In budding yeast, the mitotic spindle protein She1 is a key regulator of dynein pathway activity that functions to dampen productive microtubule-cortex interactions in the mother cell in order to achieve polarized spindle movements toward the bud. While the role for She1 is well established in the cytoplasm, its role in the nucleus is poorly understood. Here, we show that She1 is required for proper timing of Ipl1/Aurora B recruitment onto the mitotic spindle to ensure spindle integrity for dynein-dependent pulling from the cell cortex. Ipl1/Aurora B localizes in the nucleus with a diffusive pattern during metaphase and loads onto the mitotic spindle immediately prior to anaphase onset. Loss of She1 leads to premature loading and enhancement of Ipl1 on the spindle, whereas overexpression of She1 delays loading. In *she1Δ* metaphase spindles, enhanced Ipl1 resulted in a decreased level of microtubule-stabilizing +TIP protein Bim1 and an increased rate of anaphase spindle elongation due to cortical dynein activity. Additionally, *she1Δ bim1Δ* double mutant exhibited a synthetic broken spindle phenotype. The N-terminal conserved region of She1 is sufficient for restricting Ipl1, whereas the C-terminal domain is required for dampening cortical dynein. Our results establish a new role for She1 in ensuring spindle integrity through restricting Ipl1 in the nucleus, while promoting spindle positioning through cortical dynein.

P1728**Board Number: B245****Development and characterization of a cytoplasmic dynein mutant mouse carrying a human Charcot Marie Tooth mutation.**S. Nandini¹, T. Sabblah¹, N. Patwardhan¹, A. Ledray¹, V. Nascimento¹, J. Pasos¹, R. Love¹, L. Ehler¹, S.J. King¹;¹Burnett Sch. Biomed. Sci., Univ Central Florida, Orlando, FL

Charcot Marie Tooth disease (CMT) is the most common inheritable peripheral neuropathy in the United States. Individuals with CMT experience a range of symptoms, ranging from mild loss of motor coordination and some muscle weakness to debilitating pain and muscle weakness, often leading to the need for therapeutic intervention. Dynein is an essential molecular motor that functions to transport cargos in all cells. Multiple human dynein mutations have recently been shown to cause a variety of neurological disorders, including CMT, suggesting that dynein transport along nerve axons may be more sensitive than in other cells to genetic and physical dysfunction. To test this hypothesis we developed and are characterizing a novel mutant mouse model that carries a human dynein mutation found in a hereditary form of CMT. We found that heterozygous dynein^{CMT}/+ mice have motor skills behavioral phenotypes that are consistent with a loss of muscle strength and/or muscle coordination. The phenotypes we observed appear to be distinct and less severe than the motor skills phenotypes seen in Cra, Loa, and Swl mutant dynein mice, which do not have corresponding mutations in humans. Most interesting, homozygous dynein^{CMT}/dynein^{CMT} mice have survived up to 9 months and counting, whereas Cra/Cra, and Loa/Loa mice die within 24 hours of birth. We have determined that homozygous dynein^{CMT}/dynein^{CMT} mice have more severe motor skills behavioral phenotypes. With this mouse model in hand, it is now possible to study the effect of a known human disease causing DHC mutation on development, whole animal neurodegeneration, and axonal transport at the cellular level. In vitro analyses of pure mutant protein can now be performed without the confounding background of wildtype DHC dimers or mixed DHC/+ dimers. By correlating the behavioral phenotypes with the molecular characterization of the mutant dynein and cellular transport assays, we hope to generate a more comprehensive understanding of the key role dynein plays in neurological disease, ultimately leading to better human therapeutics including potential drug intervention strategies.

P1729**Board Number: B246****Role of NDE1 in T cell effector functions.**S. Nath¹, S.F. Lee², J. Artz³, S. Wong¹, M. Poenie¹;¹Department of Molecular Biosciences, The University of Texas at Austin, Austin, TX, ²Neogenomics Laboratories, Fort Myers, FL, ³Graduate School of Biomedical Sciences, University of North Texas Health Science Center, Fort Worth, TX

Helper and cytotoxic T cells exert their effector functions mainly through focused secretion. This process is thought to be accomplished by clustering of secretory vesicles at the centrosome or microtubule organizing center (MTOC) and translocation of MTOC up to the site of contact (the immunological synapse or IS). Our studies and those of others have implicated dynein in the process of MTOC translocation. Here we have examined the role of the dynein-binding protein NDE1 in the process of MTOC translocation. We recently found that NDE1 is recruited to the immunological synapse when Jurkat T cells engage superantigen-coated Raji cells or when cells from an NK cell line (NK92) engage Daudi cells. In both the cases both NDE1 and dynein form a ring-like structure corresponding to the pSMAC of the immunological synapse. Immunoprecipitation of either dynein or NDE1 show that both proteins form a complex that includes Lis1. When expression of NDE1 was reduced using siRNA, MTOC polarization process was reduced nearly to levels of a negative control. Moreover, when NDE1 expression was reduced by siRNA, dynein failed to localize at the synapse. Depletion of NDE1 did not interfere with other aspects of T cell activation such as accumulation of actin or phosphorylated LAT at the synapse or calcium signaling in response to stimulation with anti-TcR mAb. Localization of NDE1 was also examined in live cells using GFP-NDE1 chimeras. Interestingly, studies of GFP-NDE1 (GFP at the N-terminus) showed that the expressed construct failed to accumulate at the synapse, that it completely inhibited MTOC translocation, and that it displaced dynein from the synapse. On the other hand, expressed NDE1-EGFP (C-terminal EGFP) did accumulate at the synapse and did not interfere with either MTOC translocation or accumulation of dynein at the synapse. Dynein forms mutually exclusive complexes either with dynactin or with NDE1 and Lis1. These results combined with previous studies of Lis1 and dynein trapping using molecular traps show that the dynein-Lis1-NDE1 axis is required for MTOC translocation.

P1730**Board Number: B247****Characterization of Novel Splicing of Dynein's Microtubule-Binding Domain.**S. Bernard¹, J. Wildonger²;¹Integrated Program in Biochemistry, University of Wisconsin-Madison, Madison, WI, ²Biochemistry, University of Wisconsin-Madison, Madison, WI

The distribution of mRNAs, proteins and organelles within cells depends on the activity of molecular motors. While the kinesin family of motor proteins includes many members that transport cargo to the

plus-ends of microtubules, dynein is the major cytoskeletal motor responsible for minus-end-directed transport along microtubules. We have identified novel alternative splicing of the microtubule-binding domain in the *Drosophila* dynein heavy chain gene (Dhc64C) encoding the motor subunit of dynein. This alternative splicing affects helices within the microtubule-binding domain that are predicted to directly interact with microtubules. These isoforms are expressed throughout *Drosophila* development and in the adult. To determine the biological function of alternatively spliced microtubule-binding domains, we are utilizing the CRISPR-Cas9 system to generate animals that selectively express either isoform. We are also analyzing the microtubule-binding domain of the heavy chain gene in other organisms to determine how this alternative splicing evolved. These studies of novel microtubule-binding domain splicing will serve to define the effect of microtubule-binding domain residues upon dynein function.

Initial Characterization of a Probe to Measure Microtubule Sliding Forces in Living Cells.

P. Mooney^{1,2}, M. Tomschik¹, J. Gatlin^{1,2};

¹Department of Molecular Biology, University of Wyoming, Laramie, WY, ²Molecular Cellular Life Sciences Program, University of Wyoming, Laramie, WY

Microtubules play critical roles during many cellular processes, often functioning directly in the transport and movement of various intracellular components. Microtubules can affect these movements actively by using energy stored in their lattice to push or pull, or passively by acting as a scaffold upon which motor proteins and their associated cargoes can travel. In either capacity, microtubules must bear loads imparted by forces. Thus, full understanding of microtubule function within the cell will require measuring and characterizing these forces. Toward this end, we have developed a genetically-encoded probe designed to measure the forces that slide microtubules relative to one another in living cells. This probe consists of a FRET-based tension sensor flanked on either side by microtubule binding domains derived from tau. Truncated versions of this probe decorate spindle microtubules homogeneously, in contrast to similar probes derived from the microtubule binding domain of ensconsin. Using *in vitro* microtubule gliding assays, we demonstrate that the full-length tension sensor can crosslink microtubules and that it is indeed sensitive to the forces that are generated between them. Future work will involve calibration of the tension sensor, development of single molecule imaging strategies, and construction of a spatial map of microtubule sliding forces in the mitotic spindle.

P1732**Board Number: B249****Role of Dynactin in HTLV-1 Infection.**T.M. Gibson¹, R. Sperl¹;¹Biology, University of Texas of the Permian Basin, Odessa, TX

The cytoskeleton is responsible for overall cell shape and structure, as well as movement and organization of cellular organelles. Motor proteins, which associate with components of the cytoskeleton, facilitate many different types of intracellular movement. This includes organization of organelles and movement of chromosomes during cell division. Cytoplasmic dynein is a motor protein complex that mediates some of the retrograde movement in the eukaryotic cell. Dynein is known to interact with an activator protein called dynactin, which has been proposed to be critical for most of cytoplasmic dynein's activity. Evidence has shown that viruses, such as adenovirus and retroviruses, utilize the cytoskeleton for intracellular movement. One retrovirus termed Human T-cell Leukemia Virus-1 (HTLV-1) exhibits microtubule-dependent movement. HTLV-1 is a retrovirus that can cause a rare blood cancer called Adult T-cell Leukemia (ADL). HTLV-1 movement toward the nucleus during the infection process is poorly understood. Our laboratory has evidence that HTLV-1 binds to the dynein motor protein complex. Therefore, we hypothesize that dynactin is required for HTLV-1 intracellular movement. To investigate the role of dynactin in HTLV-1 movement during infection, siRNA will be used to knockdown dynactin expression in HEK 293 T-cells. The dynactin siRNA is not tagged, therefore a GFP-tagged GAPDH siRNA knockdown will be performed simultaneously to determine transfection efficiency of the dynactin knockdown. Next, the cells be infected with GFP-tagged HTLV-1, and infection and intracellular movement will be monitored using fluorescent microscopy. It can be predicted that HTLV-1 will not be able to properly attach to the dynein motor protein complex, resulting in little to no retrograde movement based on the fact that dynactin is required for most of dynein's activity. Western blot analyses of knockdown cell lysis have revealed a decreased GAPDH expression. Additionally, quantitative analysis of these Western blots has shown a 90 – 95% reduction in GAPDH compared to control samples. If a dynactin knockdown results in limited intracellular movement of HTLV-1, these results will reveal new information about the mechanism used by viruses to maneuver throughout the host cell. Additionally, antivirals and therapeutics could be developed to stop this interaction, thus halting the viral cycle.

P1733**Board Number: B250****Veza, a novel factor required for dynein-mediated early endosome transport.**X. Yao¹, H.N. Arst², X. Wang³, X. Xiang¹;¹Department of Biochemistry and Molecular Biology, USUHS - F. Edward Hébert School of Medicine, Bethesda, MD, ²Microbiology Section, Department of Medicine, Imperial College London, London, UK,³Department of Plant Genetics and Breeding, College of Agronomy and Biotechnology, China Agricultural University, Beijing, China

Cytoplasmic dynein transports organelles/vesicles and proteins/mRNA along microtubules. However, how dynein function is regulated *in vivo* remains unclear. We have been using *Aspergillus nidulans* as a model organism to dissect the regulation of dynein-mediated transport of early endosomes. Using a classical genetic approach, we have identified genes that are required for dynein-mediated early endosome distribution, and we recently reported the identification of *A. nidulans* HookA and FhipA proteins that link dynein-dynactin to early endosomes (Zhang et al., 2014; Yao et al., 2014). From the same genetic screen that allowed us to identify HookA and FhipA, we have recently identified Veza (vezatin-like protein in *A. nidulans*), another novel factor critical for dynein-mediated early endosome transport. The identification of the *veza* gene was achieved by using a combination of classical genetic and whole genome sequencing approaches. The Veza protein contains a vezatin domain that shows weak similarity to the mouse vezatin protein and the budding yeast protein Inp2p. Vezatin in mammalian cells binds myosin VIIA to bring it close to the cadherin-catenins complex (Küssel-Andermann et al., 2000), while the yeast Inp2p is a peroxisomal receptor for the myosin V protein Myo2p (Fagarasanu et al., 2006). Our current data show that, unlike HookA or FhipA that associate with early endosomes, Veza does not co-localize with early endosomes. In addition, Veza is not required for HookA-early endosome interaction, which is in contrast to the function of FhipA. We are in a process of further studying the mechanism of Veza action in dynein-mediated early endosome transport.

P1734**Board Number: B251****Functional analyses on the p25 and p27 components of dynactin in *Aspergillus nidulans*.**R. Qiu¹, J. Zhang¹, X. Xiang¹;¹Department of Biochemistry and Molecular Biology, USUHS - F. Edward Hébert School of Medicine, Bethesda, MD

Within the dynein-accessory complex dynactin, the two left-handed beta-helical proteins p25 and p27 locate at the pointed-end of the Arp1 mini-filament and are required only for a subset of dynein functions (Eckley et al., 1999; Lee et al., 2001; Schroer 2004; Parisi *et al.*, 2004; Zhang et al., 2011; Yeh et al., 2012; 2013). In *Aspergillus nidulans*, dynein-mediated early endosome transport requires p25, which is necessary for dynactin-dynein to interact with the early endosome adapter protein, HookA (A.

nidulans Hook) (Zhang et al., 2011; 2014). In the vertebrate dynactin complex, p25 and p27 form a heterodimer (Eckley et al., 1999), and RNAi of p25 makes p27 unstable and vice versa (Yeh et al., 2012). Thus, whether it is p25 or p27 that is more directly involved in early endosome transport and HookA-dynein-dynactin interaction would need to be addressed. Here we found that in *A. nidulans*, loss of p27 does not apparently affect p25-dynactin-dynein interaction or p25 protein level, but loss of p25 abolishes p27-dynactin-dynein interaction and reduces the level of p27. However, p25 function in early endosome transport is not mediated by p27 because loss of p27, unlike loss of p25, does not significantly affect HookA-dynein-dynactin interaction and dynein-mediated early endosome movement. We performed homology-based modeling of p25 structure and predicted that *A. nidulans* p25 contains, besides the core structure of the left-handed beta-helix core, two loop regions and a C-terminal alpha helix. We also identified several amino acid clusters whose side chains face outside of the core structure. Our functional analysis revealed three peripheral regions of p25 that contribute to dynein-mediated early endosome transport. These regions include Loop-1, the C-terminal region and the K36-Y83-H113 cluster. Importantly, these amino acids only play a minor role in p25-dynactin-dynein association but play a significant role in HookA-dynein-dynactin interaction. These data support the notion that within the dynactin complex, p25 is the protein specifically required for mediating HookA-dynein-dynactin interaction.

Board Number: B252

The manner by which dynactin regulates mammalian cytoplasmic dynein is dependent on the dynein intermediate chain isoforms.

W. Smiley¹, K. Blasier¹, D.J. Mitchell¹, K. Pfister¹;

¹Cell Biology, Univ Virginia Sch Med, Charlottesville, VA

Cytoplasmic dynein is a motor protein responsible for the movement of membrane bounded organelles and other cargo toward microtubule minus ends. The dynactin complex is associated with several of dynein's functional properties. We previously reported that specific phosphorylation of the dynein intermediate chain isoforms (IC) was important for dynein binding to endosomes and that this phosphorylation did not modulate IC binding to the p150 subunit of dynactin. We therefore sought to directly examine the functional significance of the interaction of dynactin and dynein complexes for dynein motility in axons. We disrupted the interaction of dynactin and cytoplasmic dynein by over-expressing the first coiled-coil region (CC1) of the p150 subunit of dynactin in neurons. This domain competes with endogenous p150 for binding to the dynein IC, but does not dissociate the dynactin complex. Using live cell imaging of axons expressing fluorescent-tagged ICs, we found that there was significantly less movement of dynein containing IC-2C in the presence of CC1 than in the control. The motility of dynein containing IC-2C was significantly reduced in both directions of movement, 40% in the anterograde direction and 70% in the retrograde. These results are consistent with previous observations that disruption of the dynein-dynactin interaction reduces organelle motility. Importantly, we also observed that there was no inhibition of the motility of dynein complexes containing IC-1B in

either direction. We then examined the motility of two dynein cargoes. In the presence of CC1 we observed reduced motility of mitochondria, which we previously reported were transported by IC-2C containing dynein, but no inhibition of the motility of Rab7 containing endosomes, a cargo transported by IC-1B containing dynein. In the presence of CC1, we also observed a 33% decrease in run length for IC-2C dynein, but no effect on IC-1B dynein run length. These results demonstrate that when cytoplasmic dynein is detached from the dynactin complex *in vivo*, there are two distinct dynein motility responses which are correlated with specific dynein intermediate chain isoforms. The disruption of dynactin binding has minimal effects on the motility of dynein containing IC-1B or its cargo, while the disruption significantly inhibits the motility of dynein containing IC-2C and its cargo. Furthermore, the data strongly suggest that the interaction between the IC and p150 is not required for dynein containing IC-1B to bind to cargo, and that dynein containing IC-1B does not require signals transmitted through the intact dynactin complex (via p150) for normal motility. These data have important implications for studies of dynein populations that have mixtures of IC isoforms.

Microtubule Nucleation and Organization

Microtubule asters grow to span a millimeter-sized egg by nucleation remote from centrosomes.

K. Ishihara¹, P. Nguyen¹, A.C. Groen¹, C.M. Field¹, T.J. Mitchison¹;

¹Department of Systems Biology, Harvard Medical School, Boston, MA

The large cells in early vertebrate development face an extreme physical challenge in organizing their cytoplasm. For example, frog embryos are 1.2 mm in diameter but have to divide every 30 min. In these cells, radial arrays of microtubules called asters grow, interact and move to precisely position the cleavage plane. Although the rapid expansion of asters, spanning the entire cytoplasm, is required for cells to explore its size and shape, it is unknown how microtubules assemble at such large distances from their presumable nucleation centers or centrosomes. Here, we combine quantitative imaging and cell-free reconstitution to show that microtubule asters grow by microtubule nucleation away from the centrosome. Aster growth occurs in the absence of microtubule transport while plus ends undergo both polymerization and depolymerization. Further, we report that the embryonic interphase cytoplasm supports spontaneous microtubule assembly independent of centrosomes, consistent with previous reports *in vivo*. We propose that aster growth, initiated by the centrosome, is supported by microtubule nucleation and is stimulated by the presence of pre-existing microtubules.

P1737**Board Number: B255****A new microtubule end-binding protein, NOCA-1, coordinates with patronin to control assembly of non-centrosomal microtubule arrays in *C. elegans*.**S. Wang¹, K. Oegema¹, A. Desai¹;¹Ludwig Institute for Cancer Research, La Jolla, CA

In contrast to the centrosomal microtubule arrays in dividing cells, many differentiated cells assemble non-centrosomal microtubule arrays adapted for specific cellular functions. In an RNAi screen in *C. elegans*, we identified NOCA-1 as a novel protein that does not contribute to centrosome-driven embryonic cell divisions but is required to form microtubule arrays in the germline that are essential for organismal fertility. The *noca-1* gene encodes 8 isoforms expressed in a variety of tissues. Two distinct long isoforms control assembly of microtubule arrays in the germline and embryonic epidermis, respectively. In contrast, a short isoform functions in parallel to the microtubule minus end-binding protein Patronin (PTRN-1) to control assembly of microtubule arrays in the post-embryonic epidermis. Evidence for the redundant activity of NOCA-1 and PTRN-1 includes synthetic lethality and early larval stage dye permeability of *noca-1Δ;ptrn-1Δ* double mutants, both of which are rescued by selectively expressing PTRN-1 in the post-embryonic epidermis. In support of the genetic interaction, NOCA-1 co-sediments with taxol-stabilized microtubules from worm lysates and purified recombinant NOCA-1, like PTRN-1, binds to microtubule ends in a microtubule-anchoring assay. Live imaging of the epidermal syncytium where NOCA-1 and PTRN-1 function redundantly revealed an array of evenly spaced microtubule bundles that run circumferentially around the animal. This array, comprised of both stable and dynamic microtubules, is subtly affected in single *noca-1Δ* and *ptrn-1Δ* mutants but nearly completely eliminated in *noca-1Δ;ptrn-1Δ* worms, suggesting that this specialized non-centrosomal array supports epidermal integrity during animal growth. We conclude that NOCA-1 represents a new class of microtubule end-binding proteins with essential functions of its own, as well as parallel functions with Patronin, in the assembly of non-centrosomal microtubule arrays in multiple *C. elegans* tissues.

P1738**Board Number: B256****A Detailed Centrosome Interactome Reveals a Novel Role for Asterless/CEP152 in Controlling Centriole Length Via Cep97.**B.J. Galletta¹, K.C. Jacobs², C.J. Fagerstron², K.C. Slep³, N.M. Rusan¹;¹National Heart Lung, and Blood Institute, NIH, Bethesda, MD, ²NHLBI-NIH, Bethesda, MD, ³Department of Biology, University of North Carolina, Chapel Hill, NC

A critical gap in our understanding of how centrosomes are built and subsequently mature into microtubule organizing centers (MTOC) is the relative lack of information on the direct interactions

among the constituent proteins. To address this deficiency in our knowledge, we performed a directed yeast two-hybrid screen to identify the possible, direct interactions among 22 conserved *Drosophila* centrosome proteins. To provide additional detail about how centrosomal proteins interact, these 22 proteins were subdivided into smaller fragments, keeping known domains and predicted secondary structures intact. In total, 67 full-length proteins and subfragments were tested. We identified more than 100 interactions among these proteins, the majority of which are novel, significantly increasing our understanding of the protein-protein interaction network within the centrosome. With this new interaction information, we attempted to better understand the role of Asterless (Asl)/CEP152. Since Asl is essential for the duplication of the centrosome, the molecular mechanism of its function and if it plays roles in addition to centriole duplication remains somewhat unclear. We have studied the loss of *asl* in the male germline stem cells (mGSCs) of *Drosophila melanogaster* larvae, which reproducibly harbor Asl-free centrioles. These remnant centrioles were built during embryogenesis using maternally provided Asl, but by this stage no longer have any associated Asl protein. Amazingly, in the mGSCs of *asl* mutants, the remnant centrioles are 10 to 30 fold longer than in wild-type mGSCs. Examining the localization of all of the Asl interacting proteins identified in our screen, we found proteins that localize to the proximal end of the giant centrioles in wild type spermatocytes extend the entire length of the centriole in the mGSCs of *asl* mutants. Interesting, the localization of proteins along the long centrioles in *asl* mGSC appears unique in comparison to previously described long centrioles, suggesting they may arise by a novel mechanism. To understand the possible mechanism of centriole length control by Asl in mGSCs, we examined flies with a mutation in *cep97*, which has been suggested to regulate centriole length. These flies have long centrioles in mGSCs, similar to Asterless. This is consistent with a model where in mGSCs, Asl plays a role in controlling the length of centrioles via Cep97. To test this model we have engineered a centriole-targeted version of Cep97 and show that expression of this construct can partially rescue the length of centriole in *asl* mGSCs. Finally, we are exploring the consequences of loss of Asl and the resulting increased length of centrioles on the interphase positioning of centrioles in mGSCs.

From Yeast to Human: Kinesin Regulators of γ -TuRC Structure and Nucleation.

Z.T. Olmsted¹, T. Riehlman¹, A. Colliver¹, J.L. Paluh¹;

¹SUNY College of Nanoscale Sci and Eng, Albany, NY

Members of two conserved mitotic kinesin-like protein (Klp) families, Kinesin-14 and Kinesin-5, have emerged as direct regulators of the γ -tubulin ring complex (γ -TuRC) microtubule organizing center (MTOC) in fission yeast and humans. While Klp members in these families are most studied for microtubule based organization roles in spindle assembly, a subset of members also localize to γ -TuRC at spindle poles to regulate microtubule nucleation. Genetic analysis, biochemical sedimentation of γ -TuRC complexes, co-immunoprecipitation assays and in vivo cell studies reveal a competitive mechanism between Kinesin-5 and Kinesin-14 that balances γ -TuRC structure and nucleation capacity.

We recently investigated details of the Kinesin-14 Pkl1 mechanism in fission yeast and the contribution of Kinesin-5 Cut7 to perturb the functional relationship between Kinesin-14 Pkl1 and γ -TuRC. We demonstrate that similar but counteracting forces by Kinesin-5 on γ -TuRC interfere with Pkl1 Motor and Tail domain interactions at γ -TuRC. We designed multiple unique Pkl1 Tail peptides as tools for capturing γ -TuRC or disrupting its structure by removal of γ -tubulin subunits (Cell Cycle 2013). This action is reversible and also occurs on γ -TuRC of rat and human centrosomes. New data from our lab further indicates that the normally essential fission yeast Kinesin-5 Cut7 motor protein becomes dispensable in the absence of Pkl1, emphasizing the importance of this antagonistic MTOC regulatory relationship. In yeast the action is asymmetric and additionally influences spindle microtubule numbers and microtubule overlap. We demonstrate by in vivo studies in human breast cancer cell lines that similar to as in yeast our Kinesin-14 peptides block microtubule nucleation from γ -TuRC. Previously we demonstrated in vivo that human Kinesin-14 HSET, but not Drosophila Ncd, functionally replaces Kinesin-14 Pkl1 in fission yeast and more recently that the genes encoding human γ -TuSC proteins GCP2 and GCP3 fully replace fission yeast genes for the analogous Alp4 and Alp6 MTOC proteins (JCS 2013). Our research highlights conserved in vivo regulation of γ -TuRC that informs on its structure and capacity for nucleation and reveals novel underlying mechanisms.

In vitro reconstitution of efficient microtubule formation by the combined action of TPX2 and chTOG.

J. Roostalu¹, N.I. Cade¹, T. Surrey¹;

¹Cancer Research UK London Research Institute, London, United Kingdom

Spindle assembly relies on a number of microtubule-associated proteins that contribute to microtubule organisation through microtubule crosslinking and transport, regulate microtubule dynamics and/or facilitate microtubule nucleation. TPX2 is a multi-functional microtubule-binding protein required for proper spindle formation in all higher eukaryotes. It is one of the key targets of the Ran pathway that is essential for chromatin-dependent microtubule assembly in *Xenopus laevis* egg extracts. Total spindle microtubule mass in *Xenopus laevis* is additionally controlled by the processive microtubule polymerases of the XMAP215/Dis1 protein family. The molecular mechanism of how these two proteins contribute to microtubule formation and whether they directly facilitate the nucleation process is not understood. Here we use a combination of microscopy-based in vitro reconstitution assays to elucidate the respective roles of human TPX2 and chTOG, the human ortholog of XMAP215/Dis1, in microtubule assembly. TPX2 is preferentially recruited to the microtubule lattice at growing microtubule ends by its central domain, where it prevents microtubule catastrophes without affecting microtubule growth rate. These properties are markedly different from the microtubule growth-promoting activity of the chTOG proteins. The microtubule stabilising effect of TPX2 is directly related to its function in microtubule nucleation: TPX2 also stabilises early sheet-like nucleation intermediates at the initial stages of microtubule assembly. Efficient tube formation and sheet closure, however, require the additional

presence of the microtubule polymerising activity of chTOG. Together, our results demonstrate that a combination of very distinct activities of two microtubule binders is both necessary and sufficient for efficient microtubule formation in solution. Furthermore, these findings provide important insight into the mechanism of microtubule nucleation stimulated by the Ran pathway during spindle assembly.

Genetic analysis of microtubule array organization in *Arabidopsis* hypocotyls.

A.W. Elliott¹, D. Thoms², M. Kline², S.L. Shaw²;

¹Molecular and Cellular Biochemistry Department, Indiana University, Bloomington, IN, ²Department of Biology, Indiana University, Bloomington, IN

Microtubules (MTs) organize through time and in space to affect critical processes such as cell division, morphogenetic events, and vesicle trafficking. Flowering plants produce distinct MT array patterns in the absence of centrosomes or defined MT-organizing centers. Highly dynamic cortical microtubule arrays are proposed to influence cell morphology through alignment of cellulose microfibrils in the cell wall. However, the mechanisms controlling the organizational states of these MT arrays remain largely unknown. Cortical MTs in *Arabidopsis* hypocotyl cells nucleate from γ -tubulin complexes distributed throughout the plasma membrane and remain laterally attached to the membrane. Redistribution of polymer via treadmilling leads to MT-MT interactions and formation of higher order structures such as MT bundles. We have used plant hormones to synchronously induce hypocotyl cells to reorganize the cortical MTs into a transverse co-aligned array on a 2 hr time scale. Reorganization initiates at the cell midzone and progresses bidirectionally to the apical and basal ends of the cell without transiting through an obligate intermediate pattern. To determine the genes required for this MT array patterning event, we initiated a forward genetic screen in *Arabidopsis*. EMS-mutagenized seedlings were screened for hypocotyl growth defects, including reduced hypocotyl length, radial cell expansion, and twisting cell files, and candidate mutants were rescreened for defects in hormone-induced transverse MT patterning. A systematic quantitative evaluation of cell shape and MT array pattern coupled with time-lapse imaging and supersensitivity tests for MT disrupting drugs is providing data for clustering phenotypes into distinct groups for complementation and epistasis tests. Five phenotypic groups have been initially identified with one group verified as new katanin (MT severing protein) alleles. A temperature-sensitive mutant class displays a novel radial-like MT array (termed pinwheel) with the focal point at the midpoint of the outer periclinal cell face. Pinwheel mutants fail to reorganize MT arrays to the transverse co-alignment after hormone treatment and exhibit reduced axial hypocotyl growth following long-term exposure to hormones. Outcomes from the screen and analysis of pinwheel mutants will be presented.

P1742**Board Number: B260****Linker Scanning Mutagenesis of Yeast Microtubule Nucleating Components Spc97 and Spc98.**K. Fong¹, J. Tien¹, C. Payen², A. Zelter¹, B. Graczyk¹, M. Dunham², T. Davis¹;¹Department of Biochemistry, University of Washington, Seattle, WA, ²Department of Genome Sciences, University of Washington, Seattle, WA

The mitotic spindle is a large structure responsible for the regulation and organization of chromosome segregation. Misregulation of chromosome segregation can lead to aneuploidy or genomic instability. Microtubules play several key roles during mitosis—mediating chromosomal movements, stabilizing spindle structure, and positioning the spindle within the cell. The γ -tubulin small complex is a highly conserved complex, essential for microtubule nucleation in all organisms. In budding yeast, the γ -tubulin small complex is localized to the spindle pole bodies and is comprised of two γ -tubulin molecules and one copy each of Spc97 and Spc98. Despite our advances in understanding microtubule function, dynamics and nucleation, purified γ -tubulin complexes fail to efficiently recapitulate nucleation *in vitro*, suggesting that additional regulatory processes activate the nucleating complex. Based on EM structure, we hypothesize that Spc98 undergoes a conformational change that enables the γ -tubulin small complex to serve as a template for microtubule growth. We have performed a saturating linker-scanning mutagenesis to define the regions of Spc97 and Spc98 required for the small complex to function *in vivo* and promote the formation of a microtubule. *In vitro* transposition reactions generated a library of random 15 base pair insertions in each gene, with approximately 90% coverage. This extensive transposition library was collected and transformed into yeast to screen for viability and conditional lethality using a plasmid shuffle. Mutants that abolish function identify the essential regions of the protein and mutants that are temperature sensitive can be studied after shifts to restrictive temperatures to examine nucleation activity. Over 50,000 yeast colonies were screened and 4% of the colonies contained lethal mutations and 0.02% contained temperature-sensitive mutations. Sites of lethal insertions were identified and mapped by high-throughput sequencing. Representative lethal mutations have been studied to determine the effects on protein expression, localization, and small complex formation. Temperature sensitive mutants were inspected by fluorescence microscopy and *in vitro* nucleation assays to reveal several nucleation hyperactive and deficient mutants. When combined with high-throughput sequencing, linker-scanning mutagenesis was a powerful approach to identify essential regions of the γ -tubulin small complex and provide novel temperature-sensitive mutants with specific defects in microtubule nucleation.

P1743**Board Number: B261****MAP65 acts as a molecular yardstick to minimize microtubule overlap in Dictyostelium syncytia.**M.P. Koonce¹, K. Irizarry¹, I. Tikhonenko¹;¹Wadsworth Center, Albany, NY

The MAP65/Ase1/PRC1 family is known as bundling proteins important for managing regions of overlapping antiparallel microtubules during animal cell division and for crosslinking parallel and antiparallel microtubule arrangements during interphase in plants and fungi. Homodimers work in combination with kinesins and other factors to link adjacent microtubules in a compliant manner. We postulate here that the MAP65/Ase1/PRC1 family has an additional role in sensing and coordinating the elimination of antiparallel microtubule arrangements during interphase, a process important to maintain intranuclear spacing in syncytial cells. Dictyostelium cells often fail cytokinesis and form multinucleated cells that remain viable. A striking feature of these cells is that nuclei are generally dispersed in the cytosol and their associated microtubule arrays roughly occupy spatially distinct territories. Treatment of cells with nocodazole shrinks distances between centrosomes, indicating that microtubule length plays a role in array spacing, and suggesting that nuclear spacing is actively maintained. Dictyostelium contains two homologs of MAP65 (A,B); knockout of MAP65A results in a significant collapse of inter-centrosome distances and enhances microtubule array co-mingling. The average spacing between centrosomes in wild type binucleate cells is 7.2 μm , but is only 3.7 μm in the MAP65A knockout. Disruption of MAP65B accentuates cellular branching and formation of elongated microtubules. The overall growth rate of cells lacking either MAP65 isoform is similar to wild type. However, for the MAP65A knockout, there is a marked increase in multinucleated cells. We have previously shown that the interphase microtubule array in Dictyostelium is a highly dynamic structure whose position is influenced by dynein, Kinesin-4, and Kinesin-8 activities. Our current work indicates that MAP65 also plays a role in maintaining microtubule organization, in particular with separation of multiple interphase arrays in a common cytosol. Kinesins-4 and -8 are known to interact with MAP65/Ase1/PRC1 proteins and thus potentially could be targeted to microtubule overlaps to foster sliding or depolymerase activity that minimizes antiparallel microtubules. These roles would not only facilitate endomembrane management in complex environments, but also minimize the potential for misintegration of multiple centrosomes into the same nucleus during division. For this project, we are grateful to support from the National Science Foundation (IOS-1051612 and DBI-1062963).

P1744**Board Number: B262****Identifying Pathways Directing Plant Cortical Microtubule Array Organization.**D. Thoms¹, A.W. Elliott², R. Chaudhari¹, A.J. Hill², M.A. Kline¹, S.L. Shaw¹;¹Department of Biology, Indiana University, Bloomington, IN, ²Molecular and Cellular Biochemistry Department, Indiana University, Bloomington, IN

The interphase microtubules at the plant cell cortex play a defining role in plant cell morphogenesis. Cell shape arises through a combination of forces, but relies heavily upon the mechanical properties of the cell wall. Cortical microtubules aid in patterning the extracellular deposition of cellulose microfibrils, the major structural fiber impacting wall mechanics. Cells undergoing anisotropic growth typically have co-aligned microtubule arrays oriented transverse to the dominant growth axis suggesting that the anisotropic growth arises because of strongly oriented cellulose deposition. The molecular pathways that determine how the cell organizes microtubules into a transverse coaligned pattern have not been explicitly described. We discovered a hormone treatment that synchronously induces plant hypocotyl cells to form transverse coaligned microtubule arrays and resume anisotropic growth. To identify molecules involved in the related genetic pathways, a genetic screen is underway. Candidate mutants are classed based on statistical analysis of array pattern distributions, growth morphology, and chemical sensitivity to drugs targeting microtubule and cellulose synthase activity. Approximately 60,000 seedlings from 1350 mutant lines were screened, and 55 initial lines were identified as having a hypocotyl growth defect along with the inability to form transverse arrays. The majority of mutants show subtle hypocotyl growth phenotypes such as cells with slightly decreased cell anisotropy or twisting cell files. The most common phenotypes are found in mutants with disorganized, basket arrays, and normal cell anisotropy, but are hypersensitive to treatment with oryzalin. Other common phenotypes occur in mutants which form co-aligned array patterns other than transverse, but have significantly decreased cell anisotropy. Less common phenotypes are in mutants with dense and disorganized arrays, abnormal cell files and cell morphology, normal or slightly increased anisotropy, and varying sensitivities to oryzalin treatment. Rarer phenotypes are in mutants with a threefold increase in cell anisotropy in comparison to light grown wild type seedlings, and a novel array patterning consisting of multiple swirl-like regions of co-alignment in each cell. Single mutant phenotypes include an inefficient ability to bundle microtubules, a wispy microtubule defect with extreme oryzalin hypersensitivity, or a hypocotyl defect exhibiting projecting cell files when grown in 30°C with extreme oryzalin hypersensitivity. Future work includes full genomic sequencing to identify underlying mutations, epistasis tests, and localization studies of identified proteins during the formation of transverse arrays.

P1745**Board Number: B263****Paternal Poc1 is Essential for the Function of the Zygote Centrosome.**A. Khire¹, S. Hynek¹, E.D. Rodriguez¹, T. Avidor-Reiss¹;¹Biological Sciences, University of Toledo, Toledo, OH

Centrioles are conserved microtubule-based organelles that, together with pericentriolar material (PCM), form the centrosome. During oogenesis in animals, the centrioles are eliminated, and therefore, the ovum does not contribute centrioles to the zygote. Instead, centrioles are provided to the zygote by the sperm. However, compared to centrioles in somatic cells, in many animals, including *Drosophila*, the spermatozoa centriole has a different structure and/or protein composition. Recently, we showed that *Drosophila* spermatozoa provide, in addition to the giant centriole (GC), a centriole precursor, which we named the proximal centriole like (PCL). The PCL resembles a centriole precursor, but lacks the centriole hallmark of microtubules. In the zygote, the GC and PCL recruit maternally contributed PCM, and form a centrosome. This centrosome, which is found near the male pronucleus, forms astral microtubules that reach out to the female pronucleus. Then, the female pronucleus migrates along the astral microtubules until it fuses with the male pronucleus. Later, the GC and PCL duplicate and form the poles of the zygote's spindles. Here, we report that the centriolar protein, Poc1, plays a role in fertilization in *Drosophila*. Poc1 is a conserved centriolar protein that is essential for centriole elongation and centrosome function. In an EMS screen, we identified a missense point mutation in poc1 that effects the recruitment of Ana-1 to the PCL, but does not effect Ana-1 recruitment to the GC or the length of the GC in the sperm. Males with this mutation, which preferentially affects the sperm PCL, have reduced fertility. This reduced male fertility associates with two distinct phenotypes in the zygote: failure in female pronucleus migration and formation of monopolar spindles. These findings demonstrate that poc1 is a paternal affect mutation due to dysfunction of the zygotic centrosome. It also suggests that the PCL is essential for zygotic centrosome function.

P1746**Board Number: B264****A Chlamydia effector manipulates host microtubule dynamics to promote bacterial survival.**M. Dumoux¹, A. Menny¹, D. Delacour², R. Hayward¹;¹Biological sciences, Institute of structural and molecular biology (Birkbeck college-UCL), London, United Kingdom, ²Institut Jacques Monod - CNRS, Paris, France

Chlamydia trachomatis is an obligate intracellular bacterial pathogen that causes sexually transmitted disease worldwide and is the leading cause of acquired blindness (trachoma) in developing nations. Chlamydiae employ a type III secretion system to deliver virulence effector proteins into host cells. These effectors subvert fundamental cellular processes, allowing bacterial intracellular survival and replication within a specialized membrane-bound compartment termed an inclusion. We discovered

that *C. trachomatis* dramatically reorganizes the microtubule cytoskeleton within infected cells to form a filamentous superstructure. This comprises a microtubule scaffold surrounding the inclusion and an associated nest of microtubules that originate at the inclusion and extend towards the plasma membrane. Using a bioinformatics approach, we identified a chlamydial effector (inclusion protein acting on microtubules; IPAM) that shares limited sequence similarity with eukaryotic centrosomal and microtubule-binding proteins. Using pull-down and co-immunoprecipitation assays we demonstrate that IPAM, a hydrophobic effector known to associate with the inclusion membrane, interacts with host centrosomal protein 170kDa (CEP170), a centrosome and kinesin-interacting protein, via a domain exposed to the cytosol. Ectopic expression of this IPAM domain impairs microtubule dynamics. This defect was restored by simultaneous CEP170 knock-down, demonstrating functional interplay between IPAM and CEP170 in cells. CEP170 is essential for chlamydial control of host microtubule dynamics and organelle repositioning during infection, and is necessary for inclusion morphogenesis and bacterial infectivity. Moreover, as IPAM stimulates CEP170 functions in *Chlamydia*-infected cells, this reveals potential physiological roles of CEP170 repressed in non-dividing uninfected cells. Together our data show how a chlamydial type III secretion effector stimulates a host target to promote the reorganization of the microtubule cytoskeleton in infected cells, an event required for inclusion biogenesis and bacterial intracellular survival. In turn this provides broader insight into the control of cellular microtubule dynamics.

Role of osmotic pressure in the regulation of the cytoskeleton during mitosis.

I. Dasgupta¹, C. Koh^{1,2};

¹School of Biological Sciences, Nanyang Technological University, Singapore, Singapore,

²Mechanobiology Institute, National University of Singapore, Singapore, Singapore

The actin cytoskeleton plays an important role in the regulation of many cellular activities, including cell motility and cell division. The flat, adherent cells during interphase, assume a spherical shape at the onset of mitosis, termed as “mitotic cell rounding”. This change in cell shape is essential for the proper positioning and stabilization of the mitotic spindle, thus ensuring chromosome segregation with high fidelity. The remodeling of the actin cytoskeleton and the ability of the cell to regulate its osmotic pressure are among the key forces that primarily govern this cell rounding. A balance between the outward directed osmotic pressure and the inward actomyosin contraction is instrumental in driving this process. The ERM (Ezrin, Radixin, Moesin) family of proteins, known to cross-link the plasma membrane with the underlying actin cortex, are associated with mitotic cell rounding. Previous reports suggest the ERM proteins, upon phosphorylation and activation during mitosis are redistributed towards the cell cortex, thereby contributing to the cortical rigidity. Our results show an upregulation in the p-ERM levels and increase in the cortical rigidity of the mitotic cells upon exposure to a hypertonic environment. The actin filaments in the cells undergo realignment and distribution to the spherical cortex during mitosis. The interaction of the cortical actin with the astral microtubules that radiate towards the cell cortex

from the spindle poles generates tensile forces, thus favoring proper spindle assembly. Exposure to the hypertonic stress resulted in defects in the astral microtubule arrangement and centrosome integrity. The impaired astral microtubule arrangement was restored to normal when the cells were recovered in an isotonic medium, following a hypertonic shock. We further observe that the increase in the astral microtubules is directly proportional to the duration of the hyperosmotic shock. Perturbation of the osmotic gradient also leads to a significant decrease in the length and width of the mitotic spindle, as well as shrinkage of the cortical actin. Thus, our studies suggest the existence of possible functional links between cytoskeletal regulators and proteins modulating the osmotic pressure in cells.

Bayesian analysis of FRET to quantitatively measure microtubule nucleation in vivo and in vitro.

B. Kaye¹, D.J. Needleman^{2,3,4};

¹Applied Physics, Harvard University, Cambridge, MA, ²FAS Center for Systems Biology, Harvard University, Cambridge, United States, ³School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, ⁴Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

The mitotic spindle is a self-organizing structure that segregates chromosomes during cell division. The spindle is composed of microtubules, and microtubules are composed of the protein tubulin. Understanding microtubule nucleation is critical to understanding the mitotic spindle. Microtubule nucleation can be inferred from the temporal dependence of the amount of tubulin in polymer. We use FRET, a technique to probe protein-protein interactions, to measure the amount of tubulin in polymer in cell extracts. To detect FRET, we measure the lifetime of the excited state of the donor fluorophore, a technique commonly referred to as FLIM. We developed a Bayesian framework for analyzing FLIM measurements that rigorously accounts for all known experimental complications. This novel technique will allow us to quantitatively measure microtubule nucleation in situ and dissect the biophysics, biochemistry and cell biology of microtubule nucleation.

Mechanisms controlling the microtubule organizing center state of the cell.

J.L. Feldman¹;

¹Biology, Stanford Univ, Stanford, CA

The centrosome is the major microtubule organizing center (MTOC) in dividing animal cells. In many types of differentiated cells, however, MTOC function is reassigned to non-centrosomal sites. We are using *C. elegans* intestinal cells as a model to study non-centrosomal MTOCs. The apical surfaces of intestinal cells become MTOCs during polarization: microtubule-nucleating proteins that are centrosome

components in dividing cells become localized apically and apical membranes nucleate the assembly of microtubules. Concurrently, the centrosome is turned off as an MTOC in polarized cells; centrosomes lose pericentriolar material, microtubule association, and microtubule nucleating capacity. Thus, intestinal cells switch from a centrosome MTOC during mitosis to an apical MTOC during polarization. A subset of intestinal cells divides following polarization. In these cells, the apical MTOC is removed and the centrosomal MTOC is reactivated, indicating that cells can switch in either direction between MTOC states but do not maintain both. To determine how the cell “chooses” its MTOC state, we tested dominance of MTOC states by fusing a polarized cell with a mitotic cell in developing embryos. Cell fusion experiments indicate that mitotic cytoplasm is capable of dictating the MTOC state: fusing a mitotic cell with a polarized cell results in the rapid loss of MTOC components from the apical surface and the growth of MTOCs at normally quiescent centrosomes. We are now pursuing the mechanism that “flips the switch” in cellular MTOC state and will present our results.

A Novel Proximal Centriole-Like (PCL) Structure Becomes the Second Centriole in the Zygote of *Drosophila melanogaster* .

A. Khire¹, S. Blachon², E. Fishman¹, T. Avidor-Reiss¹;

¹Biological Sciences, University of Toledo, Toledo, OH, ²Hybergenics, Paris, France

Centrioles are conserved organelles that form centrosomes, or microtubule organization centers that are essential for cell division and function. As a result, they are essential for fertilization, development, and physiological functions. During oogenesis in animals, centrioles are lost, and thus, the oocyte does not contribute any centrioles to the zygote, the first cell of the embryo. Instead, it has been reported that zygotic centrioles are inherited from the sperm. In animals like sea urchins, frogs, and *Caenorhabditis elegans*, the sperm provides two centrioles, which is the normal number of centrioles in a cell. In contrast, in humans and in most mammals, the sperm contributes only a single centriole. This reduced contribution is due to a process known as “centrosome reduction,” in which one of the spermatid’s two centrioles degenerates during the last phase of spermatogenesis. Thus, the origin of the second zygotic centriole is uncertain.

