell fluorescence microscopy experiments to demonstrate the importance of a specific interaction between Sla1 and Bzz1 for SLAC activation both in vitro and in vivo. Release of Las17 NPF

activity is essential for normal progression of endocytosis and the data presented here suggest activation occurs through a Bzz1-mediated mechanism, where LGM is accessible to bind actin, without requiring SLAC complex dissociation.

Dissecting contributions of the Arp2/3 complex activators to the endocytic actin patch assembly in fission yeast.

E.F. Barone¹, H. Bellinger², M.L. James¹, V. Sirotkin¹;

¹Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY,

²Department of Biology, Syracuse University, Syracuse, NY

In yeast and other organisms, endocytosis is dependent upon Arp2/3 complex-mediated actin assembly into endocytic actin patches. Nucleation Promoting Factors (NPFs) control actin assembly by binding and activating Arp2/3 complex via their C-terminal Central-Acidic (CA) domains. In fission yeast, three activators of Arp2/3 complex, Pan1, myosin-1 Myo1, and WASp Wsp1, participate in actin patch assembly. To assess the contributions of these proteins, we tracked the dynamics of actin patches, labeled with GFP-tagged actin binding protein fimbrin Fim1, in pan1, myo1 and wsp1 mutants with deleted CA domains. Deletion of CA domains had no effect on the ability of NPFs to localize to endocytic patches but caused defects in actin patch dynamics specific to each NPF CA deletion. In myo1 CA deletion cells, patch dynamics and internalization was the same as in the wild type cells. In pan1 CA deletion cells, patches internalized normally but accumulated 2.3 times more actin. In wsp1 CA deletion cells, the rate of patch assembly decreased compared to the wild type cells and more than 60% of the patches failed to internalize. To examine patch dynamics in cells that had only one remaining functional NPF, we used genetic crosses to combine two NPF CA deletions in the same cell. While combinations of myo1 CA deletion with pan1 CA deletion or wsp1 CA deletion were viable, the combination of wsp1 and pan1 CA deletions was synthetically lethal. Imaging Fim1-mGFP in cells combining the myo1 CA deletion with pan1 or wsp1 CA deletions revealed the same actin patch dynamics as in cells with single pan1 or wsp1 CA deletions, respectively. Thus, activation of Arp2/3 complex by either Wsp1 or Pan1 alone but not Myo1 alone is sufficient to promote actin patch assembly and cell viability. To directly test the inability of Myo1 to stimulate actin patch assembly, we created a conditionally lethal strain combining pan1 CA deletion with a shut-off or Degron-tagged alleles of wsp1 that allow depletion of Wsp1 from cells. Imaging Fim1-mGFP in these cells revealed a substantial reduction in the number of patches, while few remaining patches had a greatly extended lifetime and failed to internalize. Interestingly, in cells where all three NPFs were disabled by a combination of wsp1 shut-off with both pan1 and myo1 CA deletions, the number of patches and the rate of patch initiation were greatly reduced, although a few patches persisted but failed to internalize. This residual patch assembly may be due to incomplete depletion of Wsp1 or the presence of additional NPFs, such as Dip1. We concluded that Wsp1 is the primary Arp2/3 complex activator at the endocytic sites, minimally sufficient to support actin assembly, endocytic internalization, and cell viability.

P1629**Board Number: B141****In vitro reconstitution of actin filament networks that drive cell motility.**C. Suarez¹, J.D. Winkelman¹, A.J. Harker², D.R. Kovar^{1,2};¹Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, ²Biochemistry and Molecular Biology, University of Chicago, Chicago, IL

Cells simultaneously assemble and maintain different actin filament networks involved in diverse processes such as cell motility and division. Filopodia are finger-like membrane protrusions proposed to be sensors that determine the direction of cell displacement. Filopodia are composed of long actin filament bundles. It has been hypothesized that filopodia are generated from a dense short, branched and capped network of actin filaments. We propose that the combined action of seven actin binding protein (Arp2/3 complex, WASP-pWA, Ena/VASP, formin, fascin, profilin, capping protein) is necessary and sufficient for their formation. In order to determine if the combination of these proteins is sufficient for the generation of filopodia, we have reconstituted in vitro the self-assembly of filopodia-like networks from these seven purified proteins. To this end, we used innovative techniques such as cover glass surface micropatterning and two-color Total Internal Reflection Fluorescence (TIRF) microscopy. These techniques allow spatial control of actin filament assembly and the continuous observation of fluorescently labeled single proteins. This setup has allowed us to test the role of each component of the system in filopodia formation in a polymerizing network. These experiments revealed that in the presence of a saturating concentration of barbed end capping protein, filopodia-like networks are rapidly facilitated by addition of the processive actin filament barbed end binding competitors formin or Ena/VASP. Our reconstituted system provides a unique platform to follow the assembly of filopodia-like networks upon systematically varying the participating components.

P1630**Board Number: B142****C. elegans apical junction complexes interact with the WAVE/SCAR complex and regulate its stability.**M. . Agapito¹, M. Honarbakhsh¹, Y. Bernadskaya², F. Patel¹, M. Soto¹;¹Pathology, Rutgers-RWJMS, Piscataway, NJ, ²Biomedical Sciences, NYU, Manhattan, NY

During *C. elegans* embryogenesis movements of cells and tissues depend on dynamic reorganization of the actin cytoskeleton. Results from our lab showed that WAVE/SCAR and Arp2/3 are needed for the membrane enrichment of proteins that regulate apical junctions in developing epithelial cells of *C. elegans*. We will present recent results addressing how Arp2/3 and its WAVE/SCAR nucleation-promoting factor help build and maintain apical junctions. Particularly exciting is the finding that WAVE/SCAR components associate with junctional complex components and that loss of WAVE/SCAR components strongly reduces the apical enrichment of alpha-catenin/HMP-1, the protein that connects

the cadherin junction to F-actin. In addition, studies have shown that WAVE/SCAR is phosphorylated at multiple sites, but *in vivo* validation is limited. Using a dephosphorylation assay we determined that the levels of dephosphorylated (and presumably active) WAVE-1 are affected by the junctional proteins. These results provide organismal evidence for the role of branched actin regulators in assembling and maintain the apical junction during embryonic development.

Regulation of Neural Wiskott Aldrich Syndrome (N-WASP) expression under hypoxic conditions.

A. Salvi¹, T. Thanabalu¹;

¹School of Biological Sciences, Nanyang Technological University, Singapore, Singapore

Oxygen supply is diminished in highly proliferative, solid tumors especially at the center of the solid tumor resulting in low oxygen tension referred to as hypoxia. Hypoxia inducible factors (HiFs) are heterodimeric transcriptional factors induced under conditions of hypoxia. HiFs consist of two subunits: an alpha subunit and beta subunit. The alpha subunit is regulatory and stable under hypoxic conditions, whereas the beta subunit is expressed constitutively and is also involved in xenobiotic responses. The HiFs regulate the expression of target genes by binding to the hypoxia response element (HRE) present in the promoter of the target genes. Expression of (N-WASP) has been shown to be upregulated under hypoxic conditions. We have found that the activity of N-WASP promoter is enhanced in the presence of hypoxia inducible factor suggesting a possible regulatory mechanism exerted by HiF1 α on N-WASP promoter activity. Sequence analysis of the N-WASP promoter revealed the presence of two HRE elements characterized by the HRE consensus sequence. In order to characterize the regulation of N-WASP promoter by HiF we have generated sited directed mutants of N-WASP promoter in which either of the HRE or both of the HRE have been mutated. The promoter activity of these constructs will be determined to characterize functionality of the two HRE elements. The binding of HiF to the HRE in N-WASP promoter will be determined by EMSA assay to correlate the regulation of N-WASP promoter activity to binding of HiF to HRE in N-WASP promoter.

Effect of aging on thin filament length in mouse skeletal muscle.

K.Q. Lian¹, V.M. Fowler¹, D.S. Gokhin¹;

¹Department of Cell and Molecular Biology, The Scripps Research Institute, La Jolla, CA

Precise assembly and regulation of the thin and thick filaments (myofilaments) in sarcomeres are vital for determining the biomechanical and physiological properties of skeletal muscle. Since the degree of myofilament overlap determines the amount of contractile force that skeletal muscle sarcomeres can

actively generate, myofilament lengths are accurate predictors of sarcomere operating length ranges. Given the striking uniformity of thin filament lengths specified during myofibril assembly, it is widely assumed that thin filament lengths, and, hence, sarcomere operating length ranges, remain constant throughout the lifespan. However, the effect of aging on thin filament length has yet to be rigorously explored. To examine this problem, we first excised tibialis anterior (TA), extensor digitorum longus (EDL), and soleus muscles from two-month-old and two-year-old mice. Tissue cryosections were then immunostained to label tropomodulin (Tmod) and α -actinin and phalloidin-stained to label F-actin, and imaged using confocal fluorescence microscopy. Background-corrected line scans along myofibrils were then collected from these fluorescence images, and thin filament lengths, defined as Tmod distances from the Z-line, were determined using distributed deconvolution analysis. When comparing young vs. old mice, soleus muscle displayed the greatest difference in thin filament length, followed by the EDL and TA muscles. Young soleus thin filaments were 0.08 μm longer than the old soleus thin filaments ($1.19 \pm 0.07 \mu\text{m}$ vs. $1.11 \pm 0.02 \mu\text{m}$, respectively), young EDL thin filaments were 0.04 μm shorter than old EDL thin filaments ($1.07 \pm 0.07 \mu\text{m}$ vs. $1.11 \pm 0.06 \mu\text{m}$, respectively), and young TA thin filaments were 0.03 μm longer than old TA thin filaments ($1.11 \pm 0.055 \mu\text{m}$ vs. $1.08 \pm 0.07 \mu\text{m}$, respectively). These results identify a novel relationship between aging and thin filament length in skeletal muscle and may provide insight into the mechanisms of altered muscle contractile function in aging. Future investigations will focus on addressing the molecular and cellular basis for thin filament length alterations in aging, such as pathways leading to changes in the relative levels or isoform expression of Tmods, tropomyosins, and other thin filament-associated proteins.

Tks5 localizes to EPEC pedestals and may be involved in initial EPEC attachment to host cells.

H. Halkjær Jensen¹, L.N. Nejsum², H.N. Pedersen¹, E. Stenkjær¹, G.A. Pedersen³, M.R. Amieva⁴;

¹Department of Molecular Biology and Genetics, Aarhus University, Aarhus C, Denmark, ²Department of Molecular Biology and Genetics, Aarhus University, Aarhus, Denmark, ³Aarhus University, Aarhus C, Denmark, ⁴Stanford University, Stanford, CA

Enteropathogenic *Escherichia coli* (EPEC) is a pathogen that infects the lining of the small intestine causing diarrhea especially in children. EPEC injects several virulence factors into the host cell, including Translocated intimin receptor (Tir), which is inserted into the plasma membrane of the host cell where it serves as a receptor for EPEC. Clustering and phosphorylation of Tir leads to recruitment of actin-regulating proteins that polymerize actin into a pedestal-like structure beneath EPEC. The EPEC pedestal has several similarities with podosomes. Tks5 is an early podosome-specific scavenger protein involved in the formation of new podosomes by interacting with specific phosphoinositides. But despite the similarities of EPEC pedestals and podosomes, Tks5 has so far never been reported to be involved in EPEC pedestal formation. To study Tks5 in the context of EPEC infection, an epithelial MDCK cell line stably expressing Tks5-EGFP was created. Tks5-EGFP was recruited to the EPEC infection site and

localized with actin in the pedestal. The recruitment was Tir dependent, as an EPEC mutant lacking Tir (Δ Tir) was unable to recruit Tks5. In the pedestal, Tks5-EGFP colocalized with actin and N-WASp and time-lapse microscopy revealed that Tks5 was recruited simultaneously with both actin (visualized by LifeAct-mRuby) and N-WASp-mCherry, instantly following EPEC attachment. To elucidate a potential functional role for Tks5 in EPEC attachment, early infection efficiency of EPEC on WT MDCK cells versus MDCK cells overexpressing Tks5-EGFP was examined by a Colony Forming Unit (CFU) assay. After five minutes of infection, a mutant lacking bundle-forming pili had an increased attachment of $70.1 \pm 13.2\%$ to Tks5-EGFP overexpressing cells, compared to WT MDCK cells (p

The Effects of Lipopolysaccharide (LPS) on RING Finger Protein 13 (RNF13) Expression.

K.A. Touchstone¹, C.K. Mulligan², S.D. Carmicle-Davis¹;

¹Biological Sciences, Mississippi College, Clinton, MS, ²Basic Sciences, Mississippi State University College of Veterinary Medicine, Brandon, MS

Really Interesting New Gene Finger protein 13 (RNF13) is an E3 ubiquitin ligase that “tags” them for destruction via the proteasome pathway (Rao, Navin et al, 2002). RNF13 mRNA levels are up-regulated upon exposure to the extracellular matrix protein tenascin C (TNC; Midwood, Sacre et al 2009). Since lipopolysaccharide (LPS), like TNC, uses toll-like receptor 4 (TLR-4) signaling pathways (Midwood, Sacre et al 2009), we investigated the hypothesis that LPS upregulates RNF13 expressions in RAW 264.7 macrophages. Using qRT-PCR we demonstrated that RNF13 expression is increased upon LPS stimulation. Fluorescence microscopy was used to examine the localization of RNF13. It co-localizes with Arp2/3p21 in macrophages. The interaction of RNF13 and ARP2/3p21 after LPS stimulation was confirmed by co-immunoprecipitation. Additionally, the data demonstrate that LPS increases the amount of RNF13 isolated with ARP2/3p21. The role of the proteasome was investigated using MG132. Compromising proteasome function in the presence of LPS further increased the amount of RNF13-Arp2/3p21 complex that was detected. The data suggest that the interaction of RNF13 with Arp2/3p21 may facilitate its degradation in a proteasome-dependent manner. The data underscore the potential of RNF13 to impact actin cytoskeleton rearrangement just as its paralog, GRAIL, facilitates the turnover of another member of the complex ARP2/3p16 (Ichikawa, Mizuno, et al 2011).

P1635**Board Number: B147****Ewing sarcoma cell regulation of the cytoskeleton and the impact in a mouse model of tumorigenesis and metastasis.**L.M. Hoffman¹, C.C. Jensen¹, A. Chaturvedi¹, M.C. Beckerle¹;¹Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

Ewing sarcoma is an aggressive pediatric bone cancer that causes osteolytic bone destruction at the primary tumor site and metastatic spread to secondary sites such as the lung. A common chromosomal translocation t(11;22) in Ewing sarcoma generates the oncogenic transcription factor EWS/FLI. Microarray analysis of Ewing sarcoma cells with or without EWS/FLI (using RNAi knockdown) showed EWS/FLI expression repressed many genes, including focal adhesion and extracellular matrix components, and regulators of the actin cytoskeleton. This is consistent with our observation that patient-derived Ewing sarcoma cells in culture were poorly spread cells with ill-defined actin cytoskeletons and that EWS/FLI knockdown led to increased cell adhesion and spreading and robust phalloidin-stained cytoskeletons. Our findings that EWS/FLI down-regulated adhesion-related genes and compromised adhesion and the cytoskeletons in Ewing sarcoma cells led us to consider the hypothesis that these cells are more metastatic because of their poor adhesion in the primary tumor, and suggested that reversal of their cell phenotype could abrogate their metastatic capacity. Two EWS/FLI down-regulated targets are focal adhesion components zyxin and $\alpha 5$ integrin. To investigate their role in Ewing sarcoma cells, retroviral constructs were introduced to reexpress zyxin or $\alpha 5$ integrin, alone or together. Using immunofluorescent microscopy to detect focal adhesions (paxillin localization) and F-actin (phalloidin) we quantitated focal adhesions and cell area. The reexpression of zyxin alone, or with $\alpha 5$ integrin, was sufficient to increase focal adhesions and actin stress fibers, cell spreading and adhesion. To test the consequences of these cell changes in vivo, the engineered Ewing sarcoma cells were tagged with a luciferase reporter and injected into the tibias of immunodeficient mice. In vivo bioluminescent imaging was used to quantitate primary tumor growth in the injected tibias and to detect secondary metastasis. All of the engineered Ewing sarcoma cell types successfully xenografted as primary tumors at the site of injection and showed some ability to metastasize to the lung. Compared to the parent Ewing sarcoma cells, reexpression of zyxin and $\alpha 5$ integrin enhanced cell adhesion and colonization in the lung in both the tibial injection model and with tail vein injections. Oncogene-driven changes may reflect the trade-offs that occur as cells navigate the tumor environment, extravasate, migrate, adhere and re-colonize distant sites. In the future, we envision this in vivo mouse model being used to test therapeutic agents designed to globally reverse the EWS/FLI oncogene-dependent cell phenotype and impair primary tumor growth and/or secondary metastasis.

P1636**Board Number: B148****Differences in Degradation and Distribution of Mutated WWP1 E3 Ubiquitin Protein Ligase between Chicken and Mouse Skeletal Muscles.**M. Imamura¹, S. Takeda¹;¹Department of Molecular Therapy, Natl Inst Neurosci/NCNP, Tokyo, Japan

A missense mutation in a gene encoding WWP1 was identified as the cause of chicken muscular dystrophy by genetic linkage analysis. WWP1 is a HECT-type E3 ubiquitin protein ligase, composed of 922 amino acids, containing four WW domains that interact with proline-rich peptide motifs of target proteins. The mutation changes arginine into glutamine at 441st amino acid located at the center of WW domain cluster, which gives rise to speculation that the amino-acid exchange would effect some change in the function of WWP1. Thus, to test the hypothesis, we generated a mouse model expressing WWP1 transgene carrying the c.1307G>A (p.R436Q) mutation corresponding to the chicken mutation c.1322G>A (p.R441Q) in muscular dystrophy, and characterized the mutated WWP1 in the muscles. In contrast to dystrophic chicken, the transgenic (Tg) mice showed mild muscle phenotype; very few necrotic muscle fibers and adipocytes were observed although significant tubular aggregates were seen with aging. On a molecular level, we also found differences in degradation and distribution of mutated WWP1 in their muscle tissues. WWP1 is normally localized along sarcolemma and sarcoplasmic reticulum (SR) but almost all mutated WWP1s were detected at sarcolemma in mouse muscle, whereas mutated molecules were mainly observed along SR in chicken. Immunoblot analysis clearly showed specific degradation of mutated WWP1s in both animal muscles and that degraded products (90 kDa fragments) of mouse WWP1 were much more stable than those of chicken WWP1. These findings suggested that differences in localization and stability of WWP1-degraded products would relate to different muscle phenotypes between dystrophic chicken and Tg mouse model.

P1637**Board Number: B149****Biodegradable Polymers as Potential Inhibitors for Food-borne Pathogens.**R.W. McClennon¹, C. Carnegie¹, C.D. Johnson¹, E. Williams¹, J.M. Stone¹, S. Woldesenbet¹, L.E. Carson¹;¹Cooperative Agricultural Research Center, Prairie View AM University, Prairie View, TX

Meat packaging has come a long way since the early 1900's post government inspection days instated by the USDA. Due to the advancements in technology and the use of chemicals, we can better protect our food supply, but there is still contamination. This has generated a need to develop a safer natural means of food distribution and packaging without the use of chemicals. Chitosan, a biodegradable polymer found in nature, is one potential packaging material to consider. Chitosan and its derivatives have been shown to have antimicrobial properties. The purpose of this research was to observe the antimicrobial effects of chitosan and its derivatives on the growth of *Listeria*, *Staphylococcus aureus*, and *Salmonella*. These bacteria were selected because they are among the most common food-borne

pathogens. Typically, bacteria was grown in tryptic soy agar (TSA) and incubated at 35°C for *Listeria* and *Staphylococcus aureus* and 37°C for *Salmonella* in separate experiments for 24 hours. Multiple samples of chitosan film were placed on top of the bacteria and agar. Samples were then examined using a zone of inhibition test that is based on the diameter of the clear inhibition zone. The same bacteria samples were then plated, and multiple samples of chitosan powder were placed on top of the bacteria and agar plates. After 24 hours of incubation at 35°C for *Listeria* and *Staphylococcus aureus* and 37°C for *Salmonella*, the zone of inhibition test was conducted. Initial studies indicated that chitosan and its derivatives did not inhibit the growth under conditions in this study. Additionally, chitosan in the powder form had the same results as the film components. While pure chitosan and its degraded derivatives did not inhibit bacterial growth, future studies will focus on using chitosan grafted samples.

The response of bacterial growth rate to osmotic shock.

E. Rojas¹, J.A. Theriot^{2,3}, K. Huang¹;

¹Bioengineering, Stanford University, Stanford, CA, ²Department of Biochemistry, Stanford University School of Medicine, Stanford, CA, ³Howard Hughes Medical Institute, Stanford University School of Medicine, Stanford, CA

Turgor pressure, the hydrostatic pressure within bacterial cells, has long been thought to be an essential factor for their growth by providing the mechanical force necessary for expansion of the peptidoglycan cell-wall. To test this theory, we used microfluidic cell-culture and high-resolution microscopy to precisely measure the elongation rate of bacterial cells while modulating their turgor pressure via osmotic shock. Surprisingly, hyperosmotic shock, which reduces turgor pressure, had no effect on the elongation rate of the cytoplasm of *Escherichia coli* cells, and only reduced the elongation rate of their cell-walls when the osmotic shock was large enough to plasmolyze the cells. Furthermore, when turgor pressure was restored by reversing the shock, the cell wall rapidly elongated to the length that it would have attained had pressure never been depleted. This observation suggested that synthesis of peptidoglycan was unaffected by hyperosmotic shock. In support of this conclusion, we found that the dynamics of MreB, a protein whose motion is correlated with peptidoglycan synthesis, are unaffected by osmotic shock. Therefore, we propose a model of *E. coli* growth in which peptidoglycan synthesis is not driven by turgor pressure, and in which cell-wall expansion is independent of pressure except in the case of plasmolysis. In accordance with this model, hypoosmotic shock, which tends to increase turgor pressure, had little effect on the growth of the Gram-negative *E. coli*. In contrast, hypoosmotic shock had a profound and unexpected effect on the Gram-positive bacteria *Bacillus subtilis*, *Listeria monocytogenes*, and *Clostridium perfringens*. After rapidly swelling during the shock, cells from these organisms displayed damped growth oscillations. We found that this behavior is consistent with a model in which tension within the plasma membrane, induced by the shock, down-regulates peptidoglycan synthesis. Furthermore, our mathematical model correctly predicted the scaling relationships between key variables associated with these oscillations, such as the linear scaling between period of oscillation

and shock magnitude. The model also predicted that reducing membrane tension or peptidoglycan synthesis prior to the shock precludes growth oscillations, which we confirmed experimentally. Currently, we are testing whether there are integral membrane proteins that mediate this process. Finally, in stark contrast to *E. coli*, hyperosmotic shock reduces the elongation rate of *B. subtilis*, suggesting that pressure does drive cell-wall expansion in this organism. That is, whereas the Gram-negative *E. coli* is robust to changes in turgor, Gram-positive bacteria use turgor as part of multiple pathways to control growth.

Synergistic anti-cancer cell impact of anti-tropomyosin compounds with anti-microtubule drugs.