Like humans, *Drosophila melanogaster* sperm contains one centriole (Giant Centriole/GC). However, we have recently discovered that *Drosophila melanogaster* sperm contains a centriolar structure that is composed of centriolar proteins but lacks the structural characteristics of a centriole; we have named it the Proximal Centriole-Like (PCL). Based on the PCL’s presence, we propose the PCL Hypothesis, which states that the PCL is a second zygotic centriolar structure. Here we report that like the GC, the PCL also loses many of its components during the late stage of spermiogenesis. Because of centrosome reduction, centriolar proteins do not label the PCL in the sperm and therefore, we indirectly visualize the PCL and GC by their recruitment of centrosomal markers in the fertilized zygote. Immediately after fertilization, we find two centriolar structures, the GC and the PCL. As expected from the PCL hypothesis, we find that early maternally contributed centriolar proteins like Sas 4 and Sas-6, do not

label the first two-centriolar structures of the zygote, but do label their daughter centrioles. Lastly, as the PCL hypothesis predicts, we found that zygotes lacking Asterless, which is essential for centriole duplication, have two centriolar structures. Altogether, we have found that the PCL is a centriole precursor in the sperm, which functions as the second zygotic centriole in *Drosophila melanogaster*. The PCL hypothesis may be applicable to other animals; it would explain why only three centrioles have been observed in a mammalian zygote during mitosis, despite the requirement of four centrioles for normal mitosis. Further studies aim to identify the range of animals with a PCL, to identify the specific role of the PCL in the zygote, and to identify the molecular mechanism underlying PCL function

Deficiency of tuba, a cdc42 GEF, disrupts normal zebrafish ciliogenesis and kidney development.

J. Baek¹, S. Choi¹, X. Zuo², J.H. Lipschutz²;

¹Med Univ South Carolina, Charleston, SC, ²Department of Medicine, Medical University of South Carolina, Charleston, SC

Background: Dysfunction of renal primary cilia leads to polycystic kidney disease (PKD). The exocyst, a highly-conserved eight-protein membrane trafficking complex, is essential for ciliogenesis, and is regulated by Rho and Rab family GTPases, such as cdc42. We previously showed that cdc42 deficiency disrupts renal ciliogenesis and causes PKD in zebrafish and mice, and that Tuba, a cdc42-specific GEF, is necessary for ciliogenesis in cultured renal tubular MDCK cells. **Methods:** To determine how tuba affects ciliogenesis and kidney function in vivo, tuba knock-down was performed in zebrafish by microinjection of a translation blocking morpholino (MO). The phenotypic and histological defects caused by tuba deficiency were analyzed using whole-mount in situ hybridization, H & E staining and immunofluorescence. **Results:** Tuba was expressed in several tissues containing primary cilia, including the brain, neuromast cells, and renal tubules. We found that tuba morphants phenocopied cdc42 morphants, with ciliary mutant phenotypes including: a curly tail, hydrocephalus, and abdominal fluid accumulation. These defects were rescued by human tuba mRNA, which was resistant to the morpholino due to a difference in primary base pair structure, indicating that the phenotype was due to tuba deficiency, and not off-target effects. In the tuba morphant kidney, pronephric cilia were short and disordered, and the glomeruli were also disorganized. Because tuba is a known GEF of cdc42, and tuba and cdc42 morphants shared the same phenotype, we next performed a genetic synergy experiment in which we knocked down both tuba and cdc42. Co-injection of tuba and cdc42 morpholinos at low concentrations, which individually resulted in no phenotype, caused a severe phenotype, suggesting that tuba and cdc42 act in the same pathway. **Conclusion:** Our study showed that tuba deficiency causes an abnormal renal ciliary phenotype in zebrafish, demonstrating that tuba plays a critical role in

ciliogenesis and kidney development in zebrafish. We are currently generating kidney-specific tuba knockout mice to confirm these results in metanephrogenesis.

The Na⁺/H⁺ Exchanger Regulatory Factor 1 (NHERF1) regulates Wnt signaling pathways.

A. Caceres¹, D.S. Wheeler¹, S. Barrick¹, Y. Yang¹, D.B. Stolz², M. Tsang³, P.A. Friedman¹, G.G. Romero¹;
¹Pharmacology and Chemical Biology, University of Pittsburgh, Pittsburgh, PA, ²Cell Biology, Univ Pittsburgh Sch Med, Pittsburgh, PA, ³Developmental Biology, Univ Pittsburgh, Pittsburgh, PA

The Na⁺/H⁺ Exchanger Regulatory Factor (NHERF1) is a scaffolding protein of the PSD-95/Discs-large/Zo-1 (PDZ) family. NHERF1 contains two tandem PDZ domains through which it mediates protein-protein interactions. Mice that do not express NHERF1 present various pathological phenotypes including hydrocephalus associated to disorganized ependymal cilia and reduced number of ciliated cells. Our studies demonstrate that these phenotypes can be explained by deregulated Wnt signaling in the absence of NHERF1. We show that NHERF1 binds a subset of Frizzled receptors (Fzd) and inhibits activation of β -catenin. NHERF1^{-/-} animals have increased levels of nuclear β -catenin in the ependyma. We further demonstrate that NHERF1 binds the Planar Cell Polarity proteins Vangl1/2 and promotes their traffic to the plasma membrane, and in particular to the apical surface of ependymal cells. Furthermore, we show that NHERF1 assembles a ternary complex containing Fzd4 and Vangl2. We hypothesize that NHERF1 is a “signaling switch” that regulates the input to the canonical and non-canonical Wnt signaling pathways by promoting the assembly of multimolecular complexes containing Fzd receptors and PCP proteins.

Functional studies of NPHP5, a novel centrosomal protein deficient in human ciliary diseases.

M. Barbelanne^{1,2}, W. Tsang^{2,3,4}, J. Song², M. Ahmadzai²;
¹Medicine, University of Montreal, Montreal, PQ, ²Institut de recherches cliniques de Montréal (IRCM), Montreal, QC, ³University of Montreal, Montreal, PQ, ⁴McGill University, Montreal, PQ

The purpose of this project is to understand the regulatory mechanisms of centrosomes and cilia function. Centrosomes are small organelles composed of two centrioles surrounded by a pericentriolar

matrix. They are the major microtubule-organizing centers in mammalian cells and regulate diverse cellular processes such as cell division. In addition, centrosomes promote the formation of cilia, cellular protuberances on the surface of quiescent cells critical for signal transduction. Centrosome and cilia dysfunction are linked to a wide variety of human diseases such as retinal degeneration or polycystic kidney disease. I am studying the function of one novel centrosomal protein named NPHP5. First, mutations in NPHP5 have been identified in patients suffering from Senior-Løken syndrome or Leber congenital amaurosis; two diseases with renal and/or retinal failure. Second, NPHP5 mRNA is up-regulated in gastrointestinal cancer but down-regulated by p53 after DNA damage; and its depletion causes pronephric cysts in zebrafish embryos. Finally, NPHP5 interacts with another centrosomal protein involved in ciliary diseases, Cep290. Despite its importance in health and disease, the precise function of NPHP5 is not fully understood. Our hypothesis is that NPHP5 cooperates with Cep290 to modulate cilia function and that its dysfunction contributes to the development of ciliary diseases. Using indirect immunofluorescence, NPHP5 was shown to localize to the distal region of centrioles in interphase cells. I have also demonstrated by RNA interference, immunofluorescence and immunoblot that NPHP5 depletion inhibits the migration of centrosomes to the cell surface, an early step of cilia formation. Using mapping studies and immunoprecipitation experiments, it was determined that NPHP5 interaction with Cep290 via its C-terminal region is critical for ciliogenesis. During those mapping studies, I also showed that the Cep290- and CaM-binding domains of NPHP5 are separable. Both domains are also distinct from the centrosomal localization domain, which contains the coiled-coil motif. Furthermore, it was observed by immunofluorescence that NPHP5 interaction with CaM prevents its self-aggregation. It was also demonstrated that disease-causing mutations of NPHP5 lack binding to Cep290 and are mis-localized from centrosomes, thus rendering the resulting proteins non-functional. Finally, using a pharmacological approach to modulate downstream events in the ciliogenic pathway, I showed that cilia formation could be rescued in the absence of NPHP5. These studies will improve our understanding of the biology of centrosomes and cilia and can lead to the development of new diagnostic and therapeutic applications.

The coiled coil domain containing proteins CCDC39 and CCDC40 are required for assembly of the nexin-dynein regulatory complex and affect tubulin polyglutamylation.

H. Lin¹, Z. Zhang¹, S.K. Dutcher¹;

¹Genetics, Washington University School of Medicine, Saint Louis, MO

The proteins, CCDC39 and CCDC40, were identified first as causative mutations in primary ciliary dyskinesia patients (Antony *et al.*, 2013). In *Chlamydomonas*, the *pf7* and *pf8* alleles are causative mutations in CCDC40 and CCDC39, respectively, based on reversion and rescue experiments. The *Chlamydomonas* mutations result in short, paralyzed flagella in which a fraction of the outer doublets fall into the center of the axoneme by electron microscopy as was observed in the PCD patients. CCDC39 and CCDC40 were hypothesized to be part of the nexin-dynein regulatory complex (N-DRC) based on the

patient phenotypes. To test this hypothesis, we used sliding assays and immunoblots to N-DRC proteins in *Chlamydomonas*. Isolated wild-type axonemes incubated with 0.1mM ATP slide along their entire length after treatment with protease, but show no sliding with just 0.1mM ATP. Axonemes from *pf7* and *pf8* with 0.1mM ATP and no protease show splaying of the microtubules, but remain attached at the proximal end as has been observed for other N-DRC mutants (Bower *et al.*, 2013). By immunoblots, the CCDC39 protein is absent in isolated *pf7* and *pf8* axonemes. Immunoblots with antibodies to N-DRC proteins (DRC1, 2, 3, 4, 5, 7, and 11) show a reduction or absence in isolated single and double mutant axonemes (*pf7*, *pf8* and *pf7*; *pf8*), which demonstrate that the mutational loss of CCDC39 and 40 is associated with the loss/reduction of known N-DRC proteins. Several lines of evidence suggest that CCDC39 and CCDC40 play an additional and novel role in tubulin polyglutamylation. The *ssh1* allele was identified as a suppressor of mutants lacking dynein arms that have short flagella (LeDizet and Piperno, 1985). Surprisingly, *ssh1* did not act as a suppressor of the short flagellar length in *pf7* and *pf8* strains, but further reduced flagellar length. The *ssh1* allele is a mutant in *TPG2*, which is needed for localization of the TLL9/TPG1 polyglutamylase (Kubo *et al.*, 2013; 2014). By electron microscopy, a fraction of the B-tubules fail to close properly in *pf7* and *pf8* axonemes. This phenotype is observed previously in various mutants that reduce polyglutamylation. Supporting these two lines of evidence, mutants in CCDC39 and 40 show a significant reduction in tubulin polyglutamylation in isolated axonemes by immunoblots. These results suggest that CCDC39 and 40 may function or alter the tubulin polyglutamylation pathway. We are using a temperature-sensitive *ccdc39* allele identified by whole genome sequencing to investigate the effects of loss of CCDC39 on IFT and the TPG proteins during temperature shifts and in dikaryons. In summary, CCDC39 and CCDC40 play roles in assembly of the N-DRC and in interactions with the tubulin polyglutamylation pathway

The human ciliopathy protein Jbts17 is required for basal body docking and intraflagellar transport.

M. Toriyama¹, P.K. Jackson², J.B. Wallingford¹;

¹Molecular Biosciences, University of Texas at Austin, Austin, TX, ²Department Microbiology and Immunology, Stanford University School of Medicine, Stanford, CA

Ciliopathies are a broad class of human disease with a common etiology involving defective cilia structure or function. *Jbts17* (C5orf42) is a recently identified gene that has been found to be mutated in human patients with Joubert, Meckel-Gruber, and Oral-Facial-Digital Type VI syndromes, but its cellular and molecular functions have yet to be characterized. Here, we report the expression and functional analysis of *Jbts17* in *Xenopus* embryos and elucidate the pathogenic mechanism of human ciliopathy diseases associated with *Jbts17* mutations. We find that *Jbts17* is highly expressed in neural tissues and multiciliated cells (MCCs), and the expression of sonic hedgehog target genes, which is mediated through primary cilia function, is attenuated in *Jbts17* knockdown embryos. These embryos also exhibit several developmental abnormalities, including defective neural tube closure, eye formation, and

embryonic growth. We follow up by demonstrating that Jbts17 is strongly localized at basal bodies in MCCs and that Jbts17 knockdown cells are impaired in the capacity to dock basal bodies to the apical membrane. We also identified the specific domain required for Jbts17 basal body localization, which is truncated in some human ciliopathy patients. Finally, the normal expression and localization of Jbts17 at basal body is required for the basal body localization of both Inturned and Rsg1, proteins that are involved in basal body docking and intraflagellar transport. Our study provides direct evidence for the role of Jbts17 in ciliogenesis and the pathogenic mechanism of its associated human ciliopathy.

Cdc42 and sec10 are required for normal retinal development in zebrafish.

S. Choi¹, J. Baek¹, X. Zuo¹, J. Dunaief², J.H. Lipschutz¹;

¹Department of Medicine, Medical University of South Carolina, Charleston, SC, ²Department of Medicine, University of Pennsylvania, Philadelphia, PA

Cilia are essential organelles required for a broad spectrum of functions, including left-right patterning, nephrogenesis, and vision. In the eye, development/maintenance/function of the photoreceptor requires transport of vesicles containing ciliary proteins from the Golgi to the outer segment by a modified cilium, called the connecting cilium. We previously demonstrated that the exocyst, a highly-conserved eight-protein complex, is required for renal ciliogenesis, most likely due to its role in targeting and docking vesicles carrying ciliary proteins. We also showed that Cdc42, a small GTPase, localizes with the exocyst at cilia, and biochemically interacts with Sec10, a crucial exocyst component. In this study, we examined the function of cdc42 and sec10 in eye development in zebrafish. Cdc42 and sec10 knockdown in zebrafish resulted in both abnormal eye development and increased retinal cell death. Cdc42 morphants had a relatively normal retinal structure, aside from the absence of most connecting cilia and outer segments, while in sec10 morphants, much of the outer nuclear layer, which is comprised of the cell bodies of photoreceptor cells, was missing and retinal-pigmented epithelial cell thickness was markedly irregular. Consistent with the proposed mechanism, knockdown of cdc42 and sec10 resulted in an intracellular transport defect affecting retrograde melanosome transport. Furthermore, there was a synergistic genetic interaction between zebrafish cdc42 and sec10, suggesting that cdc42 and sec10 act in the same pathway in retinal development. Based on these data, we propose a model whereby sec10 and cdc42 play a central role in trafficking ciliary proteins to the outer segment of photoreceptor cell for ciliogenesis and phototransduction.

P1757**Board Number: B276****HDACs and their role in Polycystic Kidney Disease.**P. Paul¹;¹Stowers Institute for Medical Research, Kansas City, MO

Autosomal-dominant polycystic kidney disease (ADPKD) is a monogenic renal disease characterized by progressive development of bilateral renal cysts, decline in renal function and many extrarenal effects. ADPKD has a very high worldwide prevalence rate of 1:400 to 1:1000 and it typically results in end-stage renal disease. ADPKD is caused by mutation in one of the two genes PKD1 and PKD2. PKD1 encodes polycystin-1 (PC1), which is a large G-protein coupled receptor-like protein and PKD2 encodes polycystin-2 (PC2), which is a TRP calcium channel. PC1 can interact with PC2 via its C-terminal coiled-coil domain to form a calcium permeable mechanosensor. Fluid flow on renal epithelium cell stimulates calcium influx, which activate kinases like protein kinase C. Our lab has showed that this kinase then directly or indirectly phosphorylates the 14-3-3 binding sites on histone deacetylase 5 (HDAC5) and causes nuclear export of HDAC5. This leads to the derepression of MEF2C target genes, one of which is missing in metastasis. It has been shown that pan-HDAC inhibitors can reduce cyst formation in PKD2^{-/-} mouse embryos supporting the important role HDACs play in ADPKD pathogenesis and thus in maintaining the normal organization of epithelial cells in kidney tubules. Further we confirmed that HDAC5 knockout can rescue polycystic kidney phenotype in adult PKD1 mouse model. Preliminary data suggest that even HDAC5 heterozygotes have significantly less percentage of cyst area and improved renal function compared to HDAC5 wild-type in a PKD1 deletion background. This further emphasizes the potential clinical implication of using specific HDAC inhibitors to reduce the progression of renal cyst in ADPKD patients. To better understand the mechanism of epigenetic regulation of cyst formation in ADPKD and to find novel therapeutic targets we wanted to understand the biochemical complex that HDAC5 forms in renal epithelium cells. HDAC5 forms complex with a class I HDAC, HDAC3 for its enzymatic activity. So a good therapeutic approach is to find specific inhibitors for HDAC3. To find drugs that can modulate the nuclear-cytoplasmic shuttling of HDAC5 we performed a screen, using a small pool of FDA approved compounds with well characterized targets involved in diverse signaling pathways using HDAC5 export as a paradigm. These studies together will give us mechanistic insights and also has the potential to identify novel therapeutic targets for ADPKD.

P1758**Board Number: B277****Loss of ciliary gene, Thm1, reduces expression of anorectic POMC, causing hyperphagia-induced obesity, fatty liver disease, diabetes, and hypertension.**D.T. Jacobs¹, M.P. Schonfeld¹, L.M. Silva¹, A. Chatterjee¹, G.C. Talbott², D.R. Beier³, P.V. Tran¹;¹Anatomy and Cell Biology, Univ Kansas Med Ctr, Kansas City, KS, ²Genetics Division, Brigham and Women's Hospital, Boston, MA, ³Center for Developmental Biology and Regenerative Medicine, Seattle Children's Research Institute, Seattle, WA

Obesity and metabolic syndrome are serious worldwide epidemics with treatments that are costly, invasive and largely ineffective. Primary cilia are antenna-like structures present on most vertebrate cells that mediate signaling pathways. Cilia defects cause ciliopathies, which manifest clinical features that are also common in the general population, such as obesity. The ciliary gene, Thm1, negatively regulates Hedgehog signaling and is most commonly mutated in patients with ciliopathies. We examined a postnatal role for murine Thm1 in obesity using a Thm1 conditional knock-out (cko) allele together with a ubiquitous, tamoxifen-inducible Cre recombinase. Thm1 deletion during adulthood caused a two-fold weight gain relative to control mice over a 13-week period. In adult Thm1 cko mice, adipose depots were significantly larger than in wild-type, and Thm1 cko livers had numerous, large lipid droplets, indicative of fatty liver disease. Results from serum glucose, leptin and insulin levels, as well as glucose tolerance tests indicate a diabetic state in Thm1 cko mice. Thm1 cko mice are also hypertensive relative to control mice. These observations indicate metabolic distress or 'metabolic syndrome'. To determine if the 19% increase in food intake observed in Thm1 cko mice caused the obese phenotype, Thm1 cko mice were pair-fed for 13 weeks following Thm1 deletion. Indeed, body weights and fat depots of pair-fed Thm1 cko mice were similar to controls, indicating hyperphagia is a primary cause of obesity. In the Thm1 cko hypothalamic arcuate nucleus, an integrative center for signals that regulate feeding and activity, we observed stunted primary cilia and reduced levels of anorectic pro-opiomelanocortin (POMC) transcripts. These data indicate that THM1 regulates response to satiety signals. To examine this role further, we are performing a genome-wide expression analysis on extracts of Thm1 cko arcuate nucleus using RNA sequencing. We are also examining the role of Thm1 in mouse hypothalamic cell lines using lentiviruses expressing Thm1 shRNA. Our data show that primary cilia are important in regulating energy homeostasis and provide an opportunity to identify therapeutic targets against the onset of obesity.

P1759**Board Number: B278****Loss of Occludin caused mucociliary clearance defect with reduced number of multiciliated cells in mouse.**E. Herawati¹, H. Tanaka¹, K. Tateishi¹, A. Tamura¹, S. Tsukita¹;¹Graduate School of Frontier Bioscience and Graduate School of Medicine, Osaka University, Osaka, Japan

This study aims at characterizing phenotype of mice lacking occludin, a transmembrane protein exclusively localized at tight junction strands, with particular reference to the respiratory system. In vivo data were acquired from previously generated Occludin knock out mice in trachea. On the other hand, in vitro data were collected from either wild-type or knock out derived mouse tracheal epithelial cells (mTEC) in culture. Occludin localizes at tight junction (TJ) in mTEC, the expression level of which was markedly increased in FOXJ1 positive cells until cells generated mature cilia. Occludin knock out mouse displays reduced number of the ciliated cells in trachea and accompanied by excess mucus plug in nasal cavity, suggesting a defect in mucociliary clearance function. Although the differentiation of trachea epithelial cells are normal, the detail analysis using electron microscopic images revealed that basal bodies of the ciliated cells were often incompletely docked. Further investigation is currently underway to examine the regulatory mechanism of how occludin is involved in maintaining normal ciliogenesis.

P1760**Board Number: B279****Repurposing of targeted cancer therapies for autosomal dominant polycystic kidney disease (ADPKD).**A.S. Nikonova¹, T. Seeger-Nukpezah², H. . Hensley¹, A. Klein-Szanto³, B. Egleston¹, E.A. Golemis¹;¹Developmental Therapeutics Program, Fox Chase Cancer Center, Philadelphia, PA, ²Department of Internal Medicine, Center of Integrated Oncology, University of Cologne, Cologne, Germany, ³Cancer Biology Program, Fox Chase Cancer Center, Philadelphia, PA

Autosomal dominant polycystic kidney disease (ADPKD) is an inherited progressive genetic disease that affects 1 in 500 people. With typical onset in middle age, with normal kidney tissue is gradually replaced with fluid-filled cysts resulting in end-stage renal disease for most patients. ADPKD is caused by mutational inactivation of polycystins 1 or 2 (PC1 and PC2, encoded by PKD1 and PKD2), which abnormally activates multiple signaling pathways regulating cell proliferation, migration, and response to environmental cues. A number of these signaling pathways are also activated in cancer, and targeted drugs are available to inhibit these pathways. There are currently no approved therapies to slow or cure ADPKD. We have been exploring inhibitors of Aurora-A, EGFR, and HSP90, using mouse models for ADPKD. We have previously reported that HSP90 inhibition with the small molecule STA-2842 in Pkd1^{-/-} mice reduces initial renal cyst formation and slows the progression of these phenotypes in mice with

pre-existing cysts. We now find similar effects in Pkd2^{-/-} mice. This is accompanied with defects in ciliogenesis and striking changes in signaling. In contrast, treatment of Pkd1^{-/-} mice with the Aurora-A kinase inhibitor MLN8237 (alisertib) increased the rate of cystogenesis in these mice. This was associated with defective ciliary resorption and morphological abnormalities of cilia. Intriguingly, while the EGFR inhibitor erlotinib had little independent effect on cystogenesis in Pkd1^{-/-} mice, combination of this agent with alisertib strikingly reduced alisertib-dependent promotion of cyst growth. The mechanistic basis for these signaling relationships will be discussed.

Structural insights into the motility generation and regulation of cilia and flagella by cryo-electron tomography.

J. Lin¹, D. Nicastro¹;

¹Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

Cilia and flagella play important roles in normal development and health of many eukaryotes, including humans [1, 2]. Their motility is driven by thousands of dynein motors [3, 4] that are coordinated by regulatory complexes, such as the Nexin-dynein regulatory complex and I1 dynein [5-8]. Our recent cryo-electron tomography study of intact sea urchin sperm flagella that were rapidly frozen while actively beating, revealed the 3D structures of dynein in three distinct post- and pre-powerstroke conformations [9]. These results provided important new insights into the structural basis of dynein's force generation [9], but how ciliary dyneins are regulated in detail and their different roles in generating ciliary motility remain unclear. Here, we analyzed cryo-tomograms of actively beating sea urchin sperm flagella to determine the 3D structures and conformational changes of all major regulatory complexes and dynein isoforms in relation to different regions of the sinusoidal wave of beating flagella (i.e., curved regions of principal or reverse bend, or straight regions between bends). For some of the dynein isoforms and predicted regulatory complexes we resolved distinct structures and distribution patterns of different conformations that correlate well with specific regions along the flagellar waves. Our comprehensive high-resolution analysis provides a new understanding of the molecular mechanisms underlying ciliary and flagellar motility and suggests a model that shifts previous hypotheses.

P1762**Board Number: B281****Single-molecule three-dimensional mapping of protein trafficking in primary cilia.**W. Luo¹, A. Ruba¹, W. Yang¹;¹Biology, Temple University, Philadelphia, PA

Primary cilia are a critical sensory organelle containing microtubule-based transport paths for proteins trafficking in cilium. Yet, the size of cilium (~ 300 nm in diameter) makes imaging three-dimensional (3D) transport routes for either membrane or soluble proteins inside live cilia still a major challenge. To localize protein trafficking in cilia, we employed a newly developed super-resolution microscopy imaging technique, termed single-point edge-excitation sub-diffraction (SPEED) microscopy, to real-time track various proteins in cilia with a spatiotemporal resolution of 5 nm and 2 ms in 3D. We found that both a membrane associated protein Arl13b and a transmembrane protein HTR6 possess spatially multiple distinct pathways in the primary cilium of *Odora* cells, agreeing well with a 9+2 microtubule pattern in *Odora* cilia identified by electron microscopy. Given the successful applications in mapping protein trafficking inside the cilia and the nuclear pore complexes, SPEED microscopy is proven to be an effective super-resolution high-speed imaging approach to map 3D tomography of macromolecules in sub-micrometer biocavities.

P1763**Board Number: B282****The asymmetric flagellar beat of *Chlamydomonas* corresponds to a sperm-like beat traveling around a semicircular arc.**V.F. Geyer¹, P. Sartori², F. Jülicher², J. Howard¹;¹Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, ²Max Planck Institute for the Physics of Complex Systems, Dresden, Germany

Cilia and flagella are motile protrusions of eukaryotic cells that contain an evolutionary conserved internal structure, the axoneme. The axoneme is composed of a cylindrical arrangement of 9 doublet microtubules, transiently interconnected by dynein motors. Force generation by dyneins slides adjacent doublet microtubules. As a result of periodic sliding, the axoneme bends rhythmically, leading to its characteristic waveform. Interestingly, cilia and flagella generate two different types of waveforms, a symmetric, snake-like beat that pushes sperm through the surrounding fluid, and an asymmetric, breast-stroke-like beat that pulls biflagellated microorganisms such as *Chlamydomonas* through the fluid. The latter beat is similar to that of cilia that move fluid across epithelia. We have asked the question: what is the geometric difference between these different beating patterns? To answer this question, we have developed a simple, yet complete, shape characterization of the axonemal beat that can be used to compare waveforms both quantitatively and through theoretical modeling. We applied this approach to wild-type *Chlamydomonas* as well as to flagella from MBO2 mutants that have a symmetric beat. The

characterization uses Fourier analysis to decompose the periodic beat, expressed as tangent angle as a function of arc length and time, into a set of bending modes that include the time-averaged shape (“zeroth mode”), the waveform at the beat frequency (“first mode”) and higher order modes. We find that in both waveforms, the higher order modes make only a minor contribution. While the properties of the first order mode are similar in amplitude and phase, the zeroth modes are very different. While the MBO2 beat has a very small zeroth mode, corresponding to a mean shape that is almost straight, the wildtype beat has a much larger zeroth mode whose amplitude increases approximately linearly with arc length. This corresponds to a time-average angular shape that is a semicircular arc, around which the first mode propagates. We conclude that the dramatic differences between flagellar waveforms can be accounted for by differences in mean shapes.

Primary cilia bend and pivot in response to intracellular and extracellular forces.

C.M. Ott¹, C. Battle², J. Lippincott-Schwartz^{3,4}, C.F. Schmidt⁵;

¹NIH/NICHD, Bethesda, MD, ²Drittes Physikalisches Institut, Georg-August-Universität, Göttingen,, Germany, ³Physiology Course at Marine Biological Laboratory, Woods Hole, MA, ⁴Cell Biology and Metabolism Program, NICHD, NIH, Bethesda, MD, ⁵III. Physikalisches Institut-Biophysik, Georg-August-Universität, Göttingen, Germany

Primary cilia are ubiquitous, microtubule-based organelles which play diverse roles in sensory transduction in many eukaryotic cells. They interrogate the cellular environment through chemosensing, osmosensing and mechanosensing, using receptors and ion channels in the ciliary membrane. Little is known about the mechanical and structural properties of the cilium and how these properties contribute to ciliary perception. We probed the mechanical responses of primary cilia from kidney epithelial cells (MDCK-II), whose role it is to sense fluid flow in renal ducts. We found that upon manipulation with an optical trap, cilia deflect by bending along their length and by pivoting around an effective hinge located below the basal body. The calculated bending rigidity indicates weak microtubule doublet coupling. Primary cilia of MDCK cells lack inter-doublet dynein motors. Nevertheless we found that primary cilia display active motility. Three-dimensional tracking demonstrated correlated fluctuations of the cilium and basal body. These angular movements appeared random, but were dependent on ATP and cytoplasmic myosin-II in the cell cortex. We conclude that force generation by the actin cytoskeleton surrounding the basal body results in active ciliary movement. We speculate that actin-driven ciliary movement might tune and calibrate ciliary sensory functions.

P1765**Board Number: B284****IDA6 encodes a conserved subunit required for assembly of the N-DRC and several inner arm dyneins.**R. Bower¹, D. Tritschler¹, K. VanderWaal¹, E. O'Toole², T. Heuser³, D. Nicastro⁴, M.E. Porter¹;¹Genetics, Cell Biology, and Development, University of Minnesota Medical School, Minneapolis, MN,²MCD Biology, University of Colorado, Boulder, CO, ³Biology, Brandeis University, Waltham, MA,⁴Department of Biology, Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

The nexin-dynein regulatory complex (N-DRC) is a group of polypeptides thought to coordinate dynein activity and interconnect doublet microtubules (Piperno et al., 1994; Gardner et al., 1994; Heuser et al., 2009; Lin et al., 2012), but its precise role in flagellar motility is poorly understood. We have analyzed several *drc* mutants in *Chlamydomonas* to identify novel N-DRC subunits, to study N-DRC assembly, and to probe N-DRC function. To better understand the relationship between the N-DRC and the inner dynein arms, we characterized the *IDA6* gene. *ida6* is a motility mutant that fails to assemble dynein *e* and is associated with reduced levels of tektin, similar to the *drc* mutant, *pf3* (Kato et al., 1993; Gardner et al., 1994; Yanagisawa & Kamiya, 2004). Electron microscopy and 2D averaging revealed a major defect in assembly of the N-DRC, and so we tested candidates in the flagellar proteome (Li et al., 2004; Pazour et al., 2005) for rescue of *ida6* and identified the DRC2 subunit, FAP250, as the *IDA6* gene product (Austin-Tse et al. 2013). Mutations in the zebrafish and human orthologue CCDC65 are linked to defects in ciliary motility and primary ciliary dyskinesia. More recently we identified *sup-pf5* as another *drc2* mutation. DRC2 co-extracts, co-purifies, and co-IPs with other DRC subunits (Bower et al., 2013). iTRAQ labeling and MS/MS identified >10 axonemal proteins that are missing or reduced in *ida6* and *sup-pf-5*, and are restored in rescued strains. Spectral counting of dynein heavy chains (DHCs) revealed deficiencies in DHC8 and several other DHC isoforms. Cryo-electron tomography and 3D averaging further demonstrated that both *ida6* and *pf3* display similar defects in the assembly of the N-DRC and inner dynein arms, plus additional irregularities in the positioning of radial spokes. Thus *IDA6* encodes FAP250, which corresponds to DRC2, and DRC2 together with DRC1 plays a key role in assembly at the junction between the N-DRC, the radial spokes, and the dynein arms. Current studies focus on identifying the components that specify the binding sites for DRC1 and DRC2 on the outer doublet (Supported by NIH).

P1766**Board Number: B285****The ciliary N-DRC and B-tubule polyglutamylation are required for axoneme integrity and outer doublet alignment.**L.M. Alford¹, E.L. Hunter¹, M.E. Porter², W.S. Sale¹;¹Department of Cell Biology, Emory University School of Medicine, Atlanta, GA, ²Genetics, Cell Biology, and Development, University of Minnesota Medical School, Minneapolis, MN

The N-DRC is a large multi-subunit complex that interconnects adjacent doublet microtubules (Heuser et al., 2009). The N-DRC is predicted to limit microtubule sliding and to align outer doublet microtubules in the distal axoneme (Bower et al., 2013). To test this hypothesis, we examined ATP-induced reactivated motility of demembrated *drc* cells, commonly termed “reactivated cell models.” As described previously (Kamiya and Witman, 1984), ATP-induced reactivation of wild-type cell models resulted in the forward swimming of >90% cell models, similar to the movement of live cells. In contrast, ATP-induced reactivation failed in a subset of *drc*-cell models, despite obvious motility in live *drc*- cells. Dark field microscopic observations of *drc*-cell models revealed various degrees of axoneme splaying in *pf2*, *pf3*, *ida6*, *sup-pf3*, and *sup-pf5*. Immunofluorescence microscopy using an anti-tubulin antibody revealed that the distal axoneme was splayed in 60-85% of reactivated *drc*-mutant cell models, in contrast to wild-type cells in which >85% of axonemes remained intact. *sup-pf4*, unlike the other *drc*-mutants, retains most of the interdoublet linker domain of the N-DRC (Heuser et al., 2009). Notably, *sup-pf4* reactivated cell models displayed nearly wild-type levels of *in vitro* motility, and most *sup-pf4* and *sup-pf4*-rescued axonemes remained intact. These data strongly support the hypothesis that the N-DRC, particularly the interdoublet linker domain, is required for the integrity and interdoublet alignment of the distal axoneme. We also tested the idea that tubulin polyglutamylation plays a role in interdoublet interactions and axoneme integrity (see Kubo et al., 2012). Like the N-DRC mutants defective in the interdoublet linker domain, ATP-induced splaying of the distal axoneme was also observed in *tpg* mutant cell models. As proposed by Kubo et al., (2012), we postulate that the functional interaction of the N-DRC with the adjacent B-tubule is facilitated upon tubulin polyglutamylation.

P1767**Board Number: B286****Basal foot MTOC organizes pillar MTs required for coordination of beating cilia.**D. Clare¹, J. Magescas², T. Piolot³, M. Dumoux¹, C. Vesque⁴, E. Pichard⁵, T. Dang⁵, B. Duvauchelle⁵, F. Poirier⁵, D. Delacour²;¹Biological sciences, Institute of structural and molecular biology (Birkbeck college-UCL), London, United Kingdom, ²Institut Jacques Monod - CNRS, Paris, France, ³Curie Institute CNRS, Paris, France, ⁴INSERM, Laboratoire de Biologie du Développement, Paris, France, ⁵Institut Jacques Monod CNRS, Paris, France

Coordination of ciliary beating is essential to ensure mucus clearance in the airway tract. The orientation and synchronization of ciliary motion are controlled by the polarized organization of cilium bases at the

apical domain of epithelial cells, as illustrated by basal feet aligned in the same direction, and respond in part to the organization of the underlying cytoskeletal networks. Using dual-axis electron tomography procedure on mouse trachea, we show that microtubule (MT) and actin networks are independently organized in tracheal cells. On one hand, we observed sinuous actin microfilaments forming a dense meshwork encircling the basal bodies (BBs). On the other hand, the cortical cytoplasmic MTs originate from the BBs, mainly from the basal foot caps, where γ -tubulin is enriched. Most of the MTs are orientated obliquely and perpendicularly, with only a few that run parallel to the apical membrane connecting neighboring BBs. Then, BBs are collectively hooked at the cortex by a regular MT array composed of 4-5 MTs, and these cortical MTs may behave as cilium “pillars”. Removal of Galectin-3, one of basal foot cap components, provokes misrecruitment of γ -tubulin and disorganization of this cortical MT framework. Perturbation of the subciliary MT network at the base of the cilium had direct consequences on BB organization. The BBs were normally spaced but their alignment was impaired in *gal3*^{-/-} multiciliated cells, clearly showing that rotational cell polarity is disrupted in the absence of Galectin-3. Motile cilia do exist in *gal3*^{-/-} tracheas, but their structure and organization are affected, and reduced fluid flow is generated in mutants. Our data further emphasize the longstanding hypothesis that the basal foot cap is the main cilium base MicroTubule-Organizing Center (MTOC). In addition, we conclude that Galectin-3 plays a crucial role in the maintenance of the BB MTOC and the “pillar” MT units, and that this network is instrumental for the coordinated orientation and stabilization of motile cilia.

A spinning puzzle of the release of a giant multinucleate multiflagellate zoospore.

J. Urzay¹, D. Ott², M. Prakash¹;

¹Bioengineering, Stanford Univ, Stanford, CA, ²University of Akron, Akron, OH

Asexual reproduction in aquatic algal species of *Vaucheria* occurs by the formation of large multinucleate multiflagellate single cell. Termed as a zoospore, it is an elongated club-shaped zoosporangia at the tips of young branches. During development, the zoosporangia are separated from the rest of the thallus by membranes, resulting in multiple chambers hosting zoospores which will be released and dispersed in the surrounding aqueous environment. The apical gelatinization of the zoosporangial tip, together with the turgor pressure in the segregated portion of the filament, lead to a narrow aperture through which the zoospore escapes. However ordinary this may seem, *Vaucheria* zoospores have a unique multiflagellated patterned surface that warrants helicoidal flow entrainment at relatively high speeds, and which enables them to undergo a spinning motion that elastohydrodynamically assists the rather unfavorable escape maneuver. Experimental observations of this phenomenon, together with quantitative interpretations, are provided.

P1769**Board Number: B288****Structural analysis of the intraflagellar transport trains.**L. Stepanek¹, G. Pigino¹;¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Intraflagellar transport (IFT) is a non-vesicular transport pathway, which moves cargo proteins along the outer microtubule doublets of the axoneme. While primarily necessary for flagella/cilia assembly and maintenance, IFT also plays a role in cellular signaling and membrane trafficking.

The anterograde IFT trains move from the flagellar base to the tip, where they undergo rearrangement, possible cargo unloading and return in the form of retrograde IFT trains. Many aspects of these processes are poorly described, including the structural differences between the anterograde and retrograde particles. To characterize the differences in movement patterns of the two directions of transport I use total internal reflection fluorescence (TIRF) microscopy and single particle tracking techniques. To verify the results and to study the different morphology of the trains, I use TIRF correlated with transmission electron microscopy (TEM). The model organism of choice is biflagellate alga *Chlamydomonas reinhardtii*.

The results of particle tracking show that the IFT tracks are not evenly distributed throughout the cross-section of the flagellum of the gliding cells. Majority of the particles are moving along the lateral parts of the flagellum, indicating preference of some microtubule doublets as tracks for the IFT. To verify and refine these results, I use time-resolved correlative TIRF and TEM microscopy. Briefly, the IFT movement is stopped by fixative addition during time-lapse TIRF acquisition, so the directionality of the particles is known when the sample is imaged by TEM / TEM tomography. The high resolution of TEM is used to identify the microtubule doublets involved in IFT transport and to characterize the morphological difference between the anterograde and retrograde particles. This is the first time to show the structural properties of IFT trains related to their *in vivo* motility, opening further possibilities for more detailed studies of the IFT machinery.

Ciliopathies are genetic disorders of cilia dysfunction. These cellular appendages possess a microtubule based axoneme with either a doublet arrangement of 9+0 (primary/non-motile) or 9+2 (motile). Primary cilia have diverse sensory and signaling roles and as such, defects in primary cilia are associated with a wide spectrum of clinical features. Abnormalities in motile cilia result in Primary Ciliary Dyskinesia (PCD) which is characterized by chronic respiratory infections, situs inversus, infertility, and occasionally hydrocephalus. Here we demonstrate that mutations in the Growth Arrest Specific 8 (GAS8) gene, a putative homolog of Chlamydomonas Paralyzed Flagella 2 (PF2), cause PCD phenotypes in mice. We show Gas8 is required for proper assembly of the inner dynein arms (IDA) and the Nexin-Dynein Regulatory Complex (NDRC), and for normal cilia motility. Gas8^{GT} mice display abnormal cilia beat pattern and a lower beat frequency that Gas8^{WT} mice. Additionally, a screen for GAS8 mutations in PCD patients with situs defects identified two independent homozygous missense mutations whose pathogenicity is being confirmed utilizing model systems. The two independent mutations at c.595G>A and c.1172C>T interrupt a Gas8 Microtubule Association Domain (GMAD) and a Smoothened binding domain respectively. Currently, the pathogenicity of these human mutations is being tested in zebrafish and chlamydomonas. Utilizing CRISPR technology, we generated several Gas8 mutant zebrafish of which we will attempt rescue experiments with human WT, CT, and GA mRNA. Similarly, we are generating zebrafish with corresponding human mutations to analyze pathogenicity. Chlamydomonas is being used to investigate mechanistic defects associated with these human mutations by creating humanized mutations in PF2 and studying the effects on NDRC component docking. We hypothesize that both of these mutations will result in disruption of NDRC assembly and dyskinetic motile cilia.

Kinetochores Assembly and Functions 2

P1771

Board Number: B291

Measuring Force at the *Drosophila* Kinetochores.

A.A. Ye¹, S. Cane¹, T.J. Maresca¹;

¹Biology Department, Univ Massachusetts-Amherst, Amherst, MA

To maintain genomic stability, cells need to properly segregate their replicated chromosomes through cell division. As cells prepare to divide, a multi-protein structure called the kinetochores assembles at the

centromeres of each sister chromatid to mediate interactions with spindle microtubules. Proper chromosome segregation requires that microtubules emanating from opposing spindle poles bind sister kinetochores to form bioriented kinetochore-microtubule (kt-MT) attachments. Erroneous kinetochore kt-MT interactions lead to unequal chromosome segregation and aneuploidy. Therefore, kt-MT attachment stability must be carefully and tightly regulated during cell division to ensure the fidelity of the process. The application of opposing forces to kinetochores by dynamic MTs upon chromosome biorientation leads to a structural rearrangement of the kinetochore called intrakinetochore stretch in which the outer plate moves away from the inner plate. Since intrakinetochore stretch is an important regulator of kt-MT attachment stability, characterizing the properties of force-transducing kinetochore components and the magnitude of forces applied to these components are essential prerequisites for understanding how forces impact kinetochore structure and function. Existing measurements of the amount of force that is applied to kinetochores differ by orders of magnitude. To address this major discrepancy, calibrated force sensors were inserted into the *Drosophila* kinetochore. Since we acquired evidence that CENP-C is a central force-transducing component of the *Drosophila* kinetochore, two different calibrated force sensors were inserted into the middle of CENP-C to measure the force applied to bioriented kinetochores in living cells. One CENP-C reporter was built using a previously calibrated spider-silk-based FRET sensor and the second force reporter was made by inserting the rod domain of the focal adhesion protein Talin into CENP-C, and simultaneously expressing the head domain of Vinculin (a force-sensitive Talin binding partner) in the same cell line. Quantitative measurements of both reporters indicated that each CENP-C molecule is, on average, under 1 pN of force at bioriented kinetochores. Given that a *Drosophila* kinetochore has between 12-30 CENP-C molecules per MT that are envisioned as linkages arranged around the MT as a set of parallel springs, we propose that, on average, a kt-MT in *Drosophila* generates ~12-30 pN of poleward-directed force at metaphase. Furthermore, since there are 11 microtubules bound to *Drosophila* S2 cell kinetochores, we propose that each bioriented kinetochore, as a whole, experiences poleward-directed pulling forces between ~130 and 330 pN of force. It is noteworthy that this magnitude of force, in the hundreds of piconewtons range, differs significantly from recent measurements but is in close agreement with those initially measured by Bruce Nicklas in insect spermatocytes.

Mechanical Deformations Within Kinetochores During Chromosome Directional Instability.

C. Smith¹, A.D. McAinsh², N. Burroughs¹;

¹Mechanochemical Cell Biology, University of Warwick, Coventry, United Kingdom, ²Mechanochemical Cell Biology, University of Warwick, Coventry, United States

During mitosis, chromosomes move towards and away from spindle poles, and can undergo directional switches (Skibbens et al. 1993). These are driven by forces generated by the kinetochore, whose attached microtubules can switch between either polymerising or depolymerising states. These states

are associated with deformations within the kinetochore itself (Uchida et al. 2009, Dumont et al. 2012), and are also thought to respond to tension generated by the inter-sister linkage. To further understand these dynamics, we have recently advanced our kinetochore tracking assay (Jaqaman et al. 2010) in order to track eGFP-labelled CENP-A position at high temporal resolution (every 2s), which allows directional switch events to be carefully interrogated. We have also used Monte Carlo Markov chain methods to compare this data to a model of kinetochore dynamics, yielding information about forces within the system, providing new insight into the force-dependent mechanism that controls sister kinetochore switching. However, this does not incorporate kinetochore deformations, and therefore forces therein. Here I will present the evolution of our assay to simultaneously track mCherry-labelled Ndc80 position every 2s, thus allowing measurements of kinetochore deformations. Our initial analysis of inter- and intra-kinetochore distances yields key dynamic behaviour in the CENP-A-to-Ndc80 linkage both during continued directional motion and at directional switch events. We are also currently integrating these deformations in CENP-A-to-Ndc80 linkage into our modelling framework.

Investigation of the *in vivo* mechanical properties of the kinetochore.

I. Ross¹, P.S. Maddox¹, I. Filiatreault², J. Dorn²;

¹Department of Biology, University of North Carolina, Chapel Hill, NC, ²Univ De Montreal, Laval, QC

The kinetochore is a macromolecular structure that is assembled on chromosomes during mitosis. The kinetochore provides the mechanical linkage between chromosomes and microtubules to translate microtubule dynamics into coordinated chromosome movement. As the sole connection of microtubules to chromosomes, kinetochores are essential to maintaining the fidelity of the genome during mitosis and, therefore, it is paramount to understand the mechanical properties of the kinetochore. In order to establish the *in vivo* mechanical properties of the kinetochore, I am using super-resolution live-cell imaging of chromosome movement upon depletion of kinetochore components. This assay is composed of acquiring spatially oversampled data followed by sub-pixel (super) resolution segmentation and tracking. I am using a strain of *C. elegans* expressing two GFP fusion proteins: GFP- γ -tubulin and GFP-histone H2B, allowing precise tracking and measurement of chromosome movements relative to the spindle poles (GFP- γ -tubulin). Each dataset is collected in 4D (x, y, z, t) to maximally capture chromosome movements from nuclear envelope breakdown through anaphase. In preliminary

experiments, I have achieved diffraction-limited 3D imaging at 100x 1.4NA with 3 second sampling. Each dataset is subjected to analysis using a custom Matlab program (celX) designed to automatically segment and track individual chromosomes in 4D. The output of celX manifests as numerous metrics of chromosome dynamics including, but not limited to, distance from the spindle axis, orientation of chromosomes relative to microtubules, and chromosome velocities. celX will allow me to track dynamic behaviors, such as oscillations or bending of chromosomes, with high spatial and temporal resolution. Chromosome movements are directly proportional to force imbalances, thus the tracking data can be transformed into relative force revealing the roles of individual kinetochore protein complexes. Initial RNAi screening of kinetochore components has focused on outer kinetochore complexes that are directly implicated in microtubule binding. Of particular interest is the KMN network that is proposed as the mechanical linkage between microtubules and kinetochores. The KMN network is composed of the Knl1, Mis12, and Ndc80 complexes and is the major player in end-on kinetochore-microtubule attachment. The measured velocities will provide insight into the mechanical properties of the kinetochore and begin to build a more comprehensive picture of the force landscape of chromosome movement. In sum, this analysis will provide accurate in vivo measurements of the movement and forces of chromosomes within the complex setting of the spindle.

Accurate chromosome segregation depends on proper attachment of kinetochores to microtubules. Mounting evidence suggests that the mechanical properties of the kinetochore are fundamentally important for faithful segregation of chromosomes. We developed an assay where we use merotelic kinetochore as a model for studying mechanical properties of the kinetochore in vivo. A merotelic kinetochore is attached to microtubules emanating from both spindle poles and during anaphase, pulling forces exerted by microtubules lead to lateral stretching of such kinetochore. In our assay, we use laser ablations to sever microtubules attached to a stretched merotelic kinetochore, thus releasing the forces acting on this kinetochore. The mechanical properties of the kinetochore can then be inferred from the change of the kinetochore shape after microtubule severing. We used Hec1/Ndc80 and CenpA/Cnp1 fused to GFP to visualize outer and inner kinetochore domains, respectively, in mammalian

PtK1 cells and in the fission yeast *Schizosaccharomyces pombe*. In both model systems, kinetochores shortened after severing microtubules. An initial rapid shortening was followed by a period of slow relaxation. Interestingly, the inner kinetochore relaxed faster than the outer kinetochore. Whereas yeast kinetochores typically regained their unstretched size, many PtK1 kinetochores remained stretched over a longer period of time after microtubule severing. Our analysis of the time dependent kinetochore shortening reveals a viscoelastic behavior of the kinetochore that is evolutionarily conserved between yeast and mammalian cells.

Nanoscale patterning of the Ndc80 complex using a programmable DNA origami scaffold for architecture-function analysis of the kinetochore.

V. Verma¹, R.F. Hariadi¹, S. Sivaramakrishnan¹, A.P. Joglekar^{1,2};

¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, ²Biophysics, University of Michigan, Ann Arbor, MI

The eukaryotic kinetochore is a macromolecular machine that uses multiple copies of many different proteins to mediate bidirectional chromosome movements during cell division. In budding yeast, three different microtubule-binding proteins: Ndc80, Dam1, and Stu2 are necessary for chromosome motility and their accurate segregation. In vivo studies also reveal that the yeast kinetochore incorporates a specific number of copies of each of these proteins: 8 copies of Ndc80, 16-20 copies of the of the Dam1 complex, and 7-8 Stu2 dimers. Moreover, these molecules are situated in a well-defined nanoscale organization at the microtubule plus end. This precise organization may be the key to achieving persistent kinetochore movement coupled to the polymerization and depolymerization of the microtubule. To directly test this hypothesis, we are developing an in vitro assay to pattern kinetochore proteins in pre-defined architectures and numbers. We have engineered a programmable DNA origami scaffold that provides up to six stable anchoring positions specified in an accurately defined geometry. Each position can be individually addressed so that either the number or the geometry or both can be varied to suit experimental design. Additionally, we are creating DNA origami scaffolds of different shapes and sizes to mimic/understand the kinetochore geometry at nanometer scale. We can achieve > 90% position occupancy with hybridizing DNA oligomers to the DNA origami scaffold as revealed by stepwise photobleaching using TIRF microscopy. We can attach recombinant Ndc80 complexes with a SNAP tag fused to the centromeric globular domain of the Ndc80 complex, and obtain homogenous populations of origami scaffolds for the given number of molecules as confirmed by gel-shift assays. Using this technique, we are systematically exploring the influence of the number and geometry of Ndc80 complexes on microtubule-binding and on generating persistent attachment. This technique provides a versatile and effective platform for a systematic study of the role of kinetochore architecture in defining the mechanism of kinetochore motility.

P1776**Board Number: B300****Chromosome segregation depends on a negatively-charged region of the β -tubulin carboxy-terminal tail.**C.P. Fees¹, J.K. Moore²;¹Univ Colorado Sch Med, Aurora, CO, ²Cell and Development, University of Colorado School of Medicine, Aurora, CO

Proper chromosome segregation requires carefully choreographed interactions between kinetochores and dynamic spindle microtubules. Whereas the roles of kinetochore proteins are relatively well understood, how tubulin proteins contribute to the fidelity of chromosome segregation is poorly understood. Here we investigate the negatively-charged carboxy-terminal tail (CTT) domains of the α - and β -tubulins, which are thought to promote electrostatic interactions with kinetochore proteins. CTT sequences are highly variable across species and tubulin isoforms, and are major sites of post-translational modifications. CTTs are, therefore, a possible point of regulating kinetochore-microtubule interactions that determine the fidelity of chromosome segregation. Using a series of mutants that alter or ablate CTTs of α - and β -tubulin in budding yeast, we identify a specific role for β -CTT in chromosome segregation. Mutant strains lacking the β -CTT exhibit delayed progression into anaphase and elevated rates of chromosome loss. In contrast, mutants lacking the α CTT appear similar to wild type. Using live cell imaging to measure the dynamics of kinetochores labeled with Nuf2-GFP, centromeres labeled with CENP-A/Cse4-GFP, and single centromeres labeled with CENIV-GFP, we show that loss of the β -CTT disrupts the bi-orientation of sister kinetochores. To elucidate the molecular role of the β -CTT, we map the residues that are necessary for function, and identify a short region of negatively-charged residues. Altering the charge of these residues disrupts chromosome segregation and microtubule dynamics. Furthermore, this negatively charged region may play an important role in facilitating interactions between the CTT and microtubule binding proteins. We provide evidence that this region supports the activity of the kinetochore protein, Ndc80. Based on these results, we propose that the β -CTT promotes proper chromosome segregation in two ways; by regulating the dynamics of spindle microtubules and by tuning kinetochore-microtubule interactions.

P1777**Board Number: B301****A Novel Role for the Rod-Zw10-Zwilch (RZZ) Complex in Modulating Microtubule (MT) Attachments at Kinetochores.**A.Z. Raja¹, J.M. Kasuboski¹, J. Kaneshiro¹, M. Joyce¹, W. Boggess¹, P.S. Vaughan¹, K.T. Vaughan¹;¹University of Notre Dame, Notre Dame, IN

Kinetochores utilize a combination of dynamic and stable MT attachments during the processes of chromosome alignment and chromosome segregation. Although phosphorylation is implicated in

regulating the MT-binding activities of some candidates, a mechanism that explains when each protein is dominant remains elusive. In previous work, we reported premature formation of stable MT attachments by HEC1/Ndc80 as a consequence of inhibiting Aurora B (AurB). This phenotype reflected the loss of the RZZ complex and all proteins dependent on RZZ, including cytoplasmic dynein, dynactin, spindly and MAD1/2. Testing a model in which RZZ masks the MT-binding activity of HEC1/Ndc80 until late stages of chromosome alignment, we sought additional kinases that regulate RZZ and identified Monopolar Spindle 1 (MPS1). MPS1 inhibition induced chromosome alignment defects including premature formation of stable MT-attachments. MPS1 inhibition also blocked recruitment of transient kinetochore proteins including RZZ and proteins that depended on RZZ. To define the requirements for MPS1 activity, we tested relevant candidates and identified Zwilch as a novel substrate for MPS1. MS/MS analysis revealed phosphorylation at three sites near the N-terminus of Zwilch and mutant analysis demonstrated that MPS1 phosphorylation is essential for RZZ function. 3A-mutant (T85A/S88A/S91A) Zwilch mimics MPS1 inhibition and blocks RZZ recruitment to kinetochores. 3E-mutant (T85E/S88E/S91E) Zwilch mediates recruitment of RZZ and RZZ-dependent proteins to kinetochores and renders cells resistant to MPS1 inhibition. Finally, phospho-mimetic Zwilch binds directly to Zw10, revealing a novel requirement for Zwilch phosphorylation in RZZ assembly. These findings support a model in which RZZ assembly and recruitment are responsible for modulating MT-attachments during prometaphase, perhaps through regulation of access to MTs by stable MT-binding proteins such as HEC1/Ndc80.

Ndc80 Tail Phosphorylation Controls Kinetochore-Microtubule Attachment Formation via Modulation of the Adjacent Calponin Homology (CH) Domain.

D.K. Cheerambathur¹, M. Moyle¹, K. Oegema¹, A. Desai¹;

¹Ludwig Institute for Cancer Research, La Jolla, CA

The 4-subunit Ndc80 complex is a central component of the attachments between kinetochores and spindle microtubules that segregate chromosomes during cell division. The Ndc80 subunit of the complex has a conserved architecture with an unstructured N-terminal tail (N-tail) adjacent to a calponin homology (CH) domain. Although the N-tail is divergent in primary sequence between species, it harbors two conserved features: a highly basic nature (pI =10-12) and the presence of Aurora kinase target sites. Both the CH domain and N-tail have been proposed to make essential contributions to microtubule binding. The CH domain docks onto the microtubule lattice, while the basic N-tail is thought to promote binding through electrostatic interactions with the acidic C-terminal tails of α/β -tubulin. Correction of aberrant kinetochore-microtubule attachments requires Aurora B kinase, which is proposed to phosphorylate Ndc80 N-tails to counter their electrostatic interaction with the microtubule surface. Here we use the *C. elegans* embryo as a model system to test these ideas and examine the interplay between the CH domain, N-tail and Aurora B-mediated phosphorylation in controlling the formation of microtubule attachments. We show that, as expected, mutation of the CH domain prevents

the formation of load-bearing kinetochore-microtubule attachments *in vivo*. In contrast, whereas the N-tail is essential for microtubule binding *in vitro*, it is dispensable for both attachment formation and embryonic viability *in vivo*. Despite the fact that the N-tail is not essential for attachment formation *in vivo*, introducing phosphomimetic mutations into the 4 Aurora target sites in the N-tail perturbs attachment formation, phenocopying mutations in the CH domain. This observation suggests that rather than releasing an electrostatic interaction between the N-tail and the microtubule lattice, N-tail phosphorylation promotes attachment release by allowing the tail to function as an intra-molecular inhibitor of the CH domain. In support of this idea, synthetic genetic analysis in one-cell embryos revealed that the phosphomimetic N-tail resembles mutations in the CH domain instead of the N-tail deletion. These results lead to a new model in which Aurora kinase-mediated Ndc80 N-tail phosphorylation modulates activity of the adjacent CH domain to control kinetochore-microtubule attachment formation and ensure accurate chromosome segregation.

Spindle checkpoint protein Bub3 promotes mitotic cell cycle progression by activating APC/C-Cdc20 in budding yeast.

Y. Yang¹, D. Tsuchiya¹, S. Lacefield¹;

¹Indiana University Bloomington, Bloomington, IN

The spindle checkpoint is a well-conserved surveillance mechanism, which functions at the metaphase-anaphase transition. In the presence of improperly attached kinetochore, the spindle checkpoint forms an effector complex to delay anaphase onset by binding and inhibiting Cdc20, the co-activator of APC/C (Anaphase Promoting Complex/Cyclosome). This effector complex is comprised of the spindle checkpoint proteins Bub3, Mad2 and Mad3. Here we show that deleting BUB3, but not MAD2, results in a prominent delay of anaphase onset. The delay is not a result of the other cell cycle checkpoints, or a result of aneuploidy. Surprisingly, co-immunoprecipitation studies show that Cdc20 binding to the APC/C complex is impaired in *bub3Δ* cells. In addition, the delay is also observed when Bub3 is prevented from localizing to the kinetochore. Bub3 and Cdc20 co-localize to the kinetochore in metaphase, indicating their interaction at the kinetochore could be important for timely anaphase onset. This study reveals the multifaceted function of the spindle checkpoint by illuminating a novel role of Bub3 in APC/C-Cdc20 modulation.

P1780**Board Number: B304****Mad1 and Bub1 – more than kinetochore recruitment factors in the spindle assembly checkpoint.**K. Sewart¹, N. Schmidt², S. Heinrich², M. Langeegger², S. Hauf^{3,4};¹Department of Biological Sciences, Virginia Tech, Blacksburg, VA, ²Friedrich Miescher Laboratory of the Max Planck Society, Tuebingen, Germany, ³Dept. of Biol. Sciences and VBI, Virginia Tech, Blacksburg, VA,⁴Friedrich Miescher Laboratory, Max Planck Society, Tuebingen, Germany

To maintain genome integrity, the genetic material has to be equally distributed during cell division. The spindle assembly checkpoint is a conserved surveillance mechanism that delays anaphase as long as any of the chromosomes is not properly attached to the mitotic spindle. Malfunction of this checkpoint causes erroneous chromosome segregation and has been implicated in tumorigenesis. Despite a wealth of information on the localization and interaction of checkpoint proteins, the *in vivo* signaling mechanism is still only partially understood.

A complex between the proteins Mad1 and Mad2 is crucial for the spindle assembly checkpoint. Kinetochore-bound Mad1:Mad2 binds a second molecule of Mad2 through Mad2:Mad2 dimerization, which is necessary for binding of this second Mad2 to the anaphase activator Cdc20. This ultimately prevents anaphase. Work of several labs, using different organisms, consistently showed that Bub1 is required for kinetochore recruitment of Mad1 and that kinetochore-bound Mad1 serves as binding platform for Mad2. Employing a combination of biochemical methods, yeast molecular genetics and live cell imaging approaches, we recently showed that the roles of Mad1 and Bub1 go beyond this role in bringing Mad2 to the kinetochore. We introduced mutations in the Mad1 C-terminus that preserved Mad1 kinetochore localization, its interaction with Mad2, and the capability for Mad2 dimerization, but nevertheless impaired checkpoint functionality. Similarly, artificial tethering of Mad1 to the kinetochore in cells depleted of Bub1 also did not rescue checkpoint functionality, although Mad2 was co-recruited with Mad1 and was able to dimerize. These results indicate that Mad1 and Bub1 are more than mere recruitment factors for Mad2. We are in the process of determining, which step, downstream of Mad2 dimerization, is defective and use the separation-of-function mutants of Mad1 to investigate the molecular role of the Mad1 C-terminus in this process.

P1781**Board Number: B305****Toward quantitative theoretical description of the kinetochore-microtubule interactions and their roles in ensuring accurate chromosome segregation.**A. Zaytsev¹, F.I. Ataulakhanov^{2,3}, E.L. Grishchuk¹;¹Physiology Department, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA,²Center for Theoretical Problems of Physicochemical Pharmacology, Russian Academy of Sciences,Moscow, Russia, ³Physics Department, Moscow State University, Moscow, Russia

Mitotic chromosomes segregate equally between two daughter cells with the help of spindle microtubules (MTs). MTs attach dynamically to chromosomal kinetochores, but little is known about how molecular characteristics of kinetochore proteins contribute to the dynamicity and robustness of MT attachments, and how quantitative characteristics of these interactions affect the accuracy of chromosome segregation. Our long term goal is to use quantitative “bottom-up” modeling to link the molecular parameters of key kinetochore proteins with physiology of mitotic processes, seeking novel insights and predictions. To investigate chromosome segregation at different organizational scales we developed several theoretical models. The molecular-kinetic determinants of kinetochore MTs stability were examined using probabilistic single-molecule model of the MT binding at the kinetochore site with 12-20 molecules. We show that when these molecular interactions are independent and stochastic, the physiological rate of MT turnover is achieved only when the bindings are transient, each lasting fraction of a second (Zaytsev et al., CaMB 2013). MT bindings in vitro by the single molecules of the core kinetochore protein NDC80 last only 20-400 ms, so we next modeled the kinetochore interface using the experimentally determined NDC80 constants. We demonstrate that the stability of kinetochore MTs and its regulation during mitosis can be largely explained by the phosphoregulatable MT-binding affinity of just this one kinetochore component. Interestingly, the interactions between NDC80 complexes and kinetochore MTs are predicted to be unconstrained, meaning that the NDC80 molecules are able to alternate their binding between adjacent kinetochore MTs (Zaytsev et al., JCB 2014). Finally, we developed a probabilistic model for dynamic kinetochore-MT interface to systematically and quantitatively examine the impact of transient MT attachments on the accuracy of chromosome segregation. We show that the rate of kinetochore-MT turnover on its own has little impact on the final accuracy of MT attachments. Strikingly, a model that combines the optimal rate of MT turnover with the plate-like kinetochore geometry predicts the frequency of chromosome loss $(2.6 - 47) \times 10^{-2}$. The lower value is similar to what is seen in tumor-derived cells, but this simplified model cannot explain low chromosome loss frequency in normal human cells. Together, these theoretical approaches provide novel mechanistic insights into the molecular mechanisms of accurate chromosome segregation. This work should assist developing the comprehensive quantitative understanding of chromosome segregation in normal cells, and help to uncover how pathological chromosomal instability can be prevented.

P1782**Board Number: B306****Studying kinetochore-microtubule attachment using fluorescence lifetime imaging microscopy with Bayesian analysis.**T. Yoo¹, D.J. Needleman^{2,3,4};¹Harvard University, Cambridge, MA, ²FAS Center for Systems Biology, Harvard University, Cambridge, United States, ³School of Engineering and Applied Sciences, Harvard University, Cambridge, MA,⁴Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

Accurate segregation of chromosomes requires the proper attachment of microtubules to chromosomes via the kinetochore. Kinetochore-microtubule attachments are thought to be predominately mediated by the Ndc80 complex, which is modified by Aurora B kinase, but the mechanism by which attachment is maintained and regulated is poorly understood. We are studying these processes with Bayesian analysis of Fluorescence Lifetime Imaging Microscopy (FLIM), a form of Forster Resonance Energy Transfer (FRET) capable of quantitatively measuring the dynamics of protein-protein interaction in cell with millisecond time resolution. We are investigating the dynamics of the binding and clustering of Ndc80 complexes on microtubules at kinetochores in human tissue culture cells. We are also studying phosphoregulation of kinetochore-microtubule attachment in cell by monitoring the activity of Aurora B kinase using a Aurora B biosensor.

P1783**Board Number: B307****A minimal model of kinetochore-microtubule dynamics captures metaphase oscillations, error-correction and effects of Aurora B hyperactivation.**K.K. Chiu¹, E.R. Ballister², E.J. Banigan³, A.M. Mayo², M.A. Lampson², A.J. Liu¹;¹Physics and Astronomy, University of Pennsylvania, Philadelphia, PA, ²Department of Biology, University of Pennsylvania, Philadelphia, PA, ³Physics and Astronomy, Northwestern University, Evanston, IL

Successful eukaryotic cell division requires the formation of correct attachments between kinetochores and spindle microtubules. In the correct (bioriented) configuration, sister kinetochores attach exclusively to microtubules from opposite spindle poles; these microtubules exert opposing poleward forces, resulting in inter-kinetochore tension. Kinetochore-microtubule interactions are dynamic and subject to tension-dependent regulation that destabilizes improper attachments. Tension acts directly via catch-bond-like effects and indirectly through Aurora B phosphorylation of kinetochore proteins. We developed a minimal stochastic model incorporating previous in-vitro biophysical measurements of kinetochore-microtubule interactions and their dependence on both tension and phosphorylation. These previous experiments used kinetochores that bind single microtubules; our model builds on these measurements to describe kinetochores that bind bundles of microtubules and qualitatively captures key phenomena including error correction and metaphase chromosome oscillations. We challenged this

model by experimentally manipulating kinetochore phosphorylation using chemically induced dimerization in living cells. Recruiting Aurora B to metaphase kinetochores caused a dramatic disorganization of the metaphase plate. Systematic analysis of our computational model showed that varying the simulated rates of microtubule catastrophe, rescue and detachment, but not other parameters, provided a good fit to experimental results. These are the same parameters which were independently shown to be modulated by Aurora B phosphorylation in vitro. These results establish a minimal physical model for kinetochore-microtubule dynamics that provides a framework for further theoretical development and quantitative interpretation of in vivo experiments.

Bi-stability of Aurora B kinase activity underlies spatial gradients in dividing cell.

D. Segura-Pena¹, A.V. Zaytsev^{2,3}, E.R. Ballister¹, R. Stamatov⁴, F.I. Ataullakhanov^{5,6}, M.A. Lampson¹, E.L. Grishchuk²;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA, ²Physiology Department, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ³Center for Theoretical Problems of Physico-chemical Pharmacology, RAS, Moscow, Russia, ⁴Bioinformatics, Duke University, Durham, NC, ⁵Center for Theoretical Problems of Physicochemical Pharmacology, Russian Academy of Sciences, Moscow, Russia, ⁶Physics Department, Moscow State University, Moscow, Russia

Aurora B kinase, the enzymatic component of the chromosome passenger complex, is a key regulator of cell division that provides temporal and spatial coordination for chromosome segregation. Gradients of Aurora B activity are implicated in regulating kinetochore-microtubule interactions and cytokinesis, but the mechanisms underlying these spatial patterns are unknown. Spatial phosphorylation gradients extend beyond known locations of Aurora B binding sites, suggesting that these patterns form by a Turing mechanism through dynamic self-organization of a coupled kinase-phosphatase system. Such a mechanism implies that the system contains positive feedback and exhibits bi-stability. To test the hypothesis that self-organization can establish spatial patterns of Aurora B activity, we use a coupled Aurora B kinase and phosphatase system in vitro, which is biochemically and theoretically tractable. We show that Aurora B kinase activation by auto-phosphorylation in trans leads to a bi-stable switch, and we experimentally define a hysteretic region for Aurora B activity that matches the theoretical prediction. In living cells, we find similar bi-stability using a FRET-based phosphorylation sensor: partial kinase inhibition leads to two distinct populations of mitotic cells with either high or low levels of Aurora B substrate phosphorylation. Together these results suggest that spatial patterns of Aurora B activity in cells are established around sites of CPC concentration by a Turing self-organization mechanism.

P1785**Board Number: B309****The spindle checkpoint components Mad1 and Mad2 have an essential, checkpoint-independent function in *C. elegans*.**P. Lara-Gonzalez¹, M. Moyle¹, T. Kim¹, D.K. Cheerambathur¹, K. Oegema¹, A. Desai¹;¹Ludwig Institute for Cancer Research, La Jolla, CA

The spindle assembly checkpoint promotes accurate chromosome segregation by restraining progression through mitosis until all the chromosomes are attached to the microtubules of the mitotic spindle. The most downstream components of this pathway are the “mitotic arrest deficient” (Mad) proteins Mad1, Mad2 and Mad3, which are conserved throughout evolution. While the spindle checkpoint and its components have been studied extensively from a single-cell perspective, we aimed to understand the consequences of disrupting this pathway in a developing organism, and ask whether the resulting phenotypes are explained by lack of checkpoint function. For this, we employed CRISPR-Cas9 to generate strains of *C. elegans* in which *mad-2* and *mad-3* were fully deleted; a full deletion of *mad-1* was previously generated. We found that, consistent with previous observations using partially deleted alleles, complete deletion of *mad-1* and *mad-2* has a profound effect on viability and fertility. Surprisingly, deletion of *mad-3* has only a mild effect on viability. Thus, despite all of the MAD proteins being essential for the spindle checkpoint, MAD-1 and MAD-2 have additional, checkpoint-independent roles, which are essential for organismal development. We confirmed this conclusion by analyzing mutations that disrupt the ability of MAD-1 to localize to unattached kinetochores; despite their lack of checkpoint activity, these mutant forms of MAD-1 supported normal viability and fertility. In addition, MAD-1 localizes to the nuclear envelope during interphase, but we engineered a mutant form of MAD-1 that abolishes this localization and found that it still supports normal viability and fertility. In contrast, a MAD-1 mutant that cannot interact with MAD-2 was phenotypically similar to a *mad-2* deletion, exhibiting severe loss of viability and fertility. These data indicate that the MAD-1/MAD-2 complex has an essential function during organismal development in *C. elegans*, which is unrelated to its known role in the spindle checkpoint. We are currently testing if the well-described MAD-1/MAD-2 complex-mediated control of the anaphase promoting complex/cyclosome (APC/C) underlies this essential function. In addition we are performing unbiased biochemical, molecular genetic, and developmental analyses to elucidate the non-checkpoint function of MAD-1/MAD-2 that is essential for organismal development.

P1786**Board Number: B310****The nanoscale organization of Spc105 in metaphase and its role in silencing the Spindle Assembly Checkpoint.**B. Roy¹, J. Sim¹, A.P. Joglekar^{1,2};¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, ²Biophysics, University of Michigan, Ann Arbor, MI

Faithful chromosome segregation during cell division requires that the kinetochore, a multi-protein machine built on every chromosome, is stably attached to spindle microtubules. Whether or not the kinetochore is attached is monitored by a surveillance mechanism known as the Spindle Assembly Checkpoint (SAC). The SAC delays the cell cycle as long as even a single kinetochore is unattached. It gets silenced rapidly once stable attachments form. The physical platform for the SAC is provided by Spc105, a conserved kinetochore protein that is large protein (~ 900 amino acids) and consists of a large, unstructured amine-terminal (~ 500 amino acids) signaling domain with microtubule-binding activity. Upon phosphorylation by the Mps1 kinase, this domain recruits SAC proteins to activate the SAC. Just as the organization of microtubule-binding kinetochore proteins plays a key role in executing kinetochore movement, the organization of Spc105 in the attached kinetochore may be important for the reliable silencing of the SAC. Therefore, using in vivo Forster Resonance Energy transfer (FRET) and high resolution co-localization measurements, we defined the average localization and distribution of five different positions spanning the length of the Spc105 molecule. We find that the entire Spc105 molecule is compacted within a 30 nm zone bookended by the centromeric end of the Ndc80 complex (C terminus of Spc24) up to the C terminus of Ndc80 (subunit of the Ndc80 complex). Detectable FRET between Stu2, a microtubule plus-end binding protein, indicates that the N-terminus is proximal to the microtubule lattice. FRET between two different positions in the N-terminus of adjacent Spc105 molecules can also be detected, which is consistent with the disordered nature of this domain. This compact Spc105 organization is surprising, given its large size and disordered nature. We hypothesize that the microtubule-binding activity in Spc105 restrains it within the inner kinetochore in metaphase, and that this organization is required for reliable silencing of the SAC. We will test these hypotheses by abrogating the microtubule-binding activity of Spc105, and studying whether its nanoscale organization changes and if timely SAC silencing is impaired.

P1787**Board Number: B311****TRIP13 AAA-ATPase is a novel mitotic checkpoint silencing protein.**K. Wang¹, B. Sturt-Gillespie¹, J. Hittle², D. Macdonald³, G. Chan³, T.Y. Yen⁴, S. Liu¹;¹Biol Sci, University of Toledo, Toledo, OH, ²Fox Chase Cancer Center, Philadelphia, PA, ³Cross Cancer Inst, Edmonton, AB, ⁴Developmental Therapeutics Program, Fox Chase Cancer Center, Philadelphia, PA

The mitotic checkpoint (or spindle assembly checkpoint) is a fail-safe mechanism to prevent chromosome missegregation by delaying anaphase onset in the presence of defective kinetochore-microtubule attachment. The target of the checkpoint is the E3 ubiquitin ligase anaphase promoting complex/cyclosome (APC/C). Once all chromosomes are properly attached and bi-oriented at the metaphase plate, the checkpoint needs to be silenced. Previously we and others have reported that Thyroid hormone receptor interacting protein 13 (TRIP13) AAA-ATPase interacts with the mitotic checkpoint silencing protein p31comet. Here we show that endogenous TRIP13 localizes to kinetochores. TRIP13 knockdown delays metaphase-to-anaphase transition. The delay is caused by prolonged presence of the effector for the checkpoint, the mitotic checkpoint complex (MCC) and its association and inhibition of the APC/C. These results suggest that TRIP13 is a novel mitotic checkpoint silencing protein. The ATPase activity of TRIP13 is essential for its checkpoint function, and interference with TRIP13 abolished p31comet mediated mitotic checkpoint silencing. TRIP13 overexpression is a hallmark of cancer cells with chromosomal instability, particularly in certain breast cancers with poor prognosis. We suggest that premature mitotic checkpoint silencing triggered by TRIP13 overexpression may promote cancer development.

P1788**Board Number: B312****BUB-1 promotes the onset of anaphase independently of its role in the spindle checkpoint and chromosome alignment.**T. Kim¹, M. Moyle¹, C. De Groot¹, K. Oegema¹, A. Desai¹;¹Ludwig Institute for Cancer Research, La Jolla, CA

Bub1 is a conserved kinase implicated in spindle checkpoint signaling and chromosome alignment. Bub1 targets Mad1 to the kinetochore to initiate spindle checkpoint signaling. In addition, Bub1 promotes chromosome alignment by phosphorylating histone H2a to direct recruitment of the chromosomal passenger complex via the adaptor Shugoshin. Unexpectedly, we found that depletion of BUB-1 significantly extended the duration of mitosis in one-cell *C. elegans* embryos: the NEBD-anaphase interval was extended by 61% (from 188 ± 2.0 sec in control embryos to 303 ± 5.6 sec in BUB-1 depleted embryos). This extension was independent of checkpoint signaling as it was unaffected by co-depletion of MAD-2 and was observed in a checkpoint signaling-defective allele of *bub-1*. The promotion of anaphase onset by BUB-1 required kinetochore localization—mutants of BUB-3 and of the BUB-1/BUB-3 kinetochore receptor KNL-1 that perturbed kinetochore recruitment of BUB-1 delayed anaphase onset

to a similar extent as BUB-1 depletion. In addition, engineered mutant forms of KNL-1 that recruit variable amounts of BUB-1 to the kinetochore resulted in NEBD–anaphase onset durations that correlated with the magnitude of BUB-1 recruitment. To analyze the biochemical events underlying anaphase onset, we engineered a sensor for activation of separase, the protease that cleaves cohesin. Use of this sensor indicated that BUB-1 depletion delayed separase activation. Once activated, the kinetics of separase-mediated cleavage of the sensor was not affected by BUB-1 depletion, suggesting that the delay in separase activation is a consequence of delayed APC/C activation. Mutational analysis revealed that the BUB-1 kinase domain, but not its kinase activity, are important for promoting separase activation and anaphase onset. Notably, a mutant allele in the kinase domain that did not perturb chromosome alignment and rescued a *bub-1* null mutant delayed separase activation and anaphase onset. These results reveal an unexpected role for Bub1 in the promotion of anaphase onset, independently of its functions in checkpoint signaling and chromosome alignment, and suggest a new mechanism contributing to the switch-like transition from metaphase to anaphase.

N-terminal modification of Ndc80 can induce a spindle assembly checkpoint arrest in mouse oocytes.

Y. Yun¹, S. Lane^{1,2}, J. Holt¹, K. Jones^{1,2};

¹University of Newcastle, Callaghan, Australia, ²University of Southampton, Southampton, United Kingdom

Correct microtubule-kinetochore (MT-KT) interactions are essential to achieve faithful chromosome segregation and prevent aneuploidy. The spindle assembly checkpoint (SAC) helps ensure the fidelity of this process, by coupling anaphase-onset with MT-KT attachment. A key component of the MT-KT interface is Ndc80 (Hec1 in humans), which is essential for maintaining kinetochore integrity and the stability of MT-KT interactions during mitosis. However, in mammalian oocytes, which are susceptible to aneuploidy, its function remains unclear. In this study, by expressing fluorescently tagged C- or N-terminally coupled Ndc80 protein in mouse oocytes, we examined the effect on chromosome dynamics and SAC activity. Both of the fused proteins showed specific kinetochore localization, however, majority of the N-terminal tagged Ndc80 (Ndc80-N) oocytes failed to complete meiosis I, and instead arrested at metaphase I (MI completion rates: 12.5% of Ndc80-N oocytes, n=80; vs. 67.5% of Ndc80-C oocytes, n=40; p<0.0001, Fisher's exact test), and this was associated with an increased percentage of incorrect MT-KT attachments (17.7% in Ndc80-N injected oocytes, n=355 kinetochores examined; vs. 7.6% in H₂O injected oocytes, n=158; p=0.0027, Fisher's exact test). Interestingly, live cell imaging revealed that these attachment errors had no significant effect on chromosome congression and bivalent tension establishment during meiosis I. Nevertheless, securin degradation in Ndc80-N expressing oocytes was prevented, suggesting inhibition of Anaphase-Promoting Complex/Cyclosome (APC/C) activity. Consistent with this, an increase in kinetochore Mad2 localization was identified (357 ± 14.9 arbitrary intensity in Ndc80-N injected oocytes, n=280 kinetochore examined; vs. 252 ± 12.4 in H₂O injected

oocytes, $n=280$; $p < 0.0001$, Mann-Whitney test). Furthermore, polar body extrusion (PBE) and securin degradation in these arrested oocytes was efficiently rescued by inhibiting either Aurora or Mps1 kinase, both of which are key SAC components (PBE rate: 20.9% in DMSO control group, $n=67$ oocytes examined; vs. 69.6% with Aurora inhibition, $n=46$; vs. 90.2% with Mps1 inhibition, $n=51$). Therefore, despite the fact that mammalian oocyte meiosis I is unique in having sister kinetochores that co-segregate in pairs, the data that modification of the N-terminal Ndc80 causes MT-KT attachment errors and a persistent SAC activation in mouse oocytes suggested that Ndc80 may serve a meiotic function that parallels its mitotic one, and emphasized the essential role of its N-terminal region in which interaction with microtubules occurs.

Micro-RNAs (miRNAs) are highly conserved small non-coding RNA molecules (~21 nucleotides in length) implicated in the control of diverse biological processes such as cell differentiation, proliferation and growth. Altered miRNA expression is a contributing factor in cell transforming processes that can trigger cancer initiation or promote tumor growth and metastasis. A miRNA regulates gene expression by binding to complementary sequence in its target messenger RNA (mRNA), which is then directed for degradation or translational inhibition. Since mitotic fidelity is essential for maintenance of genomic balance and normal cell growth, we were interested to get insights on how miRNAs participate in regulation of mitosis. To this end, we designed and executed a high-throughput screen to identify miRNAs that abrogate normal Spindle Assembly Checkpoint (SAC) signaling when overexpressed. Here we report a novel mitosis perturbing miRNA, miR-493, which binds to the 3' untranslated region (3' UTR) of Mad2 mRNA and thereby controls the Mad2 protein levels in cells. Overexpression of miR-493 led to a significant suppression of Mad2 mRNA and protein levels, and reduced Mad2 accumulation to the unattached kinetochores. As a consequence, the cells underwent a forced mitotic exit and antagonized microtubule drug effects. Moreover, cells with excess miR-493 exhibited a significant increase in the frequency of aneuploidy, apoptosis and cellular senescence when compared to controls. The specificity of miR-493 action on Mad2 was confirmed using a Mad2-target site blocker, which competes with miR-493 for binding to Mad2 mRNA. The Mad2-target site blocker restored Mad2 protein levels, reactivated SAC, and prevented aneuploidy and cellular senescence caused by the excess miR-493. Our results reveal a new miRNA-mediated control mechanism of mitosis, deregulation of which can contribute to

genomic instability. Moreover, the findings can help to understand how Mad2 expression may be altered during malignant cell growth *in vivo*.

A genetic view of metazoan mitotic exit through Protein Phosphatase 2A.

V. Boudreau¹, P.S. Maddox¹, V. Archambault²;

¹Department of Biology, University of North Carolina, Chapel Hill, NC, ²Biochemistry Department, Université de Montreal, Montreal, QC

Mitotic progression is largely governed by kinases, phosphatases and ubiquitin ligases. Whereas high levels of CycB-Cdk1 kinase activity trigger mitotic entry, mitotic exit requires the inactivation of this kinase and the activation of one or several phosphatases at the onset of anaphase. It has recently been determined that PP2A-B55/Tws plays a major role in CycB-Cdk1 substrate dephosphorylation in mitotic exit in higher eukaryotes. The precise substrates that must be dephosphorylated by PP2A-B55/Tws to allow mitotic exit events including chromosome segregation are unknown.

Here, a genetic screen was used to identify genetic PP2A-B55/Twins collaborators. We exploited the fact that meiosis and early embryonic mitoses of *Drosophila* syncytial embryos are particularly sensitive to cell cycle perturbations. We conducted a second-site non-complementation, maternal effect lethal screen. Several PP2A-Twins collaborators for cell cycle progression such as CycB3, CENP-C, LamB and main components of the nuclear-cytoplasmic protein import-export machinery were identified. To identify potential genetic networks governing mitotic exit, hits were cross-screened using the same approach. Distinct genetic networks were identified, governed mainly by CycB3 and Polo, in addition to PP2A-Tws.

Taken together, our genetic results suggest that PP2A-B55/Twins regulates mitotic exit through several pathways. Identified PP2A-B55/Tws genetic interactors form distinct genetic networks that are likely to regulate several mitotic exit events such as chromosome segregation, chromosome decondensation, nuclear envelope reformation and spindle assembly checkpoint inactivation. Future work will be aimed at understanding how these genetic components regulate mitotic exit processes individually and within their proposed networks.

P1792**Board Number: B316****Characterization of a novel splice site mutation in *CASC5* identified in a large Pakistani primary microcephaly family.**S. Szczepanski^{1,2}, M. Hussain^{1,2}, S. Baig³, P. Nürnberg^{2,4,5}, A. Noegel^{1,2,4,5};

¹Institute for Biochemistry, Medical Faculty, University of Cologne, Cologne, Germany, ²Cologne Center for Genomics (CCG), Cologne, Germany, ³Human Molecular Genetics Laboratory, Health Biotechnology Division, National Institute for Biotechnology and Genetic Engineering (NIBGE), Faisalabad, Pakistan, ⁴Center for Molecular Medicine Cologne (CMMC), Cologne, Germany, ⁵Cluster of Excellence, Cellular Stress Responses in Aging-Associated Disease, Cologne, Germany

Autosomal recessive primary microcephaly (MCPH) is a rare neurodevelopmental disorder characterized by the reduced size of the cerebral cortex at birth accompanied by intellectual disability whereas the architecture of the brain does not show any abnormalities. MCPH genes code for proteins implicated in cell division and cell cycle regulation thereby being important components controlling brain size as a consequence of a reduced pool of neurons. To date 13 causative genes, named *MCPH1*, *WDR62*, *CDK5RAP2*, *CASC5*, *ASPM*, *CENPJ*, *STIL*, *CEP135*, *CEP152*, *ZNF335*, *PHC1*, *CDK6* and *SASS6* have been described for this disease.

We ascertained a primary microcephaly family from a remote region of Pakistan. Combination of homozygosity mapping and whole-exome sequencing identified a novel splice site mutation (c.6673-19T>A) in *CASC5*, a gene encoding a protein important for kinetochore formation and proper chromosome segregation during mitosis. Post-hoc Sanger sequencing of patient cDNA revealed the skipping of exon 25 of *CASC5* causing a frameshift and introducing a premature stop codon (p.Met2225Ilefs*7) which ultimately resulted in a C-terminally truncated protein. Furthermore, we found a down-regulation of *CASC5* mutant mRNA as measured by quantitative RT-PCR.

Upon analyzing the patient primary fibroblasts we observed a defective nuclear structure as the major phenotype. Additionally, micronuclei were found in these cells. Immunofluorescence analyses of the patient fibroblasts revealed a mislocalization of *CASC5* in dividing cells during metaphase as compared to wild type. Since the nuclear abnormalities are considered as a hallmark of genetic instability, an altered DNA damage response was studied. Upon UV-DNA damage, a higher percentage of H2AX foci were detected in the mutant fibroblasts as compared to wild type. Comparable results were obtained in western blot analysis.

Taken together these results show not only a second novel pathogenic mutation in *CASC5* but also underscore the function of the gene in proper kinetochore formation. Moreover, we demonstrate the mutation's consequence on the chromosome integrity and therefore indicating a distinct role in genomic maintenance and stability of the cell.

P1793**Board Number: B317****Chromosomally unstable cancer cells develop adaptive resistance to targeted therapy.**B. Orr^{1,2}, L. Talje³, B.H. Kwok³, D.A. Compton^{1,2};¹Department of Biochemistry, Geisel School of Medicine at Dartmouth College, Hanover, NH, ²Norris Cotton Cancer Center, Lebanon, NH, ³Institute for Research in Immunology and Cancer, University of Montreal, Montréal, QC

Aneuploidy is a hallmark of solid tumors and many aneuploid tumor cells display high rates of chromosome mis-segregation in a phenomenon termed chromosomal instability (CIN). This property distinguishes cancer cells from normal cells providing an opportunity for cancer-specific targeted therapy. CIN is most commonly caused by the persistence of errors in kinetochore-microtubule (kMT) attachments. Moreover, it has been shown that many cancer cells with CIN have hyperstable kMT attachments and that strategically destabilizing kMT attachments by overexpressing the kinesin-13 proteins Kif2b and MCAK suppresses CIN in cancer cells. This establishes the principle that CIN can be suppressed by destabilizing kMTs, but the broader application of protein overexpression for this purpose has severe technical limitations. To overcome this technical constraint, we performed a high throughput screen to identify small molecules that specifically modulate the microtubule depolymerizing and/or ATPase activities of kinesin-13 proteins. This screen identified one compound (Cp57) that potentiates the microtubule depolymerizing activity of MCAK in vitro. Cp57 is cell permeable and specifically potentiates MCAK activity because it selectively destabilizes kMT attachments only during metaphase without affecting non-kMTs, and induces a reduction in MCAK phosphorylation at Serine 92 and 95. Furthermore, sensitivity to Cp57 decreases sharply in MCAK-depleted cells and increases in cells over-expressing MCAK. Importantly, short term treatment with Cp57 reduces the rate of lagging chromosomes in anaphase in CIN cancer cells with no detectable effect on chromosome segregation in diploid cells. Surprisingly, the rate of lagging chromosomes in anaphase and the phosphorylation of MCAK at Serine 92 and 95 rebound in CIN cancer cells treated with Cp57 for >72h. Moreover, kMT attachments become hyperstable in prometaphase of mitosis following treatment for >72h. Thus, the CIN status rapidly returns to the cancer cells. These data demonstrate that cancer cells with CIN rapidly acquire adaptive resistance to targeted therapy.

P1794**Board Number: B318****VTT-006, a novel anti-mitotic compound, binds to the Ndc80 complex and suppresses cancer cell growth in vitro.**

¹VTT Health, VTT Technical Research Centre of Finland, Turku, Finland, ²Centre for Biotechnology, University of Turku, Turku, Finland, ³Department of Pharmacology, Drug Development and Therapeutics, University of Turku, Turku, Finland, ⁴Drug Research Doctoral Programme and FinPharma Doctoral Program Drug Discovery, Turku, Finland, ⁵Department of Biosciences, Åbo Akademi University, Turku, Finland, ⁶Department of Biochemistry, University of Washington, Seattle, WA, ⁷Harvard Medical School, Boston, MA, ⁸Department of Physiology and Biophysics, University of Washington, Seattle, WA, ⁹School of Pharmacy, University of Eastern Finland, Kuopio, Finland

Hec1 (Highly expressed in cancer 1), a member of the Ndc80 complex, resides in the outer kinetochore plate where it works to facilitate proper kinetochore-microtubule interactions. Hec1 is overexpressed in various cancers and expression shows correlation with high tumour grade and poor patient prognosis. Based on previous RNAi studies, chemical inhibition of Hec1 is anticipated to hyperactivate the spindle assembly checkpoint (SAC) and suppress cell proliferation which may possess therapeutic value. In this study, we designed and executed a high-throughput screen to identify novel low molecular weight (LMW) compounds that target Hec1 calponin homology domain (CHD), which is needed for normal microtubule attachments. First, 4 million compounds were virtually fitted against the CHD to discover compounds that potentially interfere with Hec1-microtubule interaction. This approach led to the identification of VTT-006 that showed binding to recombinant Ndc80 complex and modulated Hec1 association with microtubules in vitro. In cells, VTT-006 treatment resulted in chromosome congression defects, accumulation of Aurora B to centromeres, and loss of interkinetochore tension that triggered a SAC-dependent mitotic arrest followed by cell death. Furthermore, VTT-006 suppressed the growth of several cancer cell lines and enhanced the sensitivity of HeLa cells to taxol treatment. Our findings propose that VTT-006 is a potential anti-mitotic compound that disrupts normal mitotic progression by modulating kinetochore-microtubule interactions.

P1795**Board Number: B319****Abrupt sister chromatid splitting in anaphase without obligatory positive feedback.**J. Kamenz^{1,2}, T. Mihaljev³, S. Legewie³, S. Hauf^{1,4};¹Friedrich Miescher Laboratory, Max Planck Society, Tuebingen, Germany, ²Dept. of Biol. Sciences, Virginia Tech, Blacksburg, VA, ³Institute of Molecular Biology (IMB), Mainz, Germany, ⁴Dept. of Biol. Sciences and VBI, Virginia Tech, Blacksburg, VA

Major transitions from one cell cycle phase to the next are implemented with positive feedback loops in their regulatory pathways, which ensures that they occur quickly and are irreversible. The transition from metaphase to anaphase is visually one of the most dramatic transitions in the cell cycle. Since chromosomes split abruptly and synchronously, it is natural to assume that this transition involves positive feedback, and some evidence has been found in budding yeast. We now show that chromosome splitting can be slowed down and made more asynchronous by several different perturbations in fission yeast. We find a tendential order in the time when different chromosomes separate, which is aggravated when slowing down separation. Because affecting different steps in the segregation pathway all lead to a less abrupt separation, we conclude that feedback happens, if at all, far upstream, but not at the level of the direct regulators. Hence, sister chromatid separation, being already irreversible by nature, may be one of the few major cell cycle transitions that can operate without positive feedback.