J. Stehn¹, D. Chen², M. Currier², D. Eaves³, M. Desouza^{1,4}, T. Cripe^{2,5}, P.W. Gunning¹;

¹School of Medical Sciences, UNSW, Sydney, Australia, ²Center for Childhood Cancer and Blood Diseases, Nationwide Children's Hospital, Columbus, OH, ³Division of Oncology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, ⁴University of New South Wales, Sydney, Australia, ⁵The Ohio State University, Columbus, OH

We have recently developed anti-tropomyosin (ATM) compounds as anti-cancer agents for the treatment of the childhood cancer, neuroblastoma. These compounds target the tropomyosin Tm5NM1 found in most, if not all, human cancers. The ATMs target the N-, C- terminal overlap of adjacent Tm5NM1 dimers in actin filaments. We have demonstrated that the first-in-class (TR100) ATM compound disrupts the actin cytoskeleton of neuroblastoma tumour cells leading to reduced tumour growth in vivo (Cancer Res. 2013 Aug 15; 73(16):5169-5182). Exposure of neuroblastoma cells to ATMs leads to collapse of the actin cytoskeleton and deactivates cell survival pathways. In particular, the p38, MAPK, Akt/PI3K and MEK/ERK pathways are down regulated and there is an increase in the activation of cell death pathways (JNK). Since most cancer therapy involves the use of multiple anti-cancer agents we have evaluated the combinatorial impact of the ATMs with clinically relevant chemotherapeutic agents. Most combinations show additive effects as might be expected of agents which target unrelated signalling pathways and cellular processes. However, the combination of ATMs with anti-microtubule drugs shows striking synergy in the majority of independent neuroblastoma cell lines tested. The extent of synergy varies from 10 to 100 fold. We conclude that targeting the actin and microtubule cytoskeleton may be an effective therapeutic strategy for the treatment of neuroblastoma.

P1640**Board Number: B152****A novel actin filament population defined by the tropomyosin Tm4 regulates ER-to-Golgi trafficking.**E.C. Hardeman¹, L. Yang¹, A.J. Kee¹, E. Polishchuk², R. Polishchuk², I. Pleines³, B. Kile³, R. Weigert⁴, P.W. Gunning¹;¹School of Medical Sciences, UNSW, Sydney, Australia, ²Telethon Institute of Genetics and Medicine, Naples, Italy, ³Water and Eliza Hall Institute, Melbourne VIC, Australia, ⁴NIDCR, NIH, Bethesda, MD

Although the actin cytoskeleton is critical for Golgi morphology and vesicle trafficking, the specific actin filaments associated with ER to Golgi trafficking have not been clearly defined. We have shown that the actin-associated protein tropomyosin (Tm) defines in an isoform-specific manner the function of actin filament populations and that the isoform Tm5NM1 is associated with the Golgi. In this study, we have identified a second Tm isoform, Tm4, at the Golgi that co-localises with β -actin. Tm4 and β -actin localisation is sensitive to the Golgi disrupting drug Brefeldin A (BFA). With BFA removal, Tm4 and β -actin re-association with the Golgi is observed at the early stages of Golgi reformation. In mouse embryonic fibroblasts (MEFs) from a mouse line expressing a mutant Tm4 that is incapable of incorporating into actin filaments, the re-establishment of Golgi morphology after BFA treatment is altered compared with wild-type MEFs. Using the temperature sensitive VSV-G(ts045)-KDEL construct ER-to-Golgi, but not Golgi-to-ER, trafficking was shown to be altered in the Tm4 mutant MEFs. This anterograde trafficking defect is specific to Tm4 as exogenous Tm4, but not Tm5NM1 is able to rescue ER-to-Golgi trafficking in the Tm4 mutant MEFs. Treatment with Blebbistatin, but not CK666 prevented the rescue by exogenous Tm4, demonstrating that Tm4-dependent anterograde trafficking is dependent on Myosin II activity, but not Arp2/3, respectively. Consistent with impaired export from the ER, EM analysis of the Tm4 mutant MEFs revealed a number of ER and Golgi dysmorphologies including the proliferation of swollen ER structures. In conclusion, we have identified a novel Tm4/ β -actin filament population that has an important role in ER-to-Golgi vesicle trafficking.

P1641**Board Number: B153****Tropomyosin Influences on Cellular Functions in Fission Yeast.**B. MacTaggart¹, S. Cranz-Mileva², S.E. Hitchcock-DeGregori²;¹Dept. of Molecular Biology and Biochemistry, Rutgers University, Piscataway, NJ, ²Rutgers Univ-RW Johnson Med Sch, Piscataway, NJ

Tropomyosin (Tpm) binds along actin filaments and regulates actin function. Fission yeast, *Schizosaccharomyces pombe*, contains a single, essential Tpm gene (*cdc8*) that is required for formation of actin cables, the contractile ring and actin patch polarization. *In vitro* Tpm binds actin and regulates myosins, formins and actin filament stability in fission yeast and animal cells. We have tested the function of conserved residues in *cdc8* (Cranz-Mileva et al., 2013; 2013 ASCB abstract). Here we report

on two gene replacement mutants, *cdc8*^{D16A.K30A} and *cdc8*^{E104A}, in which conserved surface residues were mutated to Ala. The mutations have a small or no effect on actin affinity of recombinant Cdc8p, cellular morphology or growth but have distinct effects on the actin cytoskeleton inferring the involvement of the mutated residues in specific cellular functions.

The actin cytoskeleton of *cdc8*^{E104A} (visualized using Lifeact-GFP, LA-GFP in living cells or Alexa-phalloidin in fixed cells) has fewer actin cables and the contractile rings are often wavy or not compact as in wildtype (wt) cells (~29% in *cdc8*^{E104A}, ~2-3% in wt) as observed in strains expressing *rlc1*-mCherry, a myosin II light chain). Patch polarization, visualized using LA-GFP or coronin-GFP is affected; *cdc8*^{E104A} has a greater fraction of cells with an “uneven bipolar” distribution (~45% in *cdc8*^{E104A}, ~25% in wt) with reduced fractions of cells with monopolar patch localization. In addition, the patches are not as compact at the poles. The rate of movement of coronin-GFP patches was reduced by ~30% in *cdc8*^{E104A} cells. We suggest the *cdc8*^{E104A} phenotype reflects delayed restoration of monopolarity after completion of cell division.

Since fission yeast Tpm regulates fission yeast myosin V (Lord et al., 2014; Clayton et al., 2010), we introduced myo52-3xYFP into *cdc8*^{E104A}. As with LA-GFP and coronin-GFP the fraction of monopolar cells was reduced. Since myo52 mediates vacuole distribution (Mulvihill et al., 2001), we visualized the formation and fusion of vacuoles using the dye, FM4-64. In *cdc8*^{E104A} the vacuoles were smaller than wt, but greater in number, inferring deficiency in vacuole fusion.

In another mutant, *cdc8*^{D16A.K30A}, the actin cytoskeleton (Alexa-phalloidin) and fluorescence patterns in strains expressing LA-GFP, *rlc1*-mcherry and Fim-1-GFP were similar to wt. However, the *cdc8*^{D16A.K30A}-Fim-1-GFP cells lack actin cables (visualized using rhodamine phalloidin). Since fimbrin and Tpm compete in binding actin (Skau & Kovar, 2010), we suggest the double *cdc8* mutation and GFP tag on fimbrin have a synthetic negative effect on actin filament assembly.

New roles for Tropomyosins in controlling formin activities and actin filament dynamics.

S.L. Alioto¹, D. Bellavance², B.L. Goode¹;

¹Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA, ²Biology, Brandeis University, Waltham, MA

Tropomyosin was one of the first actin-associated proteins discovered (Bailey, 1946, Nature), and plays a prominent role in muscle tissue where it regulates myosin-actin interactions. However, Tropomyosins are also widely expressed in non-muscle tissues, where they have essential roles in a variety of actin-based functions. Based on only a limited amount of biochemical data, dogma has become that

Tropomyosins in non-muscle cells function to stabilize actin filaments and/or block association of other actin-binding proteins. Here, we investigated Tropomyosin function in *S. cerevisiae*, where two isoforms are expressed, Tpm1 and Tpm2, which are genetically redundant and have long been assumed to have similar effects on actin dynamics. Using TIRF microscopy, we uncovered new and differing functional roles for Tpm1 and Tpm2 in actin cable formation. Tpm1 strongly enhanced actin filament nucleation and elongation by the formins Bni1 and Bnr1, both in a profilin-dependent manner. In contrast, Tpm2 inhibited formin-mediated nucleation of actin filaments and had no effect on filament elongation rate. In bulk and TIRF actin disassembly assays, Tpm1 provided some protection of filaments from cofilin-mediated severing, while Tpm2 had no effect. Our results define new roles for Tropomyosins in working with formins to promote actin filament assembly, as well as key mechanistic differences between Tropomyosin isoforms expressed in the same cell type. These biochemical differences between Tpm1 and Tpm2 are supported by genetic differences revealed in directed crosses and through suppression analysis.

Myosin motor isoforms direct specification of actomyosin function by tropomyosins.

J.E. Clayton¹, L.W. Pollard¹, G.G. Murray¹, M.J. Lord¹;

¹Molecular Physiology and Biophysics, University of Vermont, Burlington, VT

Myosins and tropomyosins represent two types of actin filament-binding proteins that often work together in contractile and motile processes in the cell. While the role of thin filament troponin-tropomyosin complexes in regulating striated muscle myosin-II is well characterized, the role of tropomyosins in non-muscle myosin regulation is not well understood. We previously showed that fission yeast tropomyosin (Cdc8p) positively regulates myosin-II (Myo2p) and myosin-V (Myo52p) motors. To understand the broader implications of this regulation we examined the role of two mammalian tropomyosins (Tm3•1cy/Tm5NM1 and Tm4•2cy/Tm4) recently implicated in cancer cell proliferation and metastasis. Like Cdc8p, the Tm3•1cy and Tm4•2cy isoforms significantly enhance Myo2p and Myo52p motor activity, converting non-processive Myo52p molecules into processive motors that can walk along actin tracks as single molecules. In contrast to the positive regulation of Myo2p and Myo52p, Cdc8p and the mammalian tropomyosins potently inhibited skeletal muscle myosin-II, while having negligible effects on the highly processive mammalian myosin-Va. In support of a conserved role for tropomyosin in regulating non-muscle actomyosin structures, Tm3•1cy rescued normal contractile ring dynamics, cytokinesis, and fission yeast cell growth in the absence of functional Cdc8p. Our work reveals that actomyosin regulation by tropomyosin is ultimately dependent on the myosin isoform. The findings highlight a general role for tropomyosins in gating specific myosin motor outputs. This work has broad implications with regard to sorting of non-muscle and muscle actomyosin function in complex cellular environments such as developing muscle tissue and metastatic cancer cells.

P1644**Board Number: B156****T89 Phosphorylation is a Novel Post-Translational Modification for Critical Structure-Function Regulation of Profilin-1.**D. Gau¹, W. Veon¹, D. Koes², S. Shroff¹, P. Roy¹;¹Bioengineering, University of Pittsburgh, Pittsburgh, PA, ²Computational Biology, University of Pittsburgh, Pittsburgh, PA

Profilin-1 (Pfn1) is a ubiquitously expressed protein which is involved in a wide range of cellular functions including cell migration, proliferation, and control of gene expression. It binds to three classes of ligands including actin, proteins containing poly-L-proline motifs, and membrane phosphoinositides. Dysregulated expression and/or mutation of Pfn1 have been associated with a number of pathological scenarios. Given the importance of Pfn1 in physiology and pathology, we sought to identify novel regulatory mechanisms of Pfn1. We found that Pfn1 exists in multiple post-translationally modified states in cells that are sensitive to phosphatase treatment indicating that these states represent different phosphorylated forms. As a predominant cellular pool of phosphorylated Pfn1 did not involve tyrosine residue, we further investigated potential functional consequences of site-specific serine-threonine (S/T) phosphorylation of Pfn1. We demonstrated that protein kinase A (PKA) can phosphorylate Pfn1 at multiple sites *in vitro* and accordingly, activating PKA pathway modifies Pfn1 *in vivo*. By mass-spectrometry, we identified T89 as a novel phosphorylation site of Pfn1. Phosphomimetic mutation on T89 makes the mutant Pfn1 greatly insoluble, dramatically lowers the protein stability of Pfn1, and affects the actin cytoskeleton. Finally, molecular dynamics simulation of wild-type vs. phosphomimetic variant of Pfn1 predicted that T89 phosphorylation causes a major conformational change in an important loop structure of Pfn1 with potential consequence on its actin-binding. In summary, our studies suggest that T89 could be a novel phosphorylation site for critical structure and function regulation of Pfn1.

P1645**Board Number: B157****Kinetics of profilin-1 and periplakin in a human tongue cancer cell line.**I. Tamura¹, A. Kamada¹, S. Goda¹, Y. Yosikawa¹, E. Domae¹, T. Ikeo¹;¹Osaka Dental Univ., Hirakata-shi, Japan

Profilin-1 is an actin-binding cytoskeletal protein that acts in the regulation of actin filament dynamics. Periplakin is a 195-kDa protein belonging to the plakin family of cytoskeletal linker proteins and is generally localized to the cell membrane of normal stratified squamous epithelia. There is little information on the kinetics of profilin-1 and periplakin in oral primary cancer cells. We investigated the expression of profilin-1, periplakin and cytokeratin 18 in a human tongue cancer cell line (BICR31) and examined the relationship between their expression and oral cancer cell malignancy. The human

tongue keratinocyte line DOK and BICR31 were cultivated to sub-confluence in Dulbecco's Modified Eagle's Medium including 10% fetal bovine serum and 5 µg/ml hydrocortisone, and expression levels of profilin-1, periplakin and cytokeratin 18 were determined by Western blotting analyses and FITC- or RITC-labeled immunocytochemical staining. Moreover, BICR31 cells were split using a pipette chip on the chamber slide, incubated for one, two or three days, then immunocytochemically stained for profilin-1, periplakin and cytokeratin 18. Although an obvious band for profilin-1 was detected by Western blotting analyses in DOK cells, immunoreactions for profilin-1 were weak in BICR31 cells. In addition, anti-profilin-1 antibody reacted with DOK cells, and weakly and diffusely with cytoplasm in BICR31 cells. Conversely, expression of periplakin in most DOK cells was diffuse, and strong reactions were detected in BICR31 cells. For periplakin, there were correlations between Western blotting data and immunocytochemical observations. The kinetics of cytokeratin 18 were similar to those of periplakin. Although there were no changes in the expression of profilin-1 and cytokeratin 18, expression of periplakin tended to increase near the cell layer in the wound model. These results indicate that decreased plectin-1 expression is an index of malignancy, that periplakin is expressed by tongue epithelia during various stages in malignancy associated with the proliferation and migration of cancer cells, and that expression of cytokeratin 18 may show an epithelial-to-mesenchymal transition in squamous epithelial cells.

Drebrin modulates the effects of formins on actin dynamics.

E.E. Grintsevich¹, P. Ge², P.S. Gurel³, H.N. Higgs³, Z.H. Zhou^{2,4}, E. Reisler^{4,5};

¹University California-Los Angeles, Los Angeles, CA, ²Electron Imaging Center for NanoMachines, UCLA School of Medicine, Los Angeles, CA, ³Dartmouth-Geisel Sch Med, Hanover, NH, ⁴Molecular Biology Institute, University California-Los Angeles, Los Angeles, CA, ⁵Chemistry and Biochemistry, University California-Los Angeles, Los Angeles, CA

Drebrin A, a neuronal F-actin-binding protein enriched in dendritic spines, plays a major role in synaptic plasticity. Molecular cross-talk between drebrin and key neuronal actin-binding proteins is believed to be a part of the cytoskeleton-modulating pathway that is implicated also in synaptic dysfunction in Alzheimer's disease (AD), Down syndrome, epilepsy and normal aging. We documented that drebrin acts as a leaky capper of actin filaments. In this context, we investigated here drebrin interrelation with formins – the B-end actin binding factors. We found that drebrin inhibited mDia- and mDia2-assisted polymerization of actin. TIRF microscopy revealed that drebrin introduced heterogeneity into actin filaments population nucleated by mDia1 and mDia2 formins by reducing the fraction of fast-elongating (formin bound) filaments. This effect was not observed with INF2 formin which has also the unique feature of severing actin filaments. We documented here that drebrin strongly inhibited F-actin severing by INF2 formin and investigated the mechanism of such inhibition employing electron microscopy. We found that drebrin allowed for the side binding of INF2 to actin filaments but changed it to an isolated,

single-dimer binding mode, in contrast to continuous decoration of filaments by INF2 alone. The mechanism of formins inhibition by drebrin and its biological implications will be discussed.

Formin FH2 domains accelerate ATP hydrolysis prior to polymerization: insights into formin-specific effects on actin structure.

P. Gurel¹, H. Higgs¹;

¹Department of Biochemistry, Geisel School of Medicine at Dartmouth College, Hanover, NH

Formins are a class of actin assembly factors, and the 15 mammalian formins have wide-spread roles in many actin-based processes. Central to their effects on actin is the dimeric FH2 domain, which can accelerate nucleation of new actin filaments, then modulate elongation by remaining bound to the filament barbed end. There is considerable variation between FH2 domains in both nucleation and elongation efficiencies, and one formin, INF2, can actually enhance depolymerization. While near-atomic resolution structures of actin-bound FH2 domains are available, we do not understand how FH2 domains change actin to enhance nucleation, elongation and, in the case of INF2, depolymerization. Here, we show that formin FH2 domains cause an acceleration of actin's ATPase activity even when actin is in the monomeric state (bound to latrunculin). The magnitude of this acceleration scales roughly with the nucleation efficiency of the FH2 domain, with FH2 domains that potently nucleate being the most acceleratory to ATP hydrolysis from actin monomers. This effect had been predicted for the barbed end-capping molecule, cytochalasin D (Goddette & Frieden (1986) J. Biol. Chem.), and we recapitulate these results to show that FH2 domains act in a quantitatively similar manner. For some formins, the region C-terminal to the FH2 provides further acceleration of ATP hydrolysis. We use analytical ultracentrifugation and electron microscopy to show that actin is not polymerized under these conditions. In the case of INF2, increased ATP hydrolysis rate appears to play a role in its depolymerization activity. When added to pre-polymerized filaments, INF2 causes rapid depolymerization to a state in which filaments are no longer present, yet the system continues to hydrolyze ATP in the non-filamentous state. In summary, we reveal a fundamental effect of FH2 domains, to enhance the ATPase activity of actin monomers, suggesting that formins convert the actin monomer to the "flattened" ATPase-competent conformation (Mizuno et al (2010) Science) prior to its addition to the barbed end. Individual formins such as INF2 can tailor this activity for their specific purposes.

P1648**Board Number: B160****Identification of formin-regulating sequences common to Smy1 and other cytoskeletal proteins.**J.A. Eskin¹, A. Rankova¹, S.L. Alioto¹, A. Johnston¹, B.L. Goode¹;¹Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

In budding yeast, formins play an essential role in assembling actin cables, which serve as polarized tracks for myosin-based transport of secretory vesicles and other cargoes to the developing bud cortex. We previously showed that the myosin passenger protein Smy1, a motor-inactive Kinesin-1 homologue, directly binds and inhibits the formin Bnr1 to control actin cable length and function (Cataldo et al., 2011). However, Smy1 is a multi-functional protein and also binds F-actin and promotes myosin V (Myo2) processivity in vitro, and thus it has remained unclear whether the abnormal actin cables and defects in secretory traffic in *smy1Δ* cells result from misregulated Bnr1 activity. Here, we have identified three specific sequences in Smy1 that are required for its inhibitory effects on Bnr1 in vitro. In cells, replacement of the wild type *SMY1* gene with *smy1* alleles mutated at these sites led to defects in actin cable formation and secretory vesicle traffic similar to *smy1Δ*. Further, the mutant *smy1* alleles were pseudo-wild type for suppression of *myo2-66* growth defects. Thus, our new *smy1* alleles uncouple Smy1 functions, and demonstrate that Smy1 indeed controls Bnr1 activity in vivo. In addition, BLAST searching with the formin-regulating sequences in Smy1 identified related motifs in yeast Bud14, which is also a Bnr1 regulator (Chesarone et al., 2009). Mutation of the Smy1-like motif in Bud14 impaired its regulatory effects on Bnr1 in vitro, and compromised *BUD14* function in vivo. Further, Smy1-like motifs were identified in several mammalian proteins implicated in formin regulation.

P1649**Board Number: B161****A novel actin-adhesion structure involved in nuclear positioning requires the formin FMN2.**C.T. Skau¹, C. Waterman¹;¹National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD

Active asymmetric positioning of the nucleus in interphase cells is critical to cell functions including cell migration, particularly in complex 3D environments. Previous studies have highlighted the importance of integrin and Rho signaling in controlling nuclear orientation in migrating fibroblasts. Although these studies establish that integrins, actin, and actin-binding proteins at the nuclear envelope are critical for nuclear positioning in adherent cells, it is not known if this is mediated by linking the nucleus to the previously-characterized adhesion/actin system used for migration, or if nucleus-ECM coupling is accomplished via a specialized cytoskeletal system. We tested the hypothesis that a dedicated adhesion-

actin system is responsible for maintenance of nuclear position in adherent, migrating cells. We examined the interplay between actin, adhesions, and the nucleus in fibroblasts using fluorescence microscopy. We identified novel adhesive structures located underneath the nucleus termed subnuclear adhesions that are compositionally and dynamically distinct from the canonical focal adhesions at the leading edge. First, subnuclear adhesions have reduced levels of signaling and actin-binding proteins found in leading edge adhesions but have high levels of fibrillar adhesion proteins, although they are not required for fibrillogenesis. Additionally, unlike focal adhesions at the protruding edge, assembly of the long-lived subnuclear adhesions is coordinated with movement of the nucleus and independent of the leading edge. Furthermore, evidence from nuclear displacement experiments indicates that the number and placement of these adhesions is controlled by the nucleus. We also show that a specific set of actin fibers connecting two subnuclear adhesions can control nuclear shape by physically impinging on the nucleus. These subnuclear fibers have elevated levels of the IIB isoform of myosin as compared with dorsal stress fibers, and are less dependent on the contractile activity of myosin than dorsal stress fibers. We previously identified the actin nucleation factor formin FMN2 in a screen of adhesion components. We now find that FMN2 localizes underneath the nucleus, and that the rapid dynamics of FMN2 partially depend on myosin activity. Critically, FMN2 is essential for both subnuclear actin and adhesions. Cells lacking FMN2 and subnuclear adhesions migrate poorly in 3D environments and exhibit defects in nuclear positioning, including failure to reorient during wound healing. Together, our data reveal the critical role of an actin nucleator in a previously unidentified mechanism for control of nuclear position via a novel adhesive structure linking the actin cytoskeleton, which connects to the nucleus, to the extracellular matrix.

Nuclear actin counters gravity during cell growth.