P1796**Board Number: B320****Overexpression of Kif2b Acts Synergistically with K-Rras G12D Mutation to Accelerate Lung Tumor Progression in Mice.**C.D. Laucius^{1,2}, D.A. Compton^{1,3};¹Department of Biochemistry, Geisel School of Medicine at Dartmouth College, Hanover, NH, ²Norris Cotton Cancer Center, Hanover, NH, ³Norris Cotton Cancer Center, Lebanon, NH

Chromosomal instability (CIN) – a high rate of whole chromosome loss or gain - is a hallmark of many aneuploid solid tumors. CIN is frequently linked with drug resistance and poor patient prognosis. The persistence of mal-oriented attachment of spindle microtubules to kinetochores during mitosis is the most common cause of CIN. Correction of these mal-orientations relies on detachment of microtubules from kinetochores, a process stimulated by the microtubule-depolymerizing Kinesin 13 family motor proteins Kif2b and MCAK. We have previously shown that Kif2b overexpression is sufficient to suppress CIN in multiple human cancer cell lines grown in cell culture. Therefore, we hypothesized that Kif2b overexpression would suppress CIN in aneuploid solid tumors and would offer insight into the role of CIN in tumor initiation and/or progression. To test this, we constructed a Kif2b conditional

overexpression transgenic mouse (Kif2b COE). The transgene, containing a floxed translational stop sequence, was targeted to the endogenous mouse Rosa26 locus. Progeny of Kif2b COE mice crossed with transgenic CMV-Cre mice show robust Kif2b expression in all tissues. There is no change in the incidence of tumors in mice constitutively overexpressing Kif2b in an oncogenic K-Ras (G12D) lung cancer model. However, Kif2b expression enhanced tumor growth as the mean surface area (mm²) of pulmonary nodules increases from 0.27 to 0.43. Accordingly proliferating Ki-67 positive cells significantly increase upon Kif2b overexpression as compared to control animals. Unexpectedly, Kif2b overexpression increased the frequency of aneuploid cells from 3.8% to 6.3% ($p < 0.05$) in lung tumors driven by mutant K-Ras as judged by FISH for chromosome 2. Thus, there are distinct consequences of Kif2b overexpression in cultured cells relative to animals tissues, and we demonstrate that Kif2b overexpression drives tumor progression in the context of a mutant K-Ras G12D lung cancer model.

¹Wellcome Trust Centre for Cell Biology, The University of Edinburgh, Edinburgh, United Kingdom,

²Wellcome Trust Centre for Cell Biology, The University of Edinburgh, Edinburgh, Scotland, ³Natl Inst Genetics, Mishima, Shizuoka, Japan

The kinetochore is a highly complex proteinaceous structure located at the primary constriction of mitotic chromosomes. There, it performs an essential role in accurate chromosome segregation. More recently, interest has been directed towards the Constitutive Centromere Associated Network (CCAN) components, as they participate in the formation of a scaffold involved in kinetochore assembly. It is therefore important to fully understand their role, and their distribution, at the kinetochore. Although many kinetochore proteins have already been identified, it is still unclear how centromeric chromatin folds to form the structure of the inner kinetochore. This is an interesting yet still open field of study,

where the literature reports are still quite divided. In our study we take advantage of the high homologous recombination efficiency in DT40 B-lymphoma chicken cell lines, allowing us to obtain conditional knockouts and deletion cell lines of several CENPs subsequently engineered to stably express GFP:CENP-A. In the parental cell line the unfolding properties of the centromeric region were investigated by using TEEN buffer. Using fluorescence microscopy we were able to measure the length of many unfolded centromeric chromatin fibres, based on the signal of GFP:CENP-A. A multi-peak analysis revealed the presence of discrete populations of fibres, recognised as peaks, in both interphase and mitotic samples. Compared with interphase, mitotic centromeres showed a greater level of compaction. Next, mutants for CCAN components blocked in mitosis, were subjected to centromere chromatin unfolding. Results revealed that mitotic kinetochores depleted of CENP-C and CENP-S behaved similarly to the parental interphase samples, suggesting a role of those proteins in maintaining kinetochore structure. In contrast, CENP-O, CENP-H and CENP-I depletion in mitosis did not seem to weaken the structure of the kinetochore. Additionally, we tested a hypothesis suggested by the multi-peak analyses that chromatin layers exist in the inner kinetochore. Our data, when combined with published EM and crystallography measurements of centromere/kinetochore components, allowed us to assemble a robust and mathematically viable model that supports a boustrophedon organisation of the kinetochore chromatin fibre. This work represents an advance in our understanding of kinetochore structure in vertebrates.

Visualizing dynamic kinetochore structure using super-resolution microscopy.

D.J. Wynne¹, H. Funabiki²;

¹Rockefeller University, New York, NY, ²Laboratory of Chromosome and Cell Biology, Rockefeller University, New York, NY

During mitosis, the functions of kinetochores change from interacting with the lateral surface of microtubules and activating the spindle assembly checkpoint (SAC) to capturing microtubule ends and silencing the SAC. The molecular mechanism that couples this functional change to microtubule attachment status remains unclear. Applying 3-D super-resolution imaging to *Xenopus* egg extracts, here we reveal that the kinetochore is spatially and functionally segmented into a stable core module supporting end-on attachment and an expandable module responsible for lateral attachment and SAC signaling. Unexpectedly, the inner kinetochore component CENP-C is an integral component of the expandable module, whose assembly also depends on outer kinetochore proteins (Bub1, BubR1) and multiple protein kinases (Aurora B, Haspin, Plx1, Mps1) and is suppressed by protein phosphatase 1. We propose that the expandable module consists of a phosphorylation-dependent copolymer that spatially segregates kinetochore functions to help couple end-on attachment and SAC silencing.

P1800**Board Number: B324****Oncogenic RAS/MAPK signaling hyper-activates Aurora B kinase and weakens kinetochore-MT attachments.**J.A. Herman¹, P.J. Paddison², J.G. DeLuca¹;¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, ²Human Biology Division, Fred Hutchinson Cancer Research Center, Seattle, WA

For over a century it has been appreciated that many cancer cells exhibit a high degree of aneuploidy, which results from the incorrect segregation of whole chromosomes during mitosis. Recent evidence has also demonstrated that the chromosome segregation errors leading to aneuploidy commonly arise from defects in kinetochore-microtubule attachment regulation. Thus, successful chromosome segregation requires that kinetochores not only link the forces from dynamic spindle microtubules to chromosomes, but also precisely regulate the attachment strength to these microtubules. For example, in early mitosis, kinetochores prevent the stable binding to ends of microtubules emanating from the incorrect spindle pole to prevent the accumulation of attachment errors. Such error prevention is accomplished primarily through Aurora B kinase (ABK) dependent phosphorylation of the kinetochore factors responsible for binding microtubules and generating stable kinetochore-microtubule attachments. Despite a growing understanding of how cells become aneuploid and the mechanisms cells use to prevent this condition, the mechanism by which cancer cells become prone to errors in kinetochore-microtubule attachment remains poorly understood. To investigate this issue, we transformed primary RPE cells with various oncogenic stresses. In doing so, we found that oncogenic RAS/MAPK signaling compromises kinetochore-microtubule attachments through a phosphorylation cascade of kinetochore targets. Oncogenic RAS/MAPK signaling aberrantly hyper-activates the ABK error correction system and destabilizes kinetochore-microtubule attachments. This decreased attachment stability prolongs mitosis and increases chromosome segregation errors, and both defects are largely rescued by inhibition of RAS/MAPK signaling. This amplification of ABK activity also results in an increased dependence on recruitment of the ABK-counteracting phosphatase PP2A to kinetochores. In order to form stable kinetochore-microtubule attachments, RAS/MAPK-transformed cells require the BubR1-KARD domain, which contributes to PP2A kinetochore recruitment, while non-transformed cells do not. Together, these findings demonstrate that in at least a subset of cancers, kinetochore-microtubule attachments become weakened, and suggest that this defect may be exploited to generate new, highly specific therapeutics.

Spindle Assembly 3**P1801****Board Number: B325****Fission yeast Kinesin-8 controls chromosome alignment by containing sister chromosome oscillations and providing a length dependent pulling force.**

H. Mary¹, J. Fouchard¹, G. Gay², C. Reyes¹, T. Gauthier¹, C. Gruget¹, Y. Gachet¹, S. Tournier¹;
¹31062, Université de Toulouse, LBCMCP, Toulouse, France, ²<http://damcb.com/>, DAMCB, Marseille, France

The formation of a metaphase plate before chromosome segregation is a key step during mitosis in many species to maintain genetic stability. During this process, the motor protein Kinesin-8 is required to align chromosomes at the spindle center. In vitro evidences suggest that Kinesin-8 acts on microtubule depolymerization in a length-dependent manner but the mechanism by which this alignment occurs in vivo remains to be clarified.

Through a combination of 3D and high-speed video microscopy, we analyzed the effect of Klp5, the fission yeast Kinesin-8 homolog, on chromosome movement and positioning during mitosis. We show that Kinesin-8 accumulates at the plus-end of microtubules in mitosis and provides positional information by containing sister chromosome oscillations and restricting them at the spindle midzone during the entire metaphase. To test the possible mechanism at the origin of this centering defect, we used a simple force-balance model of the mitotic spindle. We demonstrate that a length-dependent pulling force exerted at the sites of attachment is necessary and sufficient to mimic the effect of Kinesin-8 on chromosome centering and to prevent the appearance of lagging chromosomes.

Altogether, these data bring new insight into how the local action of a single motor protein at the kinetochore can be integrated at the scale of the entire spindle to prevent aneuploidy.

Phosphorylation-dependent Regulation of the Checkpoint Kinase Kin4.

Y. Micoogullari¹, G. Pereira¹;

¹German Cancer Research Center (DKFZ), DKFZ-ZMBH Alliance, Heidelberg, Germany

Budding yeast cells are inherently polarized and asymmetrically dividing. Positioning of the mitotic spindle through the mother to daughter cell polarity axis is crucial for accurate chromosome segregation. The spindle position checkpoint (SPOC) is responsible for monitoring spindle orientation and delaying cell cycle progression in case of spindle misalignment. SPOC dependent cell cycle arrest relies on a bi-partite GTPase-activating protein (GAP) complex, composed of Bub2 and Bfa1, which inhibits the activation of the mitotic exit network (MEN, a GTPase driven signalling cascade essential for mitotic exit and cytokinesis). The function of Bub2-Bfa1 GAP complex is modulated by the protein kinase Kin4, which phosphorylates Bfa1 thereby keeping the GAP in the active state.

Kin4 kinase is a phospho-protein regulated at multiple levels. The phosphorylation status of Kin4 determines its activity and localization. Kin4 associates with the mother cell cortex during most phases of the cell cycle and localizes to the bud neck in late anaphase. Additionally, it binds to the mother spindle pole body (SPB, functional equivalent of centrosome in yeast cells) for a short period during

mitosis. However, after SPOC activation, Kin4 SPB localization becomes prominent on both SPBs. Kin4 cortex and SPB localizations and catalytic activity are phosphorylation dependent and regulated by protein phosphatase 2A (PP2A) subunit Rts1 and the kinase Elm1, respectively. Several evidences indicate the involvement of other elements to the Kin4 phospho-regulation.

In this study, we aimed to identify and characterize novel Kin4 regulators. For this, we performed a yeast kinome library screening to search for protein kinases involved in Kin4 phospho-regulation. In addition to the already known SPOC player Elm1, we identified Cdc28 as a putative kinase involved in Kin4 phosphorylation. Using genomic and cell biology approaches, we show that Cdc28 phosphorylates Kin4 *in vitro*. Furthermore, Kin4 phospho-deficient mutant at putative Cdc28 phosphorylation sites do not show *in vivo* catalytic activity and failed to engage SPOC. We propose that Cdc28 dependent phosphorylation of Kin4 is required for Kin4's role in SPOC.

Csi1p recruits alp7p/TACC to the spindle pole bodies for bipolar spindle formation.

F. Zheng¹, T. Li¹, D. Jin¹, V. Syrovatkina², K. Scheffler³, P. Tran^{2,4}, C. Fu⁵;

¹Department of Biochemistry, Univ Hong Kong, Pokfulam, Hong Kong, ²Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA, ³Institut Curie, Paris, France, ⁴CNRS UMR144, Institut Curie, Paris, France, ⁵Department of Biochemistry, Univ Hong Kong, Hong Kong, Hong Kong

Accurate chromosome segregation requires timely bipolar spindle formation during mitosis. The transforming acidic coiled-coil (TACC) family proteins and the ch-TOG family proteins are key players in bipolar spindle formation. They form a complex to stabilize spindle microtubules, mainly dependent of their localization to the centrosome (the spindle pole body/SPB in yeast). The molecular mechanism underlying the targeting of the TACC-ch-TOG complex to the centrosome remains unclear. Here, we show that the fission yeast *Schizosaccharomyces pombe* TACC ortholog alp7p is recruited to the SPB by csi1p. The csi1p interacting region lies within the conserved TACC domain of alp7p while the carboxyl-terminal domain of csi1p is responsible for interacting with alp7p. Compromised interaction between csi1p and alp7p impairs the localization of alp7p to the SPB during mitosis, thus delaying bipolar spindle formation and leading to anaphase B lagging chromosomes. Hence, our study establishes that csi1p serves as a linking molecule tethering spindle stabilizing factors to the SPB for promoting bipolar spindle assembly.

P1804**Board Number: B328****Galectin-3 as a New Dynamic Regulator of the Spindle Pole Stability.**J. Magescas¹, L. Sengmanivong², F. Poirier³, D. Delacour¹;¹Institut Jacques Monod - CNRS, Paris, France, ²Nikon Imaging Center @ Institut Curie - CNRS, Paris, France, ³Institut Jacques Monod CNRS, Paris, France

Mitosis is a highly regulated cellular process, where many internal rearrangements occur, notably for the microtubule network. Through cell division, microtubules are rearranged from a centrosome-centered array to antiparallel arrays, namely mitotic spindles, at both cell poles. Spindle microtubules connect centrosomes to kinetochores, and motor proteins and organizing/stabilizing microtubules proteins regulate / ensure minus-end microtubule dynamics there. Astral microtubules link spindles to the cell cortex, allowing control of cell division positioning and orientation. These different steps ensure the correct segregation of the sister chromatid in both daughter cells, and any defects in microtubule organization will lead to chromosomal instability and generate aneuploidy. Recently a new kind of post-translational modification, the O-linked N-acetylglucosamine addition, was reported to regulate the spindle pole assembly. However no potential molecular mechanism has been yet identified at that level. One particular protein is interesting in this regard, Galectin-3, a lectin mainly expressed in epithelial cells. Its expression has been extensively correlated with cancer progression. At the cellular level, it is described as a multifunctional protein both intra- and extracellular. Most recently, our lab described Galectin-3 as a new key player in centrosome biology. During ciliogenesis, we reported that Galectin-3 transiently associates with basal bodies in kidney cells as well as in multiciliated trachea cells. There, Galectin-3 has been shown to be important for the recruitment of γ -tubulin and thus the anchorage of microtubules to the basal body MTOC (under revision) We investigated the potential participation of Galectin-3 in mitosis and spindle dynamics in vitro in different human epithelial cell lines. We found that Galectin-3 depletion generates a large panel of mitotic defects. At the spindle pole, Galectin-3 is located at the minus-end microtubules, and interacts with NuMA, a well-known microtubule array organizer in a glycosylation-dependent manner. Altogether, our data demonstrate that Galectin-3 behaves as an oligomerization factor for NuMA, and actively takes part in the cohesion of the spindle microtubule arrays.

P1805**Board Number: B329****Calmodulin and Abnormal Spindle Cooperate to Maintain Mitotic/Meiotic Spindle Integrity in *D. melanogaster*.**T. Schoborg¹, R.X. Guillen², N.M. Rusan¹;¹Cell Biology and Physiology Center, NHLBI, NIH, Bethesda, MD, ²National Heart Lung, and Blood Institute, NIH, Bethesda, MD

Autosomal Recessive Primary Microcephaly (MCPH) is a neurodevelopmental disorder characterized by reduced brain volume and head size, leading to mild mental retardation. Mutations in at least seven different genes have been linked to this disorder, most of which are involved in mitotic spindle function. The most frequent lesions map to the Abnormal Spindle-Like, Microcephaly Associated (ASPM) locus, the vertebrate ortholog of the Abnormal Spindle (Asp) gene from *Drosophila melanogaster*. Although Asp appears to be required to focus microtubule (MT) minus ends at spindle poles during mitosis, its molecular function and etiology remain poorly understood. Here we provide evidence that Asp directly interacts with Calmodulin (CaM) and both associate with spindle microtubules during mitosis and meiosis. Asp is required for CaM localization to the spindle, an interaction that is mediated through at least five separate IQ domains present in the C-terminal region of Asp. In support of their functional dependence, we show they exhibit nearly identical and dynamic streaming behavior towards MT minus ends. This occurs during metaphase and is lost upon CaM inhibition. Reduction in Asp protein levels leads to detachment of MT minus ends from spindle poles, which can be phenocopied through CaM inhibition or loss of the N-terminus of Asp. Our results suggest that CaM and Asp cooperate to maintain spindle integrity, providing significant insight into the molecular mechanisms underlying MCPH.

P1806**Board Number: B330****The far C-terminus of MCAK regulates its conformation and spindle pole focusing.**H. Zong¹, S.K. Lamb², C. Moe¹, S.L. Shaw¹, C.E. Walczak³, S.C. Ems-McClung¹;¹Department of Biology, Indiana University, Bloomington, IN, ²School of Medicine, Vanderbilt University, Nashville, TN, ³Medical Sciences, Indiana University, Bloomington, IN

Accurate chromosome segregation relies on the proper assembly of the bipolar spindle, which is governed in part by microtubule (MT) associated proteins that regulate MT dynamics. MCAK (mitotic centromere-associated kinesin), a member of Kinesin-13 family, depolymerizes MTs from both ends and is critical for proper spindle assembly. Inhibition of MCAK causes excess MT polymer and impedes spindle assembly. Furthermore, the ability of MCAK to undergo intramolecular conformational changes throughout its catalytic cycle is critical for MT depolymerization activity. MCAK consists of an N-terminal kinetochore targeting domain, a class-specific neck, a kinesin-like catalytic domain and C-terminal

dimerization domain. We previously identified S196 phosphorylation within the neck as a major regulator of MCAK conformation, which in turn regulates MCAK MT depolymerization activity. We also found that the conformational regulation of MCAK is dependent on the C-terminus, but how the C-terminal domain is involved in this regulation was not known. Through deletion analysis and site-directed mutagenesis we identified a region in the far C-terminus of MCAK that is important for its conformation and has a role in focusing spindle poles. Mutation of two conserved glutamate residues in the far C-terminus (E715 and E716) to alanine (715AA) causes increased Förster resonance energy transfer (FRET) in solution and faster fluorescence lifetimes on MTs, suggesting a more 'closed' conformation. In depletion/add-back assays in egg extracts, MCAK containing the 715AA mutation (MCAK-715AA) rescued spindle assembly, but 44% of spindles had unfocused poles. Addition of excess MCAK-715AA to extracts caused increased free chromatin, suggesting that MCAK-715AA had higher MT depolymerization activity. This might be caused either by increased biochemical activity or by elevated targeting to sub-regions of the spindle. Time-lapse imaging of EB1 tracks in spindles suggests that MCAK-715AA preferentially disrupts the polar MT array that emanates from the spindle poles. Interestingly, an Aurora A phosphomimetic S719E mutation in MCAK also has a more 'closed conformation' and leads to an increase in unfocused spindle poles when added to extracts. These data support the model that mutation of the far C-terminus of MCAK affects Aurora A-mediated phosphorylation, which regulates both MCAK conformation and activity. We are currently probing the role of S719 phosphorylation in the formation of disrupted polar array in extracts using live imaging.

Human γ TuRC in the mitotic spindle is associated with microtubule minus ends and mediates their poleward sorting, in addition to its essential role as nucleator.

N. Lecland¹, N. Teixido-Travesa², R. Ramírez-Cota², C. Lacasa², S. Eibes², J. Roig², J. Lüders²;

¹Centre de Biologie du Développement, UMR5547: CNRS/ Université de Toulouse, Toulouse, France, ²IRB Barcelona, Barcelona, Spain

During mitotic spindle assembly multi-subunit γ -tubulin complexes nucleate microtubules at centrosomes, around mitotic chromatin, and, by interaction with augmin, from pre-existing microtubules. Whereas in yeast and flies a γ -tubulin small complex (γ TuSC) composed of only three subunits, γ -tubulin, GCP2, and GCP3, is sufficient for mitotic spindle assembly, the requirements in human cells are less clear. We will present evidence that centrosome targeting, nucleation and spindle assembly require the entire human γ TuRC and that human γ TuSC is not sufficient. In addition, we will provide insight into the non-centrosomal roles of γ TuRC within spindles. Our data indicates that γ TuRC is associated with minus ends of non-centrosomal spindle microtubules. Recruitment of γ TuRC to spindles occurs preferentially at pole-distal regions, requires nucleation and/or interaction with minus ends, and is followed by sorting of minus end-bound γ TuRC towards the poles. Poleward movement of γ TuRC exceeds k-fiber flux, involves the motors dynein, HSET (also known as KIFC1; Kinesin-14 family member), and Eg5 (also known as KIF11; Kinesin-5 family member), and slows down in pole-proximal regions,

resulting in the accumulation of minus ends. Thus, in addition to nucleating microtubules, γ TuRC actively contributes to spindle architecture by organizing microtubule minus ends.

Cell Cycle-Dependent Regulation of the TPX2-Eg5 Interaction.

B.J. Mann¹, C.L. Pelletier², S. Balchand¹, P. Wadsworth¹;

¹Department of Biology, Molecular and Cellular Biology Graduate Program, University of Massachusetts Amherst, Amherst, MA, ²Department of Biology, University of Massachusetts Amherst, Amherst, MA

Eg5 is a plus-end directed mitotic kinesin that generates outward force to establish spindle bipolarity. Using TIRF microscopy of cells expressing Eg5-EGFP, we previously observed that Eg5 punctae moved poleward during early mitosis and away from the pole in anaphase. In cells depleted of the microtubule-associated protein, TPX2, Eg5 motion was away from spindle poles; motion was blocked following inhibition of dynein. These data support a model in which TPX2 links Eg5 to dynein for poleward motion during early, but not late, mitosis. In vivo and proteomic studies show that human TPX2 is phosphorylated at a residue within the C-terminal region that interacts with Eg5 (S738), suggesting that phosphorylation could regulate the Eg5-TPX2 interaction. To test this, we performed knock-down/rescue experiments in which GFP-tagged, siRNA resistant TPX2 constructs and TPX2 siRNA were co-nucleofected into LLC-Pk1 cells and spindle morphology was quantified. The results show that the majority of cells expressing wild-type and phosphomimetic (S738D) TPX2 constructs had bipolar spindles; however, cells expressing the non-phosphorylatable TPX2 mutant, S738A, showed significantly more multipolar spindles. These results were also confirmed in live cells expressing mCherry- α -tubulin. Because the Eg5-TPX2 interaction is necessary for kinetochore microtubule stability we expressed wild-type or mutant TPX2 and performed a cold stability assay. Preliminary data show that cells expressing TPX2-S738D had more stable K-fibers.

To further explore the interaction of Eg5 and TPX2, we performed in vitro, single molecule, assays using Eg5-EGFP from cytoplasmic extracts of LLC-Pk1 cells. The results show that Eg5 velocity was reduced by TPX2 and to a lesser extent by truncated TPX2 lacking the domain that interacts with Eg5. To determine if the phosphorylation state of TPX2 contributes to inhibition, we measured the velocity of Eg5 in the presence of either S738D, or S738A TPX2. We found that S738D was a more effective inhibitor of Eg5 motility than either wild-type or S738A TPX2, suggesting that TPX2 phosphorylated at S738 is better able to interact with Eg5 than either wild-type or S738A TPX2. Together our results show that the regulation of the essential mitotic motor, Eg5, by TPX2 is modified by phosphorylation at site S738.

P1809**Board Number: B333****Structural maintenance of chromosome (SMC) proteins link microtubule stability to genome integrity.**G. Laflamme¹, T. Tremblay-Boudreault¹, M. Roy¹, P. Andersen¹, E. Bonneil¹, K. Atchia¹, P. Thibault¹, D. D'Amours¹, B. Kwok¹;¹Institute for Research in Immunology and Cancer, University of Montreal, Montreal, QC

Members of the structural maintenance of chromosome (SMC) protein family are parts of the multi-protein complexes that are key organizers of chromosome architecture and are essential for genome integrity. The cohesin (Smc1-3) and condensin (Smc2-4) complexes are known to play critical role in sister chromatid cohesion and chromosome condensation, respectively. The relatively less understood Smc5-6 complex has been implicated in DNA repair, DNA replication and telomere maintenance. In general, SMC proteins act by binding to chromatin and connecting distinct parts of chromosomes together. However, their potential roles in providing direct connections between chromatin and the mitotic spindle has not been explored. Here, we present biochemical and genetic evidence to demonstrate that yeast SMC proteins bind directly to microtubules and can provide a functional link between microtubules and DNA. We mapped the microtubule-binding region of Smc5 (a component of the Smc5-6 complex) using a chemical-based approach and generated a mutant with impaired microtubule binding activity. This mutant is viable in yeast, but exhibited a cold-specific conditional lethality associated with mitotic arrest, aberrant spindle structures and chromosome segregation defects. In an in vitro reconstitution assay, this Smc5 mutant also showed a compromised ability to protect microtubules from cold-induced depolymerization. Collectively, these findings demonstrate that SMC proteins can bind and stabilize microtubules, and that SMC-microtubule interactions are essential to establish a robust system to maintain genome integrity.

P1810**Board Number: B334****The role of the actin-binding protein MISP in mitotic spindle orientation.**M. Zhu¹, Y. Schlosser¹, I.M. Hoffmann¹;¹Cell Cycle Control and Carcinogenesis, F045, German Cancer Research Center, DKFZ, Heidelberg, Germany

For accurate placement of the cleavage plane, the mitotic spindle needs to be precisely oriented. Spindle positioning is mediated through a cortical machinery by capturing astral microtubules thereby generating pushing/pulling forces at the cell cortex. These cortical cues are spatially defined by retraction fibers modulating the positioning of actin regulators and therefore force generation. Moreover, astral MTs are engaged with these cortical structures through so-called +TIPs including adenomatous polyposis coli (APC), CLASPs and the dynein/dynactin complex, which have been shown to regulate spindle orientation and positioning. The cortically localized dynein/dynactin complex is believed

to provide pulling forces on astral MTs and is recruited by heterotrimeric G proteins/LGN/NuMA during spindle positioning in *C. elegans* embryos, *Drosophila* and human cells. However, the detailed mechanisms underlying the correct positioning and orientation of the mitotic spindle are still not fully understood and further investigation is needed to identify potential missing components involved in this process.

We have recently identified the actin-binding protein MISP as mitotic phosphoprotein and a substrate of Plk1 and Cdk1 that is required for correct positioning of the mitotic spindle. Depletion of MISP leads to a Plk1-dependent block in mitosis at the metaphase to anaphase transition with fragmented centrosomes, scattered chromosomes and misoriented, rocking spindles. Loss of MISP induces mitotic defects including spindle misorientation that is accompanied by shortened astral microtubules. Furthermore, we find that MISP forms a complex with and regulates the cortical distribution of the +TIP binding protein p150glued, a subunit of the dynein/dynactin complex. We further investigated the function of MISP in spindle orientation by identifying interacting proteins of MISP in mitosis to better understand how MISP establishes a link between astral microtubules and the cell cortex to ensure proper mitotic spindle positioning.

Elucidating the role of the RNA binding exon junction complex in mitosis.

E.E. Miller¹, A. Suzuki², L. Pilaz¹, E.D. Salmon², D.L. Silver¹;

¹Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC, ²Biology, University of North Carolina, Chapel Hill, NC

Mitosis ensures accurate chromosome segregation and requires many key regulators to organize the mitotic spindle and control cell division. There is increasing evidence implicating RNA binding proteins in the spatial and temporal coordination of RNAs throughout the cell cycle. What remains underexplored is how these proteins regulate mitosis. The exon junction complex (EJC) is an RNA binding complex known to regulate RNA localization, translation, and nonsense mediated decay. Intriguingly, our lab discovered that loss of one EJC component Magoh prolongs prometaphase in both cultured cells and the developing brain. In this study we follow up on this discovery by addressing the following questions: 1) Does Magoh regulate mitosis through EJC function, and 2) What is the cellular basis of these mitosis phenotypes? We discovered that knockdown of any of three core EJC components, Magoh, Rbm8a, and Eif4a3, results in loss of a bipolar spindle in HeLa cells. We are currently assessing whether formation of a complex is necessary for mitosis. Additionally, these proteins localize to the mitotic spindle. Further characterization of HeLa cells shows that after EJC knockdown the centrosomes fail to separate, but their maturation is intact. We tested spindle integrity by examining the microtubule subsets within a mitotic spindle. EJC knockdown spindles have phenotypically normal k-fibers with an intact connection to the centromere and an active spindle assembly checkpoint. Our future studies are aimed at determining how the EJC functions molecularly to regulate mitosis and if EJC localization impacts mitosis. In particular we are following up on the exciting hypothesis that EJC function may be influencing

the levels of candidate mitotic regulators. Understanding this will further elucidate the critical regulation of mitosis by RNA binding proteins.

Mitotic motor CENP-E cooperates with PRC1 in temporal control of central spindle assembly.

W. Wang¹, P. Yao², X. Liu², B. Qin², Y. Zhang³, X. Yao⁴;

¹Univ Sch Technol-China, Hefei, China, ²Physiology, Morehouse School of Medicine, Atlanta, GA,

³Medicine, Beijing University of Chinese Medicine, Beijing, China, ⁴Cellular Dynamics, University of Science Technology of China, Hefei, China

Mitotic motor CENP-E plays key roles in chromosome congression and spindle checkpoint satisfaction. We have recently identified and characterized syntelin, a novel allosteric inhibitor selective for CENP-E (Ding et al., 2010. Cell Res. 20, 1386-1390). Cells treated with syntelin progress through interphase, enter mitosis normally with a bipolar spindle and lagging chromosomes around the poles. Syntelin is an allosteric inhibitor which tightens CENP-E-microtubule interaction by slowing inorganic phosphate release. To delineate the role of CENP-E in reorganization of interpolar microtubules into an organized central spindle, metaphase synchronized cells were exposed to syntelin and other mitotic motor inhibitors. Syntelin does not perturb inter-polar microtubule assembly but abrogates the anti-parallel microtubule bundle formation. Real-time image shows that CENP-E inhibited cells undergo central spindle splitting and exhibits chromosome instability phenotypes. Using bio-syntelin affinity matrix, we have isolated CENP-E complex containing PRC1. Interestingly, inhibition of CENP-E did not alter the interaction between CENP-E and PRC1 but perturbed temporal assembly of PRC1 to the midzone. Surprisingly, inhibition of CENP-E perturbs the temporal control of PRC1 dephosphorylation which led to a persistent phosphorylation of PRC1 and an inhibition of central spindle assembly. These findings reveal a previously uncharacterized role of CENP-E motor in temporal control of central spindle assembly. Currently, we are reconstituting the central spindle sliding assay in vitro and test how CENP-E-PRC1 interactions orchestrate this process.

Differential sensitivity of non-transformed vs. chromosomally-unstable cells to partial inhibition of dynein.

N. Yang¹, V. Sikirzhyski¹, J.B. Steinman², T.M. Kapoor², A.L. Khodjakov¹;

¹Wadsworth Center, Albany, NY, ²Rockefeller University, New York, NY

We have recently demonstrated that poleward transport of chromosomes during anaphase in mammalian cells is enacted by two parallel yet distinctly different mechanisms. In the first mechanism,

poleward movement is coupled with the depolymerization of microtubules at the kinetochore. This mechanism, commonly referred to as 'Pacman' activity, is utilized by the majority of chromosomes in human cells. However, Pacman activity is suppressed on some chromosomes that are instead propelled by a dynein-mediated transport of the stable microtubule fiber attached to the kinetochore (Sikirzhytski et al., 2014, JCB, 206:231-243). The number of chromosomes segregating via dynein-mediated transport appears to vary in different cell types. This variability suggests that partial inhibition of dynein may selectively suppress growth of those cell types that rely more heavily on the dynein-mediated transport for chromosome segregation. To test this prediction we compare long-term effects of the cell-permeable dynein inhibitors Ciliobrevins on the growth of non-transformed vs. transformed chromosomally unstable (CIN) human cell lines. A general trend emerging from these comparisons is that chromosomally stable cells (e.g., RPE1) continue to progress through the cell cycle and divide normally when treated with concentrations of Ciliobrevin that block proliferation of chromosomally unstable transformed cells (e.g., U2-OS, HeLa). Partial inhibition of dynein in CIN cells results in prolongation of mitosis and a marked increase in the number of chromosome segregation errors as manifested by lagging chromosomes and formation of micronuclei. While the duration of mitosis increases in both non-transformed and CIN cell lines treated with Ciliobrevin, non-transformed cells progress through multiple cell cycles with normal timing. In contrast, progeny of CIN cells that undergo mitosis in the presence of Ciliobrevin tend to arrest in interphase and many subsequently die. Even those cells that ultimately re-enter mitosis are delayed in interphase. This pattern is consistent with the notion that partial inhibition of dynein increases the probability of chromosome missegregation and this increase becomes lethal in those cells that are already CIN. Differential sensitivity of non-transformed vs. CIN cell lines to dynein inhibition may open an opportunity to selective killing of cancer cells with low concentrations of anti-dynein inhibitors.

Extended prometaphase arrest induces centrosome fragmentation in cultured human cells.

M. Karki¹, N. Keyhaninejad¹, C.B. Shuster²;

¹New Mexico State University, Las Cruces, NM, ²Biology Department, New Mexico State University, Las Cruces, NM

The spindle assembly checkpoint (SAC) serves to protect chromosomal ploidy by blocking mitotic progression until all sister chromatid pairs achieve bi-orientation, and SAC activation has been used for decades to synchronize cells in mitosis. However, SAC inhibition of the Anaphase Promoting Complex (APC) is leaky, and the low-level cyclin B degradation eventually results in mitotic slippage. Recent studies suggest that even a moderate delay in mitotic progression can have significant effects on the fates of the daughter cells, including partial caspase activation and irreversible, p53-dependent cell cycle arrest. Indeed, when G2-synchronized cultures of Retinal Pigmented Epithelial (RPE1) cells were arrested in prometaphase for defined periods of time, there was a linear increase in ectopic microtubule

organizing centers (MTOC) once cells were released from mitotic arrest. Ectopic MTOC formation occurred regardless of the method used to achieve mitotic arrest, with peak MTOC formation observed at 8 hours of mitotic arrest. Immunolocalization of pericentrin revealed that in contrast to cells released from G2 arrest alone, cells that experienced prolonged mitotic delay exhibited fragmented centrosomes, with foci either clustered at the pole or as a distinct organizing center. However, centrosome fragmentation could be partially suppressed if RPE1 cells were depleted of separase or treated during mitotic arrest with the APC inhibitor, TAME. Together, these results suggest that the leaky activity of APC during mitotic arrest may compromise centrosome integrity, either by separase-mediated centriole disengagement or by APC-mediated degradation of substrates required for spindle pole integrity.

Budding yeast YBR296C-A encodes a protein that can inhibit APC-Cdc20 in vitro and contains amino acid motifs conserved with human p31comet.

W. Tsai¹, Y. Wu¹, A. Huang¹, L. Wang¹, S.C. Schuyler¹;

¹Biomedical Sciences, Chang Gung University, Taoyuan, Taiwan

The spindle checkpoint ensures accurate chromosome segregation until spindle microtubules attach to all kinetochores correctly during mitosis. p31comet is an antagonist of the spindle checkpoint effector Mad2, which can abolish the Mad2-dependent spindle checkpoint. A BLAST search of the budding yeast proteome using human p31comet yielded a putative protein encoded by an uncharacterized potential open reading frame *YBR296-A*. We have observed evidence for an mRNA and protein product produced by the putative ORF *YBR296-A*. Analysis of the protein product of *YBR296-A* demonstrates it can inhibit APC^{Cdc20} activity *in vitro*. Mutations in 5 conserved C-terminal amino acids, the 'TISLS' amino acid motif that is shared with human p31comet, weakened the proteins APC^{Cdc20} inhibitory activity. *In vivo* deletion of *YBR296-A* yielded a slight sensitivity to the microtubule poison benomyl. We have named the ORF Tiny Yeast Comet1 (*TYC1*), and are working to further characterize its function.

Board Number: B340

A peptide inhibitor of APC-Cdc20 based on the Cdc20 Mad2-binding motif can directly bind to the APC.

Y. Liao¹, Y. Wu¹, J. Jhuo¹, S.C. Schuyler¹;

¹Biomedical Sciences, Chang Gung University, Taoyuan, Taiwan

In mitosis, the spindle checkpoint ensures genome stability by delaying the onset of anaphase until all kinetochores are properly attached to the mitotic spindle. Previous studies have shown that some tumor cells treated with anti-mitotic drugs resulted in cell slippage, while after Cdc20 was knocked down by siRNA, it led to robust mitotic arrest followed by cell death. Thus, APCCdc20 inhibitors may

have potential as anti-cancer agents. We had previously observed that a Mad2-binding motif called DQ36 could inhibit APC^{Cdc20} activity *in vitro*. Here, we report that the DQ36 peptide containing Mad2-binding motif sequence can bind directly to the APC *in vitro*. Apc9 contains two small amino acid motifs similar to sequences in Mad2. We created an *apc9Δ* strain to test whether the Apc9 subunit was required for DQ36 to interact with the APC. Our data show that DQ36 peptide bound to APC^{Apc9Δ} as same as wild type APC, indicating that the Apc9 subunit is not required for the APC-DQ36 interaction. We are currently exploring which APC subunit interacts with the DQ36 inhibitor by employing peptide cross-linking experiments.

Board Number: B341

Expression in vivo of peptide inhibitors of APC-Cdc20 reduces growth rate.

H. Chen¹, Y. Wu¹, S.C. Schuyler¹;

¹Biomedical Sciences, Chang Gung University, Taoyuan, Taiwan

The mitotic spindle checkpoint monitors proper chromosome segregation. Damage to the checkpoint can lead to aneuploidy, potentially contributing to tumorigenesis. Current anti-cancer strategies, such as microtubule poisons, focus on activation of the spindle checkpoint. Unfortunately, cancer cells may undergo mitotic slippage in the presence of an activated checkpoint, resulting in re-entry into the cell cycle. Evidence has emerged to inhibition of the E3 ubiquitin ligase Anaphase-Promoting Complex (APC) or its co-activator Cdc20 can prevent mitotic slippage. In this study, we created a 65 amino acid peptide, named PQ65, based on Cdc20 of *S. cerevisiae* including the 'KILR' motif. PQ65 disrupted APC^{Cdc20} activity *in vitro*. A similar inhibitory effect was observed when PQ65 was narrowed down to its C-terminal 36 amino acids, called DQ36. To validate the inhibitory activities of PQ65 and DQ36 *in vivo*, we constructed a peptide over-expressing system employing the *pGAL1-10* promoter where the protein products included a nuclear localization sequence encoded upstream of the peptide. Constructs were integrated into the yeast genome by homologous recombination. Yeast induced to express either PQ65 or DQ36 in the presence of galactose displayed reductions in growth rates relative to the control strain. In conclusion, two peptides, PQ65 and DQ36, can inhibit APC^{Cdc20} activity *in vitro* and regulate cell cycle timing by reducing the growth rate when expressed *in vivo*, supporting the potential development of these peptides as targeted APC^{Cdc20} inhibitors.

Board Number: B342

Quantitative Assessment of Chromosome Instability Promoted by Chemotherapeutic Agents.

S. Markossian¹, A. Arnaoutov¹, V. Larionov², M. Dasso¹;

¹National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, ²National Cancer Institute, National Institutes of Health, Bethesda, MD

Most solid tumors are aneuploid, carrying an abnormal number of chromosomes, and they missegregate whole chromosomes in a phenomenon termed chromosome instability (CIN). CIN is associated with poor prognosis in many cancer types, and targeting of CIN is an attractive strategy for anti-cancer therapeutics. The mechanisms causing CIN and its contributions to tumor initiation and growth are not well defined, partly because there is no straightforward, quantitative assays for CIN in human cells. To address this problem, we have developed the first Human Artificial Chromosome (HAC)-based quantitative live-cell assay for mitotic chromosome segregation in mammalian cells, with which we can easily score the rates of CIN within one cell division under different experimental conditions.

We have constructed a HAC encoding copies of enhanced green fluorescent protein (eGFP) fused to the destruction box (DB) of anaphase promoting complex/cyclosome (APC/C) substrate hSecurin. This HAC also contains tet operator (tetO) arrays and sequences encoding the tetracycline repressor fused to monomeric cherry fluorescent protein (tetR-mCherry). We have produced human U2OS cells carrying this HAC, in which we monitor HAC segregation in two ways: First, APC/C degrades the DB-eGFP fusion expressed from the HAC at anaphase onset, and DB-eGFP re-accumulates in the daughter cells after G₁ phase, when APC/C becomes inactive. Daughter cells that do not obtain a copy of the HAC will thus be GFP negative in the subsequent interphase. Using this system, we can not only detect HAC mis-segregation within a single cell division but also extrapolate the rate of mis-segregation after a defined number of cell divisions from the proportion of GFP positive cells. Second, because tetR-mCherry binds to the tetO arrays, the HAC itself could be followed by live imaging. HAC-bearing U2OS cell lines show low inherent levels of CIN, but HAC mis-segregation is markedly increased by treatment with chemotherapeutic drugs such as Reversine, an inhibitor of Mps1, and microtubule agents Nocodazole and Taxol.

In summary, we have developed new assays to score CIN levels in human cells and have shown that CIN levels increase upon treatment with chemotherapeutic agents, which makes our assays ideal for chemical screens.

Sliding filament mechanism for anaphase B – evaluation of “slide-and-cluster” vs “slide-and-flux-or-elongate” models.

I. Brust-Mascher¹, E. Civelekoglu-Scholey¹, J.M. Scholey¹;

¹Molecular and Cellular Biology, University of California - Davis, Davis, CA

Chromosome segregation during mitosis involves chromosome-to-pole motility (anaphase A) and spindle elongation (anaphase B). We propose that, in *Drosophila* embryos, anaphase B depends on a “slide-and-flux-or-elongate” mechanism in which persistent, outward, kinesin-5-driven interpolar (ip) microtubule (MT) sliding “engages” to push apart the spindle poles when poleward flux is turned off. Thus, in pre-anaphase B (i.e. metaphase and anaphase A) spindles, the outward sliding of ipMTs is balanced by the depolymerization of their minus ends at the poles producing poleward flux, while the

spindle maintains a constant, steady state length. Following cyclin B degradation, however, ipMT depolymerization ceases so the sliding ipMTs can push the poles apart as poleward flux is turned off (Brust-Mascher et al, 2004; Wang et al, 2013). The competing “slide-and-cluster” model (Burbank et al., 2007) proposes that MTs nucleated at the equator are slid outward by the actions of the bipolar kinesin-5 plus a minus end directed motor which then pulls MTs inward as they approach the poles and clusters MTs at the poles. Here, we quantitatively compare these two models using data from *Drosophila* syncytial embryos. In both models, kinesin-5 crosslinks both parallel and anti-parallel (AP) MTs with a 3-fold preference for AP pairs which it can also slide apart (Van Wildenberg et al., 2008). In the slide-and-cluster model, minus end-directed motors bind to each MT minus end and walk on an adjacent, parallel MT if possible, while in the slide-and-flux-or-elongate model, all MT minus ends reaching the pole are depolymerized by kinesin-13. In both models MT plus ends exhibit dynamic instability described by growth and shrinkage velocities, as well as rescue and catastrophe frequencies. We find that in both models, dynamic instability parameters need to be fine-tuned to maintain a steady length spindle with fast turnover dynamics. Both models reproduce the pre-anaphase B spindle steady state length and dynamics (as evaluated using *in-silico* FRAP) as well as the rate of anaphase B spindle elongation. However, only the slide-and-flux-or-elongate model reproduces the change in MT dynamics observed experimentally at anaphase B onset (Cheerambathur et al., 2007) and consequently only this model fits all the data for *Drosophila* syncytial embryo mitotic spindles. Thus our work highlights the importance of acquiring and quantitatively evaluating experimental data on different dynamic aspects of spindle behavior in order to evaluate competing models for mitosis.

Midzone organization by the microtubule crosslinker, Feo, is required for kinesin-5-driven anaphase B in *Drosophila* embryos.

H. Wang¹, I. Brust-Mascher¹, J.M. Scholey¹;

¹Molecular and Cellular Biology, University of California - Davis, Davis, CA

During mitosis, chromosomes are separated by chromosome-to-pole motility (anaphase A) and spindle elongation (anaphase B). In *Drosophila* embryos, we propose that anaphase B depends on a “slide-and-flux-or-elongate” mechanism in which kinesin-5 motors at the spindle midzone drive outward sliding of anti-parallel interpolar (ip) microtubules (MTs) to push apart the poles when poleward MT flux is turned off. Here we investigated the contribution of the midzone-associated non-motor MAP, Feo, which shares with kinesin-5 a significant preference for crosslinking MTs into anti-parallel versus parallel polarity patterns. While Feo homologues (Ase1p/PRC1) have been shown to enhance the midzone localization of the MT-MT crosslinking motors, kinesin-4, -5 and -6 in other systems, we find that Feo antagonizes the association of kinesin-5 with the anaphase B spindle midzone. The midzone association of kinesin-5 is enhanced following antibody-induced dissociation of Feo but kinesin-5 cannot substitute for Feo function because the resulting midzone is abnormally narrow and anaphase B is impaired. Thus,

Feo organizes antiparallel ipMTs of the midzone into a configuration that facilitates the kinesin-5-driven sliding filament mechanism underlying anaphase B spindle elongation

Myosin-10 and Wee1 assist mitotic spindle positioning in *Xenopus laevis* embryonic epithelia.

M.E. Larson^{1,2}, J.C. Sandquist³, W. Bement^{1,4,5};

¹Graduate Program in Cellular and Molecular Biology, University of Wisconsin-Madison, Madison, WI,

²Medical Scientist Training Program, University of Wisconsin-Madison, Madison, WI, ³Grinnell College, Grinnell, IA, ⁴Department of Zoology, University of Wisconsin-Madison, Madison, WI, ⁵Laboratory of Cell and Molecular Biology, University of Wisconsin-Madison, Madison, WI

Maintenance of epithelial organization is dependent on the final position and orientation of the mitotic spindle. In order to investigate the mechanism controlling spindle orientation, we have performed an analysis of mitotic spindle dynamics in the embryonic epithelium of *Xenopus laevis*. First, we assessed the rotation of mitotic spindles, revealing a phase of directed rotation followed by a phase of stable rotational oscillations. Second, we identified the actin and microtubule binding motor protein Myosin-10 as an important part of the system controlling these oscillations. Knockdown of Myosin-10 results in structural instability of the spindle as well as greatly reduced rotational movement. Disruption of Myosin-10 function through expression of its MyTH4-FERM cassette results in spindle instability, exaggerated spindle movement, and spindle mis-positioning. Finally, we identified an interaction between Myosin-10-MyTH4-FERM and the Cdk1 inhibitory kinase Wee1. Inhibition of Wee1 decreased duration of mitosis and produced erratic spindle movement. Furthermore, depletion of Wee1 is sufficient to rescue many of the phenotypes of Myosin-10 depletion. Thus, Myosin-10 and Wee1 are essential for the normal function of the mitotic spindle positioning mechanism.

WRAD complex participates in a SET domain-independent function of Mixed-lineage leukemia (MLL) protein to ensure proper chromosome segregation during mitosis.