M. Feric¹, C. Brangwynne²;

¹Chemical Engineering, Princeton University, Princeton, NJ, ²Chemical and Biological Engineering, Princeton University, Princeton, NJ

Mechanics is highly influential in determining cell behavior from cell division to cell motility. However, the exact role of mechanics in controlling cell growth and cell size still remains unclear. The oocytes or immature eggs of the frog *X. laevis* are known to grow and reach extraordinarily large sizes of approximately 1 mm in diameter. During this process of growth, the oocytes actively maintain significantly high concentrations of nuclear actin. We have recently shown that this nuclear actin meshwork stabilizes the liquid-like nuclear bodies from rapid gravitational sedimentation and fusion. However, the mechanical properties of nuclear actin remain poorly characterized, despite their apparent importance in kinetically stabilizing the nucleus. Here, we use approaches in active and passive microrheology, in addition to confocal and two-photon excitation microscopy and quantitative image analysis, to probe the local mechanics and microstructure of this nuclear actin network. We find that actin forms a surprisingly soft, viscoelastic scaffold with a mesh size of ~0.5 microns. Furthermore, the

distribution of nuclear bodies within the actin network shows signatures of gravitational creep during growth. Upon application of forces of ~ 1 pN, nuclear actin exhibits shear-thickening behavior, which could serve a protective role in response to shocks. However, significantly higher forces ultimately lead to mechanical failure and rupture of the actin network. These measurements elucidate mechanical and geometric aspects of cell organization, which suggests that biophysical constraints can play an important role in cell growth and size control.

Mechanism of actin filament nucleation by Leiomodin.

M. Boczkowska¹, G. Rebowski², R. Dominguez³;

¹Physiology, University of Pennsylvania, Philadelphia, PA, ²Physiology, University of Pennsylvania, Philadelphia, PA, ³Physiology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

Actin cytoskeleton remodeling requires proteins called nucleators, which catalyze the kinetically unfavorable step of new filament formation. Among known filament nucleators Leiomodin (Lmod) is the only one specifically expressed in muscle cells. Lmod, a strong nucleator, is related to the F-actin pointed-end capping protein tropomodulin (Tmod), with negligible nucleation activity. Both proteins contain a flexible N-terminal region and a leucine-rich repeat (LRR) domain. It has been proposed that the difference in their functions originates in the presence in Lmod of a unique C-terminal extension harboring a WH2 domain, an actin barbed end-binding site. Here, we present data in support of a hypothesis that the difference between nucleation and capping activity is defined within the LRR domain. Thus, we designed a hybrid Tmod-Lmod LRR domain with nucleation activity similar to full length Lmod. On the other hand, the addition of Lmod's C-terminal extension to Tmod did not create a strong nucleator.

Structural organization of contractile ring constituents in cortices isolated from dividing sea urchin embryos.

J.H. Henson¹, C.B. Shuster²;

¹Dickinson Coll, Carlisle, PA, ²Biology Department, New Mexico State University, Las Cruces, NM

The sea urchin zygote has long served as a model system for studying changes in the cortical actin cytoskeleton, from the post-fertilization development of microvilli to the organization of the contractile ring. However, in the several decades since much of the seminal work was performed on egg cortices, great strides have been made in our understanding of how actin polymerization is facilitated, how actin filaments are organized, and how the contractile ring is assembled and regulated. In light of these

advances, we have begun to revisit the cortical actin cytoskeleton in isolated cortices using sophisticated light and electron microscopy incorporating probes specific for crucial constituents including actin, total and activated myosin II, the Arp2/3 complex, formin, and RhoA. Examination of the two principle actin nucleating factors (formin2 and the Arp2/3 complex) revealed that in unfertilized cortices, Arp2/3 appeared to associate with small collections of actin filaments inside the short microvilli. In contrast, formin2 was associated with elongate microvilli following fertilization. Examination of the contractile ring in isolated cortices indicated that while myosin II was found throughout the cortex, activated myosin (phospho-serine 19) formed a discrete band at the cell equator. 3D SIM super-resolution microscopy indicated that the activated myosin and actin filaments in the contractile ring aligned in parallel arrays. We have begun to investigate the ultrastructural organization of the contractile ring using critical point dry and rotary shadow TEM of isolated cortices. Imaging of unextracted and detergent extracted cortices showed a distribution of submembranous, elongate actin filaments. In areas outside of the cleavage furrow these filaments were organized into an isotropic network containing nodes whereas within the cleavage furrow they formed a very dense, anisotropic array of elongate filaments. To our knowledge these images offer some of the first 3D ultrastructural views of the contractile ring in animal cells and we are in the process of additional experimentation to further characterize this preparation.

Role of BMP signaling on cytoskeleton elements in the sensory placode invagination.

V. Jidigam¹, L. Gunhaga¹;

¹UCMM, Umea University, Umea, Sweden

Sensory placodes (lens, olfactory, and otic) give rise to sense organs of the vertebrate head. Despite their diversity in shape and function, the sensory organs share common morphological and molecular features during early steps of morphogenesis. The first sign of ectodermal organ formation is a local thickening of the epithelium, the so called placodes, which is accompanied by condensation of the underlying mesenchyme (placode invagination or bending). It is known that cells in placode elongate along their apical-basal axis, simultaneously change cell shape from cylindrical to conical shape due to reduction of apical cell surface (also called apical constriction). Apical constriction is at least partly due to the apically localized acto-myosin cytoskeleton. Molecular nature of the extracellular signals, and when and how they interact to convert flat ectoderm to invaginated placodes remain poorly understood. The communication between and within the two tissues, mediated by several families of signaling molecules including FGFs, Wnts, BMPs, and Notch are expressed in or around the developing sensory placodes. In our study we show that BMP signals appears to be important for the correct positioning of the olfactory, otic and lens placode, as well as for proper invagination, in part by positively regulating the expression of Six1 in the olfactory placode. BMP is also shown to play an important role on cytoskeleton elements in sensory placode invagination.

P1654**Board Number: B166****CAP2 in cardiac conduction, sudden cardiac death and eye development.**J. Field¹, D. Ye¹, M. Shinde¹, F. Liu¹, K. Schillinger¹, M. Lu¹, T. Wang¹, M. Skettini¹, A. Brice¹, D. Chung¹, V. Patel¹;¹University of Pennsylvania, Philadelphia, PA

Sudden cardiac death kills 180,000 to 450,000 Americans annually, predominantly males. A locus that causes developmental disorders and confers a risk for sudden cardiac death and conduction disease is located at 6p22, near the cytoskeletal gene, CAP2. CAP2 regulates actin dynamics in the cytoskeleton by binding actin monomers and assisting filament severing to modulate the balance of filamentous actin (F-actin) and globular actin (G-actin). To determine the role of CAP2 in vivo, we generated knockout (KO) mice. *cap2*⁻/*cap2*⁻ males were underrepresented (Mendelian ratios 5%, expected 25%) and ~70% died by 12 weeks of age, but *cap2*⁻/*cap2*⁻ females were found at close to the expected levels (17%) and lived normal lifespans. CAP2 knockouts were smaller, developed microphthalmia, cardiac conduction disease and dilated cardiomyopathy past 12-weeks of age, most noticeably in the males. To address the mechanisms underlying these phenotypes, we used Cre-mediated recombination to knock out CAP2 in cardiomyocytes and found that the mice died suddenly due to complete heart block in the absence of cardiomyopathy but no longer displayed the other phenotypes, including any evidence of sex-bias. These studies establish a direct role for actin dynamics in sudden cardiac death and cardiac conduction disease.

P1655**Board Number: B167****Drosophila Spire functions as a nucleation promoting factor (NPF) for formin-mediated actin assembly.**C.L. Vizcarra¹, R. Jaiswal², B.L. Goode², M.E. Quinlan^{1,3};¹Chemistry and Biochemistry, University California-Los Angeles, Los Angeles, CA, ²Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA,³Molecular Biology Institute, University California-Los Angeles, Los Angeles, CA

Actin nucleators must be tightly regulated in vivo, which is achieved through mechanisms involving both inter- and intra-molecular interactions. A number of actin nucleators also bind to nucleation promoting factors (NPFs) to fully realize their actin nucleation activity. The best characterized of these nucleator/NPF pairs is Arp2/3 complex/N-WASP, which catalyzes the formation of branched actin filament networks. Recently, it was shown that formins can also collaborate with NPF-like proteins, including the yeast formin Bni1 and Bud6 (Graziano et al., 2011) and the mammalian formin mDia1 and Adenomatous polyposis coli protein (Okada 2010). In vivo, the Drosophila formin Cappuccino (Capu) is associated with a cytoplasmic actin mesh that is essential for oocyte development. Mutation of Capu

leads to loss of the mesh, mislocalization of polarity cues, and female sterility. Mutation of the WH2-based actin nucleator Spire has a similar phenotype in the fly oocyte. In addition, direct interactions between Spire and Capu are essential for actin mesh formation and, subsequently, for oogenesis and fertility (Quinlan 2013). Spire contains four WH2 domains (A, B, C, and D) that each bind actin monomers. In the absence of formins, Spire mutated at WH2-D (Spire-D*) fails to nucleate actin assembly in vitro, similar to a construct with all four WH2 domains mutated (Spire-A*B*C*D*). However, in vivo Spire-D* is able to rescue fertility, while Spire-A*B*C*D* is not, suggesting that Spire's actin nucleation activity on its own may not be necessary in the oocyte. Combined with earlier studies, we conclude that Spire in vivo function during oogenesis requires at least some functional actin monomer binding sites and the ability to interact with Capu. This points to a role for Spire as an NPF for Capu. Indeed, in bulk in vitro assays, Spire stimulates Capu's actin assembly activity in the presence of capping protein and profilin, conditions under which Spire alone does not promote filament formation. To better understand the workings of these two proteins, we are defining the mechanisms underlying actin filament formation by Spire and Capu, alone and together, using multi-wavelength single molecule TIRF.

The role of Rtt102- and ATP-binding to Arp7/9 in regulating SWI/SNF remodeler structure and function.

B. Turegun¹, D.J. Kast¹, R. Dominguez¹;

¹Physiology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

Chromatin-remodeling complexes (remodelers) modulate chromatin structure and thus play important roles in regulating transcription, DNA replication, and DNA repair. Remodelers are assembled around a catalytic subunit that contains a central ATPase domain and flanking sequences that recruit auxiliary subunits. The catalytic subunits of SWI/SNF remodelers recruit actin-related proteins 7 and 9 (Arp7/9) through a helicase-SANT-associated (HSA) domain N-terminal to the ATPase domain. We previously showed that an additional auxiliary subunit, Rtt102, binds with nanomolar affinity to the Arp7/9 heterodimer. This induces a conformational change in Arp7/9, which then interacts with a shorter segment of the HSA domain. In addition, Rtt102 promotes high-affinity ATP binding to one of the Arps in the heterodimer. Here, we used x-ray crystallography to further investigate the role of Rtt102-binding on the structure and function of Arp7/9. These studies reveal the binding site for ATP within Arp7/9 while also confirming our previous findings regarding the Rtt102-induced conformational change in Arp7/9. We also present DNA-binding experiments that suggest a role for Rtt102- and ATP-binding to Arp7/9 in regulating SWI/SNF remodeler function.

Identification of Novel Components of the Intermicrovillar Adhesion Complex that Regulates Intestinal Brush Border Assembly.

S.W. Crawley¹, M.J. Tyska¹;

¹Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

Intestinal enterocytes remodel their apical surface during differentiation to form a brush border: a tightly packed array of microvillar membrane protrusions that exhibit strikingly uniform length and highly organized packing. Although the brush border is essential for maintaining physiological homeostasis in the gut, how enterocytes generate, stabilize, and organize microvilli remains an open question. Our lab recently discovered an adhesion-based mechanism that regulates brush border formation. During brush border assembly, microvilli cluster together on the apical surface of enterocytes through interactions between their distal tips. Adhesion is mediated by two protocadherin family members, protocadherin-24 (PCDH24) and mucin-like protocadherin (MLPCDH), which are found specifically at the distal tips of microvilli. By physically linking neighboring microvilli together, intermicrovillar adhesion promotes the tight packing of microvilli during enterocyte differentiation and enforces uniform length across the brush border. We previously used a candidate approach to identify cytoplasmic molecules that interact with PCDH24 and MLPCDH, including the scaffolding protein harmonin-a and the actin-based motor, Myo7b. Together, these molecules form the intermicrovillar adhesion complex (IMAC). Towards the goal of identifying additional members of the IMAC, we developed a novel protein isolation strategy that takes advantage of the inherent adhesion activity of microvillar protocadherins, to purify intact IMAC from brush borders isolated from native intestinal tissue and polarized CACO-2_{BBE} monolayer cultures. Here we present data on the characterization of novel IMAC components including: (1) their subcellular localization in native intestinal tissue and CACO-2_{BBE} cells (2) their functional role in promoting microvillar clustering and brush border formation using knockdown and overexpression studies performed in CACO-2_{BBE} cells, and (3) their interactions with other IMAC components using pull-down analyses with recombinant proteins. In summary, our data suggest the IMAC is a large multi-protein complex that resides at the tips of brush border microvilli, where it plays a central role in promoting normal brush border formation.

P1658**Board Number: B170****The actin nucleator Cordon-Bleu plays a role in building enterocyte brush border microvilli.**N.E. Grega Larson¹, M.J. Tyska¹;¹Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

The absorptive epithelial cells that line the small intestine, also known as 'enterocytes', exhibit remarkable apical-basal polarity. The apical surface of the enterocyte displays an array of tightly packed microvilli referred to as the brush border. A single microvillus is a membrane protrusion supported by a linear F-actin bundle, with the plus ends of actin filaments oriented toward the distal tip. Despite the importance of the brush border in nutrient absorption and host defense, the mechanism of brush border assembly has remained unclear. A previous proteomic analysis of isolated brush borders performed by our laboratory identified two actin nucleators in brush border-enriched fractions: the Arp2/3 complex and Cordon-Bleu (COBL). Inhibition of the Arp2/3 complex had no impact on brush border assembly in Ls174T-W4 (W4) cells, which act as a single cell model of enterocyte polarization and differentiation. However, we found that the linear actin nucleator, COBL, localizes to the base of the brush border in rat and mouse small intestine, and in W4 cells. COBL is thought to nucleate F-actin polymerization using three C-terminal WH2 domains that each bind G-actin. shRNA knockdown of COBL in W4 cells causes a significant decrease in the fraction of cells that form brush borders. This effect was fully rescued with a COBL variant that was refractory to knockdown, and partially rescued by a C-terminal fragment containing the G-actin binding WH2 domains. Overexpression of full-length and truncated forms COBL accentuated brush border morphology, with microvilli that were longer, straighter, and contained more F-actin. Moreover, a COBL construct that is unable to bind actin did not rescue COBL knockdown or impact brush border morphology when it was overexpressed, suggesting that actin binding is critical for COBL's role in brush border assembly. To examine how COBL impacts actin dynamics in live cells, we introduced GFP-tagged COBL into B16F1 melanoma cells. Overexpression of COBL in these cells induces the formation of linear actin bundles throughout the cytoplasm. Strikingly, these bundles are highly dynamic, growing and shrinking over the course of two to three minutes. Moreover, COBL is enriched at slow/non-growing end of the bundle (presumably, the minus ends). Finally, these bundles can be stabilized to effect protrusion at the cell periphery by co-expressing F-actin bundling proteins that are normally found in the microvillus, such as espin. Together, these data suggest that COBL plays a role in building brush border microvilli, most likely by nucleating actin filament polymerization from the terminal web.

P1659**Board Number: B171****Endogenous species of mammalian nonmuscle myosin IIA and IIB include activated monomers and heteropolymers.**M. Shutova¹, W.A. Spessott², C.G. Giraudo³, T. Svitkina¹;¹Department of Biology, University of Pennsylvania, Philadelphia, PA, ²Children's Hospital of Philadelphia, Philadelphia, PA, ³The Children's Hospital of Philadelphia - University of Pennsylvania, Philadelphia, PA

Class II myosins generate contractile forces in cells by polymerizing into bipolar filaments and pulling on anchored actin filaments. Nonmuscle myosin II (NMII) plays central roles during cell adhesion, migration, cytokinesis, and tissue morphogenesis. NMII is present in virtually all mammalian cell types as tissue-specific combinations of NMIIA, NMIIB, and NMIIC isoforms. It remains poorly understood how the highly dynamic NMII-actin contractile system begins to assemble at new cellular locations during cell migration and how incorporation of different NMII isoforms into this system is coordinated. Using platinum replica electron microscopy in combination with immunogold labeling, we demonstrate that individual activated (phosphorylated on the regulatory light chain and unfolded) NMIIA and NMIIB molecules represent a functional form of NMII in motile cells and that NMIIA and NMIIB copolymerize into nascent bipolar filaments during contractile system assembly. Using subdiffraction STED microscopy together with a pharmacological block-and-release approach, we report that NMIIA and NMIIB simultaneously incorporate into the cytoskeleton during initiation of contractile system assembly, whereas the characteristic rearward shift of NMIIB relative to NMIIA is established later in the course of NMII turnover. We show existence of activated NMII monomers in cells, copolymerization of endogenous NMIIA and NMIIB molecules, and contribution of both isoforms, rather than only NMIIA, to early stages of the contractile system assembly. These data change the current paradigms about dynamics and functions of NMII and provide new conceptual insights into organization and dynamics of the ubiquitous cellular machinery for contraction that acts in multiple cellular contexts.

P1660**Board Number: B172****Investigation of beta-Spectrin function in the Hippo signaling pathway.**Y. Yan¹, K. Wong¹;¹Division of Life Science, HKUST, Hong Kong, Hong Kong

The Hippo signaling pathway is an evolutionarily conserved pathway regulating a wide range of developmental and cellular processes such as growth, differentiation, and morphogenesis. Importantly, the Hippo signaling pathway is known to respond to regulatory signals from the actin cytoskeleton. However, the mechanism of how the actin cytoskeleton regulates the Hippo pathway remains largely elusive.

We identified beta-Spectrin as a protein required for Hippo signaling activity in a genetic screen for oocyte polarity defects during *Drosophila* oogenesis. Spectrins are known for linking the actin cytoskeleton to the plasma membrane. In beta-spectrin mutant cells the actin filaments lose the planar polarized orientation and frequently form abnormal stress-fiber-like structures on the basal side of the epithelium. Increased cellular tension associated with formation of stress fibers is likely a critical link between the beta-spectrin mutations and the Hippo signaling defect. Moreover, the function of beta-Spectrin in the Hippo signaling pathway is likely to be conserved in the mammalian cells.

Effects of a putative male contraceptive on the ultrastructure of actin filament bundles in the seminiferous and other epithelia.

A. Adams¹, F. Hosseini¹, G. Georg^{2,3}, T.G. Kinzy^{3,4}, A. Vogl¹, J.S. Tash^{3,5};

¹Cellular and Physiological Sciences, UBC, Vancouver, BC, ²Medicinal Chemistry, University of Minnesota, Minneapolis, MN, ³Interdisciplinary Center for Male Contraceptive Research and Drug Development, University of Kansas Medical Center, Kansas City, KS, ⁴Biochemistry and Molecular Biology, Rutgers University, New Jersey, NY, ⁵Molecular and Integrative Physiology, University of Kansas, Kansas City, KS

H2-Gamendazole is a non-hormonal compound being actively investigated as a male contraceptive. It targets eEF1A, a protein synthesis factor that also influences the arrangement of actin filaments. In the testis, the drug causes loss of intercellular adhesion and detachment of developing sperm cells. Ectoplasmic specializations (ESs) are Sertoli cell specific adhesion junctions that consist of a layer of actin filaments situated between the plasma membrane and a cistern of endoplasmic reticulum. The filaments are unipolar in orientation and packed into hexagonal arrays, like the arrangement of filaments in microvilli. Here, we explore the effects of H2-gamendazole on ESs, and determine if drug-related effects occur in the microvilli of other epithelial cell types. Rats were given a single oral dose of H2-gamendazole (30 mg/Kg). This dose is near the maximum tolerated dose and is 10-20x the expected dose for contraceptive use. It was chosen to maximize any potential effects in off-target tissues. At 6 & 24 hrs after dosing, samples of testis, small intestine, large intestine, and kidney from control and treated animals were processed for electron microscopy. Actin filaments in ESs were disrupted in drug treated animals compared to controls. In addition, microvilli in other tissues were short, developed an irregular shape, and in some cases completely lost their actin cores. Our data are consistent with the conclusion that H2-gamendazole causes premature detachment of spermatogenic cells by targeting the actin cytoskeleton in ESs. Our results also indicate that the drugs effects at a high dose are not absolutely restricted to the testis.

P1662**Board Number: B174****F-actin and Golgi rearrangement around the *Chlamydia trachomatis* inclusion is mediated by the Arf-recruiting bacterial protein InaC.**M. Kokes¹, R.H. Valdivia²;¹Molecular Genetics and Microbiology, Cell and Molecular Biology, Duke University, Durham, NC,²Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC

Chlamydia trachomatis is the most common sexually transmitted bacterial pathogen, and is the leading cause of preventable blindness worldwide. As an obligate intracellular pathogen, *Chlamydia* resides within a membrane-bound vacuole (inclusion) within host cells. A filamentous actin structure surrounds the inclusion, and disruption of actin polymerization in host cells leads to increased exposure to cytosolic innate immune receptors and increased expression of pro-inflammatory cytokines, suggesting that F-actin maintains *Chlamydia* in a 'hidden' state within cells.

To identify *Chlamydia* factors involved in cytoskeletal cage assembly at inclusions, we screened an arrayed library of chemically-mutagenized strains and identified one mutant lacking F-actin at inclusions. Using genetic tools recently developed for *Chlamydia*, we show that a secreted bacterial protein associated with the cytosolic surface of the inclusion membrane, renamed InaC, is necessary for actin assembly at the inclusion. Surprisingly, InaC is dispensable for suppression of host cytokine production. To further define roles of InaC in modifying the host intracellular environment, we used a combination of immunoprecipitation and mass spectroscopy to identify host proteins that interact with InaC. We show that InaC interacts with and recruits host Arf GTPases – important regulators of trafficking and organization at the Golgi – to the inclusion. Remarkably, during *Chlamydia* infection, the Golgi ribbon fragments into ministacks which rearrange around the periphery of the inclusion. We find Golgi re-distribution around the inclusion to be mediated by InaC in an F-actin-dependent manner. Sphingolipids normally trafficked from the Golgi to the plasma membrane are intercepted by *Chlamydia*, and host sphingolipids are incorporated into bacteria and the inclusion membrane. Golgi re-distribution around the inclusion has previously been proposed to enhance bacterial acquisition of host sphingolipids. However, we find that InaC-deficient *Chlamydia* lacking actin assembly at the inclusion acquire normal levels of sphingolipids, suggesting an alternative role for InaC-mediated Golgi re-distribution around the inclusion.

P1663**Board Number: B175****Acetylation of K326 and K328 of actin depresses contractile performance of skeletal and cardiac muscle.**M.C. Viswanathan¹, A. Blice-Baum¹, D.B. Foster¹, A. Cammarato¹;¹Medicine, Johns Hopkins University, Baltimore, MD

Striated muscle contraction results from transient interactions between myosin-containing thick and F-actin-containing thin filaments. Tropomyosin (Tm) extends along the F-actin thin filament surface. Its location governs access of myosin binding sites and, hence, force production. Models of the F-actin-Tm and F-actin-Tm-myosin binding interfaces have been proposed based on evolutionary analysis, computational chemistry, and image reconstructions. Intermolecular electrostatic associations mediate critical interactions between the proteins. For example, actin residues K326, K328 and R147 were predicted to establish contacts with E181 of Tm. Moreover, K328 also potentially forms direct interactions with E286 of myosin when the motor is strongly bound. Post translational modifications (PTMs) alter the chemical nature of thin filament subunits. These modifications are widespread and play both physiological and pathological roles. Yet relative to the extensive study of disease-causing mutations, the impact of relatively few PTMs on contractile performance has been examined in the physiological context of muscle. Recently, LC-MS/MS analysis of the cardiac acetyl-lysine proteome revealed K326 and K328 of actin were acetylated; a reaction that masks the residues' inherent positive charge. Here, we tested the hypothesis that removing vital actin charges at residues 326 and 328 diminishes actomyosin interactions by altering Tm positioning and/or strong myosin binding, *in vivo*, as manifest by depressed skeletal and cardiac muscle function. Transgenic *Drosophila* lines were created that permit tissue-specific expression of K326Q, K328Q, or K326Q/K328Q acetyl-mimetic actin and of wild-type actin. Muscle-restricted transgene expression was confirmed with a GFP-based reporter. Compared to wild-type actin, expression of mutant actin had a dose-dependent effect on flight ability. Moreover, relative to K326Q actin, K328Q and K326Q/K328Q actin induced a more severe reduction in flight performance. High-speed video microscopy and motion analysis of beating hearts with cardiac-restricted transgene expression revealed significant reductions in systolic intervals among all acetyl-mimetic lines vs. control. Based on F-actin-Tm and F-actin-Tm-myosin models and on our physiological data, we conclude that acetylating K326 and K328 of actin alters electrostatic associations with Tm and/or myosin and thereby modifies actomyosin associations and muscle performance. Our findings highlight the utility of *Drosophila* as a model that permits efficient targeted design and assessment of molecular and tissue-specific responses to muscle protein modifications, *in vivo*.

P1664**Board Number: B176****Computational Modeling of Complex Mechano-Chemical Feedbacks in Acto-Myosin Networks.**G. Papoian¹, K. Popov¹, J. Komianos¹;¹Univ Maryland College Park, College Park, MD

Acto-myosin network growth and remodeling *in vivo* is based on a large number of chemical and mechanical processes, which are mutually coupled and spatially and temporally resolved. To investigate the fundamental principles behind the self-organization of these networks, we have developed detailed physico-chemical, stochastic models of actin filament growth dynamics, where the mechanical rigidity of filaments and their corresponding deformations under internally and externally generated forces are taken into account. Our work sheds light on the interplay between the chemical and mechanical processes, and also will highlight the importance of diffusional and active transport phenomena. For example, we showed that molecular transport plays an important role in determining the shapes of the commonly observed force-velocity curves. We also investigated the nonlinear mechano-chemical couplings between an acto-myosin network and an external deformable substrate.

P1665**Board Number: B177****Organization of actin cables in budding yeast: a computational model.**H. Tang¹, T.C. Bidone¹, D. Vavylonis¹;¹Department of Physics, Lehigh University, Bethlehem, PA

Budding yeast actin cables function as tracks for delivery of cellular organelles to the growing bud during polarized cell growth and aid in spindle orientation during mitosis. For proper cellular function, actin cables must form polarized bundles that grow from the bud to the mother, spanning the whole cell. Overexpression of Bni1 leads to increased density of actin cables and appearance of cable loops, while disruption of Bni1 leads to disappearance of actin cables. Regardless of the consistent body of experimental observations, what molecular mechanisms impact the large scale organization of actin cables in budding yeast remains elusive. Here, we develop a 3D computational model of actin cable dynamics to study the interplay between molecular mechanisms and large scale organization of actin cables in budding yeast. This model extends our prior study of actin cables in fission yeast (Tang et al. MBoC 2014). In this model, formins Bni1 and Bnr1 promote actin filament barbed end polymerization. The actin filaments are simulated as semiflexible polymers composed of beads connected by springs. Formin turnover is incorporated as filament detachment and recruitment at cortical sites. Cross-linking by fimbrin Sac6 is simulated as a short-range attractive interaction. Pulling by class V myosin and class II myosin are simulated as tangential forces on filament beads. Cofilin-induced severing is implemented as breaking and disassembly of filament segments. We show that with these mechanisms, the model can generate the actin cable structures similar to those observed in experiments. We use this model to study

what is the origin of the transition between straight cables and cables forming loops as a function of different combinations of the molecular mechanisms and to identify patterns of forces leading to cable buckling. These simulations illustrate how biophysical and biochemical properties combine to establish different types of cytoskeletal organization at the cellular scale.

Forces driving epithelial wound healing.

A. Bruges¹, E. Anon², V. Conte¹, J. Veldhuis³, M. Gupta⁴, J. Colombelli⁵, J. Muñoz⁶, G. Brodland³, B. Ladoux^{4,7}, X. Trepats^{8,9,10};

¹IBEC, Barcelona, Spain, ²Univ Paris Diderot, Paris, France, ³University of Waterloo, Waterloo, ON, ⁴Mechanobiology Institute, National University of Singapore, Singapore, ⁵Institute for Research in Biomedicine, Barcelona, Spain, ⁶Universitat Politècnica de Catalunya, Barcelona, Spain, ⁷Institut Jacques Monod, Université Paris Diderot CNRS, Paris, France, ⁸Institute for Bioengineering of Catalonia (IBEC), Barcelona, Spain, ⁹University of Barcelona, Barcelona, Spain, ¹⁰Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain

The rapid restoration of epithelial integrity after wounding is a crucial process for the survival of complex organisms. Epithelial wound healing is commonly attributed to a combination of two mechanisms. The first one is the so-called purse-string contraction, whereby cells lining the wound assemble and contract a supracellular actomyosin cable. The second mechanism is cell crawling driven by lamellipodial and filopodial protrusions. The relative contribution of these two mechanisms to wound healing remains controversial, however. Here we combined laser ablation, traction force microscopy and micropillar force detectors to measure the first complete maps of the mechanical forces driving wound healing. These maps demonstrate that migration is driven initially by the cooperative action of multiple cell rows crawling into the wound. At later stages, we observed traction forces with unanticipated components radial and tangential to the wound boundary. We show that these force components arise from tensions in a heterogeneous actomyosin ring and that these tensions are transmitted to the underlying substrate through focal adhesions. A computational model we developed captures tractions and tensions in the monolayer and their relationship to cellular shapes and motions. These findings demonstrate that the actomyosin ring is a much more versatile structure than previously thought and serves at least two purposes. First, it contributes to wound closure through its well-known purse-string mechanism. Second, it contracts heterogeneously to compress the underlying substrate.

P1667**Board Number: B179****Spatial organization of the cellular actin cortex during the cell cycle.**P. Chugh¹, A.G. Clark¹, M.B. Smith¹, K. Dierkes², G. Salbreux³, E.K. Paluch¹;¹MRC-LMCB, UCL, London, United Kingdom, ²Centre for Genomic Regulation (CRG) and UPF, Barcelona, Spain, ³MPI PKS, Dresden, Germany

Cell shape regulation is key to a number of fundamental biological processes, including cell migration and division. In animal cells, cell morphology is controlled primarily by the cortex, a thin actomyosin network underlying the plasma membrane. The cortex determines global physical properties of the cell such as tension and stiffness. Previous studies have shown that spatial and temporal changes in cortical tension drive shape changes during the cell cycle such as mitotic rounding and cytokinetic furrow ingression. However, the precise changes in cortical structure and composition required to generate changes in cortical tension during the cell cycle remain unclear. We are investigating this question using a combination of cell biology experiments, quantitative imaging and modeling. As the cortex dimensions are below the resolution limit of conventional light microscopy, we have developed a dual-color localization method to investigate the spatial organization of the cortex. This method is based on estimating the relative localization of cortex components with respect to one another by labeling them with chromatically different fluorophores. Using our method, we quantified cortex thickness and compared the localization of key actin binding proteins in different stages of the cell cycle. We could show that cortex thickness is lower in prometaphase than in interphase. Interestingly, we also observed that myosin motors differentially localize in the cortex during interphase as compared to mitosis. We are currently investigating the factors that control cortex thickness as well as the localization of myosin and other key cortical components during the cell cycle. Combined with a physical model of the cortex, our systematic analysis will help uncover the mechanism by which cortical structure and organization regulate cortical mechanics, thereby driving cellular morphogenesis.

P1668**Board Number: B180****Spatial organization of nuclear membrane cytoskeleton.**J. Usukura¹;¹Structural Biology Center, Nagoya University, Nagoya, Japan

The spatial organization of nuclear cytoskeleton was investigated at high resolution using simultaneous imaging of cryo-bright field, dark field STEM and SEM, and also conventional immune-freeze-etching methods. Nuclear cytoskeleton showed quite different spatial structure from plasma membrane cytoskeleton, though it consisted of actin filaments, microtubules and intermediate filaments. Nuclear surface was covered with thick layer of intermediate filaments (Vimentin in NRK cells), while many actin filaments extend from the nuclear membrane and form stress fibers similar to the plasma membrane cytoskeleton. However, they never organize a meshwork by branching with Arp 2/3 that is commonly

seen in cortical area of cell membrane. Instead, they are intimately associated with intermediate filaments. In particular, at the surface of nucleus, intermediate filaments surrounded actin filaments like a sheath, which extended from the periphery of nuclear pores forming complicated meshwork and covered the total surface (depending on unroofed cryo-SEM images). Actin filaments were secondary major components in nuclear cytoskeleton. We investigated polarity of actin filaments by S1 decoration method. Both pointed and barbed ends were detected on the surface of nucleus, that is, both origin and termination of actin filaments present on the nuclear membrane. Probable candidate of actin binding site has been considered to be Nesprin 1 and 2 so far. Indeed, they were found abundantly on the nuclear surface in immuno-labeling. Unfortunately, however, we were not able to observe directly the binding between actin filaments and Nesprins, because actin filaments were covered with intermediate filaments on closing the nuclear surface. Under careful observation, some actin filaments appeared to extend from nuclear pores, judging from EM photographs.

Probing *in vivo* dynamics of mitochondria and cortical actin networks using high-speed atomic force/fluorescence microscopy.

K. Takeyasu¹, A. Yoshida¹, N. Sakai², Y. Uekusa², K. Deguchi¹, J.L. Gilmore¹, M. Kumeta¹, S. Ito²;

¹Graduate School of Biostudies, Kyoto University, Kyoto, Japan, ²Corporate RD Center, OLYMPUS, Tokyo, Japan

Dynamics of the cell membrane and submembrane structures are closely linked to achieve various cellular activities. Although cell surface research and cortical actin studies have revealed their mechanisms of action independently, it has been difficult to obtain a comprehensive understanding of the dynamics of these structures in live cells. Here we utilized a high-speed atomic force microscopy combined with an optical microscopy system to analyze membrane-based cellular events at nano-scale resolution in live cells. Imaging the COS-7 cell surface revealed detailed structural properties of membrane invagination events corresponding to endocytosis and exocytosis. In addition, the movement of mitochondria and the spatiotemporal dynamics of cortical F-actin network were directly visualized *in vivo*. Cortical actin microdomains with an average size of 231 ± 69 nm were dynamically rearranged by newly appearing actin filaments, which sometimes accompanied membrane invaginations, suggesting that these events are integrated with the dynamic regulation of submembrane organizations maintained by actin turnovers. These results provide novel insights into the structural aspects of the entire cell membrane machinery which can be visualized with high temporal and spatial resolution.

P1670**Board Number: B182****Formins are essential contributors to the assembly and maintenance of *Drosophila* sarcomeric thin filament arrays.**A. Shwartz¹, E.D. Schejter¹, B. Shilo¹;¹Department of Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel

Structural organization of striated skeletal myofibers, and of the repeating sarcomere units from which they are composed, is critical for efficient performance of muscle motor functions. Our study focuses on assembly of the sarcomeric actin-based thin filament array and its subsequent maintenance, using the sarcomeres of *Drosophila* indirect flight muscle (IFMs) as our model system. Employing GFP-tagged G-actin incorporation as a tool to monitor the dynamic assembly of microfilaments, we have been able to follow the events underlying thin-filament array generation and provide a timeline for their progression. This sequence includes bundling of pre-existing filaments, nascent array elongation, and array “thickening” via addition of peripheral filaments. Monitoring of array dynamics in adult flies suggests that maintenance via filament turnover occurs primarily at the barbed (Z-disc associated) and pointed ends of the arrays. Using genetic approaches we have identified a variety of functional requirements for the formins Fhos/FHOD and Form3/INF2 in establishment and maturation of the IFM thin-filament arrays. Fhos in particular appears to play several key roles during the different phases of array assembly and growth, as well as contributing to maintenance of mature arrays. Current studies are aimed at validating a model by which these formins use their capping, bundling and elongation capacities to perform their different roles.

P1671**Board Number: B183****Arp2/3 complex-dependent assembly of filopodia by the formin FMNL3 contributes to cell-cell adhesion.**L.E. Young¹, T.J. Gauvin², E.G. Heimsath³, H. Higgs⁴;¹Dartmouth College, Hanover, NH, ²Dartmouth-Geisel Sch Med, Hanover, NH, ³NIH/NIDCD, Bethesda, MD, ⁴Department of Biochemistry, Geisel School of Medicine at Dartmouth College, Hanover, NH

Filopodia are finger-like, actin-dependent membrane protrusions that play fundamental roles in directional cell migration, cell-cell adhesion and chemosensing. The mechanism for filopodial assembly remains to be established, with two predominant mutually exclusive models: 1) the tip nucleation model describes that filopodia are created de novo by a molecule that nucleates new actin filaments; or 2) the convergent model describes that filopodia are re-modeled from Arp2/3 complex-nucleated dendritic networks, such as lamellipodia. Previously, we have shown that two formin proteins, FMNL3 and mDia2, are potent filopodial inducers, but whether they act by the tip nucleation or convergent model was uncertain. Here, we show that both FMNL3- and mDia2-induced filopodia are largely Arp2/3 complex-

dependent in multiple cell types (non-adherent and adherent). Interestingly, a small percentage of these filopodia are Arp2/3 complex-independent, suggesting that FMNL3 and mDia2 may use actin filaments generated by alternative nucleators in certain situations. Biochemical assays show that, under conditions that mimic mammalian cytosol, both FMNL3 and mDia2 are poor nucleators, further suggesting the need of a separate nucleation factor during filopodial assembly. To address the physiological function of FMNL3, we show that the full-length protein (both endogenous and GFP-tagged proteins) localizes predominately at the plasma membrane, where it enriches in filopodia, membrane ruffles, and at cell-cell contact sites. Interestingly, FMNL3-enriched filopodia are 10-fold more stable when at the cell-cell interface in comparison to when interacting with the cell-free coverslip surface. A small proportion of FMNL3 localizes to dynamic vesicular structures in the cytoplasm; and these structures can migrate to and fuse with the plasma membrane at cell-cell contact sites. Suppression of FMNL3 causes defects in filopodial assembly and cell-cell adhesion. To summarize, our results show that FMNL3 and mDia2 assemble filopodia in an Arp2/3 complex-dependent manner. FMNL3-dependent filopodia in particular are specialized for cell-cell adhesion.

Colocalization of RhoGAP restricts the size of pulsatile actomyosin foci in *C. elegans* embryos.

M. Fujita¹, S. Onami^{1,2};

¹RIKEN Quantitative Biology Center, Kobe, Japan, ²National Bioscience Database Center, JST, Tokyo, Japan

Cortical actomyosin often forms pulsatile foci during tissue morphogenesis. How the foci structure is organized is under intense study. Pulsatile actomyosin foci are also found in one-cell stage embryos of *C. elegans*. Although numerous foci cover the cell surface, these foci are largely uniform in size, suggesting size regulation. However, it is unknown how the size of myosin foci is regulated.

Here we show that a RhoGAP protein RGA-3 colocalizes with the myosin foci and this colocalization regulates the size of myosin foci. We observed that GFP::RGA-3 colocalizes with a mCherry fusion of myosin regulatory light chain MLC-4. In order to investigate the function of this colocalization, we expressed a truncated form of RGA-3 that localizes to cytoplasm in *rga-3/4(RNAi)* background. This cytoplasmic RhoGAP is functional because it rescued the hypercontractile phenotype of *rga-3/4*. However, there was a marked difference in the cortical myosin organization. Myosin in wild-type embryos forms multiple foci, whereas myosin in the cytoplasmic RhoGAP embryos formed a large ring-like structure. This difference is not due to the expression level of RhoGAP because neither partial depletion nor overexpression did not cause the ring formation.

Next, we fused an F-actin binding domain to the cytoplasmic RhoGAP. When this actin-binding RhoGAP was expressed, cortical myosin formed multiple foci similarly to wild type, indicating that the colocalization of RhoGAP and actomyosin is sufficient to prevent the formation of the large ring. Based

on these observations, we propose the following model. The colocalization of RhoGAP to myosin foci constitutes a negative feedback, which restricts the size of myosin foci by preventing overgrowth.

Septin complexes assemble end-over-end in cells.

C. Kaplan¹, B. Jing², C. Winterflood³, A.A. Bridges⁴, J. Schmied⁵, S. Grinhagens⁶, T. Gronemeyer⁷, P. Tinnefeld⁸, A.S. Gladfelter⁹, J. Ries¹⁰, H. Ewers¹¹;

¹ETH Zurich, Inst Biochemistry, Zurich, Switzerland, ²Oxford University, Oxford, United Kingdom, ³King's College London, London, United Kingdom, ⁴Dartmouth College, Hanover, NH, ⁵Braunschweig University, Braunschweig, Germany, ⁶University of Ulm, Ulm, Germany, ⁷Ulm Univ Molec Genetics and Cell Biology, Ulm, Germany, ⁸Braunschweig University, Braunschweig, Germany, ⁹Biological Sciences, Dartmouth College, Hanover, NH, ¹⁰EMBL, Heidelberg, Germany, ¹¹Freie Universität Berlin, Berlin, Germany

The septins are an essential family of filament-forming GTP-binding proteins with conserved functions in cell division. Yeast septins form octameric, nonpolar, rod-shaped complexes of about 32 nm length and assemble further into higher-order structures that perform a variety of functions in the cell cycle. While in vitro the assembly of complexes into filaments is quite well understood, how the complexes assemble into the higher-order structures in cells remains unclear. Here, we used single molecule localization microscopy to visualize both termini of septin rods at nanometer resolution in vitro and in cells. Single septin complexes appeared as pairs of localizations around 30 - 35 nm apart and revealed the exact spatial orientation of the complex in space. Under in vitro conditions favorable to septin polymerization, we detected septin assemblies as very thin, elongated stretches of equidistant localizations both when Cdc11, the terminal subunit of the rod, and when Cdc10, the central subunit of the rod, was labeled and detected. These filaments were mostly straight and occasionally appeared bundled. In a filamentous fungus, we resolved similar localization pairs and thin filaments of equidistant localizations. Our work demonstrates that septin complexes assemble end-over-end into filaments in cells and that if paired, filaments are aligned in register.

Long cytoplasmic projections (“cytonemes”) in antral follicles in mouse ovary.

V. Baena¹, A. Hand¹, M. Yankova¹, M. Terasaki¹;

¹Cell Biology, Univ Connecticut Hlth Ctr, Farmington, CT

We used serial section electron microscopy to examine mouse ovarian antral follicles. The granulosa cells around the follicle periphery and the cumulus cells surrounding the oocyte are in constant communication with each other and with the oocyte. We found long cytoplasmic projections (“cytonemes”) from granulosa and cumulus cells that are likely to have an important role in cell-cell

interactions. Similar filipodia-like projections emanate from sea urchin blastomeres, *Drosophila* cells, and lymphocytes in culture; they have also been called 'nanotubes', or 'thin projections'. In *Drosophila*, there is evidence that they take part in decapentaplegic signaling. The serial section electron microscopy was done using a new method developed by Lichtman and collaborators. Sections are cut on a conventional ultramicrotome, collected on tape using an "ATUM" instrument, and examined by field emission scanning electron microscopy. The sections are collected more reliably than with conventional methods. Furthermore, large sections (2 x 4 mm) are collected, which increases the area that can be searched. For this study, approximately 100 sections of 60 nm thickness were examined. In preliminary observations, there are ~6-10 cytonemes per cell. They have a diameter of ~150 nm, are between 1 and 2 cell diameters in length (5-10 um), and appear to have no preferred directional orientation within the follicle. They sometimes form bundles, and touch or make invaginations into neighboring cells without any apparent specialization at the end. The zona pellucida is a thick acellular region surrounding the oocyte. Long filamentous projections, called trans-zonal processes, originate from cumulus cells and cross the zona pellucida. At the oocyte, the ends of these processes form a specialized structure which are the sites of gap junctions between cumulus cells and the oocyte. We suggest that cytonemes have cell to cell functions between cumulus / granulosa cells, but they also can traverse the zona pellucida and become induced to form a trans-zonal process when they contact the oocyte.

Intersectin-1 mediates recruitment of AP-2 and clathrin to Vaccinia virus.

X. Snetkov¹, I. Weisswange², A.C. Humphries³, M. Way⁴;

¹Cell Motility Group, London Research Institute - Cancer Research UK, London, England, ²Eupheria Biotech, Dresden, Germany, ³Developmental and Regenerative Biology, Icahn School of Medicine at Mount Sinai, New York, NY, ⁴Cell Motility Group, London Research Institute - Cancer Research UK, London, UK

Immediately following fusion with the plasma membrane, Vaccinia virus recruits clathrin in an AP-2 dependent fashion before undergoing actin-based motility. The recruitment of clathrin helps polarize the integral viral membrane protein, A36 beneath the virus. Polarization of A36 in turn leads to clustering of N-WASP enhancing Arp2/3 complex dependent actin polymerisation to promote viral spread.

We now sought to uncover the molecular basis by which Vaccinia recruits clathrin via its adaptor protein AP-2. Using a combination of approaches we have uncovered that AP-2 and clathrin recruitment is dependent on three NPF (Asn-Pro-Phe) motifs in the C-terminus of A36. These NPF motifs mediate clathrin recruitment by interacting with the Epsin15 Homology (EH) domains of intersectin-1. A recombinant A36 Vaccinia virus lacking all three NPF motifs is deficient in intersectin-1, AP-2 and clathrin recruitment. This results in a delay in the initiation of actin polymerization and a decrease in viral spread

that is reminiscent to that seen in the absence of clathrin.

To our knowledge A36 represents the first viral protein containing NPF motifs that interacts with endocytic machinery. The three NPF motifs are highly conserved in A36 homologues in other Orthopoxviruses, suggesting they provide a selective advantage for viral spread. The presence of the NPF motifs is also predicted to aid recycling of viral proteins from the plasma membrane to the TGN for additional cycles of viral assembly. Future studies will examine if this is the case and the role of other endocytic components in viral assembly.

Plasma Membrane Tension Triggers Adhesion Positioning in the Leading Edge of Cells.