S. . Tyagi¹;

¹Laboratory of Cell Cycle Regulation, Centre for DNA Fingerprinting and Diagnostics (CDFD), Hyderabad, India

Histone 3 lysine 4 tri methylation is a mark of active gene transcription and this mark is deposited by a family of Su(var)3-9, Enhancer of Zeste, Trithorax (SET) domain containing proteins in mammals. Mixed-lineage leukemia (MLL) protein, a member of this family, is best characterized for its essential role in

Hox gene regulation during development and its chromosomal translocations associated with aggressive leukemias. Like their yeast counterpart Set1, MLL (and other SET family members), occur in COMPASS-like multi-subunit complex, which consists of four common structural components called WDR5, RbBP5, Ash2l and Dpy30 (WRAD). WRAD is essential for stability and histone methyl transferase (HMT) activity of MLL.

However, the functions of MLL in cellular processes like cell-cycle regulation are not well studied. Here we show that the MLL has a regulatory role during multiple phases of the cell cycle. RNAi mediated knockdown reveals that MLL regulates S phase progression and, proper chromosome segregation and cytokinesis during M phase. Based on reconstitution of knock-down cells with mutant MLL, we narrow the cell-cycle regulatory role to the C subunit of MLL. Our analysis reveals that the transcriptional activation domain and not the SET domain is important for the S phase function of MLL.

Surprisingly, disruption of MLL-WRAD interaction is sufficient to disrupt proper mitotic progression. These mitotic functions of WRAD are independent of SET-domain of MLL and, therefore, define a new role of WRAD in subset of MLL functions. Further characterization of loss-of-function of MLL complex exhibits delay in mitotic progression and prolonged prophase. Immunofluorescence staining and time-lapse microscopy reveals that MLL knockdown results in defects in chromosome congression, and DNA alignment, resulting in chromosome loss. Finally, we address the overlapping and unique roles of the different SET family members in the cell cycle.

Regulation of spindle length by microtubule-destabilizing enzymes.

K. Tarnawska¹, A. Politi¹, F. Nédélec¹;

¹EMBL, Heidelberg, Germany

The transmission of a complete genome to each daughter cell requires the correct partitioning of chromosomes in every cell division. In eukaryotes this process is achieved by the spindle. Although the metaphase spindle appears static, it is actually a highly dynamic structure composed of short-lived microtubules (MTs). Once assembled, it can last for hours and its structure continuously rebuilds itself to maintain its size and shape. The steady state results from the competition of motor proteins, dynamic instability and poleward flux of MTs. MTs focusing into spindle poles has been initially thought to be a result of their nucleation from centrosomes, however in plant mitosis and meiosis of most of animal species, MTs grow from multiple sites around chromatin and self-organize into a bipolar spindle even in the absence of centrosomes. MTs undergo poleward flux, which is a result of coordinated MT sliding and pole-localized disassembly factors. The characteristic bipolar shape is generated by the action of two molecular motors: (i) plus-end directed kinesin-5 (Eg5) cross-links and slides MTs poleward, generating an outward force, and (ii) the minus-end directed dynein focuses MTs creating spindle poles. Dynein is required for the spindle pole formation, both in the presence and in the absence of centrosomes and its function depends strongly on its interaction with dynactin, which increase dynein's processivity in vivo

and in vitro. By inhibiting the interaction between dynein and dynactin we can trigger the dissociation of the complexes leading to disruption of spindle poles. Cell-free extracts prepared from unfertilized *Xenopus laevis* eggs have been used to study spindle assembly in vitro because spindles are not constrained in any fixed volumes, which allow investigating the assembly mechanism more in details. Here we study the difference between the mechanisms of two commonly used dynein inhibitors: dynamitin and CC1. Whereas the size of dynamitin-treated spindles is not altered, CC1-treated spindles elongate dramatically because of the displacement of MT destabilizing enzymes from spindle poles without affecting MT growth rate and poleward flux. These recent findings will be implemented into a computational model of MT nucleation and spindle assembly, which will help us to better understand the importance of pole integrity in spindle formation and maintenance.

Multiple requirements of PLK1 during mouse oocyte maturation.

P. Solc¹, T. Kitajima², S. Yoshida², A. Brzakova¹, M. Kaido², V. Baran³, A. Mayer¹, P. Samalova¹, J. Motlik¹, J. Ellenberg⁴;

¹Laboratory of DNA integrity, Inst. of Animal Physiology and Genetics AS CR, Libečov, Czech Republic,

²Laboratory for Chromosome Segregation, RIKEN Center for Developmental Biology, Kobe, Japan,

³Institute of Animal Physiology, Kosice, Slovakia, ⁴Cell Biology and Biophysics Unit, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

Polo-like kinase 1 (PLK1) orchestrates multiple events of cell division. Although PLK1 function has been intensively studied in centriole-containing and rapidly cycling somatic cells, little is known about its function in the meiotic divisions of mammalian oocytes, which arrest for a long period of time in prophase before meiotic resumption and lack centrioles for spindle assembly. Here, using specific small molecule inhibition combined with live mouse oocyte imaging, we comprehensively characterize meiotic PLK1's functions. We show that PLK1 becomes activated at meiotic resumption on microtubule organizing centers (MTOCs) and later at kinetochores. PLK1 is required for efficient meiotic resumption by promoting nuclear envelope breakdown and chromosome condensation, partly independently of CDK1. PLK1 is also needed to recruit centrosomal proteins to acentriolar MTOCs to promote bipolar spindle formation, as well as for stable kinetochore-microtubule attachment. Consequently, PLK1 inhibition leads to metaphase I arrest with misaligned chromosomes activating the spindle assembly checkpoint (SAC). Unlike in mitosis, the metaphase I arrest is not bypassed by the inactivation of the SAC. We show that PLK1 is required for the full activation of the anaphase promoting complex/cyclosome (APC/C) by promoting the degradation of the APC/C inhibitor EMI1 and is therefore essential for entry into anaphase I. Moreover, our data suggest that PLK1 is required for proper chromosome segregation and the maintenance of chromosome condensation during the meiosis I-II

transition, independently of the APC/C. Thus, our results define the meiotic roles of PLK1 in oocytes and reveal interesting differential requirements of PLK1 between mitosis and oocyte meiosis in mammals.

A cell free assay to study chromatin decondensation at the end of mitosis.

A. Magalska¹, A. Schellhaus², W. Antonin²;

¹Nencki Institute of Experimental Biology of Polish Academy of Sciences, Warsaw, Poland, ²Friedrich Miescher Laboratory of the Max Planck Society, Tuebingen, Germany

Chromatin undergoes fascinating structural and functional changes during the metazoan cell cycle. It massively condenses at the beginning of mitosis with a degree of compaction up to fiftyfold higher than in interphase. At the end of mitosis, mitotic chromosomes decondense to re-establish their interphase chromatin structure. This process is indispensable for reinitiating transcription and the perpetuation of genomic information, and is thus of central importance in the cellular life cycle. Despite its significance to basic research as well as its potential medical implications, postmitotic chromatin decondensation is only poorly understood. It has been well described cytologically, but we lack an understanding of the underlying molecular events. We are ignorant about the proteins that mediate chromatin decondensation, the distinct steps in this multi-step procedure and their regulation.

We have developed an *in vitro* assay, which recapitulates the process in the simplicity of a cell free reaction. Highly compacted chromatin isolated from metaphase arrested HeLa cells is incubated with *Xenopus laevis* egg extract. This induces faithful chromatin decondensation in a time dependent manner. At the end of a process the chromatin is surrounded by a nuclear envelope with functional nuclear pore complexes. We show that this process depends on ATP and GTP hydrolysis. Furthermore, using a fractionation approach we identified the ATPases pontin and reptin (RuvBL1 and RuvBL2, respectively) as chromatin decondensation factors. These proteins and their ATPase activity are essential for decondensation *in vitro*. The fact that chromatin decondensation also depends on GTP hydrolysis suggests that also a GTPase is involved in this process. The elucidation of this GTPase is still ongoing.

P1826**Board Number: B350****The DNA damage response during mitosis induces whole chromosome mis-segregation and reduces cellular viability.**S.F. Bakhoun¹, L.C. Kabeche², J. Murnane³, B.I. Zaki⁴, D.A. Compton^{5,6};

¹Radiation Oncology, Memorial Sloan Kettering Cancer Center, New York, NY, ²Genetics, Geisel School of Medicine at Dartmouth College, Lebanon, NH, ³Radiation Oncology, University of California, San Francisco, San Francisco, CA, ⁴Radiation Oncology, Geisel School of Medicine at Dartmouth College, Lebanon, NH, ⁵Department of Biochemistry, Geisel School of Medicine at Dartmouth College, Hanover, NH, ⁶Norris Cotton Cancer Center, Lebanon, NH

The DNA damage response (DDR) prevents cells from entering mitosis in the presence of DNA breaks. However, cancer cells often encounter DNA damage during mitosis secondary to checkpoint slippage with persistence of pre-mitotic damage or due to de novo induction of DNA breaks by therapeutic agents such as ionizing radiation. Mitotic cells do not possess the capacity to repair DNA breaks. Yet, DNA damage during mitosis results in a partial DDR, whose consequences, at a time when the cell is chiefly preoccupied by the process of chromosome segregation, remains elusive.

Here we show that activation of the DDR during mitosis selectively stabilizes kinetochore-microtubule (k-MT) attachments to chromosomes through Aurora-A and Plk1 kinases, thereby increasing the frequency of lagging chromosomes during anaphase. These lagging chromosomes subsequently generate a preponderance of micronuclei that predispose chromosomes to subsequent catastrophic pulverization. Genetic depletion or pharmacologic inhibition of DDR proteins, ATM or Chk2, abolishes the effect of DNA damage on both k-MTs and chromosome segregation. Activation of the DDR in the absence of DNA damage is sufficient to induce chromosome segregation errors. Interestingly, inhibition of the DDR during mitosis, in chromosomally unstable cancer cells with pervasive DNA damage, suppresses inherent chromosome segregation defects.

We then examine the consequences of generating lagging chromosomes in response to mitotic DNA damage on cellular viability. We find that suppressing chromosome mis-segregation by reducing k-MT stability leads to reductions in downstream chromosomal defects and a significant increase in the viability of irradiated mitotic cells. Further, orthotopically transplanted human glioblastoma tumors in which chromosome mis-segregation rates have been reduced are rendered markedly more resistant to ionizing radiation, exhibiting diminished markers of cell death in response to treatment.

In summary, activation of the DDR during mitosis inappropriately stabilizes k-MTs creating a link between structural and numerical chromosomal instabilities. Our work identifies an unexpected adaptive pathway in response to DNA damage during mitosis that propagates genomic instability and genetic heterogeneity at the expense of cellular viability.

P1827**Board Number: B351****Paired movement of the kinetochores and dynamic microtubules can explain the observed capture times of the kinetochores during meiosis I.**G. Cojoc¹, A. Florescu², A. Krull³, N. Pavin⁴, F. Jülicher², I.M. Tolic^{5,6};

¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ²Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, ³Fakultät Informatik, Technische Universität Dresden, Dresden, Germany, ⁴Department of Physics, Faculty of Science, University of Zagreb, Zagreb, Croatia, ⁵Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ⁶Dept. Molecular Biology, Ruder Boškovic Institute, Zagreb, Croatia

Accurate cell division depends on proper segregation of chromosomes. This requires all chromosomes to be attached to the spindle microtubules (MTs) via the kinetochores (KCs). The mechanisms that facilitate the interaction between MTs and KCs have been debated for a long time. However, all previous models are based on in vitro or perturbed in vivo systems and a precise contribution of individual mechanisms is still unknown. In this study we analyze the kinetics of KC capture in an unperturbed system in vivo, in combination with a theoretical model. A model organism where the capturing mechanisms can be followed live with high spatial and temporal resolution is *Schizosaccharomyces pombe* during the meiosis I. At the onset of meiosis I, the SPBs are near each other and nucleate MTs that form the spindle. At the same time other MTs grow in other directions, having a fast turnover. We observed that some of them grow directly toward the KCs and others perform angular movement with respect to the spindle. When MTs reach a KC, the KC is captured and is subsequently retrieved to the SPB. We observed that the KCs are clustered in three pairs at the beginning of meiosis I. KCs in the same pair move in a correlated manner, but there is no correlation in the movement between KCs from different pairs. The movement of KC pairs is diffusive before a capturing event occurs, but directed afterwards. Their retrieval velocity toward the SPBs is similar to the shrinking velocity of the MTs. In order to understand the contribution of the mechanisms that lead to the observed kinetochore capture times, we developed a theoretical model. The model includes MT pivoting around the SPB (Kalinina et al., Nat Cell Biol 2013), MT dynamics and paired movement of the KCs. Our simulations show that paired movement of the KCs, in addition to dynamic MTs, can explain the observed capture times of KCs during meiosis I.

P1828**Board Number: B352****DNA segregation before mitosis: Re-entering mitosis after multiple S-phases.**B. Stormo¹, D. Fox²;¹Cell Biology, Duke University, Durham, NC, ²Pharmacology and Cancer Biology, Duke University School of Medicine, Durham, NC

The canonical cell cycle alternates rounds of DNA replication, which generate pairs of homologs held together by cohesin, with rounds of division that separate these pairs into two cells. This cycle is essential for ensuring accurate segregation of chromosomes and preventing the generation of aneuploidy. In contrast, in specific metazoan tissues including in humans, some cells undergo an alternate cell cycle termed the endocycle in which there are multiple rounds of S-phase without karyokinesis. Endocycles can also occur pathologically, including after treatment with many current cancer therapeutics, yielding aberrant mitotic divisions. These mitotic cells are known to have diplochromosomes, in which four homologous chromatids are conjoined. How diplochromosomes can be resolved without causing aneuploidy is unknown. To study this question we have used a naturally occurring population of mitotic endocycled cells. The rectal papillar cells of *Drosophila melanogaster* undergo repeated rounds of S-phase to generate DNA content of 8N then these cells undergo two full rounds of mitosis. Using a combination of time-lapse fluorescence microscopy and classical cytology we report a mechanism we term “pre-mitotic DNA segregation (PMDS).” Rather than forming persistent diplochromosomes, papillar cells instead form transient conjoined chromosomes that are accurately and elegantly separated into sister chromatid pairs prior to metaphase. We argue that PMDS prior to mitotic division is an extra step that any cell must undergo in the first division following multiple S-phases, but not in subsequent divisions. In addition to PMDS, our research also likely suggests that papillar cells periodically release chromatid cohesion in a non-canonical manner during the endocycle to prevent the formation of diplochromosomes. How these processes are controlled during the endocycle and during PMDS in papillar cells has implications for the aneuploidy described in the numerous documented cases of multiple S-phases without karyokinesis in the cancer literature.

P1829**Board Number: B353****Coordinated chromosome movement in the absence of physical connection in spider spermatocytes.**A.O. Nedo¹, C.M. Andreychik¹, R.N. Doan¹, L. Jamrog¹, L.V. Paliulis¹;¹Biology Department, Bucknell University, Lewisburg, PA

In cell division, physical connection guarantees that movement of partner chromosomes is coordinated; i.e. connected sister chromatids move together toward their associated spindle pole in anaphase I of meiosis. Interestingly, there are some cell types in which unconnected chromosomes always move together, allowing study of how chromosomes communicate their position in the cell in the absence of

physical connection. We use spiders with the $X_1X_1X_2X_2$ (female)/ X_1X_20 (male) sex determination system to study coordinated chromosome movements. In males the nonhomologous X_1 and X_2 chromosomes always associate with the same spindle pole from prometaphase I through anaphase I. After seeing a visible gap between X_1 and X_2 , we hypothesized that the gap was reflective of a lack of connection between X_1 and X_2 . We found that X_1 and X_2 are easily separable using a micromanipulation needle in metaphase I, showing that they move together in the absence of physical connection. When we used a micromanipulation needle to separate X_1 and X_2 such that they associated with opposite poles, we found that cells could progress into anaphase. This showed that cosegregation of X_1 and X_2 is not monitored by the cell following initial chromosome attachment in prometaphase I, which would seemingly lead to error-prone segregation of sex chromosomes in male meiosis. We found that consistently correct segregation of X_1 and X_2 occurs because X_1 and X_2 appear to associate with a spindle pole while in the nuclear envelope and, under our observation, never reorient during meiosis I, suggesting that continuous monitoring of the position of X_1 and X_2 is not necessary in normal meiosis I. Spindle breakdown and reassembly during prometaphase I could, however, lead to sex chromosome aneuploidy.

Mitotic chromosome alignment is dispensable for accurate segregation of the genome.

C. Fonseca¹, L. Reinholdt², J.K. Stumpff¹;

¹Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, ²Genetic Research Science, Jackson Laboratory, Bar Harbor, ME

Chromosome alignment at the equator of the mitotic spindle is a highly conserved step during cell division. This process requires spatial control of kinetochore microtubule (k-fibers) dynamics and is widely believed to promote the equal distribution of replicated sister chromatids during anaphase. However, this latter assumption has never been experimentally tested due to the difficulty of disrupting chromosome alignment without also compromising the attachments between kinetochores and spindle microtubules. We find that depletion of the kinesin-like motor Kif18A from diploid human cells significantly disrupts chromosome alignment while only modestly affecting mitotic progression. Surprisingly, loss of Kif18A does not lead to an increase in aneuploidy, suggesting that chromosome alignment is largely dispensable for accurate chromosome segregation. Instead, we find that disrupting chromosome alignment leads to defects in the organization of the nucleus during the subsequent interphase. These data suggest that mitotic chromosome alignment may function to preserve the three-dimensional organization of interphase chromosomes from cell cycle to cell cycle.

P1831**Board Number: B355****A computer program to identify meiotic recombination hotspots with unprecedented precision.**O. Miura¹, Y. Kojima¹, T. Ohyama¹;¹Biology, Waseda University, Tokyo, Japan

The meiotic recombination events occur in specific chromosomal regions. These regions are called recombination hotspots. In the yeasts *S. cerevisiae* and *S. pombe*, no motif sequence has been identified in the recombination hotspots, while in mice and humans, some motifs have been reported. However, regions besides the hotspots also contain them with no small frequency, which indicates that they are not sufficient as the marks for the formation of recombination hotspots. We have investigated the relationship between the recombination hotspots and the physical properties of DNA.

Meiotic recombination events are initiated by formation of DNA double-strand breaks (DSBs). Thus, using the genome databases of *S. cerevisiae*, *S. pombe* and *Mus musculus*, we investigated characteristics of the physical properties (e.g., flexibility, duplex disruption energy, protein-induced deformability) of DSB hotspots. When averaged, a common distinctive property was clearly detected at DSB hotspots for each organism, which allowed us to develop a computer program that can identify DSB hotspots of a given genomic DNA. When applied to *S. cerevisiae*, this program showed a high performance with the accuracy rate of identification of ~77%, suggesting that our program is a promising tool to understand the mechanism underlying the generation of the recombination hotspots.

P1832**Board Number: B356****Karyotypes of *Anopheles gambiae* s.l. in forest and arid zones of Nigeria and Cameroon.**A.M. NOUTCHA¹, C.I. Anumudu²;¹Dept of Animal Environmental Biology, University of Port Harcourt, Port Harcourt, Nigeria,²Department of Zoology, University of Ibadan, Ibadan, Nigeria

Fast and reliable recognition of malaria vectors in an area is a basic prerequisite for the utilization of appropriate malaria control strategies. Three of the 7 sibling species of the African malaria mosquito *Anopheles gambiae* s.l. are found in Nigeria and Cameroon: (*Anopheles arabiensis*, *Anophelesgambiae* s.s. and *Anopheles melas*). Of these species *Anopheles arabiensis* and *Anopheles gambiae* s.s. present polymorphic paracentric inversions in their chromosomes, which generate diverse chromosomal karyotypes. These chromosomal arrangements are thought to impart selective advantages for each form to survive in arid and forest environments. In West Africa, studies on cryptic karyotypes of *An. gambiae* s.l. have been concentrated in Mali and coastal Cameroon. This study was undertaken in two villages (Bama and Mora) of an arid zone, and two villages (Fokoué and Igbo-Ora) of a forest zone. Bama and

Igbo-Ora are in Nigeria while Mora and Fokoué are in Cameroon. Mosquito collections were made for 7 consecutive days in each month from bedrooms/houses over an 18-month period. Indoor collections were from May to October of the following year, covering two rainy and one dry seasons. Chromosomal preparations were based on a modified Coluzzi method. Species identification and chromosome scoring were undertaken with a phase-contrast microscope. Slides were analyzed under a fluorescent microscope to observe inversions. These inversions were summarized to obtain karyotypes and chromosomal forms. Among the karyotyped anophelines (n=20), 35% were *An. gambiae s.s.* and 65% were *An. arabiensis*. The karyotypes were: 15% standard +/+, 5% ab/b, 25% bc/b, 10% bc/bc, 35% b/b, 5% b/+, 5% bd/bf and varied among *An. gambiae s.l.* The standard +/+ (43%), the b/+ (14%) and bc/bc (29%) karyotypes, characterized *An. gambiae s.s.*, while b/b (53%) ab/a (8%) and bd/bf (8%) karyotypes characterized *An. arabiensis*. Variation of karyotypes across ecozones showed that 22% were caught in arid zone and 78% in the forest zone. The temporal distribution revealed that 48% were caught in the first rainy season and 52% in the dry Harmattan and second rainy seasons. The implications of the speciation process in *An. gambiae s.l.* in the epidemiology of malaria in Nigeria and Cameroon will guide their malaria control strategies.

Key Words: Paracentric Inversions, Karyotypes, Chromosomal forms, *Anopheles gambiae s.l.*, Ecozones, Nigeria-Cameroon.

Divergent kleisin subunits of cohesin specify mechanisms to tether and release meiotic chromosomes.

A.F. Severson^{1,2}, B.J. Meyer³;

¹BGES Department, Cleveland State University, Cleveland, OH, ²Center for Gene Regulation in Health and Disease, Cleveland, OH, ³Univ California-Berkeley/HHMI, Berkeley, CA

Proper establishment and two-step release of meiotic sister chromatid cohesion (SCC) is critical for the production of haploid gametes. We have shown that multiple, functionally specialized cohesin complexes mediate meiotic SCC in *C. elegans*. These complexes differ in a single subunit, called the α -kleisin. Unexpectedly, the meiotic kleisins REC-8 and COH-3/4 endow cohesins with distinctive properties, specifying how complexes load onto chromosomes, become triggered to tether sisters, and then are removed from complementary chromosomal regions in late prophase of meiosis I. While stable association of REC-8 cohesin with meiotic chromosomes requires HTP-3, a component of meiotic chromosomal axes, and TIM-1, a *C. elegans* TIMELESS ortholog, COH-3/4 cohesin loads onto chromosomes independently of these factors. Once loaded, REC-8 cohesin appears to establish SCC during premeiotic S phase. In contrast, COH-3/4 cohesin becomes cohesive through a replication-independent mechanism initiated by the double-strand DNA breaks that induce crossover recombination. Break-induced SCC is thus an essential means for tethering replicated meiotic chromosomes rather than simply a specialized mechanism to repair stochastic DNA damage in proliferating cells. Later, recombination stimulates separase-independent removal of REC-8 and COH-

3/4 cohesins from reciprocal chromosomal territories that flank the crossover site. This region-specific removal occurs during late prophase and prometaphase I and likely promotes the two-step separation of homologs and sisters. Unexpectedly, we found that COH-3/4 cohesin performs cohesion-independent functions in synaptonemal complex assembly. Our findings establish new models for cohesin function in reducing genome copy number. These models diverge from those established in yeast but likely apply directly to plants and mammals, recently shown to utilize similar sets of meiotic kleisins.

Holding homologs together: centromere-centromere interactions during meiotic prophase.

E.L. Kurdzo^{1,2}, D.S. Dawson^{1,2};

¹Oklahoma Medical Research Foundation, Oklahoma City, OK, ²Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK

Proper chromosome segregation in meiosis is important for maintaining the fidelity of the genome from generation to generation. In humans, improper chromosome segregation during meiosis is the leading cause of infertility, miscarriage, and genetic birth defects. During prophase of meiosis in budding yeast, homologous chromosomes become tethered in a number of ways, but all of these are mediated in part by Zip1. In early prophase, centromeres undergo a period of pairing with non-homologous partner centromeres – a process called centromere coupling; the function of this process is yet unknown. As prophase progresses, homologous chromosomes find their partner and zipper together along their length by a structure called the synaptonemal complex. Zip1 is a major structural component of the synaptonemal complex; during this time Zip1 also promotes the maturation of cross-overs. In late prophase, the synaptonemal complex along the chromosome arms disassembles, but Zip1 remains at the centromeres where it tethers the homologous chromosomes together until metaphase onset. This association of the centromeres is termed centromere pairing. Recent evidence from mice suggests SYCP1, the functional homolog of Zip1, may be playing a similar role in pairing centromeres. We aim to better understand the contributions made to meiotic segregation fidelity by Zip1, especially in its roles in pairing centromeres. We have created a series of in-frame deletion mutants of ZIP1 in *Saccharomyces cerevisiae* that we are using to identify functional domains of Zip1 that are critical for centromere pairing and coupling.

P1835**Board Number: B359****Defining the mechanism by which polyploidy contributes to genomic instability.**S. Chen¹, J. Stout², B.R. Calvi¹, C.E. Walczak²;¹Department of Biology, Indiana University, Bloomington, IN, ²Medical Sciences, Indiana University, Bloomington, IN

Changes in cell cycle progression are known to lead to genomic instability. One type of variant cell cycle is the endocycle in which cells go through alternating periods of synthesis (S) and gap (G) phases without an intervening mitosis, which leads to polyploidy. Polyploid cells are one hallmark of cancer, but the mechanisms that induce polyploidy and how they contribute to oncogenesis are not well understood. Traditional anti-mitotic drug treatments were reported to induce polyploidy in cancer cells in multiple types of cancers. Here, we showed that multiple anti-mitotic drugs induced polyploidy in MDA-MB-231 breast cancer cells and in HeLa cervical carcinoma cells. Of these drugs, RO3306 (a Cdk1 inhibitor) and SU6656 (a Src kinase inhibitor) reproducibly induced a large fraction of the cells to have higher DNA content, indicative of an endocycle. We showed that cells undergo mitotic-like rounding after drug addition, but then re-flatten without completing division, resulting in large, multi-lobed nuclei. Combined with analysis of fixed cells in the rounded state showing early but not late mitotic features, we found that RO3306 and SU6656 cause a specific type of endocycle known as endomitosis. Furthermore, we analyzed cell fate after RO3306/SU6656 withdrawal by FACS, time-lapse microscopy and fixed cell analysis. We found that polyploid MDA-MB-231 cells were able to resume mitotic divisions and returned to a pseudo-diploid state after drug withdrawal. Mitotic polyploid cells with supernumerary centrosomes formed large multi-polar spindles that contained hundreds of extra chromosomes. Upon cell division there were lagging chromosomes and chromosome bridges, suggesting that mitotic errors in these cells contribute to further aneuploidy. Our results demonstrate that inhibition of normal cell cycle progression can lead to polyploidization and genome instability. Cancer cell polyploidization may represent a survival mechanism for cancer cells in response to cancer therapies and may be a major contributor to disease relapse.

P1836**Board Number: B360****Sperm DNA positioning during female meiosis in *C. elegans*.**M. Panzica¹, F. McNally¹;¹Univ California-Davis, Davis, CA

In most animals, fertilization occurs prior to the completion of female meiosis, raising the question of how the oocyte can tolerate an extra copy of the genome (the sperm DNA), while still segregating its own genomic copies. Evidence from mouse, starfish and *C. elegans* suggests that fertilization occurs at a site far from the meiotic spindle, however, some mechanism must exist to maintain the distance between the sperm and meiotic spindle.

A recent study demonstrated the importance of this distance in preventing capture of the oocyte meiotic spindle by the sperm aster when the sperm aster forms prematurely (McNally et al. 2012. *Dev. Cell* 22:788). It remains unknown if this interaction can occur independently of microtubule asters or the consequences of such an interaction. In the *C. elegans* meiotic embryo, yolk granules and sperm DNA are both moved inward in a kinesin-dependent manner. However, the sperm is restricted to the opposite end of the embryo from the meiotic spindle. We hypothesize that an actin network with a defined mesh size restricts kinesin-driven sperm movement while allowing transport of the smaller yolk granules throughout the embryo.

To test this hypothesis, zygotes in which F-actin was disrupted by depletion of profilin (PFN-1) were analyzed by fixed immunofluorescence. The average distance between the sperm and oocyte meiotic spindle in control embryos was $76.30 \pm 0.93\%$ embryo length (n=78), whereas pfn-1 (RNAi) embryos averaged $51.15 \pm 3.76\%$ embryo length (n=51), with some as close as 5% embryo length. Time-lapse imaging of meiotic embryos from worms expressing GFP-yolk protein and mCherry:histone revealed that yolk granules move rapidly over long distances whereas the sperm moved only within a confined volume at a slower velocity. In pfn-1(RNAi) embryos, the sperm moved over long distances with the yolk granules. Preliminary analysis indicates that while the trajectory of sperm DNA movement changes upon profilin depletion, the velocity does not. These results support the hypothesis that an actin meshwork restricts sperm DNA movement while allowing long-range transport of smaller yolk granules.

Chromosomes mis-segregated into micronuclei cause chromosomal instability by further mis-segregating at subsequent mitoses.

B. He¹, A. Hinman², N. Gnawali², D. Cimini¹;

¹Biological Sciences, Virginia Bioinformatics Institute, Virginia Tech, Blacksburg, VA, ²Virginia Tech, Blacksburg, VA

A micronucleus (MN; plural MNi) is a small nucleus that emerges from a chromosome or chromosome fragment that fails to segregate into a daughter nucleus during cell division. Here, we specifically focused on whole-chromosome MNi and investigated the behavior of such chromosomes (mnChrs) at the mitotic cell division following MN formation. To this end, we used PtK1 cells and experimentally induced anaphase lagging chromosomes, which are known to form MNi upon mitotic exit (Cimini et al., *J. Cell Sci.*, 2002). The day following MN formation, most MNi (80%) maintained nuclear protein localization, indicating that the MN nuclear envelope preserved its integrity. Moreover, many micronucleated cells (MNed cells) underwent further mitotic division and a vast majority (89%) exhibited chromosome segregation errors. To investigate the contribution of mnChrs to such segregation errors, we used PtK1 cells expressing Photoactivatable GFP-histone H2B, and marked MNi in prophase cells, just before nuclear envelope breakdown. We found that the majority of MNed cells progressed into anaphase, but the mnChrs displayed a number of chromosome segregation defects, including sister chromatids that failed to fully separate at anaphase and co-segregated to the same

daughter cell, formation of new MNi in the daughter cells, and delayed condensation. We also found that such under-condensation could lead to lagging chromatin that became trapped by the cleavage furrow and caused cytokinesis failure. However, this was never the case for well condensed anaphase lagging chromosomes that did not come from a MN, which, instead, were invariably pushed to one side of the ingressing cleavage furrow. In conclusion, our work shows that although anaphase lagging chromosomes may initially segregate to the correct daughter cell, the MN that they form represents a severe threat to chromosomal stability at subsequent cell cycles.

Scaling chromosome compaction to cell size.

A. Ladouceur¹, L. Smith¹, P.S. Maddox¹;

¹Department of Biology, University of North Carolina, Chapel Hill, NC

During development in many organisms, cells reduce in size due to consecutive cell divisions without an increase in embryo volume and must adapt organelle sizes accordingly. Despite dramatic changes in cell size, the genome size is constant in all diploid cells of an organism. Thus, it is expected that during anaphase, condensed mitotic chromosomes must be half the length of the mitotic spindle to be properly segregated to each daughter cell, a length that varies according to cell size. Using high-resolution time-lapse microscopy of *C. elegans* embryos expressing H2B-GFP and γ tubulin-GFP, we developed a 3D method to measure chromosome length in living, developing embryos of different developmental stages, ranging from the 1 cell to the 16 cells stage embryos. We confirmed that prometaphase condensed chromosomes are smaller in length as cells reduce in size. In order to identify regulators of chromosome scaling, we design a large-scale RNAi screen in *C. elegans* based on a differential embryonic lethality of a sensitized worm strain compared to control N2 (wild-type). The sensitized animals have a telomeric fusion between the 2 longest chromosomes resulting in an abnormally long chromosome without changing total amount of DNA. We hypothesized those worms would be more susceptible to any defect in chromosome scaling compared to control. As a proof of concept, we depleted a major regulator of chromosome compaction, Condensin. Depletion of the condensin II complex in *C. elegans* completely abolishes chromosome compaction however there are no changes in F1 embryo viability after Condensin I depletion. We measured a 8-fold increase in lethality when we depleted condensin I in the long chromosome strain compared to control, indicating that a subtle change in chromosome compaction could be sufficient to result in increased embryonic lethality of the sensitized strain. Subsequently, we used a sub-library of the whole genome RNAi library that includes 438 genes known or predicted to be chromatin binding and/or modifying enzymes. The screen resulted in a total of 15 hits that we are currently validating using high-resolution microscopy. In summary, we are using large-scale RNAi depletion and high resolution imaging to determine the mechanisms of mitotic chromosome size regulation. Our research capitalizes on a normal developmental context to study a cell biological problem (chromosome condensation). We predict that these results will reveal fundamental concepts in chromosome biology.

P1843**Board Number: B363****Sister chromatid cohesion and chromosome condensation are separable pathways.**K. Tong¹, R.V. Skibbens¹;¹Lehigh University, Bethlehem, PA

High-fidelity chromosome segregation is critical for cell division and organism development. During the cell cycle, replicated DNA is identified as sister chromatids, condensed into chromosomes, and segregated into daughter cells. Cohesin complexes tether together sister chromatids and also promote chromosome condensation, indicating that these two processes are linked. Cohesion and condensation both require that chromatin-associated cohesins become modified by the S-phase acetyltransferase Ctf7/Eco1. Recent findings provide important insights into the mechanism through which Eco1 regulates cohesins. For instance, deletion of *RAD61/WAPL* from *eco1* mutant cells rescues the condensation defects, but not the cohesion defects, that otherwise occur in *eco1* mutant cells. These findings not only document that the role for Eco1 and cohesins in cohesion is separable from that of condensation, but contradict the notion that Rad61 functions as an "anti-establishment" cohesion factor. Like Eco1, Pds5 impacts cohesins and is required for both cohesion and condensation. Recent studies reveal that *ELG1* deletion suppresses both the temperature sensitivity of *pds5* mutant cells as well as *eco1* mutant cells. However, the mechanism through which Elg1 regulates cohesion and condensation remains unknown. Prior analyses suggest that yeast cell lethality in cohesin mutants is tied to loss of condensation – not cohesion. Here, we show that *ELG1* deletion in *pds5-1* mutant cells results in a significant rescue of cohesion, but not condensation. Thus, a rescue of cohesion in *pds5* mutants is sufficient to maintain cell viability despite persistent and profound condensation defects. Primarily, Elg1 unloads the DNA replication clamp PCNA from DNA during S phase. We show that PCNA overexpression also rescues the temperature sensitivity, but not the condensation defect, in *pds5-1* mutant cells. These findings suggest that *ELG1* deletion rescues *pds5-1* mutants through PCNA regulation. In contrast to results that *RAD61* deletion rescues both *eco1* mutant cell condensation defects and cell viability, we find that *RAD61* deletion fails to rescue *pds5-1* mutant cell temperature sensitivity – even though the condensation defect is rescued. In conclusion, we provide new evidence that Eco1 and Pds5 perform separable and distinct roles in cohesion and condensation and that both pathways impact cell viability in non-redundant mechanisms.

P1844**Board Number: B364****The unique structural features of CENP-A nucleosomes in solution are highly pronounced on α -satellite DNA sequence.**N. Sekulic¹, K. Gupta¹, G. Van Duyne¹, B.E. Black¹;¹Department of Biochemistry and Biophysics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

The centromere is a locus present on each chromosome to ensure their proper segregation during cell division. Centromeres are defined by the presence of nucleosomes containing a histone H3 variant, CENP-A. Many eukaryotic centromeres are found on slightly A/T rich and repetitive DNA. In humans, centromeres typically are found on highly repetitive DNA, termed α -satellites, where the smallest repetitive unit is 171 bp. Centromeres known to exist at genomic locations without any detectable α -satellite DNA, at so-called neocentromeres. Thus, there is not an absolute requirement for any particular DNA sequence for centromere function and inheritance, but it is likely that the preponderance of these sequences at typical human centromeres is a result of a functional benefit they provide. In this context, we now explore the role of DNA sequence in the physical properties and shape of the CENP-A nucleosome in solution. Our present studies include analytical ultracentrifugation and contrast variation by small-angle X-ray and neutron scattering (SAXS/SANS). Contrast variation is a powerful approach that leverages the scattering powers of protein and DNA components in different solution environments to resolve properties of the parts from the whole. The DNA templates that we used to reconstitute nucleosome core particles were the widely used synthetic nucleosome positioning sequence, termed Widom 601, and an α -satellite sequence where the position within the α -satellite monomer corresponds precisely to what we recently mapped as the most heavily occupied site at centromeres (Hasson et al., 2013, Nat. Struct. Mol. Biol. 20:687-95). While the gross properties of canonical H3 and CENP-A nucleosomes on Widom 601 DNA were similar by sedimentation velocity analysis, contrast variation analysis reveals discrete differences in both the protein and DNA components that can be correlated with the structural features of available atomic models. When CENP-A nucleosome core particles are assembled with its native α -satellite DNA, however, we observed significant changes in the solution structure of the CENP-A nucleosome relative to on Widom 601 DNA. In sum, our findings support the notion that CENP-A confers conformational changes to both the histones and the DNA at the termini of nucleosomes and that these changes are magnified on its preferred native DNA sequence. Our findings should be considered in the ongoing effort to provide a structural framework to understand the physical basis for how CENP-A distinguishes centromeres from the rest of the genome.

P1847**Board Number: B365****Complex chromosomal rearrangements from the missegregation of intact chromosomes.**D. Pellman¹, A. Spektor¹, C. Zhang², J. Francis², M. Meyerson³;¹Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, ²Broad Institute of MIT and Harvard, Cambridge, MA, ³Dana-Farber Cancer Institute, Boston, MA

Whole chromosome segregation errors are among the most common alterations in cancer genomes. However, whether they are cause, consequence, or neutral bystanders in malignant transformation has been debated. The debate about the significance of whole chromosome aneuploidy has been fueled by the paucity of mechanisms linking chromosome segregation errors to tumorigenesis. We previously reported that missegregation of chromosomes can result in DNA damage, if the missegregated chromosome is partitioned into abnormal nuclear structures called micronuclei. Micronuclei are well-described features of cancer cells. We proposed that localized DNA damage in micronuclei might be a mechanism to explain “chromothripsis”, a pattern of complex chromosomal rearrangements restricted to one or a few chromosomes discovered from cancer genome sequencing. To test this hypothesis, we developed an approach to combine live-cell imaging with single-cell genome sequencing (Look-seq). We used this approach to sequence pairs of daughter cells after the division of micronucleated cells. The analysis revealed complex chromosomal rearrangements restricted to the missegregated chromosome. In some cells, a single chromosome was fragmented, with different fragments being partitioned into different daughter cells. Together these findings define a new mutagenesis mechanism where errors in mitosis produce chromosome rearrangements relevant to cancer and developmental diseases.

P1849**Board Number: B366****Size matters: analyzing the rate of mis-segregation and incidence of aneuploidy in Indian and Chinese Muntjac cells.**J.M. Nicholson¹, N. Baudoin¹, D. Cimini¹;¹Biological Sciences, Virginia Bioinformatics Institute, Virginia Tech, Blacksburg, VA

Aneuploidy, the presence of an abnormal number of chromosomes, causes gross transcriptomic and proteomic imbalances due to the gain/loss of hundreds to thousands of genes. Such imbalances are typically detrimental to cell survival and proliferation, however can be beneficial to cells in certain contexts (e.g., cancer and evolution). Accordingly, mechanisms that allow cells to attenuate or tolerate the effects of aneuploidy are important for cell survival and adaptive potential. Recently, it was shown that tetraploidy can buffer the effects of aneuploidy on cells (i.e., tetraploid cells continue to divide after mis-segregation events whereas diploid cells arrest/die) (Dewhurst et al., Cancer Discov., 2014). Moreover, it is widely acknowledged that only aneuploidies for smaller, gene-poor chromosomes are

tolerated in utero in humans and it has been reported that cancer cells tend to lose smaller chromosomes (Duijf et al., *Int J Cancer*, 2012). Such observations suggest that the degree of aneuploidy (as fraction of genes lost/gained) is important to consider when evaluating the effects of aneuploidy. To investigate how cells with different karyotypic backgrounds tolerate such effects, we analyzed mis-segregation rates and karyotypic heterogeneity in Indian Muntjac ($2n=6$, very large chromosomes) and Chinese Muntjac cells ($2n=46$, small chromosomes) cells (IMJ and CMJ, respectively). These cells display dramatically different karyotypes yet are evolutionarily close relatives of one another. Indeed, there is convincing evidence that the large IMJ chromosomes evolved via numerous tandem fusion events from a common ancestor with a CMJ-like karyotype. We found that despite similar mis-segregation rates (measured as frequencies of anaphase lagging chromosomes), karyotypic heterogeneity (evaluated by chromosome counts in metaphase spreads) was primarily observed in CMJ and not IMJ cells, indicating that mis-segregation of small chromosomes (loss/gain of fewer genes) is better tolerated. We also found that a subpopulation of IMJ cells with near-tetraploid karyotype displayed significantly higher chromosome number variability compared to the diploid population, indicating that loss/gain of a chromosome out of two has a smaller impact than gain/loss of a chromosome out of four. Our data suggest that the degree of aneuploidy in cells is important and support recent findings showing that tetraploidy is one mechanism that allows cells to tolerate the gain or loss of genetic information.

Ki-67 is a PP1-interacting protein that organises the mitotic chromosome periphery.

D.G. Booth¹, M. Takagi², L. Sanchez-Puillido³, E. Petfalski¹, G. Vargiu⁴, K. Samejima¹, N. Imamoto², C.P. Ponting⁵, D. Tollervey⁶, W.C. Earnshaw⁴, P. Vagnarelli⁷;

¹Wellcome Trust Centre for Cell Biology, The University of Edinburgh, Edinburgh, Scotland, ²Cellular Dynamics, Riken Advanced Science Institute, Wako Saitama, Japan, ³MRC functional genomics unit, university of oxford, oxford, United Kingdom, ⁴Wellcome Trust Centre for Cell Biology, The University of Edinburgh, Edinburgh, United Kingdom, ⁵Physiology, anatomy and genetics, University of Oxford, Oxford, United Kingdom, ⁶University of Edinburgh, Edinburgh, United Kingdom, ⁷Life sciences, Brunel University, Uxbridge, England

When the nucleolus disassembles during open mitosis, many nucleolar proteins and RNAs associate with chromosomes, establishing a perichromosomal compartment coating the chromosome periphery. At present almost nothing is known about the function of this poorly characterised compartment. During interphase, Ki-67 is predominantly localised in the cortex and dense fibrillar components of the nucleolus, but relocates to the periphery of condensed mitotic chromosomes. In this study, we report that Ki-67 is ancestral to the PP1 targeting subunit Repo-Man and is required for the assembly of the perichromosomal compartment in human cells. We go on to show that Ki-67 is a cell-cycle regulated PP1 binding protein that is involved in phospho-regulation of the nucleolar protein B23/nucleophosmin. Following siRNA depletion, Ki-67, NIFK, B23, nucleolin, and four novel chromosome periphery proteins

all fail to associate with the periphery of human chromosomes. Correlative light and electron microscopy (CLEM) analysis of cells depleted of Ki-67 suggest a near-complete loss of the entire perichromosomal compartment. Mitotic chromosome condensation and intrinsic structure appear normal in the absence of the perichromosomal compartment but significant differences in nucleolar reassembly and nuclear organisation are observed in post-mitotic cells. Remarkably, although the abnormalities in the dispersal and re-aggregation of nucleolar components during mitosis appear quite dramatic, Ki-67-depleted cells appear to survive with a single nucleolus and can proceed to another cell cycle. This second division becomes more problematic and we have observed an increase of apoptosis together with mitotic delay. The mitotic defects that occur at the second mitosis after loss of the perichromosomal layer, could be related to a necessary interphase function of Ki-67 or reflect decreased synthesis of a key component required for chromosome segregation, and therefore will require future investigation.

Regulation of multiple cohesin complexes in *Drosophila* meiosis.

L. Wang¹, M. Gyuricza¹, K.S. McKim¹;

¹Waksman Institute, Piscataway, NJ

The cohesin complex is a ring-shaped protein complex that is important for holding sister chromatids and is also required for assembling synaptonemal complex (SC), a protein structure situated between meiotic homologous chromosomes. The cohesin complex consists of four subunits, SMC1, SMC3, a kleisin member (Rad21 in *Drosophila*) and SCC3 (stromalin/SA in *Drosophila*). In *Drosophila* meiosis, after knocking down SMC1 and SMC3, we found that the SC fails to form. However, when knocking down SA and Rad21, the SC phenotypes differ: SA knockdown has a patchy SC phenotype, whereas Rad21 has wild-type like phenotype. These results suggest that there is another subunit substituting for Rad21 possibly leaving Rad21 defunct in *Drosophila* meiosis. In addition, because various cohesin mutants show different SC defect phenotypes, we suggest there might be at least two types of cohesin complexes involved in *Drosophila* meiosis. One complex might include SA and C(2)M, a kleisin-like protein; the other might include SUN and SOLO. Differential regulation of these complexes might allow for separately regulating arm and centromere cohesion, required for separation of homologous chromosomes at meiosis I which maintaining sister chromatid cohesion until meiosis II. However, little is known about how these cohesin complexes are regulated and ultimately released at the right time for chromosome segregation. To examine the consequences of no cohesion during meiosis I, we generated SMC1 mutant oocytes. These oocytes showed precociously separated homologous chromosomes and more than 8 foci of centromere staining, confirming that SMC1 is required for sister cohesion at meiosis I. These results are similar to our observations of *ord* mutants, which had previously been shown to be required for proper segregation of sister chromatids. Our future work will be focused on examining the function and regulation of each cohesin complex. We will examine the phenotype of *c(2)M* and *c(2)M ord* double mutants to determine if the phenotype of losing two putative cohesin complex will be similar

to the SMC1 mutant phenotype. To examine how the different cohesin complexes are regulated during meiosis, we will examine chromosome behavior in oocytes lacking both positive (eco and Nipped-B) and negative (wapl and separase) cohesin regulators. These experiments will provide insights into how arm and centromere cohesin is regulated during the metaphase-anaphase transitions of the two divisions of meiosis.

The Use of Ellman's Reagent in the Isolation of Mitotic Chromosomes for Structural and Biochemical Studies.