N. Gauthier¹, B. Pontes¹, L. Gole¹, P. MONZO², W. Luo³, V. Viasnoff^{4,5}, T.Z. Yang¹, L. Tucker-Kellogg¹; ¹Mechanobiology Institute, Singapore, Singapore, ²Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ³National University of Singapore, Singapore, Singapore, ⁴MBI/DBS, Mechanobiology Institute, Singapore, Singapore, ⁵UMI3639, CNRS, Singapore, Singapore

Cell migration is dependent on adhesion deposition and actin cytoskeleton remodeling at the leading edge. These events may be physically constrained by the plasma membrane. Here, we report that the mechanical signal produced by an increase in plasma membrane tension triggers the positioning of new rows of adhesions at the leading edge. During lamellipodial protrusion, as membrane tension increases, the protrusion velocity slows, and the polymerizing actin buckles upward in a myosin II independent manner. The buckling occurs between the front of the lamellipodium, where nascent adhesions are deposited in rows (containing integrin, paxillin, vinculin, talin, vasp and zyxin) and the base of the lamellipodium, where a vinculin-dependent clutch couples actin to previously deposited adhesions. As membrane tension decreases, protrusion resumes and buckling disappears until the next cycle. We propose that the mechanical signal of membrane tension exerts an upstream control in mechanotransduction by periodically compressing-relaxing the lamellipodium.

Role of actin filaments in mobility of connexin 36 in HeLa cells.

H. Wang^{1,2}, B. Chen³, C.K. Mitchell², E. Betzig³, J. O'Brien^{1,2};

¹Graduate School of Biomedical Sciences, University of Texas Health Science Center at Houston, Houston, TX, ²Dept. of Ophthalmology and Visual Science, University of Texas Health Science Center at Houston, Houston, TX, ³HHMI/Janelia Farm Research Campus, Ashburn, VA

Electrical synapses formed of the gap junction (GJ) protein Cx36 exhibit a high level of functional plasticity. Changes in connexin phosphorylation alter channel permeability on a minutes time scale,

while connexin turnover may alter channel abundance on longer time scales of minutes to hours. In order to better understand mechanisms of turnover we studied the role of cytoskeletal elements, actin filaments in particular, in Cx36 vesicle trafficking and GJ mobility. We utilized HaloTag technology with fixed and live-cell imaging to track the movement of Cx36 GJ plaques and vesicles in transiently transfected HeLa cells. The HaloTag protein forms irreversible covalent bonds with chloroalkane ligands, allowing specific protein labeling. The HaloTag open reading frame was inserted into an internal site in the C-terminus of Cx36 designed not to disrupt regulatory phosphorylation sites or C-terminal protein-protein interactions of Cx36. Pulse-chase labeling with fluorescent HaloTag ligands allowed clear discrimination of newly formed and pre-existing Cx36. Cx36-Halo formed large junctional plaques at sites of contact between transfected HeLa cells and was also contained in many intracellular vesicles. Phalloidin labeling showed that thick actin bundles connected all edges of GJ plaques, but actin filaments were rare within any plaque. Actin filaments were also found associated with small, chase-labeled delivery vesicles. Many GJs showed substantial numbers of finger-like filadendrites extending from both the edges and the center of the plaques, and the morphology of these filadendrites changed at a fast pace. These filadendrites consisted solely of pulse labeled Cx36, and their morphology was constantly rearranged by breaking off and fusing back with the plaques. Double labeling of HaloTag ligand and phalloidin showed that these filadendrites colocalized with thin actin filaments. Disruption of actin filaments with Cytochalasin D by binding to F-actin polymers caused loss of GJ at cell-cell contacts. Treatment with Latrunculin A, which binds to actin monomers and prevents polymerization and filament elongation, did not disrupt GJ plaques and only partially suppressed Cx36 turnover, but eliminated the filadendrite extensions. We conclude that actin bundles are critically important for the stabilization of Cx36 GJ plaques and that actin filaments are involved in the dynamic mobility of these plaques. The role of rapid mobility of elements of GJ plaques in functional plasticity is unknown, but we hypothesize that it is related to the mechanisms that control turnover of connexin protein.

Novel roles for cholesterol and the cytoskeleton in the formation of neutrophil extracellular traps.

M. Liu^{1,2,3}, M. Bashir^{1,2}, K.J. Williams³, V.P. Werth^{1,2};

¹Dermatology, University of Pennsylvania, Philadelphia, PA, ²Philadelphia VA Medical Center, Philadelphia, PA, ³Medicine, Temple University, Philadelphia, PA

Background/Purpose: The role of neutrophils in immunity has drawn increasing attention over the last decade. A recently discovered structure made by these cells, neutrophil extracellular traps (NET), form from disintegration of the nuclear envelope and mobilization of nuclear material from the nucleus to the extracellular milieu. NETs have been found to be important in infectious, autoimmune and cardiovascular diseases. Recent articles reported the presence of NETs in atherosclerotic lesions, and NETs promote thrombosis. Blockade of peptidylarginine deiminase, an enzyme that mediates chromatin decondensation and NET formation, attenuates atherosclerosis burden and arterial thrombosis in mice.

Hypercholesterolemia is a primary risk factor for athero-thrombotic cardiovascular diseases. However, the effect of cholesterol loading on NET formation and the relevant cellular mechanisms have not been investigated.

Methods: Primary human neutrophils were isolated from the blood of healthy donors by sequential centrifugation with Histopaque 1077 and 1119. Exogenous cholesterol was delivered to these cells as a water-soluble complex with methyl- β -cyclodextrin (MCD, Chol/MCD), which has been widely used to modify the cholesterol content of cultured cells without potentially confounding effects from receptor engagement. Incubations lasted for up to 6 hours, followed by fixation with 2% PFA and then Sytox Green staining for NET formation. In some experiments, neutrophils were pretreated with inhibitors of myosin II ATPase (blebbistatin) or myosin light chain kinase (ML7), or with the inhibitors of actin (Cytochalain D) or microtubule (Cochicine and XRP44) polymerization.

Results: We found that cholesterol loading with Chol/MCD induced NET formation in a dose-dependent manner in primary neutrophils, as quantified by a fluorescent microplate reader and the NET structure confirmed with fluorescent microscopy. Inhibition of myosin II ATPase or myosin light chain kinase, or inhibition of actin or microtubule polymerization by pretreatment of neutrophils with their inhibitors significantly attenuated cholesterol-induced NETosis in vitro.

Conclusion: Our studies indicated that cholesterol loading induces neutrophil extracellular trap formation in vitro. Inhibition of actin and microtubule cytoskeletal machinery attenuates cholesterol loading induced NETosis. Our findings may provide a mechanistic basis for the role of neutrophils and NETs in complications of hypercholesterolemia.

Cholesterol regulation plays a crucial role in our physiology, with high levels resulting in formation of atherosclerotic plaques, stroke and cardiovascular diseases. Cholesterol lowering drugs, such as statins, are ubiquitous means to treat these diseases by inhibiting HMG-CoA reductase, which regulates cholesterol synthesis. Recently, statins are also being used to prevent cardiovascular diseases in individuals with normal cholesterol levels which might cause a drastic diminishment in their cholesterol levels. The consequences of reduced levels of cholesterol on cell physiology have not been well

explored, specifically; the effects on cardiac cells. In this work we have studied the effects of cholesterol depletion in neonatal rat cardiomyocytes using M β CD, a cyclodextrin that depletes cholesterol from the plasma membrane, and H γ CD, a cyclodextrin that has low affinity for cholesterol, as a control. By using immunofluorescence we observed that cholesterol depletion impacted the organization of striated myofibrils, changing the density and distribution of α -actinin bands. To assay the mechanical consequences of this altered actin cytoskeleton, we examined the contractility of myocytes and we found that cholesterol depletion increased the rate and variability of cell contraction. We also measured changes in the cortex mechanics by pulling tethers using optical tweezers and found that cholesterol depletion increased both the surface tension and bending modulus in those cells. Overall, these results bring the attention to possible side effects of cholesterol lowering therapies in normal individuals.

Membrane retrieval coincides with the filopodia formation in the neuronal growth cone.

M. Nozumi¹, M. Igarashi¹;

¹Dept Neurochem and Mol Cell Biol, Niigata Univ Grad Sch Med Dent Sci, Niigata, Japan

The neuronal growth cone is a motile tip of the growing neurite at the times of the neuronal development and the regeneration. At the leading edge of the growth cone, the continuous rearrangement of actin cytoskeletons, and the membrane retrieval from the plasma membrane, are observed. These two events should be essential to the accurate navigation of neurite, however, the relationship between them is not clearly understood. To visualize the vesicular trafficking and actin reorganization of the growth cone in detail simultaneously, we analyzed the dynamics of GFP-synaptophysin and mCherry-actin in the growth cone of NG108-15 cells, using a superresolution microscopy SR-SIM. We found that the vesicles arose near the filopodia, and most of them were retrogradely moving along the actin bundles. When actin polymerization inhibited by latrunculin B, such vesicles accumulated at the leading edge, accompanied with disappearance of the actin bundles. RNAi of fascin also decreased the numbers of vesicles localized at the leading edge. Moreover, Eps15, a component of clathrin-mediated or -independent endocytosis, was localized along the actin bundles. These results suggest that there is a novel mechanism of membrane retrieval in the growth cone; the vesicle production by endocytosis occurring at the leading edge, coincides with filopodia formation and these vesicles are moving along the retrograde flow of the actin.

P1681**Board Number: B193****Mechanochemical model of cell blebbing with actin cortex healing allows elucidation of traveling bleb dynamics.**K. Scannell^{1,2}, J.F. Allard^{1,2,3};¹Dept. of Mathematics, University of California, Irvine, Irvine, CA, ²Center for Complex Biological Systems, University of California, Irvine, Irvine, CA, ³Dept. of Physics and Astronomy, University of California, Irvine, Irvine, CA

Blebs are pressure-driven cell protrusions implicated in cellular functions such as cell division, apoptosis, and cell motility including motility of protease-inhibited cancer cells. Because of their mechanical nature, blebs can inform us about general cell mechanics including membrane dynamics, pressure propagation throughout the cytoplasm, and the architecture and dynamics of the actin cortex. Mathematical models including detailed fluid dynamics have previously been used to understand bleb expansion. Here we develop mathematical models that recapitulate the full bleb life cycle, including both expansion and healing by cortex reformation. The model can be reduced to a set coupled partial differential equations with a non-diffusion-like spatial operator, amenable to two-component phase-plane analysis. The model provides conditions under which blebbing occurs, and predicts how bleb size and shape vary with experimentally-accessible biophysical parameters such as myosin contractility, osmotic pressure, and turnover of actin and ezrin. The model also exhibits traveling blebs that move along the cell periphery. We predict the conditions under which blebs travel or remain stationary, and predict the bleb traveling velocity, a quantity that has remained elusive in previous models.

P1682**Board Number: B194****MyoGEF localizes to the bleb membrane and promotes bleb retraction.**M. Jiao¹, D. Wu¹, S. Zu¹, C.C. Sollecito¹, A.J. Mold¹, K. Jimenez-Cowell¹, Q. Wei¹;¹Department of Biological Sciences, Fordham Univ, Bronx, NY

Membrane blebbing has been implicated in cytokinesis, cell migration, and apoptosis. The life cycle of a bleb consists of initiation, expansion, and retraction. Following bleb initiation and expansion, re-assembly of a contractile actomyosin network underneath the bleb membrane results in bleb retraction. RhoA/Rho-kinase (ROCK) signaling can stimulate the formation of the contractile actomyosin cytoskeleton. Rho GTPase proteins such as RhoA are primarily activated by guanine nucleotide factors (GEFs). It is generally thought that RhoA can promote bleb retraction by driving the re-assembly of a contractile actomyosin network underneath the bleb membrane. However, it is still unclear how GEFs are implicated in promoting bleb retraction through activation of RhoA at the bleb membrane. MyoGEF is a GEF that can promote cytokinesis and breast cancer cell invasion through activation of RhoA. Here we report that MyoGEF is implicated in the regulation of membrane blebbing. Live cell imaging analysis shows that MyoGEF colocalizes with ezrin, a membrane-cortex linker, to the bleb membrane during late

stages of bleb expansion. More importantly, the arrival of ezrin and MyoGEF at the bleb membrane is coincident with bleb retraction. We propose that the ezrin-MyoGEF interaction results in the recruitments of MyoGEF to the bleb membrane, where MyoGEF activates RhoA and promotes the assembly of a contractile actomyosin network, leading to bleb retraction.

Re-organization of the local membrane environment upon Integrin engagement.

J.M. Kalappurakkal¹, S. Ghosh¹, S. Mayor¹;

¹National Centre for Biological Sciences (NCBS), TIFR, Bangalore, India

The plasma membrane of the living cell acts as an interface between the cell and its external milieu. It serves as a dynamic conduit for information transduction and response. It has been proposed that the regulated lateral segregation of plasma membrane associated molecules into distinct domains help in coordinating various signal transduction functions. Previous work from our laboratory and others has shown that proteins such as the outer leaflet GPI-anchored proteins, the inner leaflet Ras proteins and several glycolipids form dynamically reorganizing domains consisting of nanometer sized clusters^[1]. These passive molecular arrangements are a consequence of the local dynamics and organization of cortical actin filaments^[2]. In contrast, we had proposed that signaling receptors such as the Integrin receptors actively regulate the composition of the membrane in their vicinity by controlling the actin dynamics. Integrins represents a family of hetero-dimeric trans-membrane receptors that link extracellular ligands to a multitude of signaling and structural molecules^[3]. Although previous experiments have reported that the zones of integrin activation are enriched in lipid-raft like elements^[4,5], the molecular mechanism as well as the physiological relevance of creating such domains has not been explored.

Here we present our understanding of the molecular machinery that regulates the dynamics of cortical actin filaments, which in turn facilitate the generation of localized actin asters that leads to the active focusing of cell surface molecules. Using the technique of homo-FRET based fluorescence emission anisotropy, we report that the engagement of integrins that bind the extracellular matrix ligand fibronectin, results in the enrichment of GPI-anchored proteins clusters in the vicinity of the activated receptor. Our results suggest that Integrin receptors may fine-tune membrane organization by exploiting the mechanism regulating the dynamic cortical actin filaments, thereby facilitating the creation of localized domains. The subsequent recruitment of molecules that have an affinity for these domains is likely to play an important role in the regulation of Integrin function itself.

Role of Bar-domain containing protein Syndapin in remodeling actin in the early *Drosophila* embryo.

A. Sherlekar¹, P. Richa¹;

¹Indian Inst Science Ed/Res, Pune, India

Rapid remodeling of the plasma membrane (PM) and actin cytoskeleton is crucial during the syncytial stages of development in the *Drosophila* embryo where rapid and concerted nuclear divisions occur in mitotic waves across the length of the embryo. Syndapin has an F-Bar domain that can induce membrane curvature as well as SH3 domain that is known to interact with actin-modulating proteins N-Wasp and Anillin and is thus poised to orchestrate concerted membrane and actin remodeling. We have investigated the role of Syndapin in these syncytial stages of *Drosophila* embryo development. Like Actin, Syndapin is localized along both the apical and lateral membranes during the syncytial nuclear cycles, with a distinct enrichment at the tip or furrow canal. Syndapin mutant embryos show depletion of both Syndapin and Actin levels. This has distinct morphological effects during the syncytial cycle – defects in separation of nuclei and apical caps and shorter membrane furrows are seen. These defects could be in part due to a lowering and mislocalization of cytokinetic proteins Anillin and a member of the septin family, Peanut. We examined the distribution of Syndapin in Anillin and Peanut mutant embryos to test for their interdependence for associating with the PM. Anillin mutant embryos showed both Peanut and Syndapin mislocalization from the membrane. Peanut mutant embryos, however, showed only partial Anillin mislocalization and normal Syndapin. These data together confirm the requirement of Anillin and Syndapin on the PM for proper association of Peanut to give rise to concerted actin cap and membrane remodeling during the syncytial cycles. Actin cap morphology was further assessed in detail using live imaging with lifeact-GFP using Confocal and TIFR microscopy. Actin protrusions were found to remain longer in Syndapin mutant embryos during the syncytial cycles as compared to wildtype where the size of protrusions was relatively longer in interphase. There were also a greater number of protrusions with greater residence time, further illustrating poor actin remodeling. These defects could be explained due to a mislocalization of Arp2/3 on the PM. While fluorescently-tagged actin-associated proteins marked protrusions on the PM surface, Syndapin-GFP showed a remarkable punctate pattern, suggesting localization to the tip of the protrusion on the PM cortex. Taken together, our data shows that Syndapin recruitment along with Anillin and Arp2/3 is required for actin remodeling on the apical membrane and in furrows in metaphase to maintain membrane and actin dynamics in the early *Drosophila* embryo.

P1685**Board Number: B201****Contact Localized β -actin Translation Drives Epithelial Adherens Junction Assembly and Establishes Tissue Barrier Permeability.**N. Gutierrez¹, A.J. Rodriguez¹;¹Federated Department of Biology, Rutgers University, Newark, NJ

Adherens junctions are multi-protein adhesion complexes that anchor to the actin cytoskeleton at cell-cell contact sites to stimulate tissue assembly and thereby regulate embryonic development, barrier maintenance, and epithelial tissue homeostasis. Previously it was demonstrated that the mRNA for β -actin contains a nucleotide sequence in its 3' UTR, called the zipcode, which is necessary for targeting and translational regulation of this transcript. The zipcode sequence is recognized by the translation regulator zipcode binding protein-1, ZBP1. Additionally, deleting zipcode sequences causes mislocalization of their mRNA transcript. Here we show mislocalizing β -actin's monomer synthesis inhibits adherens junction assembly following epithelial cell-cell contact. Additionally, inhibiting RhoA and Src signaling, required for β -actin mRNA zipcode-mediated spatially regulated β -actin translation, prevents adherens junction assembly and significantly perturbs epithelial barrier integrity. In fact, barrier permeability significantly increases in epithelial cells expressing β -actin transcripts without the 3' untranslated region (Δ 3'UTR- β -actin) during TransWell tissue permeability experiments. Moreover, in full-length β -actin GFP (FL- β -actin GFP) expressing cells, β -actin mRNA zipcode antisense oligonucleotide masking of the zipcode sequence also perturbs barrier maintenance. Intriguingly, chemically inhibiting the signaling pathways required for β -actin mRNA localization and local translation (RhoA and Src) also perturbs epithelial barrier maintenance. Taken together we demonstrate epithelial cell-cell contact stimulates E-cadherin mediated signaling to spatially regulate β -actin mRNA zipcode-dependent monomer synthesis thereby driving adherens junction assembly and tissue adhesion required for proper epithelial tissue function.

P1686**Board Number: B202****Septins are essential for tissue integrity during epithelial morphogenesis.**M. Mavrikis¹, Y. Azou-Gros¹, A. Kress², S. Brasselet², T. Lecuit¹;¹Institut de Biologie du Développement de Marseille, CNRS UMR 7288, Marseille, France, ²Institut Fresnel, CNRS UMR 7249, Marseille, France

Septins are highly conserved cytoskeletal proteins that have been mostly studied in dividing cells. Besides their role in cytokinesis, recent studies suggest that septins might regulate the organization of the actin cortex in nondividing cells. However, the precise contribution of septins to the architecture of the cortex in nondividing cells is still unknown, and the molecular functions of septins altogether are poorly understood. To test the role of septins in actin-driven cell shape changes *in vivo*, we studied

epithelial tissue morphogenesis using the gastrulating *Drosophila* embryo as a model system. To study the architecture of the actin cortex and the overall organization of the epithelial tissue during morphogenetic movements, we used a combination of live two-photon imaging, transmission and scanning electron microscopy and polarization-resolved fluorescence microscopy in wild-type and septin-deficient whole embryos. Importantly, septins appear to have a major role in maintaining the integrity of the remodeling epithelial tissue. In the absence of septins, epithelial polarity is lost, the bases of epithelial cells open up, cell membranes undergo excessive blebbing and are eventually fragmented leading to the complete loss of cell integrity and the collapse of the epithelial tissue within an hour after the onset of gastrulation. We will discuss these findings in the context of our recent report on the capacity of septins to cross-link and organize actin filaments in contractile rings (Mavrakakis et al, 2014).

Actomyosin drives membrane dynamics in an in vitro active composite layer.

D.V. Köster¹, K. Husain¹, E. Iljazi¹, P. Bieling^{2,3}, R.D. Mullins², M. Rao^{1,4}, S. Mayor¹;

¹National Centre for Biological Sciences (NCBS), TIFR, Bangalore, India, ²Department of Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA, ³Department of Bioengineering, University of California, Berkeley, Berkeley, CA, ⁴Raman Research Institute, Bangalore, India

The surface of a living cell provides a platform for processes such as receptor signaling, protein sorting, transport and endocytosis. The regulation of these processes requires the controllable organisation of membrane components. A recent framework for the organisation of a certain class of plasma membrane components is based on the active mechanics of acto-myosin juxtaposed to the membrane (Gowrishankar et al., 2012; Rao & Mayor, 2014). A systematic study of the dynamics and consequences of this active composite in living cells is challenging. Here we reconstitute an active composite in vitro, by a stepwise addition of the minimal ingredients: a supported lipid bilayer with an actin-binding component, short actin filaments and myosin motors. By systematically varying the concentrations of actin and myosin as well as the level of ATP we find a rich phase diagram of membrane-confined actin and myosin configurations. By increasing the level of available ATP we induce a constitutively remodeling state, in which asters composed of short actin filaments form and dissolve. In this state, the coupling of actin to the bilayer drives the membrane components out of equilibrium, imparting distinct signatures of activity in a manner entirely consistent with measurements in the living cell. These results highlight the fundamental basis of the active composite framework and indicate its relevance in the study of membrane organisation.

P1688**Board Number: B204****Microvillar tip-localized interaction between IRSp53 and PI(4,5)P₂ drives brush border assembly in kidney epithelial cells.**S. Kurisu¹, T. Itoh¹, T. Takenawa¹;¹Kobe Univ. Biosignal Research Center, Kobe, Japan

Kidney epithelial cells lining the proximal tubule develop a highly ordered, closely packed array of actin-based protrusions, known as brush border microvilli. Despite their importance in renal resorption, little is known about the shape regulation of membrane-cytoskeleton organization. Initially, we found that IRSp53, a member of the I-BAR family proteins, is concentrated at the tip of brush border microvilli both in the proximal tubule of mouse kidney and in cultured cells. Depletion of IRSp53 resulted in severe impairment of brush border formation. Each microvillus became short and dynamic in contrast to an ordered array of static microvilli of control cells, indicating a role for IRSp53 in converting short individual microvilli into a bunch of long microvilli forming brush border. Using stable cell lines that express several different GFP-tagged PH domains that recognize a specific phosphoinositide species, we show that IRSp53 induces brush border formation by binding to PI(4,5)P₂ at the tip of microvilli. As reported previously, the distal part of microvilli is enriched with PLCδ1-PH (δ1PH) domain, a PI(4,5)P₂ sensor. Notably, depletion of IRSp53 results in separation of PI(4,5)P₂-enriched membrane microdomains from microvillar F-actin bundles in the apical membrane. Expression of IRSp53 I-BAR domain mutants that are defective in phosphoinositide-binding show similar effects, indicating a possible role for the I-BAR domain in clustering PI(4,5)P₂ at the growing ends of microvilli. Surprisingly, a fusion protein consisting of δ1PH domain fused to IRSp53 I-BAR mutant induces ectopic brush border formation in basolateral membranes, suggesting that IRSp53 binding to PI(4,5)P₂ irrespective of the curved surface of I-BAR domain is sufficient to drive brush border assembly. The microvillar tip localization of IRSp53 is primarily governed by interaction with Eps8, a well-characterized interactor of IRSp53. Thus, in cells the interaction between IRSp53 and PI(4,5)P₂ only occurs at the tip of microvilli. Together, our data illustrate a previously unappreciated mechanism of brush border formation involving IRSp53 and PI(4,5)P₂.

P1689**Board Number: B205****Visualizing collective dynamics of endocytic proteins.**Y. Yang¹, M. Su¹, M. Wu¹;¹Mechanobiology Inst, Centre for BioImaging Sciences, Department of biological science, Natl Univ Singapore, Singapore, Singapore

Cdc42 and actin waves have been observed in multiple cellular contexts such as cell polarization, migration and divisions. Multiple models have proposed for the mechanisms of wave formation, with some involving vesicular trafficking and others not. In this work, we experimentally tested the

involvement of endocytosis in Cdc42 waves in stimulated mast cells 1 . Using total internal reflection fluorescence microscopy, we observed coordinated clathrin waves and Cdc42 waves. In addition, proteins involved in different modules of endocytic machinery(pit initiation, coat formation and scission) are sequentially recruited in the travelling waves in a manner similar to canonical clathrin-mediated endocytosis. Although clathrin may have intracellular localizations, assembly of these endocytic players, in particular, plasma membrane-specific adaptor proteins (AP2 and FCHO1) supports the plasma membrane association of the clathrin waves. Furthermore, the membrane identity of the travelling waves can be determined using optogenetic tool to deplete phosphatidylinositol 4,5-bisphosphate. Finally, perturbation of the endocytic machinery inhibits wave formation. Collectively our results indicates that endocytic waves not only accompanies but also upstream of actin and Cdc42 waves in stimulated mast cells.

Microtubule-dependent actin polymerization is necessary for growth cone protrusion in developing rat hippocampal neurons.

J. Chia¹, T. Svitkina¹;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA

Major cytoskeletal components, actin filaments and microtubules, play important roles in cells motility. Actin polymerization is the major mechanism to drive plasma membrane protrusion, adhesion and contraction in motile cells whereas microtubules are responsible for directional migration via poorly understood mechanisms. In neuronal growth cones, microtubules are believed to be capable of driving membrane protrusion in an actin-independent manner, because actin polymerization inhibitors enhance neurite elongation. We demonstrate contrary to this assumption that actin polymerization is necessary for neurite elongation in developing rat hippocampal neurons treated with varying concentrations of the actin polymerization inhibitors latrunculin B and cytochalasin D. Specifically, F-actin is invariably located at the tip of elongating neurites independent of the concentration of the inhibitors. We confirm that although neurites can grow longer than controls in the presence of low concentrations of the inhibitors, they cannot at higher concentrations, supporting the idea that neurite growth requires actin polymerization. Using platinum replica electron microscopy in combination with immunogold labeling, we report that branched actin filament networks physically associate with the tips of microtubules and occupy the foremost position at the leading edge of both drug-treated and untreated growth cones, whereas distal tips of microtubules lag behind. These data suggest that Arp2/3 complex-dependent actin polymerization, rather than growing microtubules, are responsible for neurite elongation in the presence of actin polymerization inhibitors. More importantly, our results suggest that actin

polymerization off microtubule tips can represent a mechanism by which microtubules guide directional cell migration.

¹Physiology, University of Pennsylvania, Philadelphia, PA, ²Department of Biology, University of Pennsylvania, Philadelphia, PA, ³Physiology, University of Pennsylvania, Philadelphia, PA, ⁴Physiology, University of Pennsylvania, Philadelphia, PA, ⁵Physiology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

PICK1 (Protein Interacting with C-Kinase1) is a key regulator of receptor trafficking in neuronal cells and synaptic plasticity. PICK1 consists of an N-terminal PDZ domain, a central BAR domain, and a C-terminal acidic domain (CTail). The dimeric BAR domain mediates membrane binding and curvature inducing/sensing. The PDZ domain links PICK1 to the tails of receptors. Small angle x-ray scattering analysis yields a model that places the membrane-binding surfaces of the BAR and PDZ domains adjacent to each other, on the concave side of the banana-shaped PICK1 dimer. Full length PICK1 shows cytosolic distribution but it clusters on vesicles upon deletion of the CTail or PDZ domain. Activation is expected to expose the PDZ domain for binding to receptors at the plasma membrane. CTail containing PICK1 associated vesicles moves faster than the CTail deletion constructs. Thus, the CTail links PICK1-associated vesicles to motility factor, but in contrast to previous reports PICK1 neither binds nor activates Arp2/3 complex.

¹Department of Biomedical Engineering, Pennsylvania State University, University Park, PA, ²Interdisciplinary Graduate Degree Program in Bioengineering, Pennsylvania State University, University Park, PA, ³Physical and Theoretical Chemistry Laboratory, Oxford University, Oxford, UK

Kinesin-1 is the most well studied member of the kinesin superfamily of molecular motors and is responsible for the trafficking of vesicles and organelles towards terminal branches of axons. This motor hydrolyzes ATP in a tightly coupled fashion in order to take directed 8 nm steps along a single

protofilament of a microtubule. However, the comprehensive mechanochemical cycle of kinesin-1 remains elusive, due largely to the technical limitations of fluorescence spectroscopy and microscopy approaches at the single-molecule level. Questions remain in identifying the rate limiting step in the hydrolysis cycle as well as the time spent in the one head bound state. To address these questions, we employ a fluorescence-free imaging technique, interferometric scattering microscopy (iSCAT), to track kinesin-1 at saturating ATP in a reconstituted system with greatly improved spatiotemporal resolution. With point spread function fitting, 8 nm and 16 nm steps are measured for C-terminus and N-terminus labeled motors, respectively. Using novel differences of means and Gaussian mixture model algorithms for the identification of step and sub-step regimes, we investigate the information present in both on-axis and off-axis positional data. Overall, these results point towards new insights into mechanochemical cycle of kinesin-1. The optical system and data analysis tools used present a new platform for investigating the stepping cycles of diverse molecular motors.

In early *Drosophila* embryos, lipid droplets exhibit highly coordinated bidirectional transport, powered by Kinesin-1 and cytoplasmic Dynein. Motor activity on droplets is temporally regulated, resulting in global shifts of the entire droplet population as embryogenesis proceeds. Three phases can be distinguished (I, II, and III). The novel protein Halo is the key factor controlling this timing; its new expression mediates the switch to net plus-end transport in Phase II, by upregulating Kinesin-1 and downregulating Dynein activity on lipid droplets (Gross et al., 2003). During Phase III, Halo mRNA and protein levels drop sharply and net motion is minus-end directed. We find that in embryos mutant for the *lin-41/TRIM71* ortholog *Wech*, Halo mRNA and protein levels remain high and motion stays plus-end directed in Phase III; thus, abrogating Halo expression may be essential for the switch in net directionality. The objective is to understand how Halo acts molecularly. Previous work suggested three models: 1) Halo is a member of a small family, and one member, SNCF, has been proposed to be a co-factor of a transcriptional activator. 2) Halo is necessary for the Phase II-specific dephosphorylation of LSD-2, a lipid-droplet protein from the Perilipin family, essential for proper temporal regulation of transport. 3) Data from high-throughput screens suggest that several Halo family members physically interact with motors. Thus Halo might be a transcription factor, a phosphatase acting on LSD-2, or a motor cofactor. We find that Halo's intracellular distribution is consistent with all three models: Halo is present in nuclei as well as in the cytoplasm, and a small fraction copurifies with lipid droplets. Providing Halo (from injected *halo* mRNA) is sufficient to affect droplet motion even when transcription is pharmacologically inhibited; thus, Halo does not control transport by regulating transcription. Epistasis analysis revealed that Halo modulates transport even in the absence of LSD-2; thus Halo can act

independent of LSD-2. Using immunoprecipitation, we find that Halo and Kinesin-1 exist in common protein complexes in the embryo cytoplasm. Kinesin-1 and Halo indeed function in the same pathway as absence of either leads to failure of net plus-end transport during Phase II. Reducing Halo dosage delays this net plus-end transport, but – surprisingly – when levels of Halo and Kinesin-1 are reduced simultaneously, transport kinetics reverts back to wild type. We show that the critical parameter is the Kinesin-1/Halo ratio and propose that Halo is a limiting cofactor whose binding to Kinesin-1 increases motor processivity. Halo's inhibitory effect on Dynein may also be mediated by binding of Halo to the motor as Halo coimmunoprecipitates Dynein as well.

Intraflagellar transport (IFT) is essential for building and maintaining cilia, the microtubule-based mechanosensory organelles of eukaryotic cells. In the chemosensory cilia of *Caenorhabditis elegans* two kinesin-2-family motors, kinesin-II and OSM-3, cooperate to drive IFT-trains that deliver ciliary cargo along the axoneme; consisting of doublet microtubules (the middle segment) that extend into singlet microtubules (the distal segment). Both kinesins are active in the middle segment, however, OSM-3 alone maintains and builds the distal segment. It is unclear how these two different kinesins collaborate and why their cooperation is beneficial to the IFT-system. Here, we study the dynamics of fluorescently labeled kinesins expressed at endogenous levels using ultrasensitive fluorescence microscopy to reach single-molecule sensitivity deep inside living *C. elegans*. Novel automated kymograph analysis tools and single-particle tracking analysis, provides unprecedented, quantitative insight into the cooperation between both kinesins. We reveal that the two kinesins have different roles, closely connected to their individual motility parameters. Kinesin-II, the slower and less processive motor, is mainly active at the ciliary base and the transition zone (a complex structure close to the base that is thought to function as a "ciliary gate"). Kinesin-II is responsible for loading IFT-trains and subsequent navigation through the protein dense transition zone. Once the IFT-trains have traversed this zone, kinesin-II gradually undocks, while the faster and more processive OSM-3 motor starts to dock on the IFT-trains propelling them towards the ciliary tip. This intricate, dynamic interplay between kinesin-II and OSM-3, ensures reliable entry, handover, and fast distribution of the IFT-trains. Our results demonstrate the power of *in vivo* single-molecule fluorescence microscopy to unravel motor cooperation and, more generally, motor-driven intracellular processes.

Members of the kinesin superfamily are characterized by a conserved motor domain but there is a significant variability in the length and predicted structure of their stalk domains. Centromere-associated protein E (CENP-E) is kinesin-7 with a 230 nm long discontinuous coiled-coil stalk, which based on electron microscopy imaging is predicted to be flexible (persistence length 26 nm). The biological role of this unusual stalk is not known but its highly extended length has been proposed to facilitate kinetochore capture of microtubules by searching a cytoplasmic volume. Interestingly, a mutant "Bonsai" version of CENP-E with a shortened stalk fails to support normal chromosome segregation during mitosis. To test whether CENP-E kinesin can provide a long reach from a cargo to microtubules we developed a modified Tethered Particle Motion (TPM) assay. Traditionally this method is used to analyze thermal motion of beads attached to a substrate via dsDNA molecules of a known length. However, microtubule-free CENP-E molecules are folded due to auto-inhibition, prohibiting analysis of this kinesin's conformation by TPM. Instead, we analyzed motions of the beads carried along the microtubules by the walking motors. To validate this approach we used a well-characterized kinesin-1, which was conjugated to the bead's surface via dsDNA 200 nm in length. We show that such assay, which we have called Tethered Cargo Motion (TCM) assay, provides a good measure of the tether length between the moving bead and microtubule, but the radial bead excursions can be underestimated due to several factors: non-specific motor absorption, multiple motor attachments and excessive density of dsDNA linkers. We then used the TCM assay to estimate the tether length formed by the walking CENP-E motor. We show that truncated CENP-E kinesin with no stalk behaves like a 2-5 nm tether, as expected. However, the full length CENP-E is not fully extended and behaves as a short tether with length.

P1696**Board Number: B213****Pavarotti/MKLP1 regulates microtubule sliding and neurite outgrowth in *Drosophila* neurons.**U. del Castillo¹, W. Lu¹, M. Winding¹, M. Lakonishok¹, V.I. Gelfand¹;¹Department of Cell and Molecular Biology, Northwestern University, Feinberg School of Medicine, Chicago, IL

Sliding of microtubules against each other, driven by kinesin-1, generates the mechanical force required for initial neurite extension in *Drosophila* neurons. This sliding is only observed in young neurons actively forming neurites and dramatically downregulated in older neurons. The downregulation of sliding is not caused by the global shut-down of kinesin-1, as the ability of kinesin-1 to transport membrane organelles is not diminished in mature neurons, suggesting that microtubule sliding is regulated by a dedicated mechanism. Here we identified a “mitotic” kinesin Pavarotti (Pav-KLP) as an inhibitor of microtubule sliding. Depletion of Pav-KLP from neurons strongly stimulated the microtubule sliding and neurite growth, while ectopic overexpression of Pav-KLP in the cytoplasm blocked both sliding and neurite extension. Furthermore, postmitotic depletion of Pav-KLP in *Drosophila* neurons in vivo reduced embryonic/larval viability, with only a few animals surviving to the third instar stage. In agreement with data observed in cultured neurons, surviving *elav>Pav* RNAi larvae showed overextended neurite outgrowth and mistargeting of motor neuron axons. Taken together, our results identify a new role for a “mitotic” kinesin as a negative regulator of neurite formation, and suggest an important parallel between microtubule-microtubule sliding in the mitotic spindle and sliding of interphase microtubules during formation of cellular processes.

P1697**Board Number: B214****Short stop mediates a regulatory actin-microtubule interaction to control cell shape.**M. Winding¹, V.I. Gelfand¹;¹Department of Cell and Molecular Biology, Northwestern University, Feinberg School of Medicine, Chicago, IL

The formation of processes by neurons is fundamental to neurodevelopment and the establishment of an interconnected nervous system. Neurons start as spherical cells and must break symmetry and extend processes called neurites. Our lab has recently demonstrated that microtubule-microtubule (MT) sliding by kinesin-1 is required for this dramatic change in cell shape. MT sliding occurs in many cell types besides neurons and yet these cells do not change shape or form cellular processes, suggesting regulatory mechanisms are present. In order to uncover this regulation, we utilized cultured *Drosophila* S2 cells as a model. Disruption of the actin filament (F-actin) network by the actin-depolymerizing toxin

Latrunculin B (LatB) greatly increased MT sliding by kinesin-1 in S2 cells. Strikingly, as MT sliding increased with increasing LatB concentration, cells began forming processes. This result suggests that F-actin inhibits MT sliding and also prevents sliding microtubules from forming processes. In order to determine how F-actin prevents process formation, we knocked down several actin-binding proteins with dsRNA. Depletion of the actin-microtubule crosslinking protein, short stop (shot), was sufficient to relieve the effects of F-actin on MT sliding. However, shot knockdown alone was not sufficient to relieve the inhibition of process formation by F-actin. Only combined shot depletion and loss of retrograde actin flow at the cell lamella by knockdown of an Arp2/3 subunit, Arpc4, allowed S2 cells to extend large >20µm processes without depolymerization of F-actin. These results suggest that the formation of processes is regulated by the combined action of shot crosslinking microtubules to actin and retrograde flow of the actin network preventing kinesin-powered microtubules from pushing on the membrane.

Depletion of Kinesin-12, a myosin IIB interacting protein, promotes rat cortical astrocytes migration.

J. Feng¹, J. Hua¹, H. Chen¹, R. Wu¹, Z. Dong¹, Y. Liu¹, P.W. Baas², M. Liu¹;

¹Jiangsu Key Laboratory of Neuroregeneration, Co-innovation Center of Neuroregeneration, Nantong University, Nantong Jiangsu 226001, China, ²Department of Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA

Kinesin-12 is a member of a group of microtubule-dependent motor proteins that are known to play key roles in cell division, contributing to the formation of the mitotic spindle, chromosome separation and cytokinesis. We have found that some of these motor proteins continue to be expressed in terminally post-mitotic neurons, where they contribute to important events such as migration of young neurons through the brain and the establishment of axons and dendritic arbors. Kinesin-12 is a mitotic motor that participates in all of these events during neuronal development, and appears to do so by contributing to microtubule movements and organization. However, the molecular mechanisms of kinesin-12 function remain to be revealed. In addition, little is known about the roles kinesin-12 may play in other cell types of the nervous system. In the present study, we have shown that depletion of kinesin-12 from cultured rat cortical astrocytes decreases cell proliferation but increases cell migration. We previously reported that kinesin-12 interacts either directly or indirectly with actin, which distinguishes it from kinesin-5, another motor with some overlap in functions both in mitosis and in neurons. Here we show that kinesin-12 directly interacts with myosin IIB, a non-muscle myosin II heavy chain, via their tail domains by CO-IP, GST pull-down and siRNA experiments. In addition, we used the fluorescence resonance energy transfer (FRET) method to show the interaction of kinesin-12 with myosin IIB protein. Finally, immunostain analyses revealed co-localization of kinesin-12 and myosin IIB in the lamellar region of the astrocytes. We posit that kinesin-12 and myosin IIB together can form a hetero-oligomer that uses force to integrate microtubules and actin filaments in certain regions of various cell types that comprise the developing nervous system.

P1699**Board Number: B216****Septin 9 interacts with KIF17 and regulates kinesin binding to cargo and microtubules.**X. Bai¹, E.T. Spiliotis¹;¹Biology, Drexel University, Philadelphia, PA

Septins are hetero-oligomeric GTP-binding proteins that assemble into non-polar filamentous structures, which associate with membranes and the microtubule and actin cytoskeleton. In mammalian cells, septins bind and bundle microtubules (MTs) and affect MT dynamics and post-translational modifications. Septins are also required for chromosome congression and biorientation during mitosis and vesicle transport in interface cells. Previous work has shown that SEPT7 interacts with the mitotic motor CENP-E (kinesin 7), but the function(s) of septins in kinesin-mediated cargo transport are unknown. Here, we have identified SEPT9 as a novel interactor of the kinesin-2 motor KIF17. We show that SEPT9 interacts strongly with the cargo-binding C-terminal tail of KIF17 and weakly with its motor domain. Pull down experiments show that SEPT9 interacts with the tail of KIF17 in E18 rat brain and MDCK cell lysates. In vitro binding assays show that the interaction is specific for SEPT9 as SEPT2/6/7 do not interact with the KIF17 tail. Conversely, SEPT9 does not interact with the C-terminal tail of the kinesin 13 motor MCAK. We show that SEPT9 interacts with the same domain of the C-terminal KIF17 tail that binds Mint1(mLin10), a scaffold protein that mediates the interaction of KIF17 with membrane cargo such as the NMDA (N-methyl-D-aspartate) receptor subunit 2B (GluN2B). Similar to the effects on the interaction of Mint1 with KIF17, mutations in the last 3 amino acids of the KIF17 tail decreased SEPT9 binding. Moreover, competitive in vitro binding assays showed that SEPT9 competes with Mint1 for KIF17 tail binding. Because the tail of KIF17 interacts weakly with MTs and the motor domain of KIF17, which is autoinhibited by its tail domain, we asked how these interactions are affected by SEPT9. Biochemical assays indicate that SEPT9 competes with the C-terminal tail for binding to MTs and conversely, enhances KIF17 motor-tail binding. Taken together, these data suggest that SEPT9 would inhibit both GluN2B-KIF17 cargo binding and KIF17 motor movement. Preliminary experiments in E18 rat hippocampal neurons suggest that SEPT9 may indeed interfere with transport of GluN2B and KIF17 to dendritic processes. Our results indicate that membrane- and microtubule-bound septins could regulate the motility of kinesins at the levels of cargo- and microtubule-binding, respectively.

P1700**Board Number: B217****Characterization of two novel kinesins that localize to distinct cytoskeletal structures in the human pathogen *Toxoplasma gondii*.**J.M. Leung¹, Y. He¹, F. Zhang², Y. Hwang³, E. Nagayasu⁴, J.M. Murray¹, K. Hu⁵;¹Department of Biology, Indiana University, Bloomington, IN, ²School of Medicine, University of Miami, Miami, FL, ³Nikon Instruments Inc., Melville, NY, ⁴Department of Infectious Diseases, University of Miyazaki, Miyazaki, Japan, ⁵Department of Biology, Indiana University Bloomington, Bloomington, IN

Toxoplasma gondii is a protozoan parasite that chronically infects ~20% of the global human population; it can cause life-threatening complications in immunocompromised individuals and is a leading cause of congenital neurological defects. This parasite is also a powerful model organism for studying aspects of cell biology shared with less experimentally tractable members of the phylum Apicomplexa, including *Plasmodium* spp., the causative agents of malaria. *T. gondii* has at least five tubulin-containing structures: the spindle pole, centrioles, conoid, intraconoid microtubules as well as cortical microtubules that spiral down two-thirds the length of the parasite. These play a number of important roles in the parasite including providing a scaffold for daughter cell construction during endodyogeny, structural stability and maintenance of parasite shape. However, little is known about the molecular motors that associate with these structures, and what role(s) they play during the lytic cycle of the parasite. Here we characterize two novel kinesins, TgKinesins 1 and 2, that were previously identified by proteomic analysis to be enriched in the conoid and cortical microtubule fractions, respectively. Both kinesins are conserved in several other apicomplexan parasites including *Plasmodium* spp., *Neospora caninum* and *Eimeria* spp. Fluorescently-tagged kinesins had unique subcellular distributions in knockin parasites. TgKinesin1 co-localized with a marker for the apical polar ring, which is thought to be a microtubule organizing center (MTOC) at the base of the conoid. In contrast, TgKinesin2 localized to the cortical microtubules, but was excluded from the most apical third of the microtubules as delineated by the markers TgCentrin2 and TgISP1. Fluorescence recovery after photobleaching (FRAP) experiments suggest that the diffusion rate and/or turnover of both TgKinesin1 and TgKinesin2 is slow in mature parasites. These data suggest that not only do TgKinesins 1 and 2 localize to distinct structures within the parasite, but that TgKinesin2 can only access a defined region of the cortical microtubules. Experiments to determine the functionality of these two intriguing microtubule-associated motors is currently underway.

P1701**Board Number: B218****Kinesin-2 mediated axonal transport facilitates synaptogenesis in *Drosophila* Central Nervous System.**S. Dey¹, R. Chakraborti¹, S. Shirolkar¹, A. Sadananda¹, A. Jain¹, M. Girotra¹, K. Ray¹;¹Department of Biological Sciences, Tata Institute of Fundamental Research, Mumbai, India

Axonal transport plays an important role in synapse assembly and maintenance in neurons. Synapse morphology and composition is severely affected due gross disruption of axonal transport in model organisms. In addition, abnormal axonal transport is predicted to cause synaptic dysfunction and progressive neurodegenerative disorders. In order to understand the correlation between selective axonal transport and synapse assembly, we studied the role of kinesin-2 based transport on synaptogenesis in developing central nervous system of *Drosophila* larvae. Here, we describe a fresh synaptogenesis event in the larval ventral ganglion during 78-84 hours After Egg Laying (AEL). Average number of synapses containing Dense Core Vesicles increases by three folds in this period. The step increase in synapse density is blocked in homozygous kinesin-2 mutants and ectopic expressions of appropriate transgenes in cholinergic neurons rescued the mutant phenotype. Kinesin-2 transports a variety of soluble and membrane associated cargoes in the axon which include choline acetyltransferase, acetylcholinesterase, rab4, etc. The synaptogenic phase is preceded by brief periods of kinesin-2 mediated ChAT and Rab4 (associated with presynaptic vesicles) transport in cholinergic neurons during 77-79 hours AEL. Altogether, these results provide a strong correlation between the Kinesin-2 dependent axonal transport and synapse assembly during development. In addition, it also suggests that specific loss of transport in cholinergic neurons could lead to synaptic atrophy and widespread neurodegeneration.