J.R. Paulson¹, E.R. Vander Mause¹, B. Usman¹;

¹Dept of Chemistry, Univ Wisconsin Oshkosh, Oshkosh, WI

Histones H1 and H3 are highly phosphorylated during mitosis in vertebrate cultured cells, but they are rapidly dephosphorylated by endogenous protein phosphatases when the mitotic cells are lysed. This dephosphorylation can be prevented by including sulfhydryl reagents in the lysis solutions, and p-chloromercuriphenyl sulfonate (PCMPS) is particularly effective. However, the toxicity of PCMPS and the fact that it is no longer available in the U.S. led us to examine another sulfhydryl reagent, Ellman's Reagent (5,5'-dithiobis-(2-nitrobenzoate), or DTNB). DTNB reacts efficiently with sulfhydryl groups and can be used for their quantitation.

Using acid-urea polyacrylamide gel electrophoresis, which separates phosphorylated and unphosphorylated histone species, and SDS-polyacrylamide gel electrophoresis combined with phosphoprotein-specific stains or western blotting with phosphohistone-specific antibodies, we show that DTNB is very effective in preventing dephosphorylation of histones H1 and H3. The minimal effective DTNB concentration is approximately stoichiometric with the concentration of sulfhydryl groups in the lysate, and the phosphatase inhibition can be reversed by treatment with 2-mercaptoethanol or dithiothreitol. DTNB is compatible with several available procedures for the isolation of metaphase chromosomes.

Interestingly, chromosomes isolated with DTNB are "cleaner" in that they have fewer and less intense non-histone protein bands on gels. This suggests that DTNB may prevent the artefactual association of non-chromosomal proteins with the chromosomes during isolation.

P1857**Board Number: B370****Post-mitotic transcription reactivation: insights into cell identity maintenance.**K. Palozola¹, J.S. Becker¹, G. Donahue¹, J. Caravaca¹, K.S. Zaret¹;¹Institute for Regenerative Medicine, Univ Pennsylvania, Philadelphia, PA

The goal of our research is to understand how a cell accurately reinitiates its cell type-specific transcriptional program after mitotic division. During mitosis, the genome becomes transcriptionally silent. Yet, after each cell division, cells retain their identity by reinitiating their pre-mitotic, cell-type specific transcriptional program. Because a cell's gene expression profile largely determines its identity, cells may be more susceptible to reprogramming to alternate cell fates in mitosis than in interphase. Thus, understanding the mechanisms of genome-wide transcription re-initiation following mitosis would contribute to our understanding of cell identity and aid in the development of cell reprogramming technologies. During mitosis, RNA polymerase II (Pol II) and most transcription factors are excluded from mitotic chromatin. However, recent studies have identified a subset of cell type-specific transcription factors, such as FoxA1 in hepatocytes, that are retained on mitotic chromatin and promote the rapid re-activation of target genes at mitotic exit – a mechanism termed mitotic bookmarking. Yet, the timing and mechanism of genome-wide transcription re-activation has not been studied. Since the nuclear envelope is disassembled in mitosis, existing methods for labeling nascent RNAs, such as GRO-seq, are not applicable due to their reliance on the presence of the nuclear envelope. Accordingly, we have employed new methods to label nascent transcripts as cells exit mitosis. Specifically, a human hepatoma cell line, HUH7, was arrested in prometaphase, released from arrest, and the nascent transcripts were pulse-labeled with 5-ethynyluridine (EU). Subsequent isolation, and high throughput sequencing of cDNA from pulse-labeled RNA suggests that not all genes are re-activated with the same kinetics. Continuing analysis aims to understand the role of mitotic bookmarking factors and Pol II recruitment in this process.

Tumor Invasion and Metastasis 2**P1860****Board Number: B372****Role of E-cadherin cell surface activation in cancer progression.**Y. Petrova¹, B.M. Gumbiner¹;¹UVA, Charlottesville, VA

E-cadherin is a tumor suppressor protein and the loss of E-cadherin expression promotes tumor progression and metastasis. However, in many cases cells of epithelial tumors and metastases still express E-cadherin. We have found that E-cadherin exists in different activity states at the cell surface, and we hypothesize loss of cadherin activity regulation, rather than expression, may promote cancer

progression. To study whether adhesion activation can inhibit metastasis, we tested the effects of mAbs that activate E-cadherin at the cell surface. Orthotopic tumors were formed by injecting mouse mammary 4T1 cells expressing human E-cadherin into mammary fat pads of Balb/c mice. The experimental group received twice weekly intraperitoneal injections of adhesion-activating mAb, while the control group similarly received treatment with a neutral nonactivating E-cadherin-specific mAb. We found that activating Ab treatment significantly reduced the number of 4T1 mammary tumor cells that metastasized to lung after 4 weeks. We also asked whether naturally occurring missense mutations in the E-cadherin ectodomain known to promote hereditary diffuse gastric cancer (HDGC) in humans specifically affect the regulation of adhesive activity at the cell surface. To examine basic adhesive function several HDGC E-cadherin mutants were expressed in cadherin-free CHO cells. Using a quantitative flow adhesion assay, we observed that some mutants exhibited normal adhesion strength while others exhibited substantially reduced adhesion strength, although they still had greater adhesion than the totally inactive W2A cadherin mutant. To test whether the mutant E-cadherins can be activated at the cell surface they were expressed in Colo 205 cells after depletion of endogenous E-cadherin via shRNA. Parental Colo205 cells are normally nonadhesive despite having a full complement of E-cadherin-catenin complexes at the cell surface, but they can be triggered to adhere strongly, either by treatment on the outside with our activating mAbs or internally by treatment with nocodazole. Some mutants showed impaired activation upon activating mAb and nocodazole treatment even though they exhibited basic adhesion functionality in the CHO adhesion assay. Others were as sensitive to adhesion activation as wild type E-cadherin. One mutant was strongly activated from the outside by the activating mAbs, but could not be activated from the inside by nocodazole or by activating p120-catenin mutations. These findings show that regulation of E-cadherin activity on cell surface is a mechanism that contributes to cancer progression, in addition to the known mechanism of loss of E-cadherin expression.

Nuclear pyruvate kinase M2 regulates epithelial–mesenchymal transition by controlling E-cadherin expression.

A. Hamabe¹, M. Konno², H. Yamamoto¹, T. Mizushima¹, I. Takemasa¹, N. Tanuma³, H. Shima³, N. Nishida², J. Koseki⁴, K. Kawamoto², Y. Doki¹, M. Mori¹, H. Ishii⁴;

¹Department of Gastroenterological Surgery, Graduate School of Medicine, Osaka University, Suita, Japan, ²Department of Frontier Science for Cancer and Chemotherapy, Graduate School of Medicine, Osaka University, Suita, Japan, ³Division of Cancer Chemotherapy, Miyagi Cancer Center Research Institute, Natori, Japan, ⁴Department of Cancer Profiling Discovery, Graduate School of Medicine, Osaka University, Suita, Japan

Pyruvate kinase M2 (PKM2) is an alternatively spliced variant of the pyruvate kinase gene that is preferentially expressed in embryonic development and in cancer cells. PKM2 modulates the final rate-limiting step of glycolysis and plays a key roll in establishing aerobic glycolysis in cancer cells, thereby stimulating cell proliferation and tumor growth. However, there has never been a study demonstrating

the association between PKM2 and cancer cell invasion or metastasis. Recently, PKM2 was shown to translocate to nucleus in response to EGFR stimulation and regulate gene expression including Cyclin D1 and c-Myc. Here we also report that stimulation of epithelial–mesenchymal transition (EMT), the phenomenon that occurs in cancer cells in the early stage of invasion, results in the nuclear translocation of PKM2 in colon cancer cells, which is pivotal in promoting EMT. PKM2 interacted with transforming growth factor (TGF)- β -induced factor homeobox 2 (TGIF2), a transcriptional cofactor repressor of TGF- β signaling, resulting in down-regulation of E-cadherin expression. We induced EMT to SW480 with TGF β 1 and EGF stimulation, in which PKM2 was up-regulated and the translocation to nucleus of PKM2 was observed. PKM2 inhibition using siRNA suppressed E-cadherin repression and inhibited EMT. We established SW480 with either PKM1 or PKM2 overexpression followed by EMT induction. As a result, PKM2 OE cell was more sensitive to EMT stimulation than PKM1 OE cell. IP-WB and mass spectrometry analyses showed that intranuclear PKM2 directly interacted with TGIF2 during EMT and TGIF2 inhibition with siRNA abrogated the augmented sensitivity to EMT in PKM2 OE cells. IP-WB and ChIP-qPCR showed that the interaction between PKM2 and TGIF2 recruited HDAC3 to the promoter region of E-cadherin, resulting in deacetylation of Histone H3 lysine 9 and increased expression of E-cadherin. In immunohistochemical analysis using clinical samples of colorectal cancers, PKM2 positivity correlated with lymph node metastasis and distant organ metastasis, and furthermore, associated with positive TGIF2 and negative E-cadherin expression. In conclusion, our data suggested that intranuclear PKM2 had a crucial role in promoting invasion and metastasis by genetically controlling E-cadherin expression.

Macrophages orchestrate early metastatic dissemination of pre-malignant ErbB2+ mammary epithelial cells.

N. Linde¹, M.S. Sosa^{2,3}, M. Merad⁴, J.A. Aguirre-Ghiso^{2,3};

¹Division of Hematology and Oncology, Mount Sinai School of Medicine, New York, NY, ²Division of Hematology and Oncology, Mount Sinai School of Medicine, Department of Medicine, NY, ³Black Family Stem Cell Institute, Manhattan, NY, ⁴Oncological Sciences, Mount Sinai School of Medicine, New York, NY

Metastases originate from tumor cells that disseminate from the primary site. This was proposed to occur only in invasive cancers. However, detection of tumor cells in the bone marrow of patients with pre-invasive breast ductal carcinoma in situ (DCIS) showed that dissemination could, through unknown mechanisms, take place earlier. Macrophages are key for mammary gland development and remodeling and they aid metastatic dissemination during late invasive stages of cancer. We therefore investigated whether these inflammatory cells might actively participate in early dissemination. Using the MMTV-ErbB2 mouse model, we show that F4/80+ macrophages associate with mammary ducts in the periphery of the myoepithelial layer but are never inside the ducts in wild type mouse mammary glands. We found that macrophages are recruited into epithelial layers of pre-malignant lesions of MMTV-ErbB2 mice. This

is dependent on the upregulation of cytokines in mammary epithelial cells induced by the amplification of the ErbB2 oncogene. Dissemination of ErbB2+ cytokeratin 8/18+ mammary epithelial cells (MECs) detected in circulation or the bone marrow was dependent on macrophages because their depletion reduced early dissemination significantly. Sites where macrophages had invaded the ducts showed disruption of the myoepithelium and reduced E-Cadherin expression in MECs. Depletion of macrophages from pre-malignant MMTV-ErbB2 mice normalized the mammary gland phenotype. Importantly, DCIS samples from patients frequently contained intra-epithelial macrophages and their presence was also correlated with reduced E-Cadherin expression in MECs. Our data suggest that macrophages actively aid early dissemination during pre-malignant stages of breast cancer. Further, when macrophages contact the luminal ductal cells, they induce a loss of E-cadherin junctions, possibly enhancing migration/invasion. Our data shifts the paradigm of metastasis by revealing that macrophage-assisted dissemination occurs much earlier than anticipated. This might be useful to better identify patients with early stage breast cancer that are at high risk of already carrying disseminated disease. More importantly, it provides a new understanding of the natural history of disseminated cancer, which is largely incurable for reasons that might be linked to early dissemination and divergent evolution of metastasis.

Linoleic acid promotes the localization of fascin in focal contacts in breast cancer cells MDA-MB-231.

C. Gonzalez-Reyes¹, P. Cortes-Reynosa¹, C. Rodriguez-Monterrosas¹, F. Candanedo-Gonzalez¹, E.P. Salazar¹;

¹Biologia Celular, CINVESTAV, Mexico City, Mexico

Breast cancer is a malignant proliferation of epithelial cells lining the ducts or lobules of mammary gland. Fascin is an actin binding protein of 55 kDa that plays an important role in actin organization. Particularly, it mediates the formation of cell protrusions, which mediate cell interactions and migration, as well as the formation of cytoplasmic microfilament loops that contribute to the cellular architecture and the intracellular movement. In several cancers including colon, pancreatic and breast, fascin is upregulated at both mRNA and protein, whereas its expression positively correlates with aggressivity of tumors. Linoleic acid (LA) is an essential fatty acid and the major polyunsaturated fatty acid in the diet of most humans. In breast cancer cells, LA induces proliferation, migration, invasion and the activation of signal transduction pathways. The aim of this study was to determine whether LA induces changes in the localization of fascin in breast cancer cells MDA-MB-231. Our findings demonstrate that LA induces the complex formation between focal adhesion kinase (FAK) and fascin in a time-dependent manner in MDA-MB-231 cells. Furthermore, LA also induces the localization of fascin in the focal contacts in a time-dependent manner. Since we previously demonstrated that LA induces cell migration, these findings strongly suggest that fascin plays an important role in cell migration induced by LA in MDA-MB-231 cells.

P1868**Board Number: B376****Targeting angiogenic switch for development of novel biomarker for early detection of pancreatic cancer.**

S. Ghosh¹, M.P. Brennan², W. Ahrens³, C. Jacobs³, D. Iannitti³, J. Martinie³, R. Swan³, H.L. Bonkovsky³;
¹Biomarker and Drug Discovery Section, CaresBio Laboratory, LLC, Shelton, CT, ²Cardiology, Yale University, New Haven, CT, ³Carolinas HealthCare System, Charlotte, NC

Background: There are no warning signs or accurate, quantitative biomarkers to detect pancreatic cancer (PC) at early stages. 5 year survival rate for patients with PC is less than 5%, and complete remission is rare. Early detection increases the chances of saving more lives with the recently developed treatment plans. Studies have reported that an angiogenic switch, a shift of balance between pro-angiogenic and angiogenic state is a hallmark of cancer progression. The objective of this study was to investigate whether increased angiogenesis could be a predictor of PC occurrence and progression.

Methods: We performed Immunohistochemistry and immunofluorescence staining and quantitatively assessed sub cellular protein expression of angiogenesis associated markers such as vascular endothelial growth factor (VEGF), VEGF receptor 1 (FLT-1), VEGF receptor 2 (FLK-1), neuropilin (NP-1), cytoskeletal protein filamin A (fila), a stress inducible catalytic enzyme heme oxygenase 1 (HMOX-1) and its constitutive isoform heme oxygenase 2 (HMOX-2) in human patient samples during development and progression of PC and examined their correlations with selected clinico-pathological variables. Statistical analyses were performed using SAS version 9.2.

Results: VEGF and other proteins were stained predominantly in the membrane / cytoplasm compartment of malignant epithelium and were over expressed in tumors versus adjacent stroma. Normal epithelium showed lower expression compared to tumor. Disease stage was highly prognostic for outcome. A significant association was found between high expressions of fila ($p < 0.0001$) and HO2 ($p < 0.0005$) at earlier stage. Fila and HMOX2 showed higher expression at earlier stages of PC development, whereas others showed consistent positive correlation with progression of disease including for overall expression HMOX-1 (0.02) and NP-1 (0.049). Using total expression within the tumor, high expressers consistently correlated with worse outcomes and decreased overall survival. These data have been confirmed by serum analyses.

Conclusions: VEGF, VEGFR2, NP-1, HMOX-1, HMOX-2 and fila are expressed at varying degrees in PC and are higher in tumors versus stroma. Higher expression of HMOX-2 and fila showed correlation with earlier stage of PC development. The prognostic value of these candidate biomarkers within the tumor microenvironment may facilitate the development of a much needed early stage biomarker and a potential therapeutic target for PC.

P1869**Board Number: B377****Dynamics and function of the acto-myosin cytoskeleton and apical endocytosis during junctional disassembly in Epithelial to Mesenchyme Transitions.**S. Simoes¹, R. Fernandez-Gonzalez^{2,3,4}, U. Tepass⁵;

¹Cell and Systems Biology, University of Toronto, Toronto, ON, ²Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, ³Department of Cell and Systems Biology, University of Toronto, Toronto, ON, ⁴Developmental and Stem Cell Biology Program, The Hospital for Sick Children, Toronto, ON, ⁵Cell and Systems Biology, University of Toronto, Toronto, ON

Epithelial to mesenchyme transitions (EMT) are ubiquitous during animal development, allowing the formation and migration of new cell types and tissues. EMTs are also associated with cell escape during epithelial tumor progression, yet, the mechanisms responsible for triggering this process remain poorly understood. Hallmarks of these cell transitions include the disassembly of E-cadherin-based cell-cell junctions, the disappearance of the apical membrane, loss of apical-basal polarity, and acquisition of stem cell or migratory capacity. Using a novel in vivo model – the delaminating neuroblasts of the *Drosophila* embryo – and applying quantitative live imaging and cell segmentation techniques, we are studying the molecular mechanisms involved in the early stages of EMT. First, we demonstrate that EMT can occur without the transcriptional downregulation of E-cadherin, suggesting alternative driving forces for this process. Through live imaging with high temporal and spatial resolution, we found that the disassembly of junctions during cell delamination follows a planar polarized pattern, correlating with the sequential recruitment of the actin motor myosin II to anterior-posterior and dorso-ventral junctions as they disassemble. Delamination of neuroblasts is accompanied by the enrichment of Clathrin, a marker of endocytosis, at the junctions and free apical membrane and by the internalization of the apical determinant Crumbs, an upstream regulator of E-cadherin and regulator of apical membrane size. Finally, as junctions disassemble, the free, medial apical membrane decreases its area through sequential cycles of expansion and contraction, correlating with local pulses of myosin II accumulation, which may drive and stabilize contractions. These observations suggest that the loss of the apical domain during EMT is triggered by the concerted activation of the actomyosin cytoskeleton and the endocytic machinery at two apical membrane domains, the cell-cell junctions and the medial apical membrane. We are currently exploring how post-transcriptional modes of E-cadherin regulation, including the internalization of Crumbs, could play a role in junctional destabilization during this process.

P1871**Board Number: B378****Targeting pancreatic cancer metastasis through a specific inhibition of the Rac activator Vav1, a driver of tumor cell invasion.**G.L. Razidlo¹, C. Magnine¹, A. Sletten¹, M. Fernandez-Zapico¹, B. Ji¹, M.A. McNiven¹;¹Mayo Clinic, Rochester, MN

While many therapeutic approaches focus on tumor growth, metastasis is a primary factor contributing to cancer lethality. Therefore, novel therapies to target metastatic invasion could prevent tumor spread and recurrence resulting from local and distant metastasis. The protein Vav1 is aberrantly expressed in over half of pancreatic cancers, and we have found that its expression leads to enhanced invasion and migration. Vav1 is a guanine nucleotide exchange factor (GEF) that regulates invasion by promoting activation of Rac and Cdc42 to induce the formation of lamellipodia and invadopodia. Even with the expression of multiple Rho family GEFs, tumor cells that upregulate Vav1 appear to become dependent upon this exchange factor, implicating Vav1 as a potent target for therapeutic intervention. Azathioprine, well-known an anti-inflammatory compound, was recently shown to function by inhibiting Vav1/Rac signaling in immune cells. We therefore hypothesized that azathioprine could also inhibit Vav1 in pancreatic tumor cells to reduce its pro-invasive functions. Indeed, we have found that treatment of cultured pancreatic tumor cells with azathioprine inhibited invasive cell migration and matrix degradation, processes regulated by Vav1, through inhibition of Rac and Cdc42 signaling. Further, azathioprine treatment decreased metastasis in both xenograft and genetic mouse models of pancreatic cancer. Strikingly, metastasis was essentially blocked in Vav1-expressing tumors in a genetic mouse model of pancreatic cancer (p48 Cre, KRasG12D/+, p53loxP/+). These inhibitory effects were mediated through Vav1, as Vav1-negative cell lines and tumors were largely resistant to azathioprine treatment. These data extend the cell biological findings of Vav1-dependent invasion and migration into pre-clinical models of pancreatic cancer, and uncover a surprising role for azathioprine as a potent anti-metastatic agent for Vav1-positive pancreatic tumors. Supported by R01 CA104125 and R03 CA155778.

P1872**Board Number: B379****Formin Activity is Required for Branching Morphogenesis by MDCK Acini.**T. Fessenden^{1,2}, M.L. Gardel³, M.X. Benítez-Jones⁴;¹Cancer Biology, University of Chicago, Chicago, IL, ²Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, ³James Franck Institute, Institute for Biophysical Dynamics and Physics Department, University of Chicago, Chicago, IL, ⁴Department of Physics, University of New Mexico, Albuquerque, NM

Epithelial tissues harness diverse cytoskeletal dynamics both for shape maintenance and morphogenic changes that occur during development. Misregulation of these processes lies at the foundation of many disease states including cancer metastasis, which requires polarized cytoskeletal activity to drive invasion. We investigated this phenomenon by analyzing the dynamics controlling branching

morphogenesis of Manin-Darby Canine Kidney (MDCK) cell acini embedded in collagen gels in response to hepatocyte growth factor (HGF). When exposed to HGF, all cells within the acinus underwent shape changes and moved extensively within the plane of the acinus. Very few cells, however, formed stable protrusions into the collagen matrix, which marks the initial stage of branching. The number of protrusions could be modified by changes to ECM composition and architecture, with enhanced collagen bundling and reduced basement membrane formation significantly increasing the number of protrusions. Inhibition of Arp2/3, which impairs lamellipodial activity, altered branch morphology without changing the frequency of protrusion. More surprisingly, formin inhibition abolished all protrusive activity into the surrounding ECM, but did not prevent cell shape changes or motility within the plane of the acinus. We also found that formin activity was necessary for single MDCK cells to establish protrusions in 3D collagen matrices. In contrast, 2D migration and wound healing did not require formin activity. Notably, however, formin inhibition reduced the formation of leader cells along the cell front during wound healing in 2D. This altered collective behavior also resulted in reduced curvature along the cell front. These results demonstrate a previously unappreciated role for formins in establishing highly polarized protrusions in single and multicellular contexts, and highlight differences in requirements for migration in 2D and 3D. Our findings have important implications for controlling phenotypes that require polarized protrusions, such as the invasion and migration of cells during cancer metastasis.

Macrophage-dependent activation of a non-canonical NOTCH-RhoA signaling pathway regulates tumor cell intravasation.

J.J. Bravo-Cordero¹, M. Roh-Johnson¹, J. Pignatelli¹, L. Hodgson¹, J.S. Condeelis¹;

¹Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

The tumor microenvironment plays an important role during tumor progression and metastasis. Immune cells have been shown to play a pro-tumorigenic role during several steps of the metastatic cascade. In particular, tumor-associated macrophages facilitate tumor cell invasion and intravasation in vitro and in vivo. Recently, our group has shown that heterotypic cell contact between tumor cells and macrophages induce the formation of invadopodia in tumor cells, invasive structures necessary for matrix degradation and tumor cell intravasation. Using high resolution FRET imaging, we further found that macrophage-induced invadopodium formation is dependent on RhoA activation. However, what remained to be determined was the signaling pathway that regulated this heterotypic cell contact-mediated phenomenon. NOTCH signaling is known to be involved in homotypic cell-cell communication, and has recently been shown to be involved in invadopodium formation (Diaz et al., 2013). Thus, we explored the role of NOTCH in mediating macrophage-dependent tumor cell invadopodium formation. We found that upon NOTCH depletion the number of invadopodia in tumor cells remains unchanged. But surprisingly, in the absence of Notch signaling, macrophage-induced invadopodium formation and tumor cell intravasation are abolished. Moreover, RhoA is no longer activated in tumor cells upon

macrophage contact when NOTCH signaling is perturbed. These results suggest that NOTCH signaling regulates heterotypic cell contact mediated invadopodium formation through RhoA activation, and reveals a novel mechanism for both invadopodium formation and the NOTCH signaling pathway.

Netrin-1 induced activation of Notch signaling regulates glioblastoma cell pathogenity.

I. Ylivinkka¹, Y. Hu¹, P. Chen², S. Hautaniemi², T. Nyman³, M.T. Hyytiainen¹, J.K. Keski-Oja¹;

¹Translational Cancer Biology Research Program, Department of Pathology, Haartman Institute, University of Helsinki, Helsinki, Finland, ²Institute of Biomedicine and Genome-Scale Biology Research Program, University of Helsinki, Helsinki, Finland, ³Research Program in Structural Biology and Biophysics, Institute of Biotechnology, University of Helsinki, Helsinki, Finland

Glioblastoma multiforme is the most severe human brain cancer. It is incurable: the expected lifespan of patients after diagnosis is less than two years. The main reasons for the lethality of glioblastoma are its heterogeneity and resistance to all current therapies and highly invasive nature. Axonal guidance protein, netrin-1, is overexpressed in glioblastoma. This secreted, laminin related extracellular matrix protein has been previously observed to act as a survival factor for aggressive neuroblastoma, metastatic breast cancer and non small cell lung cancer.

We observed that in glioblastoma tumor biopsies netrin-1 localized to hypoxic pseudopalisade structures around necrotic tumor areas. Furthermore netrin-1 increased glioblastoma cell invasiveness in *in vitro* invasion assays and in *in vivo* intracranial orthotopic tumor xenografts. Using tandem affinity purification and mass spectrometry protein identification we found that netrin-1 forms a complex with both Notch2 and Jagged1. Recombinant Netrin-1 colocalized with Jagged1 and Notch2 at the cell surface and was further found in the intracellular vesicles with Jagged1, but not with Notch2. Netrin-1 activated Notch signaling and subsequent glioblastoma cell invasion. Interestingly, the recombinant central domain of netrin-1 counteracted the effects of the full-length netrin-1: it inhibited glioblastoma cell invasion and Notch activation by retaining the Notch signaling complex at the cell surface. This finding may have therapeutic implications. Current results reveal a new mechanism leading to glioblastoma cell invasion, where netrin-1 activates Notch signaling.

Modeling Facility, Fox Chase Cancer Center, Philadelphia, PA, ⁴Genotyping and Real-Time PCR, Fox Chase Cancer Center, Philadelphia, PA, ⁵Medical Oncology, Fox Chase Cancer Center, Philadelphia, United States

Approximately 7% of individuals born in the United States in 2013 will ultimately be diagnosed with lung cancer, and ~160,000 in the US die from this disease each year, with the majority succumbing to metastatic disease. To better understand and therapeutically manage the most common form of lung cancer, non-small cell lung cancer (NSCLC), we first used orthotopic intrathoracic injection to analyze the metastatic potential of 14 murine lung adenocarcinoma cell lines derived from tumors of *Kras*^{LA1/+}; *p53*^{R172HdeltaG/+} mice. Expression of the Musashi-2 (*Msi-2*) stem cell-associated gene was consistently elevated on both the mRNA and protein level in the most highly metastatic cancer cells. *Msi-2* is an mRNA binding protein that regulates translation, and known to be upregulated and functionally important in hematologic malignancies (e.g., CML and AML). In orthotopic lung injections of these cells in immunocompetent 129Sv mice, *Msi-2* depletion dramatically decreased invasion of mediastinal lymph nodes and abrogated metastasis. Using immunohistochemical analysis of 120 specimens of human NSCLC, we demonstrated a statistically highly significant elevation of *Msi-2* in tumor versus normal lung tissue, suggesting relevance of *Msi-2* to human cancers. We found *Msi-2* knockdown in two independent mouse NSCLC cell lines abated matrigel invasion, and decreased the rate of cell attachment. Unexpectedly, *Msi-2* knockdown also resulted in a more mesenchymal morphology, suggesting a non-canonical action in control of cell migration and invasion. We therefore used reverse phase protein array (RPPA) screening and a candidate approach to dissect the mechanism of *Msi-2* action in NSCLC metastasis. *Msi-2* knockdown elevates translation of the Numb and TGF-beta receptor 1 proteins in mouse and human NSCLC adenocarcinoma cell lines, positioning *Msi-2* to provide direct input into two signaling cascades strongly associated with epithelial-mesenchymal transition (EMT) and metastasis. Further, *Msi-2* knockdown strongly induced both the protein and mRNA expression of fibronectin 1 (FN1), an important component of the extracellular matrix is frequently the target of remodeling in EMT. Taken together, our results for the first time define *Msi-2* as a promoter of NSCLC metastasis, and suggest that *Msi-2* may play a role in EMT process by coordinately modulating the TGF-beta, NUMB/NOTCH, and ECM/integrin pathways in NSCLC.

P1876**Board Number: B383****GPCR Signaling to p110 β is Required for Invasion and Metastasis of Breast Cancer Cells.**B.D. Khalil¹, W. Abi Saab¹, Y. Wang², A.R. Bresnick³, J.M. Backer¹;¹Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY, ²Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ³Biochemistry, Albert Einstein College of Medicine, Bronx, NY

Phosphoinositide 3-kinases (PI3Ks) mediate cell growth, survival, motility, and responses to changes in nutritional conditions, and PI3K signaling is commonly amplified in cancer. Among Class IA PI3Ks, the p110 β isoform is unique in that it is activated by both receptor tyrosine kinases (RTKs) and G-protein-coupled receptors (GPCRs). There is strong evidence implicating chemokines and their associated GPCRs in breast cancer progression and metastasis. We recently identified the G $\beta\gamma$ binding site on p110 β and defined mutants that do not affect p110 β activation by RTKs but block activation by GPCRs. To test the role of GPCR signaling to p110 β in breast cancer, we knocked down endogenous p110 β in MDA-MB-231 breast cancer cells and replaced it with wild type, kinase-dead or GPCR-uncoupled p110 β . Compared to cells expressing wild-type p110 β , MDA-MB-231 cells expressing GPCR-uncoupled p110 β showed decreased Akt phosphorylation and chemotaxis in response to lysophosphatidic acid. Similarly, these cells were defective in macrophage-stimulated in vitro invasion and matrix degradation. In murine orthotopic xenografts, cells expressing kinase-dead or GPCR-uncoupled p110 β grew at the same rate as cells expressing wild type p110 β . However, mice with GPCR-uncoupled p110 β tumors showed lower tumor cell blood burden than mice with wild-type p110 β tumors. Cells expressing GPCR-uncoupled p110 β were defective in establishing lung metastases in a tail vein experimental metastasis assay, and showed decreased extravasation in an in vitro transendothelial migration assay. These data show that GPCR signaling to p110 β is crucial for breast cancer cells to extravasate from blood to target organs. Thus, interfering with GPCR signaling to p110 β may constitute an effective strategy in targeting breast cancer progression and metastasis.

P1877**Board Number: B384****The upregulation of PTX3 is associated with the metastatic potential of gastric cancer.**S. Kim¹, B. Choi¹, E. CHANG²;¹University of ulsan college of medicine, Seoul, Korea, ²Department of Biomedical Sciences, University of Ulsan College of Medicine, Seoul, Korea

Long pentraxin 3 (PTX3), also known as TNF-inducible gene 14 protein (TSG-14), is an important mediator of tumor-associated inflammation and affects the severity of tumor malignancies but its exact

role in the progression of gastric cancer remains unclear. In our current study, PTX3 expression was found to be upregulated in metastasized gastric cancer compared with early-stage, non-metastasized gastric cancer in human patients. Most especially, PTX3 expression was prominent and surged during late stage III in comparison with early-stage (I, II) cancer, and the increase in PTX3 expression was also confirmed in a metastatic gastric cancer cell line. PTX3 expression was found to be induced by the pro-inflammatory cytokine TNF α . Exogenous PTX3 treatment promoted the migration of metastatic gastric cancer cells and the chemotaxis of macrophages to gastric cancer cells. More importantly, PTX3 treatment enhanced interactions between gastric cancer cells and osteoblasts, which are key components of the cellular niche in bone required by metastatic cancer cells. In addition, PTX3 knockdown using PTX3-specific siRNA hampered gastric cancer cell migration, the migratory capacity of macrophages, and interactions between gastric cancer cells and osteoblasts. Taken together, these findings suggest that elevated PTX3 expression is correlated with the recurrence and metastasis associated with gastric cancer by enhancing migratory potential, thereby verifying the key role PTX3 plays in the inflammation-associated metastasis of gastric cancer.

Wnt5A promotes an adaptive, senescent-like stress response, while continuing to drive invasion in melanoma cells.

M.R. Webster¹, M. Xu², K.A. Kinzler², A. Kaur¹, J. Appleton¹, M.P. O'Connell¹, K. Marchbank¹, A. Valiga¹, V.M. Dang¹, M. Perego¹, G. Zang¹, A. Slipicevic¹, F. Keeney³, E. Lehrmann², W. Wood III², K. Becker², A. Kossenkov⁴, D. Frederick⁵, K. Flaherty⁵, X. Xu⁶, M. Herlyn¹, M.E. Murphy⁷, A.T. Weeraratna¹;

¹Tumor Microenvironment and Metastasis, The Wistar Institute, Philadelphia, PA, ²The National Institute on Aging, Baltimore, MD, ³Microscopy, The Wistar Institute, Philadelphia, PA, ⁴Bioinformatics, The Wistar Institute, Philadelphia, PA, ⁵Massachusetts General Hospital Cancer Center, Boston, MA, ⁶Abramson Cancer Center, University of Pennsylvania, Philadelphia, PA, ⁷Molecular and Cellular Oncogenesis, The Wistar Institute, Philadelphia, PA

We describe a previously unexplored adaptive stress response driven by Wnt5A in highly invasive melanoma cells. We show that highly invasive melanoma cells express functional p53 and p21, and consequently undergo a G2/M growth arrest when exposed to stress such as irradiation and BRAFV600E targeted therapy. This arrest heralds the onset of an increase of senescence markers including senescence-associated beta-galactosidase activity (SA-beta-gal), senescence-associated heterochromatic foci (SAHF), promyelocytic bodies (PML) and modified chromatin, as defined by the presence of the Histone H3 trimethyl Lys9 (H3K9Me) marks. These cells, which are positive for senescence markers retain invasive capacity, and are capable of forming new colonies, both in vivo and in vitro. Silencing Wnt5A reduces expression of these senescence markers and decreases invasiveness. Mechanistically, we show that this is governed by the non-canonical Wnt molecule, Wnt5A via p21. It is these Wnt5A high, highly metastatic cells that undergo a senescent-like arrest upon induction of stress, yet retain all the hallmarks and capabilities of very aggressive cells. We propose that this adaptive stress response

may be a way for tumors to evade genotoxic damage and targeted therapy, and may select for a subpopulation of cells, which are highly invasive. Importantly, Wnt5A is emerging as a biomarker of not only metastasis in melanoma, but also of therapy resistance.

The RNA helicase Mov10 regulates Wnt5a secretion by modulating lipid synthesis in melanoma.

W. Wang¹, N. Snyder², I.A. Blair², E. Witze¹;

¹Cancer Biology, University of Pennsylvania, Philadelphia, PA, ²Pharmacology, University of Pennsylvania, Philadelphia, PA

The noncanonical Wnt ligand Wnt5a is elevated in melanoma and is thought to play an important role in promoting metastasis. The molecular mechanisms leading to increased Wnt5a expression in melanoma are still unknown. We examined the levels of Wnt5a mRNA and protein in whole cell lysates as well as the level of secreted Wnt5a protein in different melanoma cell lines. We found that the level of secreted Wnt5a does not correlate with the mRNA or cellular Wnt5a protein levels. Furthermore, the invasiveness of melanoma cell lines correlates more strongly with secreted Wnt5a levels rather than the Wnt5a protein level in cell lysates. These results indicate that Wnt5a expression is regulated post-transcriptionally and that Wnt5a secretion is an essential regulatory step to promote cell invasion in melanoma cells.

We investigated several candidate proteins involved in post-transcriptional gene regulation as possible regulators of Wnt5a production. Our results indicate that the RNA helicase Mov10 plays a critical role in regulating Wnt5a modification and secretion. Mov10 forms a complex with Ago2, a component of the RNA Induced Silencing Complex (RISC), and is required for miRNA-mediated translational repression and mRNA cleavage. Mov10 also interacts with the RNA helicase UPF1 that functions in nonsense mediated mRNA decay. IHC staining of malignant melanoma tumors reveal reduced expression of Mov10 compared to benign nevi. Inhibition of Mov10 by shRNA in melanoma cells caused an increase in cell invasion *in vitro* which was dependent on the Wnt5a receptor Ror2. Inhibition of Mov10 also increased Wnt5a secretion. The efficient secretion of Wnt5a requires a posttranslational modification with the lipid palmitoleic acid and inhibition of Mov10 increases Wnt5a lipidation. Fatty acid synthase (FASN) and stearoyl-CoA desaturase (SCD) function to synthesize palmitoleoyl-CoA. Inhibition of Mov10 increases the levels of FASN and SCD resulting in increased levels of palmitoleoyl-CoA. Consistent with the idea that elevation of FASN and SCD expression is a possible mechanism for increased Wnt5a secretion pharmacological inhibition of SCD or FASN blocked the shMov10 induced Wnt5a secretion. Mov10 regulation of FASN and SCD expression appears to be direct as Mov10 interacts with the mRNAs encoding FASN and SCD in a Wnt5a dependent manner. Mov10 also interacts with Dvl2, a key component of Wnt signaling, and this interaction is also increased by Wnt5a treatment. These results uncover a novel role for Mov10 in inhibiting Wnt5a secretion through the regulation of lipid biosynthesis in melanoma.

P1880**Board Number: B387****PEAK1 kinase acts as a molecular switch to mediate TGFbeta-induced EMT in breast cancer.**M. Agajanian¹, A. Campeau¹, D. Brambilla¹, M. Hoover¹, R. Klemke², J. Kelber¹;¹Biology, California State University, Northridge, Northridge, CA, ²Pathology, University of California, San Diego, La Jolla, CA

Epithelial to mesenchymal transition (EMT) is essential and strictly regulated during normal development and tissue homeostasis. However, EMT is deregulated during progression of epithelial cancers to promote metastasis. TGFbeta is a well-characterized inducer of EMT within the tumor microenvironment, but the molecular mechanisms by which TGFbeta switches from a tumor suppressor to EMT inducer remain to be fully elucidated. We previously identified PEAK1 as a new non-receptor tyrosine kinase that associates with the cytoskeleton; binds and facilitates signaling of HER2/Src complexes; and promotes tumor growth, metastasis and therapy resistance in human cancers downstream of oncogenic Ras. PEAK1 has also been reported to promote Src-dependent focal adhesion dynamics, Grb2/Shc signaling downstream of EGFR and EMT in mammary epithelial cells. In the current study, we analyzed PEAK1 expression across published human cancer microarrays and found that PEAK1 expression in breast tumor and stromal tissues correlated with poor disease prognosis. Additionally, we observed that PEAK1 expression increased in HRas-transformed MCF10A or Neu-transformed HMLE cells during EMT induction via in vivo propagation (MCF10CA1h cells) or in vitro exposure to exogenous TGFbeta (HMLE-Neu+T), respectively. To evaluate the role of PEAK1 in TGFbeta-induced EMT, we generated empty vector (V) and PEAK1-overexpressing (P) MCF7 breast cancer cells. Overexpression of PEAK1 induced proliferation, Smad2/3 and Erk1/2 activation, and increased Src expression. It has been previously reported that TGFbeta-induced EMT in breast cancer cells invokes non-canonical Src/Grb2/MAPK pathways and depends upon extracellular substrates. Therefore, we chronically treated MCF7-V and -P cells with TGFbeta and exposed them to various ECM proteins. While TGFbeta was unable to induce EMT in MCF7 cells on plastic or in the absence of overexpressed PEAK1, TGFbeta treatment and PEAK1 overexpression cooperatively induced EMT and cell migration velocity/displacement on the ECM component fibronectin. Importantly, under these same conditions PEAK1 overexpression enabled TGFbeta to activate non-canonical Src and Erk1/2 signaling. These studies are the first to provide evidence that PEAK1 kinase mediates signaling cross talk between TGFbeta receptors and integrin/Src/Grb2/MAPK pathways. With this important information about PEAK1 function and mechanism, unique methods and reagents may be developed to target PEAK1 expression/function or upstream/downstream pathways to abrogate breast cancer progression.

P1881**Board Number: B388****Effect of cystatin C construct clones on B16 melanoma in vitro cell behavior.**S. McIntire¹, J.L. Cox¹;¹Biochemistry, AT Still University, Kirksville, MO

Metastasis is the cause of most cancer related morbidity. A naturally occurring cysteine protease inhibitor, cystatin C, has been reported to inhibit tumor cell metastasis and migration for several different cancers, however, the mechanism is still unknown. Overexpression of cystatin C results in reduced lung seeding of secondary tumors for the metastatic B16F10 cell line. Objective: Our study focused on determining which region of cystatin C is responsible for anti-metastatic action by characterizing specific constructs of cystatin C in melanoma cells. We hypothesized cystatin C inhibits melanoma metastasis through a different mechanism than directly interfering with cysteine protease activity. In one construct, the N-terminal peptide amino acids 1-10, required for cysteine protease inhibition, were deleted. In the second construct the conserved motif QLVAG was altered to GGGGG. Methods and Results: Net proliferation, migration and invasion of the cystatin C constructs were assessed. The modified Boyden chamber revealed 75% reduced invasion of N-truncated clones compared to control B16F10. A scratch migration assay showed a three-fold reduction in migration rate. The QLVAG sequence was found to be required for inhibition of B16F10 invasion and migration. Net proliferation, as measured by MTT assay, remained constant between clones. Conclusions: Overexpression of cystatin C inhibits the migration and invasion, but not proliferation, of B16F10 melanoma cells. The conserved cystatin sequence, QVVAG, is required for cystatin actions on B16 melanoma cells.

P1882**Board Number: B389****Glycosylation of cyclooxygenase-2 (COX-2) influences the migratory and invasive potential of cells.**F.S. Algaly¹, J. Hand, M.B. Sevigny¹;¹Natural Science and Mathematics, Dominican University of California, San Rafael, CA

Prostaglandins are bioactive lipids involved in many physiological functions such as maintenance of the cardiovascular, immune, renal, and central nervous systems. They also play a role in certain diseases like arthritis, cancer, and Alzheimer's. Cyclooxygenase-2 (COX-2) is the enzyme that catalyzes the initial rate-limiting step in the pathway that converts arachidonic acid to prostaglandins. COX-2 exists as two glycoforms with the molecular weights of 72 and 74 kDa, the latter resulting from the addition of a high mannose chain to the Asn580 residue ~50% of the time. The over-expression of COX-2 is believed to be linked to cancer progression and specifically appears to promote the metastatic phenotype. The objective of this study is to determine the effect of the variable glycosylation of COX-2 at Asn580 on the migratory and invasive potential of cells. COS-1 cells and the breast cancer cell line MCF7 were first

transfected with either the wild-type or Asn580-mutant human COX-2 gene. Boyden chambers were used to determine the ability of transfected cells to migrate through the membrane, and modified Boyden chambers (BioCoat Matrigel Invasion Chambers) were used to test cells' invasive potential. Approximately 5×10^4 cells were plated onto the chambers, and cells were incubated for 16-18 h. Cells were then fixed, stained, visualized under a light microscope, and counted. In a previous study, our lab showed that COS-1 cells transfected with the Asn580-mutant COX-2 gene migrated faster through the membrane. In this current study, COS-1 cells transfected with the Asn580-mutant COX-2 gene also had a greater invasive potential; however, MCF7 cells transfected with the wild-type human COX-2 gene migrated faster. The results indicate that the ability of this additional glycosylation of COX-2 at Asn580 to either enhance or inhibit the migratory and invasive potential of cells depends greatly on cell type. To confirm this, future studies will be carried out to determine the effect of COX-2 glycosylation on the invasive potential of MCF7 cells as well as the migratory and invasive potential of other cancer cell lines such as PC-3.

HPSE 1 expression correlates with the invasive potential of DU145 prostate tumor cells.

T.M. Augusto^{1,2}, G.O. Barbosa², L.C. Dos Santos³, R.G. Jaeger³, H.F. Carvalho²;

¹Clinical Department, Faculty of Medicine of Jundiai, Jundiai SP, Brazil, ²Structural and Functional Biology Department, State University of Campinas, Campinas SP, Brazil, ³Department of Cell and Developmental Biology, University of Sao Paulo, Institute of Biomedical Sciences, Sao Paulo SP, Brazil

The prostate gland is target of several disorders including prostatitis, benign hyperplasia and cancer. Together, these diseases are responsible for a large fraction of discomfort and non-accidental deaths among men with advancing age. The knowledge of regulatory mechanisms underlying prostatic diseases would be important to better understand prostate growth and physiology. The degradation of basement membrane components and other molecules of the extracellular matrix is a critical step of the cascade events leading to metastasis. Tumor cells degrade these components using a variety of enzymes such as heparanase-1 (HPSE1) and matrix metalloproteinases (MMPs). The HPSE1 is an endoglycosidase that degrades heparan sulfate chains. HPSE1 overexpression is closely related with tumor reduced postoperative patients affected by cancer processes, metastatic potential, tumor vascularity and survival. This prompted us to modulate HPSE1 expression in a prostate cell line (DU145), to determine the effect of this modulation on invasive phenotype. DU145 cells had HPSE1 either overexpressed or depleted by shRNA. Parental cells served as controls. Cells in these different conditions were evaluated for expression of HPSE1 and other molecules related to adhesion, invasion and invadopodia activity. Fluorescent substrate degradation assay showed that the HPSE1 overexpressing clone presented HPSE1 expression colocalized with areas of substrate degradation, suggesting that heparanase would be involved with invadopodia activity. Furthermore, immunoblot showed that overexpression of HPSE1 increased levels of cortactin, a protein related to invadopodia formation and the metalloproteinase

MT1-MMP. Overexpression of HSPE1 increased invasive activity of DU145 cells, as shown in Boyden chambers coated with Matrigel. We addressed signaling mechanisms related to HSPE1 effects. Immunoblot showed that both total and phosphorylated FAK correlated with HPSE1 expression levels. We conclude that HPSE1 overexpression correlates with invasive potential of DU145 prostate tumor cells. Moreover, HPSE1 assembles with other membrane receptors/enzymes at the sites of matrix degradation. Financial support from CNPq (Universal 478813/2011-2) and FAPESP (Grants 2011/08559-1 and 2009/16150-6).

Expression and subcellular distribution of β -dystroglycan and nuclear envelope proteins in prostate cancer.

A.M. Sandoval¹, B. Cisneros²;

¹CINVESTAV, Zacatecas, Mexico, ²Genetics and Molecular Biology, CINVESTAV, Mexico, D.F., Mexico

The dystrophin glycoprotein complex, DAPC is a membranal protein complex involved in the structure and function of the plasma membrane during the muscle contraction-relaxation process. Key proteins of this complex are α - and β -dystroglycan, which provide a link between the extracellular matrix and the cyto skeleton through their interaction with extracellular matrix and cytoskeleton proteins respectively. β -dystroglycan is imported to the nucleus via recognition of its nuclear localization signal (NLS) by importins. Nuclear β -dystroglycan interacts with the nuclear envelope proteins emerin and lamins A/C and B1. β -dystroglycan has a molecular weight of 43 kDa, but a 30 kDa fragment is generated through its proteolytic cleavage by the extracellular matrix metalloprotease MMP9.