P1702**Board Number: B219****Aplip1 regulates Kinesin and Dynein during myonuclear movement in *Drosophila*.**A.L. Auld¹, E.S. Folker¹;¹Biology, Boston College, Chestnut Hill, MA

Myofibers, the cellular units of muscle, are a multinucleate cell type in which the many nuclei are positioned to maximize their internuclear distance. Although mispositioned nuclei correlate with muscle weakness, the nature of this correlation is poorly understood. Furthermore, how the destination for each nucleus is specified and the mechanisms by which each nucleus moves to its destination is not known. However, we have previously demonstrated that in vivo, translocating muscle nuclei are polarized with a distinct leading and lagging edge. We hypothesize that the polarized nature of translocating nuclei is evidence of the nucleus, or the molecules moving the nucleus, perceiving its eventual location and moving directly to this position. We have used genetic analysis to demonstrate that nuclear polarity requires the activity of Kinesin at the leading edge and Dynein at the trailing edge.

However, neither motor is polarized in its localization suggesting that only the activities of the two motors are spatially segregated. We have now screened a series of proteins known to regulate both Kinesin and Dynein to identify the mechanism of nuclear polarization, and eventually identified the mechanism by which nuclear position is specified. We identified JNK interacting protein 1 (Aplip1) as crucial to nuclear movement and nuclear polarization. Muscle specific RNAi-mediated depletion of Aplip1 resulted in mispositioned muscle nuclei. Additionally, Aplip1 interacts with both Kinesin and Dynein: Kinesin-Aplip1 double heterozygotes and Dynein-Aplip1 double heterozygotes both have defects in nuclear positioning. Time-lapse microscopy of nuclear movement in developing embryos further suggests that Aplip1 regulates the activity of each motor on the nucleus. This is illustrated by a reduction in nuclear movement velocity and an inhibition of the dynamic changes in the structure of both the leading and lagging edges of translocating nuclei. These data suggest that JNK signaling is essential for nuclei to polarize in the direction of their migration and achieve their maximal velocity. Further, these data suggest that JNK signaling may be a crucial indicator of the destination for individual nuclei.

Tubulation of Lysosomal Membranes Containing Niemann Pick Type C1 Requires StARD9 – the First Transmembrane Kinesin.

A.M. Brumfield¹, K. Huegel¹, P.S. Vaughan¹, M. Joyce¹, W. Boggess¹, E.H. Hinchcliffe², K.T. Vaughan¹;

¹University of Notre Dame, Notre Dame, IN, ²Univ Minnesota-Hormel Inst, Austin, MN

Late Endosomes and Lysosomes (LE/Ls) are microtubule-dependent organelles that play an important role in cholesterol transport and acquire pathological accumulations of cholesterol in lysosomal storage diseases such as Niemann Pick Type C (NPC) disease. 95% of NPC cases are caused by mutations in NPC1, a 13-pass lysosomal transmembrane protein. LE/Ls containing NPC1 undergo alternating, bidirectional excursions along microtubules (MTs), and project dynamic membrane tubules that are also MT-dependent. Because the projection of dynamic membrane tubules is lost in cells expressing mutant but not wild-type NPC1, we used a proteomic survey to identify differences between these two membrane populations. StARD9 emerged as a novel membrane protein present in wild-type but absent in membranes containing I1061T mutant NPC1. This 4700 amino acid protein contains a conserved kinesin domain at the N-terminus, a dileucine, lysosomal targeting signal and a C-terminal StAR domain that overlaps with predicted transmembrane segments. StARD9 expression reveals MT-binding by N-terminal constructs and lysosomal accumulation by constructs also containing the StAR domain. Full-length StARD9 targets to lysosomes and incorporates into membrane tubules. ShRNA-driven depletion of StARD9 reduces centrifugal excursions of LE/Ls and projection of membrane tubules. These activities were rescued by shRNA-resistant wild-type but not a P-loop mutant StARD9 construct. Whereas co-expression studies reveal that wild-type NPC1 incorporates into lysosomes containing StARD9, mutant NPC1 fails to incorporate into StARD9-containing lysosomes. These findings identify StARD9 as the first

transmembrane kinesin and suggest that loss of StARD9 in mutant NPC1 membranes could explain defects in cholesterol transport.

Nesprins Anchor Kinesin-1 Motors to the Nucleus to Drive Nuclear Distribution in Developing Muscle Cells.

M.H. Wilson^{1,2}, E.L. Holzbaur¹;

¹Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA,

²Pennsylvania Muscle Institute, Philadelphia, PA

During skeletal muscle development, nuclei move dynamically through the cell in a microtubule-dependent manner. The microtubule motor protein kinesin-1 drives nuclear dynamics in developing myotubes. Loss of kinesin-1 leads to improperly positioned nuclei in culture and in vivo. Two models have been proposed to explain how kinesin-1 functions to move nuclei in myotubes. In the cargo model, kinesin-1 acts directly from the surface of the nucleus, whereas in an alternative model, kinesin-1 moves nuclei indirectly by sliding anti-parallel microtubules. Here, we use two experimental strategies to test the hypothesis that an ensemble of Kif5B motors acts from the nuclear envelope to distribute nuclei throughout the length of syncytial myotubes. First, using an inducible dimerization system, we show that controlled recruitment of truncated, constitutively active kinesin-1 motors to the nuclear envelope is sufficient to prevent the nuclear aggregation resulting from depletion of endogenous kinesin-1. Second, we identify a conserved kinesin light chain (KLC) binding motif in the nuclear envelope protein nesprin-2 and show that recruitment of the motor complex to the nucleus via this LEWD motif is essential for nuclear distribution. Together, our findings demonstrate that the nucleus is a kinesin-1 cargo in myotubes and that nesprins function as nuclear cargo adaptors. The importance of achieving and maintaining proper nuclear position is not restricted to muscle fibers, suggesting that the nesprin-dependent recruitment of kinesin-1 to the nuclear envelope by binding of the conserved LEWD motif to kinesin light chain is a general mechanism for cell-type specific nuclear positioning during development. This work was supported by the National Institutes of Health [grant number PO1 GM087253 to E.L.F.H., T32 GM-07229 and T32 AR-053461 to M.H.W.]. Additional support was provided by the American Heart Association [#13PRE16090007 M.H.W.].

P1705**Board Number: B222****Mutual conformational changes of kinesin and GTP microtubule upon their binding.**M. Morikawa¹, H. Yajima¹, R. Nitta¹, S. Inoue¹, T. Ogura², C. Sato², N. Hirokawa³;¹Dept Cell Biol Anat, Univ Tokyo Grad Sch Med, Tokyo, Japan, ²Natl Inst Advanced Indus Sci Technol/AIST, Tsukuba Science City, Japan, ³Cell Biology and Anatomy, Univ Tokyo Grad Sch Med, Tokyo, Japan

The ATP-driven molecular motor kinesin moves along microtubules in an initial step coupled with ADP release. In neurons, kinesin-1/KIF5 preferentially binds to the GTP-state microtubules over GDP-state microtubules to selectively enter an axon among many processes; however, its molecular mechanism remains unresolved because the atomic structure of nucleotide-free KIF5 is unavailable. Here, the crystal structure of nucleotide-free KIF5 and the cryo-electron microscopic structure of nucleotide-free KIF5 complexed with the GTP-state microtubule are presented. The structures illustrate mutual conformational changes induced by interaction between the GTP-state microtubule and KIF5. KIF5 acquires the “rigor conformation”, where mobile switches I and II are stabilized through L7, L11 and the initial portion of the neck-linker, facilitating effective ADP release and the weak-to-strong transition of KIF5 microtubule affinity. Conformational changes to tubulin strengthen the longitudinal contacts of the GTP-state microtubule in a similar manner to GDP-taxol microtubules. These results and functional analyses provide the molecular mechanism of the preferential binding of KIF5 to GTP-state microtubules.

P1706**Board Number: B223****Direct measurement of the binding rate constant of kinesin to microtubules in living cells.**T. Kambara¹, Y. Okada¹;¹RIKEN Quantitative Biology Center (QBiC), Osaka, Japan

It has been established that conventional kinesin (kinesin-1, KIF5 in mammalian cells) selectively moves along a specific subset of microtubules in living cells. For example, KIF5 is specifically recruited to the microtubules in the axon initial segment in neurons, which would enable efficient transport into the axon. However, the mechanism of this selective binding is still controversial. Some groups have proposed that acetylation or other post translational modifications of tubulin serve as the cue for selective binding. We are proposing that conformational differences between the GTP-form and GDP-form of microtubules provide the cue. To test this idea, it would be important to examine whether kinesin binding to specific subsets of microtubules is enhanced, inhibited or both. Here, we measured the binding rate constant of kinesin to microtubules in living cells and in vitro using single molecule

fluorescence microscopy. To our surprise, the binding rate constant of KIF5 to the track-microtubule *in vivo* was nearly ten times higher than that *in vitro*, suggesting that mechanisms exist in the cell to recruit KIF5 specifically to some subset of microtubules by accelerating the binding reaction.

⁴University of Nevada, Reno, NV

Microtubule (MT)-based transport is driven by minus-end directed cytoplasmic dynein and plus-end directed kinesins simultaneously bound to the surface of cargo organelles. Activities of opposing MT motors result in back-and-forth (“salutatory”) movement of cargo organelles along MT transport tracks. MT-based movement of organelles and cytoplasmic particles is tightly regulated in cells but the mechanisms of regulation remain largely unknown. The direction of MT-based transport might be controlled by a protein complex that determines which motor type is active at any given moment of time, or determined by the outcome of tug-of-war between MT motors dragging cargo organelles in opposite directions. However, evidence in support of each mechanism of regulation is based mostly on results of theoretical analyses or indirect experimental data. Here, we directly tested whether *in vivo* bidirectional movement of membrane organelles involves a tug-of-war between opposing MT motors by simultaneously activating cytoplasmic dynein and kinesin-1 on the same membrane organelles. For the activation of opposing MT motors, we took advantage of melanophores, which provide a dramatic example of regulation of MT-based transport. In these cells, pigment-containing melanosomes move along MTs to the cell center (pigment aggregation) or to the cell periphery (pigment dispersion) driven by cytoplasmic dynein and kinesin-2, respectively. Pigment aggregation signals boost dynein activity and inhibit activity of kinesin-2 as evidenced from a sudden and dramatic increase in the length of MT minus-end runs and a simultaneous decrease in the length of plus-end runs. To induce a tug-of-war between opposing MT motors, we attached to melanosomes large amounts of constitutively active kinesin-1 using the FKBP-rapalog-FRB heterodimerization system, and activated melanosome-bound dynein by applying pigment aggregation stimuli. We found that while melanosomes loaded with kinesin-1 failed to aggregate in the cell center, they continued bidirectional movement along the radial MT tracks. Measurement of movement statistics indicated that kinesin-1 shortened the length of dynein-dependent minus-end directed runs of melanosomes and also significantly (>20%) reduced their velocity. A decrease in transport velocity is consistent with application on dynein of an external load by the kinesin-1 motors. Activation of kinesin-2 by pigment dispersion stimuli never led to a decrease in velocity of minus-end runs of melanosomes. Our data show that forced simultaneous activation of

cytoplasmic dynein and kinesin-1 leads to tug-of-war between these motors and suggest that cellular mechanisms exist that regulate cargo runs in each direction thus preventing tug-of-war.

Regulation of dynein motility by the antenna structure of dynactin p150.

T. Kobayashi¹, T. Miyashita¹, H. Kajita¹, K. Saito¹, T. Murayama², Y.Y. Toyoshima¹;

¹Dept of Life Sci, The University of Tokyo, Tokyo, Japan, ²Graduate School of Medicine, Juntendo University, Tokyo, Japan

Dynactin is an intricate complex and has been known as a dynein activator. Dynactin consists of 11 species of polypeptides, and among those p150 subunit constitutes a sidearm which extend from Arp1 rod. The coiled coil 1 region (CC1) of p150 is considered to bind directly to the N-terminal region of dynein intermediate chain (IC). Previously, we have shown that CC1 of p150 forms an antenna structure which extrude from the head within a sidearm. To elucidate the mechanism of dynein regulation by dynactin complex, we examined the effect of dynactin complex and the isolated CC1 on the dynein motility in vitro. Single molecules of cytoplasmic dynein diffusively moved on microtubules and exhibited slightly biased displacement to the minus end of microtubules as previously reported. Single molecules of dynactin complex showed diffusive movement on microtubules without unidirectional bias. When we mixed dynein and dynactin together, the fluorescent spot derived from dynein disappeared from microtubules. This was not caused by the competition of binding to microtubules between dynein and dynactin because both molecules are much fewer to occupy the binding sites on microtubules. Next, we prepared the recombinant CC1 and confirmed that the isolated CC1 directly bound to cytoplasmic dynein with a high affinity (K_d , ≈ 20 nM), but did not bind to microtubules. Single molecules of dynein associated with the CC1 released easily from microtubules and did not stay on microtubules for enough time to be detected, as is the case for the dynein-dynactin-complex. Intriguingly, when we added the CC1 to the gliding microtubules on the dynein coated surface, the moving microtubules gradually dissociated and finally disappeared from the surface. These observations suggest that the effect of CC1, the antenna structure of p150, on dynein motility is to reduce the affinity of dynein to microtubules, which appears to be inconsistent to the accepted idea that dynactin activates dynein motility by increasing its processivity.

P1709**Board Number: B226****Dynein, Dynactin and Lis1 are required for endosome maturation in *Drosophila* oocytes.**P. Sanghavi¹, G. Liu¹, N. Townes¹, G.B. Gonsalvez¹;¹Cellular Biology and Anatomy, Georgia Regents University, Augusta, GA

Several studies have demonstrated a requirement for Dynein in the transport of early and late endosomes. However, the extent to which Dynein contributes to endocytic uptake and maturation is poorly understood. Our initial experiments were focused on examining the role of p50/Dynamitin in oskar mRNA localization. Dynamitin is a component of the Dynactin complex, a core regulator of Dynein. Our findings indicate that Dynamitin is indeed required for efficient oskar mRNA localization in *Drosophila* oocytes. During the course of these studies, we unexpectedly discovered an additional role for Dynamitin in endocytic uptake and maturation. Large quantities of Yolk proteins are internalized into mid-stage oocytes via Clathrin-mediated endocytosis. Subsequently, maturation of these endocytic vesicles results in formation of condensed yolk granules. A defect in endocytosis is reflected by a reduction or loss of yolk granules. Our ultra-structural analysis indicated that oocytes depleted of Dynamitin contained significantly fewer yolk granules, but instead accumulated numerous endocytic intermediate structures. Particularly prominent were large vesicular structures that reflect an endocytic block downstream of Rab5. Similar endocytic defects were also observed upon depleting Dynein heavy chain or Lis1, another regulator of the Dynein motor. Consistent with a role for Dynein in endocytosis, we demonstrate that Dynein heavy chain is recruited to the oocyte cortex in an endocytosis-dependent manner. Our results suggest a model whereby endocytic activity recruits Dynein to the oocyte cortex. The motor in turn functions to ensure efficient endocytic uptake and maturation, ultimately resulting in the production of abundant yolk granules.

P1710**Board Number: B227****Molecular Mechanism for Dynactin Regulation of Processive and Diffusive Dynein Transport.**S.K. Tripathy¹, S.J. Weil², C. Chen³, S. Gross⁴, R. Vallee²;¹UC Irvine, Irvine, CA, ²Department of Pathology and Cell Biology, Columbia University, New York, NY,³biological sciences, Columbia university, New York, NY, ⁴Developmental and Cell Biology, UC Irvine, Irvine, CA

The dynactin complex is an important cytoplasmic dynein regulator implicated in both dynein cargo recruitment and motor regulation. Dynactin increases dynein run length along microtubules in *in vitro* assays, a function long thought to involve the N-terminal CAP-Gly microtubule-binding site within the major dynactin subunit p150^{Glued}. However, recent experiments from several labs argue against such a

role for this domain, and the mechanism for dynein regulation by p150^{Glued} remains unknown. We have produced and characterized well-behaved bacterially- and baculovirus-expressed subfragments of the N-terminal half of the major dynactin subunit p150^{Glued} and its neuronal splice variant p135, which lacks the CAP-Gly domain (Tripathy et al., ASCB 2013). We tested the effects of these constructs on dynein motor behavior by single molecule laser trap bead assays. We found that the largest p150^{Glued} and p135 fragments consisting of the N-terminal half of the full polypeptides each induce both diffusive and processive bead movement, as is the case for the complete dynactin complex. An internal fragment, CC1B, which is sufficient for dynein binding, was also sufficient to promote dynein processivity. The immediate upstream fragment, CC1A, increased dynein diffusion, whereas a complete CC1 fragment potentially inhibited dynein motility.

To address how these activities and that of the N-terminal globular domain of p150^{Glued} and p135 might be interrelated, we tested for interactions between domains. We identified a clear interaction between the individual CC1A and CC1B fragments using both size exclusion FPLC and pull-downs. In single molecule assays we also found clear CC1A dose-dependent neutralization of the ability of CC1B to stimulate dynein processivity. Together our data provide a comprehensive model for p150^{Glued}-mediated dynein regulation, involving CC1B as the prime locus for dynactin autoregulation by CC1A and, we speculate, by the N-terminal globular region of p150^{Glued}. Supp. by NIH GM102347 to RV and GM070676 to SG.

Dynactin functions as both a dynamic tether and brake during dynein-driven motility.

S. Ayloo¹, J. Lazarus¹, A. Dodda², M. Tokito¹, E. Ostap¹, E.L. Holzbaur³;

¹University of Pennsylvania, Philadelphia, PA, ²University of Massachusetts, Amherst, MA, ³Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Dynactin is a large multi-subunit complex that is an important cofactor for cytoplasmic dynein in cellular processes including organelle trafficking and mitosis. Dynactin increases the processivity of dynein and also targets dynein to specific cellular locations. Although the role of dynactin in dynein-mediated processes is well established, the underlying mechanisms involved are unknown. Here, we use single molecule approaches to investigate the contribution of the dynactin subunit p150Glued to dynein motor function. We first characterized the motility of purified GFP-tagged mammalian dynein isolated from a knock-in mouse brain tissue (Zhang et al., 2013). Consistent with previous reports (Mallik et al., 2005; Ross et al., 2006), single molecules of dynein-GFP switch stochastically from processive to diffusive states of motion. We analyzed this motion by a novel algorithm that we developed to parse trajectories into different states and found that dynein is processive 60% of the time. To examine the activation of dynein by dynactin, we investigated the formation and co-migration of a dynein-p150Glued co-complex using dual-color TIRF microscopy. We provide direct evidence that p150Glued is sufficient to recruit and tether dynein to the microtubule and that this recruitment is concentration-dependent; p150Glued

increases the on-rate and decreases the off-rate of dynein from microtubules. Single molecule imaging of motility in cell extracts demonstrates that the CAP-Gly domain of dynactin is essential for the decreased detachment rate of the dynein-dynactin complex from the microtubule and also acts as a brake to slow the dynein motor. Consistent with this important role, two neurodegenerative disease-causing mutations in the CAP-Gly domain abrogate these functions in our assays. Together, these observations support a model in which dynactin enhances the initial recruitment of dynein onto microtubules and promotes the sustained engagement of dynein with its cytoskeletal track. Thus, our work reveals new insights into the functioning of dynein and dynactin and how this process is perturbed in neurodegenerative disease.

Characterization of a dynactin p62 variant associated with increased risk of chronic *Pseudomonas* infection in cystic fibrosis.

T. Yeh¹, T.A. Schroer¹;

¹Department of Biology, Johns Hopkins University, Baltimore, MD

Dynactin is an essential component of the cytoplasmic dynein motor that contributes to interactions with dynein cargoes and other cellular components. The dynactin subunit p62 (DCTN4), along with Arp11, p27, and p25, comprise a subcomplex that is located distal to dynactin's dynein-binding site. We have shown that p62 is essential for dynactin complex integrity and targeting to specific cellular cargoes, but its full range of functions have not yet been defined. Exome sequencing has revealed that the presence of a single copy of the p62 variant (Y270C) in individuals with cystic fibrosis (CF) correlates with early onset of chronic *Pseudomonas aeruginosa* airway infection. We find that exogenously expressed p62-Y270C incorporates into the dynactin complex like p62-WT and does not affect dynactin integrity. p62 Y270, which is known to be phosphorylated *in vivo*, is a consensus site for kinases linked to cell adhesion and locomotion, so we investigated the impact of p62 Y270C on cell migration and focal adhesion dynamics. Cells expressing p62-Y270C migrate slower than those expressing p62-WT in a scratch wound assay. Centrosome reorientation in cells at the wound edge appears normal, but the morphology, location and number of actin stress fibers and focal adhesions (FAs) are altered. The level of the phosphorylated form of focal adhesion kinase (pFAK) at FAs is also significantly reduced, suggesting that the signaling at FAs may be perturbed. Live cell imaging showed that turnover of stress fibers (labeled with GFP-F-tractin) and FAs (labeled with RFP-zyxin) are also suppressed. Taken together, our results suggest that the p62-Y270C variant may reduce cell migration in the CF airway epithelium by altering stress fiber and FA dynamics, leading to decreased repair and increased susceptibility to infection. Further investigation of dynactin's contributions to cell migration is underway.

P1713**Board Number: B230****Dynein regulation by its microtubule track: Roles of tubulin carboxy-terminal tails *in vivo*.**C.E. Estrem¹, J.K. Moore¹;¹Cell and Development, University of Colorado School of Medicine, Aurora, CO

Dynein is a conserved microtubule motor with a multitude of cellular roles such as vesicle transport, mitotic spindle assembly, and spindle positioning. Despite these diverse roles, most eukaryotes express a single cytoplasmic dynein heavy chain; therefore, its activity must be highly regulated to provide specified force for different cellular functions. Here we identify a novel mode of regulation, in which dynein is regulated by tubulin carboxy-terminal tails (CTTs) that decorate its microtubule track. CTTs are negatively charged regions that differ across species and tubulin isotypes, and are major sites of posttranslational modification. We examine CTT mutants in budding yeast, where dynein generates force to move the mitotic spindle by sliding astral microtubules along the cell cortex. Using live cell imaging of fluorescently labeled microtubules, we demonstrate that truncation mutants that lack the β -tubulin CTT exhibit increased spindle movement. Microtubule sliding events in β -tubulin CTT mutants are more frequent and significantly longer-lived, producing greater displacement of the nucleus and mitotic spindle. These effects depend on dynein -- conditionally depleting dynein eliminates spindle movement in β -tubulin CTT mutants. Our results indicate that β -tubulin CTT negatively regulates dynein *in vivo*. We are investigating whether the β -tubulin CTT directly affects dynein's affinity for the microtubule or alters the activity of a different dynein regulator. This continued research offers new insight into how tubulins regulate microtubule binding proteins such as motor proteins, which in turn affects cellular processes.

P1714**Board Number: B231****The motility of axonemal dynein is regulated by the tubulin modifications.**J. Alper¹, F. Decker², B. Agana³, J. Howard¹;¹Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, ²Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ³Chemistry, Missouri State University, Springfield, MO

Microtubule diversity, arising from utilization of different tubulin isotypes and post-translational modifications, regulates many cellular processes including cell division, centriole assembly, and neuronal differentiation. In cilia and flagella, microtubule diversity is important for axonemal assembly and motility. However, it is unknown whether microtubule diversity directly regulated the activity of the axonemal dyneins, the motors that drive the beating of the axoneme, or whether the regulation is indirect, perhaps through pathways upstream of the motors. To test whether microtubule diversity directly regulates the activity of axonemal dyneins, we asked if *in vitro* acetylation or deacetylation of

lysine 40 (K40), a major post-translational modification to tubulin, or proteolytic cleavage of the C-terminal tail (CTT) of tubulin, the location of detyrosination, polyglutamylation, and polyglycylation modifications as well as most of the genetic diversity, influences the activity of outer-arm dynein in motility assays using purified proteins. By quantifying motility, we found that K40 acetylation increases and CTTs decrease axonemal dynein motility. Further mathematical modeling suggests that these modifications regulate the power stroke speed of dynein, likely by altering the unbinding rate of the microtubule. These results show that axonemal dynein directly deciphers the tubulin code, which has important implications for eukaryotic cilia beat regulation.

Emergence of large-scale vortices of microtubules collectively driven by axonemal dyneins.

N. Kanatani¹, K. Oiwa²;

¹Graduate School of Life Science, University of Hyogo, Kamigori, Hyogo, Japan, ²Advanced ICT Res Inst, Natl. Inst. Info. Commun. Technol., Kobe, Japan

Self-propelled particle models have been often used in trial that the motions often observed in biology (schools of fish, some flocks of birds, cell migrations during development and so on) are understood quantitatively. In addition to computer simulations of the models, substantial experimental systems have been demanded for the study and *in vitro* motility assays commonly used in protein-motors biophysics have provided some solutions. Using conventional *in vitro* motility assays, we reported collective behavior of microtubules driven by axonemal dynein molecules which are attached on glass surface [Sumino, Nagai, et al., *Nature* **483**, 448-452, 2012]. Under certain experimental conditions, the collective movement of microtubules generates nematic order, millimeter-scale meandering streams or millimeter-scale vortices. To explore the conditions causing such phase-shift, we have investigated collective behavior using different types of axonemal dynein subspecies and microtubules with various length. The motor proteins we used are the inner arm dynein subspecies c and g (dynein c and g) of *Chlamydomonas* flagella, both of which are single-headed dyneins composed of one heavy chain and two types of light chains, actin and p28 (for dynein c) or centrin (for dynein g). Dynein c and g are capable of moving microtubules on glass surface at velocities of ca. 12 and 6 $\mu\text{m}/\text{sec}$ in the presence of 1 mM Mg-ATP at 23 °C, respectively. Purified dynein molecules were adsorbed on a glass surface at densities higher than 1000 molecules μm^{-2} . Microtubules with length less than ca. 60 μm did not move in the absence of ATP but bound to dynein g-coated glass surface being slightly aligned by flow. Upon the addition of 1 mM Mg-ATP, microtubules started moving smoothly. Moving microtubules often collide each other and upon these collisions they are aligned through nematic interactions. Within a few minutes, microtubule-alignment gradually increases its size and finally forms streams meandering across a very large distance (longer than 400 μm). Under the experimental conditions with microtubules of less than ca. 60 μm , vortices with 200-500 μm diameter emerge from the stream tens of minutes after the ATP addition. On the other hand, microtubules with mean length of longer than 60 μm do not form

vortices. The features of vortices driven by dynein g, i.e. number, diameter and time necessary for their emergence, are different from those driven by dynein c. These results now suggest that the vortex formation is not dynein-c-specific but may reflect the mechanical properties of inner-arm dyneins. One parameters which can shift the phase is the length of microtubules but the mechanism how their length can modify the emergence still requires further investigation.

Regulation of Cytoplasmic dynein activity by GSK-3 β .

F. Gao¹;

¹biology, university of south carolina, Columbia, SC

Cytoplasmic dynein is a vitally important microtubule motor in animal cells, contributing to many aspects of cellular and intracellular motility. Genetic lesions that lead to altered dynein function have been associated with disease, but relatively little is known about signaling pathways regulating motor activity. Our studies now indicate that a prominent insulin response pathway culminating in inhibition of GSK-3 β (glycogen synthase kinase 3 β) contributes to dynein activation and increases minus end directed transport in both neuronal and non-neuronal cells. Moreover, GSK-3 β coprecipitates with dynein in mouse brain extract and phosphorylates dynein in vitro. Dynein phosphorylation by GSK-3 β reduces its interaction with Ndel1, a protein that contributes to dynein force generation. Because GSK-3 β inhibition occurs downstream of multiple receptor signaling pathways it has the potential to act as a switch, stimulating transport of dynein and local cargo away from peripheral membrane sites upon receptor activation.

Structure of human cytoplasmic dynein-2 primed for its powerstroke.

R. Zalyte¹, A.P. Carter¹, H. Schmidt¹, L. Urnavicius¹;

¹MRC Laboratory of Molecular Biology, Cambridge, United Kingdom

Dyneins are a family of microtubule motor proteins belonging to the AAA+ (ATPases associated with diverse cellular activities) family. The cytoplasmic dynein-2 subfamily play a key role in intraflagella transport and in humans deficiencies are associated with a wide range of skeletal ciliopathies such as Jeune syndrome. Here we present the crystal structure of the human cytoplasmic dynein-2 motor bound to the ATP hydrolysis transition state inhibitor ADP.vanadate. This pre-powerstroke structure explains how the dynein motile element, called the linker, is bent and primed to generate force. It also reveals how the movements within the ring of AAA+ domains are coupled to the relative sliding of two α -helices in the dynein stalk that lead to release of dynein from microtubules.

P1718**Board Number: B235****Direct observation by cryo-EM of cytoplasmic dynein motors stepping along microtubules.**H. Imai¹, T. Shima², K. Sutoh³, M.L. Walker⁴, P.J. Knight¹, T. Kon^{5,6}, S.A. Burgess¹;¹School of Molecular and Cellular Biology and Astbury Centre for Structural Molecular Biology, Faculty of Biological Sciences, Univ Leeds, Leeds, United Kingdom, ²QBiC, RIKEN, Osaka, Japan, ³Waseda University, Tokyo, Japan, ⁴MLW Consulting, Cornwall, United Kingdom, ⁵Department of Frontier Bioscience, Hosei University, Tokyo, Japan, ⁶JST PRESTO, Saitama, Japan

Cytoplasmic dynein motor proteins perform critical roles in eukaryotic cells, transporting subcellular cargoes towards the minus ends of microtubule (MT) tracks and maintaining the positions of organelles. Tracking of fluorescently-tagged dimeric dynein suggested an uncoordinated stepping by the two heads, but there is also evidence of communication between them. We have now imaged directly by cryo-electron microscopy individual *Dictyostelium discoideum* dynein dimers flash-frozen while stepping along MT at near-physiological Mg-ATP concentration. About half of the molecules show diverse configurations of the two motor heads. The other half of the molecules has the two heads closely superposed with both their linker domains in post-powerstroke conformations. This unpredicted superposed configuration reveals more clearly the coiled-coil stalk domains and their terminal stalkheads that bind the dimer to the MT. The stalks are angled at $\sim 42 \pm 11^\circ$ to the MT, and are flexible mainly about the stalkhead-stalk junction, resulting in axial and radial variation of the heads. The superposed configuration is different from any configuration of the two other cytoskeletal motor families, kinesin and myosin, and thus direct motor-motor interactions may be functionally important in stepping by dynein.

P1719**Board Number: B236****The crystal structure of the dynein heavy chain dimerization domain.**A.G. Diamant¹, M.A. Schlager¹, H. Schmidt¹, M. Yu¹, A.P. Carter¹;¹MRC Laboratory of Molecular Biology, Cambridge, United Kingdom

Cytoplasmic dynein is a molecular motor responsible for the vast majority of retrograde traffic along microtubules. The largest subunit of the dynein complex is called the dynein heavy chain (DHC). The DHC includes a C-terminal motor domain, which converts ATP hydrolysis into mechanical force, and an N-terminal tail domain. An intermediate chain (DIC) and light intermediate chain (DLIC) bind directly to the DHC tail, while light chains (DLCs) bind to the DIC. This tail complex is important for both cargo binding as well as homodimerization of the DHC, which is necessary for processive movement. Previous studies suggest that the DLCs play an important role in homodimerization of the dynein complex, but it remains unclear whether the other subunits also contribute to the dimer interface.

Using *Saccharomyces cerevisiae* as a model, we co-expressed all four dynein subunits and purified functional dynein motors that were active in an *in vitro* motility assay. In this background, we found that truncating the DHC to include only the first ~1000 residues eliminates the motor domain, while preserving binding to the DIC, DLIC and DLC. Truncating another 50 residues off of the C-terminus led to a loss of all accessory subunits, suggesting this may disrupt a domain required for binding both the DIC and DLIC. Furthermore, a construct including only the first ~500 residues of the DHC dimerizes despite not being able to bind any of the other subunits. We solved the crystal structure of this smaller DHC fragment and found that the N-terminal ~200 residues of the DHC constitute an intricate dimerization domain. Not only is this the first crystal structure of any part of the DHC N-terminus, but it reveals a previously undocumented dimerization domain within the DHC itself. These studies shed new light on the biochemical organization of this important motor complex and contribute to a better understanding of its function.

Dynein light chain 1 locates at the stalk of the outer arm dynein.

M. Ichikawa¹, K. Saito¹, H. Yanagisawa², T. Yagi³, R. Kamiya⁴, Y. Kushida⁵, K. Nakano⁵, O. Numata⁵, Y.Y. Toyoshima¹;

¹Dept of Life Sci, The University of Tokyo, Tokyo, Japan, ²Dept Cell Biology, The University of Tokyo, Tokyo, Japan, ³Pref. Univ. of Hiroshima, Hiroshima, Japan, ⁴Dept Life Science, Gakushuin University, Tokyo, Japan, ⁵Univ. of Tsukuba, Tsukuba, Japan

Cilia and flagella are highly conserved microtubule (MT)-based organelles in eukaryotes. The bending motion of cilia and flagella is driven by the motor protein called axonemal dyneins. The outer arm dynein (OAD) complex generates ~80% of propulsive force and thus OAD is an important component of cilia and flagella. OAD complex is composed of three heavy chains (α , β , γ HCs), two intermediate chains (ICs), and eleven light chains (LCs). Each of the three HCs comprises the tail and the head domains. Three HCs form a heterotrimer through their tail domains and thus the OAD complex appears as a three-headed structure. The head domain is composed of the linker, the AAA+ ring, the stalk, and the microtubule binding domain (MTBD). The stalk is a coiled-coil structure, which protrudes from the AAA+ ring, and the MTBD resides at the tip of stalk region. LC1 is a 22-kDa light chain of OAD and widely conserved among many species. While all the other smaller subunits (ICs and LCs) have been shown to associate with the tail domain, LC1 was found to associate with the head domain of the γ HC. LC1 was found to be essential for proper beating of cilia and flagella in many species. Mutation of human LC1 also leads to primary ciliary dyskinesia. Despite its importance *in vivo*, LC1's regulatory mechanism of OAD is not clearly understood because the structural basis for interaction of LC1 and γ HC has not been elucidated.

Here, by using single particle analysis of electron microscopy (EM), we have found that there is an additional density at the tip of the γ HC stalk region. By expressing His-tagged LC1 in *Tetrahymena* and *Chlamydomonas* and performing EM observation aided by Ni-NTA-nanogold labeling, we have shown

that this additional structure corresponds to LC1. This is in remarkable contrast to the previous assumption that LC1 locates at the AAA+ ring of the γ HC (Patel-King and King 2009). Pull-down assay using bacterially expressed fragments has shown that LC1 preferentially binds to the γ -stalk at a 1:1 molar ratio. Further biochemical mapping has revealed that the MTBD region of the γ HC is sufficient for the binding of LC1. These results raise the possibility that LC1 regulates OAD activity by changing γ HC's affinity to MTs.

Board Number: B238

Characterizing the Role of Cytoplasmic Dynein in HTLV-1 Intracellular Trafficking.

R.E. Alvarado¹, T.M. Gibson²;

¹Biology, University of Texas of the Permian Basin, Odessa, TX, ²Biology, University of Texas of the Permian Basin, Odessa, TX

Human T-Cell Leukemia Virus type 1 (HTLV-1) is a human retrovirus that is associated with a variety of human diseases, which include adult T-Cell leukemia/lymphoma (ATLL) and HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP). A hallmark for retroviral infection requires the integration of the viral genome into the host cell genome. One problem the virus faces is trafficking through the cytoplasm in order to reach the nucleus. Some viruses have overcome this obstacle by hijacking molecular motors that move through the cytoplasm on microtubules (MT) in a retrograde fashion. The motor protein, termed cytoplasmic dynein, mediates retrograde movement of intracellular cargo along microtubules. In previous experiments, our laboratory has demonstrated that HTLV-1 particles co-localized with cytoplasmic dynein and dynactin within HEK293T cells. Also immunoprecipitation studies revealed that HTLV-1 directly or indirectly interacts with cytoplasmic dynein in-vitro. Thus, we have hypothesized that HTLV-1 utilizes cytoplasmic dynein to travel to the nucleus in order to insert its DNA into the host genome. To investigate the role of cytoplasmic dynein in HTLV-1 trafficking, we have optimized conditions to perform experiments using short interfering RNAs (siRNA). By inhibiting the expression of this protein, we can better understand the role cytoplasmic dynein has in retrovirus movement. Through these studies, we expect to further elucidate the molecular details of HTLV-1: host cell interactions. Furthermore, these studies should reveal insights to potential therapeutic targets.

P1722**Board Number: B239****A Ras-Like Domain in the Light Intermediate Chain Bridges the Dynein Motor to a Cargo-Binding Region.**C.M. Schroeder^{1,2}, J.M. Ostrem^{1,2}, N.T. Hertz^{1,2}, R.D. Vale^{2,3};¹University of California, San Francisco, San Francisco, CA, ²The Howard Hughes Medical Institute, San Francisco, CA, ³Department of Cell and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

Cytoplasmic dynein, a microtubule-based motor protein, transports many intracellular cargos by means of its light intermediate chain (LIC). However, it is not understood how the LIC carries out intracellular transport, and structural information about the LIC is lacking. We have determined the crystal structure of the conserved LIC domain, which binds the motor heavy chain, from a thermophilic fungus. We show that the LIC has a Ras-like fold with insertions that distinguish it from Ras and other previously described G proteins. Despite having a G protein fold, the fungal LIC has lost its ability to bind nucleotide, while the human LIC1 binds GDP preferentially over GTP. We show that the LIC G domain binds the dynein heavy chain using a conserved patch of aromatic residues, whereas the less conserved C-terminal domain binds several Rab effectors involved in membrane transport. These studies provide the first structural information and insight into the evolutionary origin of the LIC as well as revealing how this critical subunit connects the dynein motor to cargo.

P1723**Board Number: B240****Dual Role for Cdk1 in Triggering Early and Late G2 Dynein Recruitment to the Nuclear Envelope.**A. Baffet¹, D.J. Hu¹, R. Vallee¹;¹Department of Pathology and Cell Biology, Columbia University, New York, NY

Cytoplasmic dynein is recruited to the nuclear envelope (NE) during G2 via two distinct nuclear pore-anchored mechanisms involving, respectively, RanBP2-BicD2-dynein/dynactin/Lis1 and Nup133-Cenp-F-NudE/L-dynein (Splinter et al, PLoS Biol., 2010; Bolhy et al., JCB, 2011). These pathways also function in neuronal progenitor cells, where they control early vs. late G2 apical nuclear migration (Hu et al., Cell, 2013). How they are activated specifically during G2 is unknown. This question has particular relevance in neuronal progenitors, in which nuclei must reverse their direction of transport from kinesin-dependent basal movement during G1 to dynein-dependent apical movement to the ventricular surface of the developing brain during G2. Failure to reach the ventricle blocks mitotic entry and neurogenesis. To address this important question we have undertaken experiments to test the role of cell cycle-dependent protein kinases in NE dynein recruitment and nuclear migration. We previously found that small molecule Cdk1 inhibitors block the recruitment of dynein, as well as dynactin and Lis1 to the HeLa

cell NE and inhibit apical nuclear migration in the developing rat brain (Baffet et al., ASCB 2013 abstract). We have now further characterized the underlying molecular mechanism for Cdk1 action. We show that Cdk1 inhibition displaces the most upstream factors in each pathway, BicD2 and Cenp-F, whereas Cdk1 stimulation results in more intense and even earlier BicD2 and Cenp-F NE decoration. We identify novel Cdk1 phosphorylation sites in the BicD2-binding region of RanBP2, phosphorylation of which strongly enhances binding to BicD2-CT in vitro. Constitutive targeting of BicD2-NT to the NE of Cdk1-inhibited cells restores dynein, dynactin and Lis1 recruitment to the HeLa cell NE and rescues apical nuclear migration in neuronal progenitor cells. These results reveal that Cdk1 phosphorylation of factors downstream of BicD2 (dynein, dynactin, Lis1) is not involved in their targeting to the NE. Surprisingly, Cdk1 inhibition affects the late dynein NE recruitment pathway by preventing Cenp-F from exiting the nucleus. In conclusion, Cdk1 independently controls both the early and late NE dynein recruitment pathways. Cdk1 phosphorylates RanBP2 to activate BicD2 recruitment to the NE, which appears to serve as the trigger for apical nuclear migration in neuronal progenitor cells. Cdk1 also activates the late NE dynein recruitment pathway by a novel mechanism, controlling the exit of Cenp-F from its default intranuclear localization. Supported by HD40182 to RV and an AHA PD Fellowship to AB.

Differential Roles for NudE1 and NudEL1 In Rat Brain Development.

D. Doobin¹, S. Kemal¹, R. Vallee¹;

¹Department of Pathology and Cell Biology, Columbia University, New York, NY

During development of the mammalian neocortex, radial glial progenitor (RGP) cells divide while undergoing cell cycle dependent interkinetic nuclear migration (INM). We have found apical nuclear migration to be dependent on cytoplasmic dynein, recruited to the nuclear envelope (NE) by sequential G2-specific mechanisms (Hu et al. *Cell*. 2013, 154:1300-13), which also control G2-dependent dynein recruitment to the NE in cultured non-neuronal cells. The specific roles of two of these component proteins – NudE and NudEL – in the NE dynein recruitment process, however, remain unexplored. NudE and NudEL are closely related throughout their length (55% identity; 70% similarity), and each interacts with cytoplasmic dynein and Lis1. However, knockout mice exhibit different brain developmental phenotypes (Feng & Walsh. *Neuron*. 2004, 44:279-93; Sasaki et al. *Mol Cell Biol*. 2005, 25:7812-27), consistent either with different functional roles or distinct brain developmental expression patterns. Using in utero electroporation of Nde1 and Ndel1 shRNAs in E16 rat brains, followed by fixed or live imaging in brain slice culture, we tested the effects of NudE and NudEL RNAi on neurogenesis and migration. NudE RNAi resulted in severe inhibition of apical INM, and strongly reduced the number of dividing cells at the ventricular surface. Ectopic divisions away from the ventricular surface were undetectable. In contrast, depletion of NudEL had no effect on INM or the frequency of dividing cells at the ventricular surface. RNAi for each gene led to an accumulation of multipolar cells in the intermediate zone, and severe inhibition of further neuronal migration of postmitotic neurons in the cortical plate. To test for inherent differences in NudE and NudEL function, we have begun series of

complementation experiments. We find that the post-mitotic neuronal migration defect seen in NudEL RNAi is largely rescued by NudE overexpression. Thus, NudE and NudEL may exhibit significant functional redundancy in the brain. Of further importance, the specific inhibition caused by NudE RNAi in INM, and the failure of NudE knockdown cells to reach the ventricle to divide, may play a substantial and previously unappreciated role in the clinical microcephaly reported in human patients with mutations in NDE1 (Alkuraya et al., *Am J Hum Gen.* 2011, 88:536-547). Correct positioning of the mitotic spindle during metaphase and spindle elongation during anaphase are critical for error-free mitosis. In human cells, the evolutionary conserved ternary complex components NuMA/LGN/G α i1-3 anchor dynein at the cell cortex, thus ensuring metaphase spindle positioning. Whether the ternary complex also participates in cortical localization of dynein during anaphase was previously not known. Importantly, mechanisms by which mitotic spindle behaviour is coupled with mitotic progression remained elusive. We discovered that cortical levels of dynein markedly increase as cells transit from metaphase to anaphase, and this in a NuMA- and CDK1-dependent manner. We showed also that this increase of cortical dynein is crucial for proper spindle elongation during anaphase. Notably, we uncovered that LGN/G α i1-3 are dispensable for NuMA-dependent cortical dynein enrichment during anaphase. In addition, we established that NuMA is excluded from the cortical equatorial region by the centralspindlin complex components CYK4 and MKLP1. Interestingly, we discovered that NuMA directly interacts with membrane phosphoinositides in vitro and in vivo, and that cortical localization of NuMA during anaphase is dependent on these lipids. In summary, our study uncovered a novel mechanism by which NuMA links cell cycle progression with proper spindle behavior by directly associating with membrane lipids to ensure faithful execution of mitosis.

The dynein cortical anchor Num1 activates dynein motility by relieving Pac1/LIS1-mediated inhibition.

Cortically anchored dynein motors orient the mitotic spindle through interactions with spindle pole anchored astral microtubules. In budding yeast, dynein is offloaded to cortical Num1 receptor sites from

the plus ends of dynamic microtubules. Rather than walking toward minus ends, dynein remains associated with microtubule plus ends due to its association with Pac1 (LIS1 homolog), a potent inhibitor of dynein motility. The mechanism by which dynein is switched from “off” at the plus ends to “on” at the cell cortex remains unknown. Here we show that overexpression of the dynein-interacting coiled-coil domain of Num1 (Num1CC) – which is insufficient for cortical anchoring – depletes dynein-dynactin-Pac1 complexes from microtubule plus ends, and reduces the extent of colocalization of dynein and Pac1. Num1CC-mediated depletion of dynein from plus ends requires an interaction between Num1 and dynein, and also requires the dynein microtubule-binding domain. Live cell imaging reveals minus end-directed motility of dynein molecules along astral microtubules upon Num1CC overexpression – an event that is never observed in wild-type cells. An enhanced Pac1-affinity mutant of dynein, or overexpression of Pac1 partly restores Num1CC-mediated depletion of dynein from plus ends, suggesting that Num1CC activates dynein-dynactin motility by inducing the release of Pac1. Our findings indicate that dynein activity can be directly switched “on” by Num1, which, upon binding to dynein-dynactin complexes, may induce the removal of the Pac1/LIS1 inhibitor.