β -dystroglycan and lamins A/C and B1 have recently been related to certain types of cancers. Particularly, nuclear accumulating of 30 kDa β -dystroglycan as well as an altered expression of lamins B1 and A/C have been revealed in prostate cancer. In the present study we analyzed the subcellular distribution of β -dystroglycan in different prostate cancer cell lines with varying degrees of invasiveness, using immunofluorescence assays. We noted that β -dystroglycan accumulates in the nucleus and nucleolus of the cancer cells with less invasiveness, and interestingly, the nuclear localization of β -dystroglycan disappeared in the more invasive cells. Then, we will examine whether the gain and subsequent loss of the nuclear function of β -dystroglycan is related to an aberrant function of nuclear envelope proteins such as emerin and lamins A/C and B1 during prostate cancer progression.

P1885**Board Number: B392****Role of Keratin 8 phosphorylation in neoplastic progression of squamous cell carcinoma.**R. Tiwari¹, H. Alam², M.M. Vaidya³;

¹Vaidya lab, Advanced Centre for Treatment, Research and Education in Cancer (ACTREC), Navi Mumbai, India, ²Dept. of Molecular and Cellular Oncology, The University of Texas M D Anderson Cancer Center, Houston, TX, ³Vaidya Lab, Advanced Centre for Treatment, Research and Education in Cancer (ACTREC), Navi Mumbai, India

Keratins were thought to be mere structural proteins whose known function was maintenance of structural integrity of cell. But recent progress in the field of keratin biology has indicated that, they do have key regulatory functions. We have previously shown role of Keratin 8 and 18 in malignant transformation in stratified epithelial cells (Raul, Sawant et al. 2004). Results from previous study in our lab suggests that K8 and K18 promote cell motility and tumor progression, possibly by deregulating $\beta 4$ integrin signaling in OSCC (Alam, Kundu et al. 2011). K8/18 undergoes several post translational modifications including phosphorylation, which is known to regulate various cellular processes; however its significance in neoplastic progression is still emerging. Our mutational studies showed that loss of K8 phosphorylation leads to increased migration and tumorigenicity (Alam, Gangadaran et al. 2011) in OSCC cells although the mechanism responsible for these phenotypes is still largely unknown. Next we wanted to investigate role of K8 phosphorylation in skin epidermoid carcinoma cell line (A431) at phenotypic and molecular levels. In order to address this question we have stably knocked down Keratin 8 in A431 cells which led to decrease in tumorigenic potential of the cell like migration and soft agar colony formation. Further in K8 null background shRNA resistant flag tagged K8 wild type, Phospho-dead and phospho-mimetic mutants were stably over expressed. To our surprise A431 cells showed significant decrease (2 fold) in cell migratory and invasive phenotype of phospho-dead clones in comparison to wild type. Contrary to that phospho-mimetic clones showed significantly more migratory and invasive behaviour compared to phospho-dead clones (1.5 folds) and is more towards wild type. To further validate our results in vivo we are investigating the role of K8 phosphorylation using transgenic mouse model system. In this direction we are generating tissue specific transgenic mouse expressing K8 wild type and phospho-mutants. We are also investigating the molecular basis for these changes related to K8 phospho- mutants in skin carcinoma derived cells. These studies would help us to better understand the role of K8 phosphorylation in tumour progression of SCC.

P1886**Board Number: B393****ELK3 expression correlates with cell migration, invasion and membrane type 1-matrix metalloproteinase expression in MDA-MB-231 breast cancer cells.**K. Park¹, S. Heo²;¹CHA University, Seong-Nam Si, Korea, ²CHA University, SungNam, Korea

ELK3 is a member of the Ets family of transcription factors. Its expression is associated with angiogenesis, vasculogenesis and chondrogenesis. ELK3 inhibits endothelial migration and tube formation through the regulation of MT1-MMP transcription. This study assessed the function of ELK3 in breast cancer (BC) cells by comparing its expression between basal and luminal cells in silico and in vitro. In silico analysis showed that ELK3 expression was higher in the more aggressive basal BC cells than in luminal BC cells. Similarly, in vitro analysis showed that ELK3 mRNA and protein expression was higher in basal BC cells than in normal cells and luminal BC cells. To investigate whether ELK3 regulates basal cell migration or invasion, knockdown was achieved by siRNA in the basal BC cell line MDA-MB-231. Inhibition of ELK3 expression decreased cell migration and invasion and downregulated MT1-MMP, the expression of which is positively correlated with tumor cell invasion. In silico analysis revealed that ELK3 expression was associated with that of MT1-MMP in several BC cell lines (0.98 Pearson correlation coefficient). Though MT1-MMP expression was upregulated upon ELK3 nuclear translocation, ELK3 did not directly bind to the 1.3 kb promoter region of the MT1-MMP gene. These results suggest that ELK3 plays a positive role in the metastasis of BC cells by indirectly regulating MT1-MMP expression.

P1887**Board Number: B394****Cytochrome c Oxidase dysfunction induces retrograde signaling and invasive phenotype.**S. Srinivasan¹, M. Guha², D. Dong¹, G. Ruthel¹, K. Whelan¹, Y. Uchikado³, S. Natsugoe³, H. Nakagawa¹, N.G. Avadhani⁴;¹University of Pennsylvania, Philadelphia, United States, ²Animal Biology, University of Pennsylvania, Philadelphia, PA, ³Kagoshima University, Kagoshima, Japan, ⁴Department of Animal Biology School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA

Defects in OXPHOS complexes are associated with several diseases including cancer. Mitochondrial DNA (mtDNA) defects such as deletions, point mutations and reduced DNA copy number, that affect activities of electron transport chain (ETC) complexes strongly correlate with incidence of cancer. Cytochrome oxidase (CcO) is the terminal enzyme of the ETC that catalyzes the transfer of electrons from reduced cytochrome C to oxygen. The mammalian enzyme is a bigenomic complex with three subunits coded by MtDNA and ten by nuclear DNA. MtDNA mutations affecting CcO subunits I, II and III are prevalent in prostate, pancreatic, colon and ovarian cancers. These mutations cause premature chain termination,

impaired proton pumping or reduced kinetic activity and possibly due to severe structural perturbation. All these mutations result in significant loss of enzyme activity and respiratory defect. However studies on loss of function of nuclear subunits affecting Cytochrome oxidase activity related to tumor progression are limited. Earlier work from our lab showed that various conditions like exposure to long term hypoxia, ischemia-reperfusion and treatment with ethanol result in selective degradation of nuclear subunits IVi1 and Vb of CcO leading to a loss of activity. Here we show a role for the disruption of CcO in cancer progression. Genetic silencing of the CcO complex in C2C12 myoblasts and loss of activity resulted in metabolic shift to glycolysis. This was complemented by increased expression of glucose transporters and glucose uptake. Interestingly, these cells formed multicellular colonies on soft agar plates suggesting anchorage independent growth, a property absent in normal cells. Disruption of CcO complex caused loss of transmembrane potential and induction of Ca²⁺/Calcineurin mediated retrograde signaling. Whole genome expression analysis showed significant up regulation of genes involved in cell signaling, extracellular matrix interactions, cell morphogenesis, cell motility and migration. In support of these, esophageal tumors from human patients revealed reduced CcO subunits IVi1 and Vb. Our results show that mitochondrial ETC defect initiates a retrograde signaling, which induces a tumorigenic phenotype. Supported by NIH grants CA-22762 and GM-34883.

Metastatic breast tumors undergo epithelial-to-mesenchymal transition (EMT) which renders them resistant to therapies targeted to the primary cancers. The mechanistic link between MtDNA reduction, often seen in breast cancer patients and EMT is unknown. We demonstrate that reducing MtDNA content in human mammary epithelial cells (hMECs) activates Calcineurin-dependent mitochondrial retrograde signaling pathway which induces EMT-like reprogramming to fibroblastic morphology, loss of cell polarity, contact inhibition and acquired migratory and invasive phenotype. Notably, MtDNA-reduction and mitochondrial respiratory stress in hMECs correlates with a high percentage of CD44^{hi}/CD24^{lo} cells, which in serial dilution assays showed increased self-renewal and mammosphere-forming capacity in 3D culture, characteristics of breast cancer stem cells. Mechanistically, we showed that Mt-retrograde signaling in hMECs regulates alternative splicing (AS) by loss of ESRP1, which favors

EMT. In addition to retrograde signaling markers, there is an induction of mesenchymal genes but loss of epithelial markers in these cells. The changes are reversed by either restoring the MtDNA content or knockdown of calcineurin α mRNA indicating the causal role of retrograde signaling in EMT. Our results point to a new therapeutic strategy for metastatic breast cancers targeted to the mitochondrial retrograde signaling pathway for abrogating EMT and attenuating cancer stem cells, which evade conventional therapies. We report a novel regulatory mechanism by which low MtDNA content generates EMT and cancer stem cells in hMECs. (Supported by NIH grant CA-22762 to NGA).

Is HPV causative factor in oral cancer?.

I. Kwon¹, S. Kim^{1,2}, H. Fan², Y. Cho², M. Eo², E.K. Amponsah³;

¹Department of Oral and Maxillofacial surgery, School of Dentistry, Seoul National Univesity, Seoul, Korea, ²Dental Research Institute, School of Dentistry, Seoul National Univesity, Seoul, Korea,

³Department of Oral and Maxillofacial Surgery, Brong Ahafo Regional Hospital, Sunyani, Ghana

Human papillomavirus (HPV) is the main source of cervical cancer. Recently, HPV, associated with oropharyngeal cancer has been reported in some literatures, but there are a few affordable data about incidence of HPV in oral cancer. The purpose of this study is to review the previous articles and to find the incidence and types of HPV in specific areas of oral cavity. We examined total 239 patients for HPV detection. Specimens were extracted from main mass during surgery, and performed for HPV typing by DNA chip kit. Available DNA chip kit (MY-HPV chip kit[®], Mygene Co., Korea) was used for detection of low risk HPV types (6, 11, 34, 40, 42, 43, 44) and high risk HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 54, 56, 58). DNA isolation was performed using DNA extraction buffer via centrifugation, and DNA amplification was carried on by polymerase chain reaction (PCR) using primer, B-globin primer for control group, taq polymerase, template DNA, four types of deoxynucleotides (dNTP) and buffer solution. Second PCR product was mixed with hybridization buffer for hybridization. Among 239 patients, histologic results showed that most of them were squamous cell carcinomas, 174 patients. Among the thirteen HPV positive cases, twelve cases was squamous cell carcinoma (6.90%). In SCC patients, five cases on tongue (11.9%), six cases on lower gum (10.5%), one case on upper gum (2.8%) had positive results. Among thirteen HPV positives, the number of high risk types was seven. Because prognosis of HPV positive tumor is known to be much better than that of HPV negative tumor, HPV detecting methods, such as HPV DNA chip method, may be great values to use. By evaluating the incidence of HPV in oral cancer, we can predict the prognosis of oral cancer patients and treat the patient properly. Vaccine may also be used to prevent HPV induced carcinogenesis in patients who are prone to develop oral cancer. "This research was supported by the International Research & Development Program of the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT & Future Plannig(Grant number: 2014K1A3A9A01033785)"

P1890**Board Number: B401****CXCR4 Gradient Sensing generates unique signaling kinetic signatures, and drives ERK to Invadopodia in Metastatic Breast Cancer Cells.**B. Winant¹, J. Freed¹, J. Stewart¹, M. Sobel¹, M. Campbell¹, K.A. Myers², C.C. Moore¹;¹Department of Pharmaceutical Sciences, Philadelphia College of Pharmacy, University of the Sciences, Philadelphia, PA, ²Department of Biological Sciences, Misher College of Arts and Sciences, University of the Sciences, Philadelphia, PA

During development, the chemokine G protein-coupled receptor CXCR4 is essential for directional migration of select neuronal, cardiovascular, and hematopoietic cells in response to sensing a gradient of SDF ligand. During disease, the SDF-CXCR4 axis plays a critical role in breast cancer metastasis by promoting the directional migration of primary tumor cells to distal SDF-expressing organs. Despite these observations, the biochemical signaling pathways downstream of motility inducing SDF gradients are unknown. Previously, we identified unique CXCR4 pathways and signaling kinetic signatures associated with SDF gradient sensing, including a novel Arf6-ERK motility pathway and a sustained MAPK signaling pathway atypical for GPCRs but reminiscent of GFR signaling during malignancy. Here we extended these findings using microarray and IB analysis, and identified that gradient SDF also leads to sustained Akt activation, and both the Akt and ERK pathways are inhibited by wortmannin or LY294002. Notably, both pathways regulate processes critical to the malignant phenotype including invadopodia formation. Here we also extended our previous findings using Matrigel invasion assays, pseudopodia isolation, and confocal imaging of invadopodia, and determined that the novel Arf6-ERK motility pathway also mediates cell invasion in metastatic breast cancer cells, and that Arf6 drives ERK to membranous structures including pseudopodia and invadopodia in response to gradient SDF. These results provide insight into the biochemical signaling pathways downstream of CXCR4 gradient sensing, with implications on the invasive phenotype of metastatic breast cancer cells.

These studies were supported by NIH grant GM-097718. JS, MS, MC contributed equally.

P1891**Board Number: B402****A noncanonical Frizzled2 pathway regulates epithelial-mesenchymal transition, tumor progression, and metastasis.**T. Gujral¹, M. Chan¹, L. Peshkin^{1,2}, P.K. Sorger^{1,3}, M.W. Kirschner^{1,2}, G. MacBeath¹;¹Systems Biology, Harvard Medical School, Boston, MA, ²Department of Systems Biology, Harvard Medical School, Boston, MA, ³Harvard Med Sch, Boston, MA

Wnt signaling plays a critical role in embryonic development, and genetic aberrations in this network have been broadly implicated in colorectal cancer. Less is known, however, about its role in epithelial-mesenchymal transition (EMT) and cancer metastasis. We found that the Wnt receptor Frizzled2 (Fzd2)

and its ligands Wnt5a/b are elevated in metastatic liver, lung, colon, and breast cancer cell lines and in high-grade tumors, and that their expression correlates with markers of EMT. Pharmacologic and genetic perturbations revealed that Fzd2 drives EMT and cell migration through a previously unrecognized, non-canonical pathway that includes Fyn and Stat3; a gene signature regulated by this pathway predicts metastasis and overall survival in patients. We have developed an antibody to Fzd2 that reduces cell migration and invasion and inhibits tumor growth and metastasis in xenografts. We posit that targeting this pathway could provide benefit for patients with tumors expressing high levels of Fzd2.

THE ROLE OF SIALOPHORIN (CD43) DURING TUMOR PROGRESION.

R. Espinosa-Neira¹, E. Melchy¹, Y. Rosenstein¹;

¹Instituto de Biotecnología, Universidad Nacional Autónoma de México, Cuernavaca, Mor., Mexico

Mucins constitute a selective molecular barrier at the epithelial surface. Alterations in their expression or glycosylation profile impact cellular growth, differentiation, adhesion, transformation and invasion, promoting the development of cancer. **CD43** (Sialophorin) is a mucin expressed by lymphoid cells. However, CD43 expression has been documented in several types of non-lymphoid tumors, such as lung, colon and breast cancer, correlating with poor prognosis. We have shown that CD43 promotes cell transformation by abrogating the contact inhibition of growth through a molecular mechanism involving Akt-dependent Merlin phosphorylation and degradation, that eventually lead to cell survival, proliferation and tumor growth in the CD43+ A549 and Caski cells. The aim of this study is to explore the biological effects and mechanisms of CD43 expression confers to highly invasive breast cancer cells **MDA-MB-231** lacking the expression of endogenous CD43. Through a structure/function analysis, we will discuss how the expression of three different constructs of the human CD43 molecule (CD43 WT, CD43 Δ Pro (-25 a.a. from COOH-terminal), and CD43 Δ IC (a form devoid of the intracellular domain) impacts processes such as proliferation, survival, migration, and invasion of MDA-MB-231 tumor cells. Likewise, we will analyze how the signaling pathways related to these biological processes, among which the PI3K/Akt and Wnt/ β -catenin pathways (involved in migration and invasion) are modified by CD43 expression. Our results provide clues about the importance of CD43 in the breast cancer biology. (Partially funded by CONACyT and PAPIIT/UNAM, Mexico).

Endothelial podosome rosettes regulate vascular branching in tumor angiogenesis.

G. Seano^{1,2,3}, G. Chiaverina^{1,2}, P. Gagliardi^{1,2}, L. di Blasio^{1,2}, A. Puliafito^{1,2}, C. Bouvard⁴, R. Sessa^{1,2}, G. Tarone⁵, L. Sorokin⁶, D. Helley⁷, R. Jain³, G. Serini^{1,2}, F. Bussolino^{1,2}, L. Primo^{1,2};

¹Department of Oncology, University of Torino, Torino, Italy, ²Candiolo Cancer Institute-FPO, Candiolo, Italy, ³Radiation Oncology, Harvard Medical School - MGH, Boston, MA, ⁴UMR-S 765, Université Paris Descartes, Paris, France, ⁵Department of Molecular Biotechnology and Health Sciences, University of Torino, Torino, Italy, ⁶Institute of Physiological Chemistry and Pathobiochemistry, Muenster University, Muenster, Germany, ⁷UMR-S 970, Université Paris Descartes, Paris, France

The mechanism, by which angiogenic endothelial cells break the physical barrier of vascular basement membrane and consequently sprout, forming new vessels in mature tissues, is unclear. Here, we show that angiogenic endothelium is characterized by the presence of functional podosome rosettes. These extracellular matrix-degrading and adhesive structures are precursor of de novo branching points and represent a key event in the formation of new blood vessels. VEGF-A stimulation induces the formation of endothelial podosome rosettes by up-regulating integrin $\alpha 6\beta 1$; in contrast, the binding of $\alpha 6\beta 1$ integrin to vascular basement membrane laminin impairs the formation of podosome rosettes by restricting $\alpha 6\beta 1$ integrin to focal adhesions and hampering its translocation to podosomes. Using ex vivo sprouting angiogenesis assay, transgenic and knock-out mouse models and human tumor samples analysis, we provide the first evidence that endothelial podosome rosettes control blood vessels branching and are critical regulators of pathological angiogenesis.

Impact of mechanical stress on Multicellular Tumor Spheroids proliferation.

V. Lobjois¹, A. Desmaison¹, L. Aoun¹, B. Ducommun¹;

¹CNRS USR3505 ITAV, Toulouse, France

A tumor micro-region consists of a 3D heterogeneous cell population in which cancer cells growth is influenced by interaction with the microenvironment. The crosstalk between tumor cells and microenvironmental components, including the extracellular matrix (ECM), fibroblasts, endothelial and immune cells, is essential for tumor progression and plays a key role in drug resistance. In such a complex environment, solid tumors are also subjected to mechanical stress that influences their growth rate and development. Indeed, modification in mechanical homeostasis within tissues are also observed during tumor growth. However, little is known about the effects of such mechanical stress on tumor cell

biology and their pharmacological consequences. To explore this issue, we investigated the impact of mechanical stress on cell proliferation in Multicellular tumor spheroids (MCTS) in which cancer cells are cultured as 3D organized spheres. Such complex multicellular model reproduces the cell-cell and cell-matrix interactions found in solid tumors. Moreover, MCTS can grow up to several hundred micrometers in diameter, thus progressively displaying a gradient of proliferating cells similar to what is found in tumor micro-regions. Specifically, in large spheroids, dividing cells are located in the outmost layers while quiescent cells are found in more central hypoxic and nutrient-poor regions. Using this model, we showed, by using PDMS microdevices, that spheroids can grow under mechanical confinement and that reciprocal resistance from the PDMS walls opposed to spheroids growth induces mechanical stress. In these conditions, we demonstrated that growth-induced mechanical stress induces mitotic accumulation inside spheroids. We then monitored the impact of mechanical stress on the progression in mitosis using light sheet fluorescence microscopy. We developed specific sample holders that enabled us to explore 3D mitosis dynamics inside spheroids in control and confined conditions. By measuring the duration of each phase of mitosis, we demonstrated that mechanical stress induces a prometaphase delay. As growing solid tumors also exert forces on their microenvironment, in order to evaluate the mechanical properties of growing spheroids, we designed and produced microdevices arrays of high aspect ratio pillars. Using these microdevices, we investigated the forces exerted by spheroids from various cell lines. We will present our latest results on the impact of these specific controlled environments on cell proliferation and 3D organization of spheroids.

Retention of Somatic Mutations in Cancers by Gain in pH Sensing.

K.A. White¹, Z.A. Szpiech², D. Garrido Ruiz³, N.B. Strauli², M.P. Jacobson³, R. Hernandez², D.L. Barber¹;
¹Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA, ²Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA, ³Department of Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA

A critical unresolved question in cancer is how somatic mutations are selectively retained and what selective pressures direct this process. One common feature of cancers is constitutively increased intracellular pH (pHi) that enables diverse cancer cell behaviors, including increased cell proliferation and migration as well as metabolic adaptation and decreased apoptosis. We propose that increased pHi provides a selective pressure for the retention of somatic mutations in some human cancers and that these mutations provide an adaptive advantage to the increased pHi of cancer cells. Here, we focus on Arg>His mutations, predicting that replacing a non-titratable arginine (pKa 12) with a titratable histidine (pKa 6.5) may confer pH sensitive function (pH sensing) to the mutant protein. To determine whether Arg>His mutations are selectively retained, we performed bioinformatics analyses of COSMIC and

tumor/normal paired sequencing datasets. These analyses revealed that Arg>His mutations are significantly overrepresented in a subset of cancers including stomach, prostate, colorectal, and glioma. Arg>His mutations are enriched even after accounting for codon bias and CpG site frequency, suggesting selective pressure may drive retention. Next, we investigated whether Arg>His mutations confer an adaptive advantage to cancer cells. We identified Arg>His somatic cancer mutations in p53 and EGFR and tested mutants for a gain in pH sensing. First, we show that the most highly recurrent p53 mutation in cancer, p53-R273H, has pH-sensitive promoter binding with decreased DNA binding at the increased pHi of cancer cells, while wild-type p53 promoter binding is pH insensitive. We predict that Arg273 interacts with the phosphate backbone of DNA, and His273 is less able to form stable interactions with negatively charged DNA at higher pHi. Second, we investigated two Arg>His mutations in EGFR that are found in mesotheliomas and lung cancer: R776H and R831H. Using both in vitro and cell-based assays, we found that the kinase activity of these mutants is pH sensitive with increased activity at higher pH, while wild-type EGFR kinase activity is pH insensitive. Additionally, molecular dynamics simulations suggest potential mechanisms for pH sensing by EGFR-R776H, including critical conformational changes in the α C helix of the kinase domain resulting from changes in histidine protonation. These data suggest that Arg>His somatic mutations can confer adaptive pH sensing to p53 and EGFR. Together, our studies integrate whole-genome bioinformatics, biochemical, cellular, and structural analyses to show that the increased pHi of cancer cells may be a selective pressure driving retention of Arg>His mutations that may confer adaptive pH sensing to tumorigenic proteins.

PDLIM2 is required for macrophage subset differentiation with implications for cytokine production in tumor microenvironment.

E. Tresse¹, O.T. Cox¹, S.J. Edmunds¹, M. Coleman¹, R. O'Connor¹;

¹Biochemistry and Cell Biology, University College Cork, Cork, Ireland

The PDZ-LIM domain protein PDLIM2 is associated with an invasive cancer phenotype [1] and integrates cytoskeleton signalling with regulation of gene expression during epithelial cell differentiation [2]. PDLIM2 is also expressed in hematopoietic cells and regulates NF κ B and STAT transcription factor stability in macrophages and lymphocytes [3] [4]. Macrophage infiltration may correlate with a poor prognosis in many types of human cancer. We hypothesized that PDLIM2 activity in macrophages may influence their phenotype and thereby the cancer microenvironment. To test this we investigated PDLIM2's contribution to the classically activated pro-inflammatory subtype (M1) and the alternatively activated (M2) macrophage subtypes using bone marrow derived macrophages (BMDM) from PDLIM2 WT and knockout (-/-) mice that were stimulated in vitro. We found that PDLIM2 moves from the nucleus to the cytoplasm in response to different activation stimuli, although NO and iNOS levels were similar in BMDM from WT and -/- mice. BMDM from PDLIM2 -/- mice exhibited altered inflammatory cytokine profiles with increased IL-6 and decreased IL-1 β compared to WT BMDM. MIF expression and nuclear retention of the IRF-3/CPB complex was also enhanced in PDLIM2-/- macrophages. M2-polarized

macrophages derived from PDLIM2^{-/-} BMDM exhibited reduced migratory capacity, delayed pro-angiogenic cytokine production, and failed to suppress pro-inflammatory cytokine expression. Altogether, our results demonstrate that PDLIM2 is essential for complete M2 polarization and for suppression of the M1 phenotype. Thus PDLIM2 expression in macrophages could have impact cancer progression by controlling macrophage phenotype and cytokines in the tumour microenvironment.

Tumor cell motility in microenvironment context: From intravital microscopy to systems view.

B. Gligorijevic^{1,2}, J.S. Condeelis³, A. Bergman¹;

¹Systems and Computational, Albert Einstein College of Medicine, Bronx, NY, ²Department of Bioengineering, Temple University, Philadelphia, NY, ³Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

While it has been established that a number of microenvironment components affect the likelihood of metastasis, the influence of various determinants between microenvironment and tumor cell phenotypes is poorly understood. Here we have examined factors affecting microenvironment control over two different tumor cell motility phenotypes required for metastasis. By high-resolution multiphoton microscopy of mammary carcinoma in mice, we detected two phenotypes of motile tumor cells, different in locomotion speed. Slow- and fast-locomotion occurred at different spatio-temporal coordinates and only 3/184 regions showed both behaviors. Slower tumor cells exhibited invadopodia, small, cortactin-rich protrusions with capability of degrading extracellular matrix. To understand how the tumor microenvironment controls invadopodium formation and tumor cell locomotion in general, we systematically analyzed components of the microenvironment previously associated with cell invasion and migration. No single microenvironmental property was able to predict the locations of tumor cell phenotypes in the tumor when used in isolation or combined linearly. To solve this, we combined multiphoton microscopy with the Support Vector Machine (SVM) algorithm to classify phenotypes in a nonlinear fashion. This approach identified conditions that promoted either motility phenotype. We then demonstrated that varying one of the conditions can either change the number of tumor cells with invadopodia or switch tumor cell behavior in a context-dependent manner. In addition,

to establish the link between motility phenotypes and cell fates, we photoconverted and monitored the fate of tumor cells in different microenvironments, finding that only tumor cells in the invadopodium-rich microenvironments, but not in microenvironments where fast-locomotion occurred, have degraded surrounding extracellular matrix and disseminated. The number of invadopodia positively correlated with ECM degradation, while the MMP-inhibitor inhibiting metalloproteases inhibited eliminated degradation and stopped lung metastasis, consistent with a direct link among invadopodia, ECM degradation and metastasis. In summary, we have detected and characterized two phenotypes of motile tumor cells in vivo, which occurred in spatially distinct microenvironments of primary tumors. We show how machine-learning analysis can classify heterogeneous microenvironments in vivo to enable prediction of motility phenotypes and tumor cell fate. The ability to predict the locations of tumor cell behavior leading to metastasis in mouse models of breast cancer models has the potential for identifying may lead towards understanding the mechanisms behind the heterogeneity of response to treatment.

Developmental control of regeneration signaling determines the timing and location of neoplastic transformation in epithelial tumors.

A. Halme¹, T. Tran², R. Garrett¹, R. Bhandari¹;

¹Department of Cell Biology, University of Virginia, Charlottesville, VA, ²University of Virginia, Charlottesville, VA

The emergence of several tumor types in humans is correlated with specific developmental transitions (e.g. thyroid carcinoma and malignant melanoma at puberty). Since the expression of tumorigenic phenotypes by cells depends on the interaction between genetic changes within the cells and their environment, tumor formation in these instances may rely on developmental signals produced within specific tissues at specific times.

To examine how developmental signaling context interacts with cellular mutations to produce tumorigenic phenotypes, we are studying the emergence of neoplastic epithelial tumors that result from mutation in the tumor-suppressor genes *avalanche* or *lethal giant larvae* in *Drosophila* wing imaginal discs. We have observed that the expression of the neoplastic tumor phenotype resulting from either of these mutations begins at a specific time in development that is correlated with the increased activity of a steroid endocrine signal, ecdysone. We have shown that ecdysone promotes neoplastic transformation in *avalanche* or *lethal giant larvae* mutant cells by signaling through its nuclear receptor (EcR) within mutant cells. Furthermore, we demonstrate that the role of ecdysone in promoting tumor progression is through regulating transcription of a specific gene, *wingless*, that functions in normal development of the wing imaginal disc, and is activated in both neoplastic tumors and during epithelial tissue regeneration. The ecdysone-dependent activation of *wingless* in both neoplastic tumors and during regeneration function through a similar mechanism and gene regulatory region. Furthermore, activation of a regenerative response in wing discs through damage can potentiate tumorigenesis. Thus,

this regulation of *wingless* provides a direct link between tissue regenerative signaling and tumor development. Additionally, in undamaged wing imaginal discs we observe a regional bias for tumor initiation in *lethal giant larvae* mutant clones. We propose that this bias reflects underlying differences in regenerative capacity across the tissue.

In summary, we observe that neoplastic transformation by tumor-suppressor mutations is dependent on a developmentally-regulated regeneration signaling response. The capacity of the tissue to activate this regenerative pathway determines the timing and location of tumor formation.

Induction of Carcinoma-Associated Fibroblasts in 3D Cell Coculture.

J.C. Hanson¹, Y. Chen¹;

¹NCI, NIH, Bethesda, MD

Carcinoma-associated fibroblasts (CAFs) play a critical role in tumor progression and are associated with poor prognoses, high-grade malignancy, and hindrance of anti-cancer drug therapies. However the process in which normal fibroblasts (NFs) are transformed into CAFs is yet to be elucidated. To gain insight of this process, we constructed a coculture system where GFP-labeled NIH3T3 fibroblasts were cocultured in 3D extracellular matrix (ECM) with preformed acini containing normal, neoplastic (early stage) or metastatic (late stage) cancer mammary gland epithelial cells, respectively. The dynamic interaction between fibroblasts and epithelial cells were recorded by timelapse microscopy between 6-hour and 20-hour post seeding and tracked to characterize the behavioral difference of the cocultures. It was found that both neoplastic and metastatic cancer cells generated at least 2-fold more mechanical forces to remodel the ECM organization compared to the normal epithelial cells. Furthermore fibroblasts cocultured with cancer epithelial cells exhibited faster mobility compared to normal controls. Immunoblots revealed CAF markers such as phospho-myosin and vimentin are elevated in fibroblasts cocultured with neoplastic and metastatic epithelial cells, indicating CAF transformation can be initiated within 20 hours after NFs are in contact with cancer cells.

Morphine and Mast Cell Activation Stimulate Endothelial Dysfunction.

T. Duong^{1,2}, K. Luk², K. Gupta²;

¹California State University, Northridge, Canoga Park, CA, ²Vascular Biology, University of Minnesota, Minneapolis, MN

Although morphine is currently a predominant treatment for cancer-induced chronic pain, its pharmacological effects accelerate tumor progression. Morphine stimulates mast cells in the skin and

tumors of mice, leading to the release of cytokines and neuropeptides. Additionally, morphine-induced activation of mast cells stimulates angiogenesis, tumor progression, and contributes to vascular leakage leading to neurogenic inflammation and pain. Therefore, we examined if mast cell activation, particularly the release of cytokines and neuropeptides, has direct effects on tumor endothelium. To demonstrate the developmental spectrum of human breast carcinoma, transgenic mice with a rat C3(1) simian virus 40 large tumor antigen fusion gene were used. We also used primary mouse brain microvascular endothelial cells (MBMEC). We observed that morphine alters the tumor microenvironment by stimulating inflammation and neuroinflammation. IL-17, the master cytokine mediating the release of other neuropeptides and cytokines, was significantly increased in tumors of morphine treated mice vs PBS treatment (p

Extracellular vesicles from women with breast cancer promotes migration in MDA-MB-231 breast cancer cells.

J. Ramirez-Ricardo¹, O. Galindo-Hernandez¹, P. Cortes-Reynosa¹, F. Candanedo-Gonzalez¹, M. Sierra-Martinez², S. Chavez-Ocaña², E.P. Salazar¹;

¹Biología Celular, CINVESTAV, Mexico City, Mexico, ²Unidad de Investigacion. Servicio de Oncologia., Hospital Juarez de Mexico, Mexico City, Mexico

Breast cancer is the most common cancer and the leading cause of death in women worldwide and affects countries at all levels of development. Extracellular vesicles (EVs) are small membrane-enclosed sacs of endosomal and plasma membrane origin secreted by normal and malignant cells. The EVs represent an important mode of intercellular communication by serving as vehicles for transfer between cells of membrane and cytosolic proteins, lipids, and RNA. Particularly, EVs from tumor cells mediate many stages of tumor progression including angiogenesis, escape from immune surveillance, invasion and metastasis. The aim of this work was to determine the EVs number in plasma of breast cancer patients and healthy women, and whether EVs from breast cancer patients are able to induce migration of MDA-MB-231 breast cancer cells. We analyzed plasma fractions enriched in EVs and deprived of platelet-derived EVs obtained by differential centrifugation from blood samples of twenty-one Mexican female patients (median age 54 years, range 38-80 years) with biopsy-proven of breast cancer at different clinical stages and without receiving therapy. The control group consisted of 13 healthy females (median age 42.7 years, range 16-86 years). EVs number was evaluated by BD TruCOUNT Tubes (BD Biosciences) and migration was studied by scratch-wound assay. Our findings demonstrated that EVs number is higher in women with breast cancer with stages II and III compared with control group. In addition, EVs from breast cancer patients are able to induce migration of MDA-MB-231 cells and secretion of MMP-9.

P1902**Board Number: B413****Extracellular vesicles from MDA-MB-231 cells stimulated with linoleic acid induce an epithelial to mesenchymal transition-like process in mammary epithelial cells MCF10A.**O. Galindo-Hernandez¹, C. Rodriguez-Monterrosas¹, N. Serna-Marquez¹, R. Castillo-Sanchez¹, P. Cortes-Reynosa¹, E.P. Salazar¹;¹Biologia Celular, CINVESTAV, Mexico City, Mexico

Extracellular vesicles (EVs) are fragments of the plasma membrane secreted from cytoplasmic membrane compartments by normal and malignant cells and their function appear to be dependent on cargo they carry and the cell type which they originate. It has been described that EVs mediate many stages of tumor progression including angiogenesis, escape from immune surveillance and extracellular matrix degradation. Linoleic acid (LA) is an essential polyunsaturated fatty acid that induces migration and invasion in breast cancer cells. However, the role of EVs secreted from MDA-MB-231 cells stimulated with LA as promoter of the epithelial-mesenchymal-transition (EMT) process in mammary non-tumorigenic epithelial cells MCF10A remains to be studied. In the present study, we demonstrate that treatment of MDA-MB-231 cells with 90 μ M LA for 48 h does not induce an increase in the number of secreted EVs, however all the secreted EVs are taken up for MCF10A cells. In contrast, only the EVs isolated from supernatants of MDA-MB-231 stimulated with 90 μ M LA for 48 h are able to induce a transient down-regulation of E-cadherin expression, an increase of vimentin and N-cadherin protein levels, as well as an increase of MMP-2 and -9 secretions in MCF10A cells. Furthermore, EVs from MDA-MB-231 cells stimulated with LA also induce an increase of NF κ B-DNA binding activity, migration and invasion. In summary, our findings demonstrate, for the first time, that EVs isolated from supernatants of MDA-MB-231 stimulated with 90 μ M LA for 48 h induce an EMT-like process in human mammary non-tumorigenic epithelial cells MCF10A.

P1903**Board Number: B414****PROTEASE ADAMTS-1 ROLE IN LOCAL AND SYSTEMIC INVASION OF FIBROSARCOMA CELLS.**V.M. Freitas¹, M.C. Cruz², H.G. NORIEGA³;¹Department of Cell and Developmental Biology, University of Sao Paulo, Institute of Biomedical Sciences, Sao Paulo SP, Brazil, ²Center of Facilities and Support Research, University of Sao Paulo, Institute of Biomedical Sciences, Sao Paulo, Brazil, ³Departament of Cell and Developmental Biology, University of Sao Paulo, Institute of Biomedical Sciences, São Paulo, Brazil

Fibrosarcoma is a malignant tumor with the presence of immature proliferating fibroblast. The growth and malignancy of a tumor is dictated by the surrounding microenvironment. The extracellular matrix is

a reservoir of cell binding proteins and growth factors. ADAMTS-1 (*a disintegrin and metalloproteinase with thrombospondin motifs*) is a secreted protease that modified the extracellular matrix during malignant progression. We aim to evaluate the role of ADAMTS-1 within the tumor microenvironment of fibrosarcoma. Furthermore, we study the effects of the growth factors-binding ADAMTS-1. For *in vivo* studies we used zebrafish embryos at 48 hours post fertilization. HT1080 fibrosarcomacells (dyed in red) were resuspended in medium with 5nM ADAMTS-1 and injected into embryos's heart. Confocal microscopy images showed that in presence of ADAMTS-1, tumor cells were into the vasculature and some of them were arrested inside the intra segmental vases. Also a higher number of tumor cells interacted with the surrounding tissue and disseminate to distant sites. Moreover, to examine the metastatic behavior of fibrosarcoma cells, we injected them into the perivitelline space. We observed tumor cells were restricted into the yolk sac with invadopodia formation in presence of ADAMTS-1. For *in vitro* studies, Bromodeoxyuridine (BrdU) incorporation assay was used to evaluate cell proliferation. According to expected, increasing concentrations of VEGF led to increase of HT1080 cell proliferation. To analyze the effect of ADAMTS-1 overexpression in HT1080 cell migration, we used time-lapse imaging and MTrackJ plugin. We observed that ADAMTS-1 overexpression not stimulated the migratory activity of fibrosarcoma cells, and these cells presented a mean velocity of 4.20 $\mu\text{m}/\text{hour}$, whereas the velocity of control cells was 18.73 $\mu\text{m}/\text{hour}$. In contrast, the treatment of cells with ADAMTS-1 overexpressed with 10ng/ml VEGF leads to increase of cell migration with a mean velocity of 26.74 $\mu\text{m}/\text{hour}$, whereas the velocity of the control cells treated with VEGF was 7.23 $\mu\text{m}/\text{hour}$. VEGF was probably involved in ADAMTS-1 effects on fibrosarcoma cells. Our results suggest that ADAMTS-1 induced the interaction of fibrosarcoma cells with the stroma *in vivo*. Also ADAMTS-1 reduced fibrosarcoma cells migration *in vitro*. This study was approved by the Ethics Committee on Animal Use - CEUA (ICB-USP) n^o009 pg. 132. Exchange of microvesicles between breast tumor cells and normal fibroblasts.

T.A. Silva¹, R.P. Iglesia¹, M.C. Cruz², A. Zelanis³, M.V. Dias⁴, M.H. Lopes¹, S. Serrano⁵, V.M. Freitas⁶;
¹Cell Biology, ICB-USP, Sao Paulo, Brazil, ²Center of Facilities and Support Research, University of Sao Paulo, Institute of Biomedical Sciences, Sao Paulo, Brazil, ³Department of Science and Technology, Institute of Science and Technology, Federal University of São Paulo, São José dos Campos, Brazil, ⁴A. C. Camargo Cancer Center, São Paulo, Brazil, ⁵Butantan Institute, São Paulo, Brazil, ⁶Department of Cell and Developmental Biology, University of Sao Paulo, Institute of Biomedical Sciences, Sao Paulo SP, Brazil

The successful development of tumors is driven by the tissue microenvironment. Cancer development is not only dependent on mutation in cancer cells, but it is also dependent on interaction of cells and their surrounding stroma. Some cell types release vesicular structures into the extracellular space. These vesicles would be involved in cellular signaling and tumor progression. The aim of this study was to analyze *in vitro* interactions between cells of tissue microenvironment (fibroblasts) and tumor cells. Co-

culture assays were carried out with non-tumoral fibroblasts and tumor breast cells (MDA-MB-231). Cells were loaded with different vital dyes. Tumor cells were plated on top of a fibroblasts monolayer. After 24 hours cells were fixed and analyzed by confocal microscopy. Three-dimensional reconstruction showed exchange of vesicles with heterogeneous size. In order to characterize these vesicles, cells were analyzed by transmission electron microscopy (TEM). Conditioned medium from tumor cells was centrifuged, and vesicles counted and analyzed by NanoSight. The conditioned medium was further characterized by LC-MS/MS and immunoblot. Protein AHNAK (desmoyokin) was identified in conditioned medium by mass spectrometry. Immunofluorescence showed the presence of the AHNAK in the exchanged vesicles from co-cultured cells. Co-culture and NanoSight showed high number of vesicles in tumor cells compared to normal cells. Our results showed evident microvesicle exchange between breast cancer cells and stroma. The protein AHNAK was detected in exchanged vesicles, and could represent a microenvironmental molecule influencing mammary tumor biology. This study was approved by and Ethics Committee on Human Research - CEPISH (ICB-USP). Supported by FAPESP (2010/07699-1 and 2011/09472-7).

Hypoxic primary tumor stress microenvironments prime DTCs in lungs for dormancy.

G. Fluegen¹, A. Avivar-Valderas¹, Y. Wang², M.R. Padgen³, Y. Estrada¹, J.K. Williams³, D. Entenberg⁴, K.W. Eliceiri⁵, P.J. Keely⁵, J. Castracane³, V.V. Verkhusha⁶, J.S. Condeelis², J.A. Aguirre-Ghiso^{7,8};

¹Icahn School of Medicine at Mount Sinai, New York, NY, ²Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ³SUNY College of Nanoscale Science and Engineering, Albany, NY, ⁴Albert Einstein College of Medicine, Bronx, NY, ⁵University of Wisconsin-Madison, Madison, WI, ⁶Anatomy and Structural Biology and Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, ⁷Black Family Stem Cell Institute, Manhattan, NY, ⁸Division of Hematology and Oncology, Mount Sinai School of Medicine, Department of Medicine, NY

The mechanisms behind dormancy of disseminated tumor cells (DTCs) are unclear. Further, whether primary tumor microenvironments might influence DTC fate has never been explored in situ. We found that breast tumors enriched for a specific dormancy signature (DS+) displayed longer metastasis-free periods than those poor (DS-) for the signature. Key genes in the DS induce quiescence and are also regulated by hypoxia. Interestingly, a main response of tumor cells to hypoxia is growth arrest. We hypothesized that hypoxic primary tumor microenvironments may spawn a subpopulation of DTCs that, by virtue of becoming dormant, might escape therapies and eventually fuel incurable metastasis. We used H2B-EGFP inducible HEp3 HNSCC and photo-switchable (green-to-red fluorescence) H2B-Dendra2 expressing MDA-MB-231 and ZR-75-1 human breast cancer cell lines to identify cells from hypoxic microenvironments. To initiate spatially defined hypoxic microenvironments in primary tumors we implanted induction NANO IntraVital Devices (iNANIVIDs) carrying hypoxia-mimetic agents (i.e. desferrioxamine - DFOM) in T-HEp3 tumors in vivo (chicken chorioallantoic membrane (CAM) model) or

exposed cultured MDA-MB-231 or ZR-75-1 cells in vitro to either 21% or 1% O₂. The regions influenced by the DFOM-iNANIVID displayed upregulation of p27, NR2F1 and DEC2 (dormancy genes), as well as induction of hypoxia markers (GLUT1, HIF1 α). We found that lung DTCs derived by mouse tail vein injection of hypoxia induced H2B-EGFP T-HEp3 or H2B-Dendra2 MDA-MB-231 cells were primed to enter dormancy in lungs > 2 weeks after extravasation, as measured using H2B-EGFP and H2B-Dendra2-RED label retention. Using Vimentin to screen for HEp3 tumor cells in lungs, we found that DTCs originating from the iNANIVID induced hypoxic regions showed a dormant profile as evidenced by significant upregulation of p27, NR2F1 and DEC2 compared to DTCs originating from a normoxic milieu. Further, analysis in 3D culture models revealed that ER+/DS+ breast cancer cells (ZR-75-1) are more prone to enter a prolonged quiescent state after a brief exposure to hypoxia (1% O₂) while this response is not observed in triple negative/DS- breast cancer cells (MDA-MB-231). We propose that hypoxic primary tumor stress microenvironments induce a subpopulation of tumor cells to express the DS. Upon spreading these DTCs may be more prone to enter dormancy, evade anti-proliferative therapies and eventually fuel metastasis.

Matrix Compliance Regulates Tetraploidy in Mammary Epithelial Cells.

A.K. Simi¹, D.C. Radisky², C. Nelson^{1,3};

¹Chemical and Biological Engineering, Princeton University, Princeton, NJ, ²Cancer Biology, Mayo Clinic Cancer Ctr, Jacksonville, FL, ³Dept. of Molecular Biology, Princeton University, Princeton, NJ

Introduction: Cancer remains the second leading cause of death worldwide. The research that drove most current cancer therapies focused primarily on cancer cells themselves, when in reality tumor cells are constantly communicating with the local microenvironment. Through defining features such as hypoxia and stiffness, the tumor microenvironment can cause changes in molecular signaling that result in tumorigenic phenotypes. This study aims to elucidate whether the mechanical rigidity of the substratum regulates chromosomal instability in the form of tetraploidy. Tumors are inherently stiffer than normal tissue, and stiffness has been shown to cause changes in cell growth and proliferation. Similarly, cell cycle errors have long been linked to chromosomal abnormalities, a phenotype common to 85% of solid cancers. The mechanisms by which tissue compliance regulates chromosomal instability remain unclear, but may provide an avenue for new cancer treatments. Here, we investigated the effects of substratum stiffness on tetraploidy.

Materials and Methods: Mammary epithelial cells were plated on polyacrylamide gels of varying compliance (to mimic normal and tumor tissue) conjugated with the extracellular matrix protein fibronectin. Using epifluorescent microscopy, tetraploidy was easily observed as multinucleation. The signaling pathways controlling mechanical regulation of multinucleation were also investigated.

Results and Discussion: Mammary epithelial cells cultured on “stiff” substrata, representing tumor tissue, showed a nearly 14-fold increase in multinucleation compared to cells cultured on “soft”

substrata, representing normal tissue. Multinucleation was regulated in part by signaling downstream of matrix metalloproteinase-3 (MMP3), a protease responsible for remodeling of the extracellular matrix, and commonly found upregulated in cancer. This signaling depended on expression of the Rac1 splice variant, Rac1b, production of reactive oxygen species, and expression of Snail. Under all conditions, cells cultured on soft substrata maintained a low frequency of multinucleation.

Conclusions: Mammary epithelial cells show increased levels of multinucleation with increasing substratum stiffness. This trend suggests that abnormal mechanical characteristics of the tumor microenvironment promote genomic instability in cancer. One responsible mechanism is induced by MMP3; regulation of each component of the pathway shows a direct relationship to multinucleation. This pathway is inhibited on soft substrata, which protects against multinucleation. These data suggest that a drug that promotes the normalization of the microenvironment may be promising.

Understanding the role of protein palmitoylation during asymmetric cell division.

E. Stypulkowski¹, E. Witze¹;

¹Cancer Biology, University of Pennsylvania, Philadelphia, PA

Generating cellular heterogeneity is fundamental for the development of multicellular organisms and tissue homeostasis. A mechanism of generating cellular diversity is through polarized cell division (or asymmetric cell divisions), where daughter cells acquire distinct identities through the unequal inheritance of cell-fate determinant proteins. Stem cells undergo asymmetric cell division to produce a self-renewing stem cell and a cell fated to differentiate. What remains unclear is how the cell fate determinant asymmetry is established. Extrinsic cues, such as signaling between cells, induce cell polarity during division. Protein asymmetry can also be established through intrinsic cues, where cells become polarized through the segregation of fate determinants before mitosis. The core polarity complex, consisting of CDC42-Par3-aPKC ζ , is asymmetrically localized to the plasma membrane in dividing progenitor cells and regulates the asymmetric partitioning of fate determinants. What remains to be determined is whether the machinery required for membrane localization is essential for establishing polarity. We propose protein palmitoylation, which is a reversible lipid modification that promotes shuttling of proteins between the membrane and the cytosol, is an attractive mechanism of regulating cell polarity and self-renewal. Similar to normal tissue, tumors consist of functionally heterogeneous cell populations differing in proliferative potential, therapeutic resistance, and apoptotic potential. Tumor heterogeneity may be maintained by tumor-initiating cells, a rare population of cells with stem-like potential. Using cancer cell lines to model generation of cellular heterogeneity through asymmetric cell divisions, we find the cell-fate determinant proteins β -catenin and Numb are asymmetrically localized during mitosis. The de-palmitoylating enzyme, APT1 is also asymmetrically localized and inhibition of APT1 disrupts the asymmetric localization of β -catenin and Numb. Our results implicate the core polarity machinery, specifically CDC42, in regulating APT1 asymmetric localization and in turn β -catenin and Numb asymmetry. To understand the role of asymmetric cell division in generating

tumor heterogeneity, we over-express APT1 in breast cancer cells and find these cells have increased self-renewal potential in serial replating assays. Furthermore, we find the self-renewal potential of APT1 over-expressing cells is Wnt-dependent. To characterized changes in cell populations we are examining expression of self-renewal genes and sorting for markers of tumor initiating cells. Taken together, our findings provide a role for palmitoylation during asymmetric cell division and cell-fate decisions in tumors.

FOCAL ADHESION KINASE INHIBITION PREVENTS MELANOMA METASTASIS TO LYMPH NODES.

J.M. Murphy¹, J. Dehart^{1,2}, H. Yoon^{1,2}, S. Lim^{1,2};

¹University of South Alabama, Mobile, AL, ²Univ South Alabama, Mobile, AL

Tumor metastasis, as opposed to primary tumor growth, is a major cause of cancer mortality. Interactions between tumor cells and stroma are critical in regulating cancer metastasis. Malignant melanoma would typically metastasize to lymph nodes as a primary or in-transit lesion before secondary metastasis occurs and lymph node biopsy is a common procedure to diagnose melanoma progression. However, the exact mechanism of melanoma metastasis to lymph nodes remains unknown. Recently, we found a new role of focal adhesion kinase (FAK) in regulating inflammatory vascular cell adhesion molecule-1 (VCAM-1) expression, which promotes leukocyte recruitment via $\alpha 4$ integrin interaction. Since malignant melanoma expresses $\alpha 4$ integrin, we hypothesized that lymph nodes express high levels of VCAM-1 due to immune cell trafficking and in turn, it can promote melanoma homing to lymph nodes. First, we tested if FAK activity is required for VCAM-1 expression in lymphatic endothelial cells (ECs) upon tumor necrosis factor- α (TNF- α) treatment to promote melanoma adhesion and transmigration. A pharmacological FAK inhibitor (PF-271, Pfizer; also named as VS-6062, Verastem) blocked TNF- α -mediated VCAM-1 expression on human dermal lymphatic ECs. PF-271 decreased B16BL6 melanoma adhesion and transmigration activity by up to 75% compared to TNF- α treated group. Importantly, oral PF-271 treatment in mice prevented VCAM-1 expression in cervical and popliteal lymph nodes compared to the untreated group. B16BL6 melanoma was injected into the right footpad of C57BL6 mice, and primary tumor growth was allowed for 1 week. Untreated mice exhibited a significant increase in both secondary melanoma growth and in signs of inflammation while PF-271 treated mice (30 mg/kg, twice daily for 1 week) only showed marginal melanoma metastasis. Reduced FAK pY397 autophosphorylation was verified with heart and lung tissues in PF-271 treated group. These results support the possibility that FAK inhibition may be a novel preventative opportunity in melanoma metastasis by blocking inflammatory VCAM-1 expression in lymphatic ECs and lymph nodes.

P1909**Board Number: B420****The role of ITGA1 in pancreatic cancer.**S. Kim¹, Y. Adamian¹, D. Brambilla¹, M. Hoover¹, J. Kelber¹;¹Biology, California State University, Northridge, Northridge, CA

Pancreatic ductal adenocarcinoma (PDAC) is currently the fourth leading cause of cancer-related deaths in the United States and the typical five-year survival rate for patients is less than 5%. PDAC is an invasive malignancy that is difficult to detect early and commonly resistant to therapeutic interventions. Thus, a more complete profiling of molecular regulators in PDAC during disease progression will aid in making novel discoveries to improve diagnostic and treatment methods. Both local invasion and systemic metastases from epithelial-based cancers are driven by pseudopodia/invadopodia formation and function. In this regard, we previously identified PEAK1 (Pseudopodium-Enriched Atypical Kinase One) as a novel regulator of tumor growth/metastasis and therapy resistance in human cancers. To identify co-regulators of pseudopodia formation and pancreatic cancer progression, we cross-referenced our previously published list of pseudopodium-enriched (PDE) proteins with the Oncomine and Babelomics online resources, allowing us to identify novel genes that have yet to be characterized in pancreatic cancer. Of these novel genes, ITGA1 (a cell surface receptor for collagen) is significantly upregulated in pancreatic cancer, yet there are no published reports on the functions of this gene in PDAC. Interestingly, we also found that the expression of ITGA1 increases in PDAC tissues that harbor inactivating mutations in the Smad4 gene, a common genetic alteration in later stages of PDAC. Our molecular analysis of PDAC cells indicates that ITGA1 is expressed at the highest levels in KRas-mutant lines that display a less differentiated morphology. We also found that ITGA1hi PDAC cells are enriched for ALDH1 activity – an indicator of stem-like properties. We evaluated changes in cell cycle profiles of four PDAC cell lines on different ECM substrates in response to various arresting agents. Interestingly, PANC1 cells underwent a significant induction of apoptosis when grown under serum starved conditions on fibronectin or laminin substrates. However, collagen inhibited this serum-starvation induced apoptotic response suggesting that ITGA1 may promote the survival of KRas-mutant PDAC cells when exposed to extracellular stress (e.g., nutrient deprivation). Thus, targeting cell-surface ITGA1 may be a viable mechanism for inhibiting PDAC cell proliferation. Future studies will evaluate the function of ITGA1 in PDAC cells using RNAi and/or immunoneutralizing methods.

P1910**Board Number: B421****Fibronectin enriched environment promotes single cell migration of high invasive Oral Squamous Cell Carcinoma.**M.L. Lamers^{1,2}, L. Bernardi³, G.d. Ramos³, M. Sant'Ana Filho³, A.R. Horwitz⁴;¹University of Virginia, Charlottesville, VA, ²Dept of Morphological Sciences, Federal University of Rio Grande do Sul, Porto Alegre, Brazil, ³Oral Pathology, Federal University of Rio Grande do Sul, Porto

Alegre, Brazil, ⁴Cell Biology, University of Virginia, Charlottesville, VA

Oral Squamous cell carcinoma (OSCC) is an epithelial neoplasm that has a low patient survival rate mainly due to the highly invasive and metastatic characteristics of this tumor. Tissue invasion and metastasis depends on the adaptation of the tumor migratory abilities to new environments, e.g., the switch between the laminin (LN) enriched composition of the epithelia basal membrane to collagen and fibronectin (FN) enriched connective tissue. The aim of this study was to analyze the role of this compositional change on the migratory behavior of cells from an oral squamous cell carcinoma. OSCC cell lines - Cal27 (high E-cadherin) and SCC25 (low E-cadherin) - were plated in 2D or 3D environment with different ECM composition, and the overall migratory properties were accessed using time-lapse microscopy. In 2D conditions, both lines migrated in collectives when plated on either Matrigel (50ml/cm²) or LN (2ug/ml); while FN (2ug/ml) produced a more rapid, single cell migration mode only in the low differentiated cell line (SCC25), a behavior that was also observed in a more complex 3D matrix (collagen 1.2mg/ml + FN 2ug/ml). To analyze the effects of ECM composition on signals that regulate cell migration, the levels of activated Rac1 were measured in cells plated on LN or FN (2ug/ml). The SCC25 cells showed intrinsically higher Rac1 activated levels when compared to the highly differentiated OSCC (Cal27) cells, and the composition of ECM did not substantially affect the activation levels. Since the observed ECM-related changes in cell migration might be due to a difference in adhesion, we analyzed their morphology and turnover using paxillin, vinculin and focal adhesion kinase as markers. Both cell lines showed highly elongated adhesions when plated on LN; however, the high invasive OSCC showed a switch to smaller and more dynamic adhesions when plated on FN. In order to translate these *in vitro* results regarding ECM-mediated tumor adhesion changes, immunostaining of human OSCC biopsies showed that leading low E-cadherin invasive cells in the FN enriched connective tissue had a more frequent distribution of these integrin-related adhesion molecules at the cell border when compared to the high E-cadherin epithelia adjacent to the tumor. We show that the differentiation level of the OSCC tumor determines the response to the ECM composition and influence the tumor migratory behavior by altering the mode from collective to single cell migration, likely due to changes in cell-ECM adhesion properties induced by fibronectin.

Role of Myosin II isoforms in MDA-MB-231 cell mediated matrix rearrangement.

B. Hindman¹, Z. Goeckeler¹, K. Sierros², R. Wysolmerski¹;

¹Mary Babby Randolph Cancer Center, West Virginia University, Morgantown, WV, ²Department of Mechanical and Aerospace Engineering, West Virginia University, Morgantown, WV

The extracellular matrix (ECM) has been shown to play a role in normal tissue development, as well as in the pathogenesis of certain diseases. Changes in ECM stiffness result in changes in cellular tension and stiffness, which in turn result in changes in cell signaling and proliferation. This delicate balance is known as mechanoreciprocity, and loss of this tensional homeostasis can promote the growth of many solid

tumors. In the case of breast cancer, it has been shown that a stiffer matrix promotes cancer progression. Nonmuscle myosin II, the main force generating protein in nonmuscle cells, may be important for the cell mediated matrix changes that occur during tumorigenesis. To determine the importance of Myosin II isoforms in regulating matrix alteration by cancer cells, we depleted MDA-MB-231 cells, an aggressive and metastatic breast cancer cell line, of specific Myosin II isoforms. shRNAs targeting nonmuscle myosin IIA and IIB heavy chains were used to make stable IIA knockdown (IIA KD) and IIB knockdown (IIB KD) MDA-MB-231 cell lines. IIA and IIB protein levels were reduced by 80-95% of vector controls and protein levels were routinely monitored to ensure myosin II KD was consistent between experiments. Loss of myosin IIA and IIB had minimal effect on cell morphology in 2-D cultures, while in 3-D cultures morphology was altered compared to parental MDA-MB-231 cells, which exhibited a pyramidal cell body with numerous cell. IIB KD cells were elongated and appeared localized to one focal plane while IIA KD cells were highly branched, sending processes in all directions. To determine if myosin II is needed for MDA-MB-231 cell mediated matrix organization, we measured the ability of cells to compress a collagen matrix at 1 and 4 days post casting. MDA-MB-231 parental cells effectively compressed constructs (to 400 μm from 1 mm) while loss of myosin IIA resulted in an 80% inhibition of gel compression. KD of myosin IIB had minimal effect on gel compression. In addition to gel compression assays, we developed a method to directly measure matrix stiffness using isometric force measurements. Engineered collagen constructs are subjected to a conditioning protocol that is used to calculate the elastic modulus of the constructs. The elastic modulus of parental MDA-MB-231 collagen constructs was 10.3 mPa, while the elastic modulus of IIA was 3.3 mPa, a 3-fold difference from parental constructs. IIB KD constructs were more similar to parental constructs with a modulus of 7.7 mPa. Collagen constructs containing no cells had an elastic modulus of 0.4 mPa. These results indicate myosin II isoform are required for matrix compression and differentially regulated the rigidity of the ECM.

Dynamically Stiffening Hydrogels Promote Malignant Transformation of Mammary Epithelial Cells.

M.G. Ondeck¹, S. Wei¹, J. Yang¹, A.J. Engler²;

¹University of California, San Diego, La Jolla, CA, ²Bioengineering, University of California, San Diego, La Jolla, CA

Mammary epithelial cells, e.g. MCF10A, are known to respond to differences in static ECM stiffness and resemble a mesenchymal, more malignant state on stiffer ECM lacking any polarized acinar structure. While this is akin to the stiff mammary tumors that one can detect with manual palpation, breast cancer fibrosis is a dynamic process that results in matrix stiffness increasing from normal ~ 150 Pa to 1500 Pa over months to years as a result of enhanced collagen expression and lysyloxidase crosslinking. To more accurately mimic the onset of tumor-associated fibrosis, MCF10A mammary epithelial cells were cultured on dynamic methacrylated-hyaluronic acid (MeHA) hydrogels, whose stiffness that can be modulated from “normal” 100 Pa to “malignant” 2000 Pa, utilizing a two step polymerization process.

MCF10A cells cultured on 100 Pa MeHA hydrogels form and remain as polarized acini and then begin to decompose and resemble a mesenchymal morphology upon matrix stiffening to 2000 Pa. However, the degree of matrix stiffening and culture time prior to stiffening play a large role in acini transformation; increasing culture time on soft matrix prior to stiffening from 6 to 10 days delayed the onset malignant transformation by as much as 35%. To ensure that early stiffening was not cell density dependent, preformed acini of differing cell density were transplanted onto stiffening MeHA hydrogels. Decomposition of the acini upon matrix stiffening is independent of acinus size and cell density, suggesting that an individual acinus responds to the stiffness of the underlying substrate but that their epigenetic state and structure can protect a subset of acini from stiffening. This data indicates a more complex interplay of intrinsic ECM cues and acinar structure in regulating signaling that results in epithelial-to-mesenchymal transition and the onset of a malignant phenotype.

Defining how the mechanical and molecular properties of the microenvironment control autophagy in breast cancer cells.

D. Oravsky¹;

¹Dept. of Molecular Biology, Princeton University, Princeton, NJ

In order to survive and progress, many tumors “co-opt” macroautophagy (hereafter autophagy), a process through which obsolete, damaged, or otherwise deleterious cytosolic components are transported to and degraded by the lysosomal pathway. Since autophagy and features of the tumor microenvironment are applicable to several types of cancer, here we explored how the molecular and mechanical microenvironment controls autophagy. The microenvironments of solid tumors tend to be fibrotic and have elevated levels of interstitial fluid pressure, both of which promote tumor progression, and both of which are implicated in the induction of autophagy. We investigated the relationship between these mechanical stressors and autophagy by using polyacrylamide gels of different stiffness and in microfluidic chambers that simulated of interstitial flow. The level autophagy in MDA-MB-231 human breast cancer cells was quantified by determining the relative expression and localization of autophagic marker LC3II using immunofluorescence. Conditions that had the strongest effect on autophagy were selected for molecular study, focusing on the phosphoinositol-3 kinase and canonical and non-canonical YAP/TAZ signaling pathways, all of which receive input from biomechanical stimuli and have been shown to play a role in the regulation of autophagy. Our data suggest that the mechanical properties of the tumor microenvironment regulate signaling that controls autophagy.

P1914**Board Number: B425****A Trio of Indices Identifies and Quantifies Heterogeneity in Cellular Systems: Application of Heterogeneity Indices to Drug Discovery and Diagnostics.**A.H. Gough^{1,2}, T.Y. Shun², M.E. Schurdak^{1,2,3}, D.L. Taylor^{1,2,3};¹Computational and Systems Biology, Univ of Pittsburgh, Pittsburgh, PA, ²Drug Discovery Institute, Univ of Pittsburgh, Pittsburgh, PA, ³Cancer Institute, Univ of Pittsburgh, Pittsburgh, PA

One of the greatest challenges in biomedical research, drug discovery and diagnostics is to understand how seemingly identical cells can respond differently to perturbagens, such as drugs for disease treatment. Although heterogeneity is an accepted and common characteristic of a population of cells, it is rarely evaluated or reported. The standard practice for cell-based high content assays, as well as other cell analysis applications, has been to assume a normal distribution and to report an average value with a standard deviation for a cell population which may not be normal distributed. To address this important gap we sought to define a method that could readily be used to identify, quantify and characterize population heterogeneity in assays of both cells and small organisms, and furthermore, to guide decisions in drug discovery, experimental cell/tissue profiling and development of diagnostics. Our study revealed that heterogeneity can be effectively identified and quantified with three indices that indicate diversity, non-normality and fraction of outliers. The indices were evaluated using the induction of STAT3 activation by interleukin-6 (IL-6) and oncostatin M (OSM) and the inhibition of STAT3 activation by known pathway inhibitors in five cell lines, where the systems response, including sample preparation and instrument performance, were well characterized and controlled. Results indicate that the heterogeneity in the activation of STAT3 varies by cell line and pathway of activation. Cal33 cells stimulated with IL-6 exhibit a distinctly bimodal distribution while OSM induces a more normal distribution of STAT3 activity. These responses are clearly identified by an increase in the non-normality index only in the IL-6 treated cells, indicating a multimodal population distribution. In contrast, 686LN and MCF10A cells show nearly identical profiles with apparently low heterogeneity when activated by IL-6 and OSM, and in both cases exhibiting a low non-normality index, statistically indicating a single normally distributed population. Neither MCF-7 nor MB468 show significant activation of STAT3 by IL-6, though in both cases there is a large percent of outlier cells that exhibit a positive IL-6 response, while the majority of both cell types respond to OSM. We will present further applications of these indices to the analysis of heterogeneity in cancer tissue and other cellular systems. Understanding heterogeneity in the response to perturbagens, as well as in cancer tissues, will become a critical factor in designing strategies for the development of therapeutics including targeted polypharmacology.

P1915**Board Number: B426****Transient external force induces phenotypic reversion of malignant epithelial structures via nitric oxide Signaling.**B.L. Ricca¹, G. Venugopalan¹, K. Tanner^{2,3}, S. Furata², W. Orellana^{2,3}, C. Reber¹, D.G. Brownfield^{1,2,4}, M.J. Bissell², D.A. Fletcher^{1,5,6};¹Department of Bioengineering, University of California, Berkeley, Berkeley, CA, ²Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, ³Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD, ⁴Biochemistry, Stanford University, Stanford, CA, ⁵Biophysics Graduate Group, University of California, Berkeley, Berkeley, CA, ⁶Physical Biosciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA

Single breast epithelial cells embedded in three-dimensional laminin-rich extracellular matrix (ECM) gels grow to form highly organized, growth-arrested structures known as acini. In contrast, malignant cells form larger, disorganized structures that grow continuously and have no lumen or apical-basal polarity. The malignant cells can be phenotypically 'reverted' by treatment with inhibitory compounds and antibodies at the single cell stage, leading them to form organized, growth-arrested structures that resemble the non-malignant acini. Here, we investigate the effects of external compression on acinar morphogenesis from both malignant and non-malignant cells and find that phenotypic 'reversion' can be accomplished mechanically. Using an elastic chamber to apply a compressive strain that generates a transient, quickly relaxing force, we show that compressed single malignant cells form growth-arrested, polarized, acinar-like structures by day 10. This phenotypic 'reversion' of malignant cells under compression is distinct in that it does not require use of exogenous molecular inhibitors/activators. We find that compressive strain stimulates nitric oxide production in breast epithelial cells and that inhibiting nitric oxide production blocks sensitivity to compression, indicating that mechanically-induced reversion proceeds via nitric oxide signaling pathways. Time-lapse microscopy of the malignant cells after compression revealed that compression restored coherent rotation of the cells, a behavior critical for acinar development but lost in malignancy. We propose that external forces modulate the acinar morphogenesis program by altering nitric oxide signaling early in development, with profound consequences for final tissue architecture.

P1916**Board Number: B427****Detection and Characterization of Infiltrating Immune Cells in Breast Cancer Tissue using Multicolor Immunohistochemistry.**S.G. Becker-Catania¹, X. Li¹, L. Ma¹, B. Atteberry¹, Q. Huang¹, P. Just¹;¹Research and Development, eBioscience, An Affymetrix Company, San Diego, CA

Breast cancer is a highly heterogeneous disease divided into four major subtypes, the identification of which is important for treatment strategy and clinical outcome. Cancers are classified into specific subtypes using hormone receptor status, levels of HER2/neu expression and proliferation rate. In addition to subtype, recent publications have documented the presence of infiltrating leukocytes within the tumor and the importance of these cells in modulating the host immune response in the tumor microenvironment. Identification and characterization of these populations of infiltrating immune cells has been limited by the number of proteins that can be examined within a single tissue section using standard colorimetric immunohistochemistry. To address this limitation, we have used panels of fluorophore-conjugated antibodies to both classic breast cancer markers such as PR, HER2, cytokeratin, mucin 1, and Ki-67, as well as immune cell antigens to stain formalin-fixed paraffin embedded tissue sections from infiltrating ductal carcinoma cases. We found cytotoxic T cells (CD8+), T helper cells (CD4+), regulatory T cells (CD4+/Foxp3+), macrophage (Ham56+), and CD45RB+ cells migrating within the tumor stroma of luminal breast cancer cases. The presence of both cytotoxic T cells and T helper cells that are known to activate anti-tumor immunity as well as regulatory T cells thought to suppress anti-tumor immunity illustrates the complexity of the tumor microenvironment and the need to multiplex markers in order to better characterize and understand the immune response in individual patients.

P1917**Board Number: B428****Pancreatic Cancer Progression Mediated by Alternatively Spliced Tissue Factor under Normoxic and Hypoxic Conditions.**D. Ramchandani¹, D. Unruh², V.Y. Bogdanov², G.F. Weber¹;¹James L. Winkle College of Pharmacy, University of Cincinnati, Cincinnati, OH, ²College of Medicine, University of Cincinnati, Cincinnati, OH

Background: Tumor progression is mediated by aberrant expression or splicing of a unique set of genes. Tissue factor is an integral membrane protein that serves as the initiator of blood coagulation. An alternatively spliced form of tissue factor (asTF) is generated by deletion of exon 5 and a resultant frameshift in exon 6, yielding a secreted protein. High expression of asTF in pancreatic tumor cells was previously reported; recently, asTF was found in abundance in pancreatic ductal adenocarcinoma lesions and lymph node metastases. asTF binds $\alpha 1$ integrins in a non-canonical region, acting as an integrin

ligand that drives pro-survival signaling pathways and metastatic spread in vivo. However, it remains unknown whether hypoxic conditions affect asTF's ability to fuel pancreatic tumor progression. **Methods:** The high grade pancreatic ductal adenocarcinoma cell line PT45P1 and its previously described asTF-overexpressing subline PT45/asTF+ were analyzed for proliferation, anti-anoikis, and motility under normoxic conditions (5% CO₂, ambient O₂, 1000 mg/ml glucose) that model early stages of cancer, and hypoxic conditions (20% CO₂, 1% O₂ and 5 mM lactate) – a characteristic of advanced malignant lesions. **Results:** asTF-overexpressing PT45P1/asTF+ cells displayed higher proliferation rates compared to PT45P1 cells. PT45/asTF+ cells retained their higher growth ability in both normoxic as well as hypoxic environments. By propidium iodide staining, the percentage of PT45/asTF+ cells in the G₂/M phase of the cell cycle was significantly elevated, whereas the majority of the PT45P1 cells remained in the quiescent G₀/G₁ phase. Similarly, under de-adherent conditions (plating on poly-HEMA) that mimic tumor spread through the vasculature, the percentage of PT45P1/asTF+ cells in G₂/M phase was significantly higher than that of PT45P1 cells under normoxic and hypoxic conditions. Interestingly, PT45P1/asTF+ cells expressed higher levels of carbonic anhydrase 9 (CAIX), a hypoxia-inducible enzyme that plays key roles in maintaining intracellular pH and increasing cancer cell invasiveness. Finally, asTF-overexpression also imparted increased directional motility in a gap closure assay. **Conclusion:** The elevated expression of asTF in pancreatic cancer enhances tumor growth and spread. The effects are sustained in the normoxic conditions of an early cancer and the hypoxic conditions that exist in late stages, likely at least in part through the induction of CAIX. Molecularly targeted treatment strategies have thus far focused on suppressing mutated oncogenes. Alternatively spliced gene products of tumor progression may also be valid drug targets.

Phenotyping and functional studies of bone marrow stromal cells in hematological malignant diseases.

M. Lopes¹, J.K. Pereira¹, P. de Melo Campos¹, J.A. Machado-Neto¹, I. Lorand-Metze¹, F. Traina^{1,2}, F.F. Costa¹, S.T. Saad³, P. Favaro^{1,4};

¹Hematology and Hemotherapy Center, University of Campinas (UNICAMP), Campinas, Brazil,

²Department of Internal Medicine, University of São Paulo at Ribeirão Preto Medical School, Ribeirão Preto, Brazil, ³Hematology and Hemotherapy Center, University of Campinas, UNICAMP, Campinas, Brazil, ⁴Department of Biological Sciences, Federal University of São Paulo, Diadema, Brazil

Background: It is now widely recognized that bone marrow stromal cells (BMMSCs) play an important role in the pathogenesis of several hematological malignancies. BMMSCs have low immunogenicity and are capable of inhibiting the proliferation and activation of T lymphocytes. These effects are mediated by cell-cell contact and soluble factors. Nevertheless, the phenotypical characteristics and biological functions of BMMSCs from patients with myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML) remain unclear. **Aims:** To characterize the phenotype, immunosuppressive ability and expression of *TGFβ1*, *IDO*, *RPGE2*, *IL1β* and *IL6* in BMMSCs from MDS and AML patients. **Methods:** At the onset of

the disease and after informed consent, bone marrow (BM) samples were collected from 17 MDS patients (aged from 50 to 83) and 7 AML patients (aged from 30 to 86). Seven healthy donors (aged from 28 to 57) were used as controls. BMMSCs were analyzed always after the fourth passage. Flow cytometry immunophenotyping was performed using the following antibodies: CD31, CD34, CD45, HLA-DR, CD73, CD90 and CD105. For the T cell proliferation assay, allogeneic CFSE-labeled CD3⁺ T lymphocytes were cultured at BMMSC/Tcells ratio of 1/2, 1/5, 1/10, 1/50 and 1/100. Stimulation of T lymphocytes was induced by adding PHA. Four days later CFSE fluorescence intensity was analyzed by flow cytometry. The relative gene expression was determined by quantitative PCR. Mann Whitney and ANOVA were used for statistical analysis. **Results:** Although MDS and AML derived-BMMSCs were similar in phenotype to the healthy donor group, the immunosuppressive effects of AML-BMMSCs on CD3⁺ T-cell proliferation were abolished. AML-derived BMMSCs presented a significant increase in expression levels of *IDO*, *IL1β* and *IL6* when compared with the healthy group. In contrast, MDS derived-BMMSCs were similar to the control group in their ability to inhibit the proliferative response of CD3⁺ T lymphocytes ($P < 0.01$), and there were no significant differences in any of the cytokines tested between these groups. **Conclusions:** The production of IDO, IL6 and IL1β by AML blasts has been demonstrated, however we have shown for the first time those cytokines being produced by AML derived-BMMSCs. IDO is an immunosuppressive agent that blocks T-cell activation in AML. The presence of pro-inflammatory cytokines IL6 and IL1β comprises a hallmark of cancer-related inflammation. Our findings indicate that although AML derived-BMMSCs are similar in phenotype to the healthy group, they lose their ability of inhibiting T-lymphocytes proliferation, possibly contributing to tumor growth.

Inflammatory Cytokines Promote Melanoma Proliferation and Migration.

M. Kamassa¹, M.S. Schwam¹, O. Ahmad¹, Y. Hegazy¹, Z. Burns¹, E. Brandon¹;

¹Department of Biological Sciences , Mississippi College, Clinton, MS

Experimental and clinical data indicate that obesity increases the risk for colorectal, esophageal, pancreatic, endometrial, renal cell carcinoma, and post-menopausal breast cancer. We found that melanoma grows much faster in obese mice than in normal body weight mice. Several metabolic, endocrine, and immune system factors are positively correlated with a poor prognosis and shorter disease-free survival times in obesity associated cancers. The paracrine signaling between tumor cells and stromal cells is a hallmark of cancer that has only recently become appreciated as a catalyst for mutagenesis, immune evasion, and metastasis. Although some mechanistic knowledge has been obtained from a “one growth factor, one effect” approach, this must be paired with a systems analysis to gain an understanding of the interactions between stromal cells and melanoma cells. Our data reveals that the inflammatory cytokines, resistin and IL-6, promote melanoma proliferation (6.1×10^5 cells/day and 1.0×10^6 cells/day v. 5.5×10^5 cells/day for controls, $p = 0.05$). There is still a wide gap in our knowledge of how obesity promotes melanoma metastasis. Individual inflammatory cytokines had no effect on melanoma migration, but co-culturing cells with macrophages significantly increases migration.

Preliminary data also suggests that co-culture with adipocytes increases melanoma migration. The influence of inflammation on tumors is well known, but the mechanisms by which fat cells affect melanomas is unknown. These results suggest that there could be many stromal cells that affect melanoma growth and metastasis in obese individuals. This work was supported by the Mississippi INBRE, funded by an Institutional Development Award (IDeA) from the National Institute of General Medical Sciences of the National Institutes of Health under grant number P20GM103476.

HERC2/USP20 coordinates CHK1 activation by modulating CLASPIN stability.

M. Zhu¹, H. Zhao¹, X. Xu¹;

¹Beijing Key Laboratory of DNA Damage Response, Capital Normal University, Beijing, China

CLASPIN is an essential mediator in the DNA replication checkpoint, responsible for ATR (ataxia telangiectasia and Rad3-related protein)-dependent activation of CHK1 (checkpoint kinase 1). Here we found a dynamic signaling pathway that regulates CLASPIN turn over. Under unperturbed conditions, the E3 ubiquitin ligase HERC2 regulates the stability of the deubiquitinating enzyme USP20 by promoting ubiquitination-mediated proteasomal degradation. Under replication stress, ATR-mediated phosphorylation of USP20 results in the disassociation of HERC2 from USP20. USP20 in turn deubiquitinates K48-linked-polyubiquitinated CLASPIN, stabilizing CLASPIN and ultimately promoting CHK1 phosphorylation and CHK1-directed checkpoint activation. Inhibition of USP20 expression promotes chromosome instability and xenograft tumor growth. Taken together, our findings demonstrated a novel function of HERC2/USP20 in coordinating CHK1 activation by modulating CLASPIN stability, which ultimately promotes genome stability and suppresses tumor growth.

Predicting the Effects of Clinically Observed Kinase Mutations using Molecular Modeling and Machine Learning Algorithms.

E.J. Jordan¹, M. Lemmon¹, R. Radhakrishnan², P.J. Huwe¹, Y.P. Mosse³;

¹Biochemistry and Molecular Biophysics, The University of Pennsylvania, Philadelphia, PA,

²Bioengineering, University of Pennsylvania, Philadelphia, PA, ³Children's Hospital of Pennsylvania, Philadelphia, PA

Many cellular processes are impacted by signaling through receptor and non-receptor kinase proteins. These include such diverse cellular actions as proliferation, differentiation, and motility, as well as tissue level phenomena such as angiogenesis and development. This important role in the cell is reflected also

in the relative overrepresentation of kinases among known cancer mutations to proteins. Through database mining, we have found that kinase domain mutations represent over 20% of somatic mutations in one cancer mutation database, COSMIC. In order to better understand the functional effects of these mutations, we have developed computational methods that seek to predict the effect of point mutations on kinase activation. By predicting whether a given mutation causes a kinase to be more active, we can gain insight into the overall impact of the mutation on cell phenotype as well as give insight to clinicians on patient cohorting for efficacious treatment with targeted kinase inhibitors. We have developed two separate but complementary methods to predict kinase activation status. The first uses molecular dynamics (MD) simulations and scoring criteria to predict if a mutation preferentially stabilizes the protein's active state. This has proven accurate for predicting the effects of intracellular kinase domain mutations of anaplastic lymphoma kinase (ALK), and has also been extended to the epidermal growth factor receptor (EGFR). We believe that the success of this method on kinases with diverse activation methods (EGFR signals through allosteric activation via homo- or heterodimeric complexes, while ALK is thought to signal through activation by trans-autophosphorylation of activation loop tyrosine) shows that this is a generally applicable method. As a complimentary approach to MD, we have developed machine learning techniques that utilize the method known as support vector machines to predict whether mutations in a large number of kinases (>300) are activating. This method has shown great promise as it can correctly distinguish between an activating mutation and one that is not activating almost 90% of the time on cross-validation. Also, this method has proven to be almost as effective at predicting activation mutations as the mechanistic picture gained from MD simulations. We think these methods are both broadly applicable and have the potential to greatly impact both our understanding of mechanisms of kinase activation as well as to guide best practices in the clinical setting of targeted therapy in cancer treatment.

We acknowledge funding from the European Commission (7th programme for research VPH-600841). Supercomputing resources were made available through XSEDE (extreme science and engineering discovery environment, MCB060006).

Persistent STAT3 signaling contributes to the resistance of anti-cancer drugs doxorubicin and cisplatin, and MEK inhibitor AZD6244 in human sarcoma cells.

J. Lin¹;

¹Center for Childhood Cancer and Blood Diseases, Nationwide Children's Hospital, Columbus, OH

Signal Transducer and Activator of Transcription 3 (STAT3) signaling pathway is activated in response to cytokines and growth factors. Persistently activated STAT3 are frequently detected in many types of human cancers and are believed to play an important role in their oncogenesis. Stat3 has been classified as a proto-oncogene because activated STAT3 can mediate oncogenic transformation in cultured cells and tumor formation in nude mice. We previously demonstrated that persistently activated STAT3 is frequently detected in human sarcoma such as rhabdomyosarcoma. To further

examine the role of persistent STAT3 signaling plays in rhabdomyosarcoma, we used genetic approaches to either knock-down the expression of STAT3 using short hairpin RNA (ShRNA) or expressed constitutive active STAT3 protein. Knock-down the expression of STAT3 in sarcoma cells that express persistent STAT3 signaling, reduced the cell viability and sensitized cells to anti-cancer drugs doxorubicin and cisplatin. On the other hand, expression of constitutive active STAT3 protein in sarcoma cell lines lacking persistent STAT3 signaling decreased the sensitivity of those cells to anti-cancer drugs doxorubicin and cisplatin. Furthermore, a MEK inhibitor, AZD6244 that is being tested in human cancer clinical trials unexpectedly induced STAT3 phosphorylation suggesting inducing of STAT3 may induce intrinsic resistance to MEK inhibitor. Accordingly, knock down of STAT3 sensitize sarcoma cells to MEK inhibitor treatments.

To further translate our finding to potential cancer therapy, we tested a small molecular STAT3-selective inhibitor LY5 in sarcoma cells expressing persistent STAT3 signaling. Our data demonstrated that LY5 inhibited STAT3 phosphorylation, STAT3 DNA binding activity, and the migration of sarcoma cells. In addition, the combination of LY5 with anti-cancer drugs doxorubicin and cisplatin and the MEK inhibitor, AZD6244 also shown stronger inhibitory effects than single agent alone. In summary, our results using both genetic and small molecule approaches demonstrated that persistent STAT3 signaling contributes to the resistance of anti-cancer drugs doxorubicin and cisplatin, and MEK inhibitor in human sarcoma cells. They also implicated a potential cancer therapy strategy with the combination of STAT3 inhibitor with doxorubicin, cisplatin, and MEK inhibitor in sarcoma cells expressing persistent STAT3 signaling.

LONG NON-CODING RNAs IN BREAST CANCER PREVENTION.

M. Barton^{1,2}, J. Santucci-Pereira², J. Russo²;

¹Temple University, Philadelphia, PA, ²Fox Chase Cancer Center, Philadelphia, PA

Our initial transcriptomic analysis of normal breast of parous and nulliparous postmenopausal women reveals that long non-coding RNA genes (lncRNAs) are up-regulated in the parous breast [Int. J. Cancer: 131, 1059-1070, 2012]. This observation provided a new paradigm in the understanding of the role of lncRNAs in the regulation of transcription and their potential function in pregnancy's preventive effect in reducing the lifetime risk of developing breast cancer. lncRNAs are RNA molecules longer than 200 nucleotides that are not translated into proteins, but regulate the transcription of genes involved in different cellular processes, including differentiation, cancer initiation and progression. The relevance of lncRNAs in the transcription field is beginning to be explored and their roles have been found to vary from guiding proteins to the genome to scaffolding proteins complexes needed for the transcription of a specific gene. In this work, RNA sequencing of healthy postmenopausal breast tissue biopsies from 8 parous and 8 nulliparous women using Illumina platform was performed. The sequencing results show that there are 42 lncRNAs differentially expressed between parous and nulliparous breast tissue. After analysis of these 42 lncRNAs using bioinformatic tools, scientific literature, and thermodynamic filters, thirteen lncRNAs have been selected to be tested in vitro. Using RT-qPCR we have determined that

eleven out of these thirteen lncRNAs are expressed in a variety of epithelial breast cancer cell lines (luminal, basal and HER2+ cells). Seven lncRNAs are upregulated and two are downregulated in breast cancer cell lines compared to normal-like cells. Also, two of the lncRNAs are not expressed in any of the three normal-like cells tested and three lncRNAs are only expressed in either luminal or basal cell lines. These results indicate that these lncRNAs may be key targets to study and potentially treat different types of breast cancers. This work provides not only novel information on lncRNAs induced by pregnancy in breast cells, but also places lncRNAs as potential key regulators in breast differentiation, cancer initiation and cancer progression. Determining their functions will render a comprehensive picture of their role in the human breast at the transcriptomic level, and will lead to the identification of key lncRNAs driving breast transformation. Furthermore, the manipulation of these lncRNAs can eventually lead to the development of therapeutics for breast cancer prevention. (This work was supported by NIH core grant CA06927 to Fox Chase Cancer Center)

Epstein-Barr Viral and Human microRNAs Target Cell Cycle and Immunoregulatory Human Transcripts.

C. Harold¹, K. Riley¹;

¹Department of Chemistry, Rollins College, Winter Park, FL

Epstein-Barr virus (EBV) is a human herpesvirus that chronically infects ~95% of the worldwide population. EBV infection can lead to the development of specific cancers including nasopharyngeal carcinoma (NPC) and Burkitt's lymphoma (BL), the latter of which is the focus of this research. MicroRNAs (miRNAs) are ~22 nt, non-coding RNA molecules that imperfectly base pair to mRNAs to repress translation. EBV produces 49 mature miRNAs that can accumulate to ~25% of total active miRNAs in infected BL cells. Our research aims to match viral miRNAs with human transcripts to better understand the mechanism of the disease and identify potential therapeutic targets. Previous high-throughput biochemical/bioinformatic experiments using HITS-CLIP identified likely human mRNA targets in the 3' UTRs of genes with a variety of important cellular functions in the context of BL cells. Using luciferase reporter assays, we demonstrate that three human transcripts involved in cell cycle progression and immunoregulation are regulated by EBV miRNAs, human miRNAs, or both. Together these results provide preliminary evidence for the involvement of EBV miRNA regulation in diverse cellular pathways.

Human papillomavirus (HPV) types that are defined, to varying degrees, as cancer-causing, have a C-terminal, 4-amino acid PDZ Binding Motif (PBM) on the E6 oncoprotein; those types that are not associated with cancer have no PBM. More than ten cellular PDZ-containing proteins have been defined as bona fide targets of E6, but not all are recognised by all oncogenic E6s. Furthermore, structural and mutational analyses of PDZ/PBM interactions have shown that the amino acid residues upstream of the PBM, which are quite diverse in different HPV types, are involved in PDZ target selection. These data suggest that E6s from different oncogenic HPV types might have individual fingerprints, with respect to their PDZ-containing targets. Using biotinylated peptides corresponding to the C-terminal 10 amino acids of the E6 proteins from a number of HPV types, we have performed pulldowns from epithelial cells and subjected these to mass spectroscopic analysis. The results confirm hDlg as the major PDZ-containing target of all cancer-causing HPV E6 proteins, but certain differences in the selection of other PDZ-containing targets appear to correlate with the degree of cancer-association reported for the various HPV types. We are now validating and extending these findings in biochemical and cellular assays.

Whole genome expression analysis of Cox4i1 knockout cells indicates increased glycolysis and carcinogenesis.

S. Srinivasan¹, M. Guha¹, D.W. Dong^{1,2}, N.G. Avadhani¹;

¹Department of Animal Biology School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA, ²Penn Genome Frontiers Institute, University of Pennsylvania, Philadelphia, PA

Cytochrome c oxidase (CcO) complex is an important enzyme for ATP synthesis in the electron transport chain of mitochondria. Here we studied the effect of CcO pathway disruption on glycolysis and carcinogenesis using whole genome microarray expression analysis of a mouse cell line with cytochrome c oxidase subunit 4 isoform 1 (Cox4i1) silenced by short hairpin RNA. The expression of Cox4i1 in the knockout was less than 5 percent of the control (p-value less than 10 to -4), indicating the successful disruption of the CcO pathway. 130 genes changed significantly between the knockout and the control. We did function and pathway analysis on those genes. Among those genes, we found that more than 50 glycolysis related genes were up regulated by more than 4-fold with an enrichment p-value less than 10 to -6. We also found that more than 20 genes related to pathways in cancer were up regulated by more than 4-fold with an enrichment p-value less than 10 to -4. These results indicate that the disruption of CcO pathway increases the glycolysis-dependent ATP synthesis and that there might be a causal effect of glycolysis on carcinogenesis.

P1927**Board Number: B438****SWAP-70 contributes to spontaneous transformation of mouse embryo fibroblasts.**Y. Fukui¹, K. Morishita², T. Ichikawa², R. Jessberger³;¹Institute of cellular and system medison, National Hlth Res Inst, Zhunan Town, Taiwan, ²Faculty of Medicine, University of Miyazaki, Miyazaki, Japan, ³Medical Theoretical Center, Technical University of Dresden, Dresden, Germany

Mouse embryo fibroblasts (MEFs) grow slowly after cultivation from animals, however, after an extended period of cultivation, their growth accelerates. We found that SWAP-70 deficient MEFs failed to increase growth rates. They maintain normal growth rates and proliferation cycles for at least 5 years. Complementing SWAP-70 deficiency in one of these MEFs, MEF1F2, by expressing human SWAP-70 resulted in fast growth of the cells after further cultivation for a long period. The resulting cells show a transformation phenotype, since they grow on top of each other and do not show contact inhibition. This phenotype was reverted when sangunarine, a SWAP-70 inhibitor, was added. Two SWAP-70 expressing clones were examined in detail. Even after cell density became very high their cdc2 and NFkB were still activated suggesting that they do not stop growing. One of the clone formed colonies in soft agar and formed tumors in nude mice, but the other did not. Lately, one more clone became transformed being able to make colonies in soft agar. We maintain 4 human SWAP-70 expressing MEF1F2 cell lines. Three out of 4 clones exhibited transforming phenotypes. The mouse SWAP-70 gene also promoted transformation of MEFs. Taken together our data suggest that SWAP-70 is not a typical oncogene, but is required for spontaneous transformation of MEFs.

P1928**Board Number: B439****Anti-neoplastic drugs at sub lethal doses augment caveolin-1 expression and caveolin-1 dependent migration and invasión of cancer cells.**N. Diaz^{1,2,3}, C. Calderon¹, J. Díaz^{1,2,4}, H. Maldonado^{1,3}, J. Castillo^{1,2}, R. Ortiz^{1,2,3}, L. Leyton^{1,2,3}, A. Quest^{1,2};¹Laboratory of Cellular Communication, Center for Molecular Studies of the Cell (CEMC), University of Chile, Santiago, Chile, ²Advanced Center for Chronic Diseases (ACCDiS), University of Chile, Santiago, Chile, ³Biomedical Neuroscience Institute (BNI), Cell and Molecular Biology Program, Biomedical Sciences Institute (ICBM), University of Chile, Santiago, Chile, ⁴Laboratory of Cellular and Molecular Biology, Department of Basic and communitarian Sciences, University of Chile, Santiago, Chile

Introduction: The key to successful cancer therapy resides in identifying the elements required within a functional oncogenic network that sustain tumor cell viability. Selective inhibition of those elements should then lead to specific elimination of tumor cells. Although some advances have been made in designing more effective treatments, relatively non-specific chemotherapeutic approaches remain the

major therapeutic tool for treating tumors despite the existence of adverse secondary effects and the development of multi-drug resistance, which both significantly reduce the efficacy of such approaches. Here we evaluated whether these treatments may alter the expression of caveolin-1 (CAV1), and favor metastasis. CAV1 plays a dual role in tumor progression and although considered a tumor suppressor at early stages of tumor development, elevated CAV1 levels are associated with metastasis and multidrug resistance in later stages of cancer. Specifically the phosphorylation of CAV1 on tyrosine 14 (Y14) by Src family kinases has been shown to increase cell migration and invasion of tumor cells. However the mechanisms that may lead to upregulation of CAV1 levels in cancer cells and whether such events may be triggered by chemotherapeutic drugs remain unclear. Here we investigated whether the treatment of cancer cells expressing low endogenous CAV1 levels with different chemotherapeutic agents induced CAV1 up-regulation and phosphorylation on Y14, as well as increased migration and invasion of colon cancer cells. Furthermore, we evaluated the signaling pathways involved in drug-induced CAV1 upregulation. Methodology: The colon cancer cell lines DLD1 and HT29(US) were treated with the anti-neoplastic drugs Methotrexate (MTX) or Etoposide (ET) and expression of CAV1 was analyzed by western blotting. To identify pathways involved in the induction of CAV1, cells were pre-treated with the MEK inhibitor (PD98059), the Src family inhibitor (PP2) or the anti-oxidant Trolox prior to MTX or ET exposure. Phosphorylation of MAPK and ROS levels were determined by western blotting and flow cytometry, respectively. Additionally, cell migration and invasion were evaluated in transwell and matrigel assays. Results: In DLD1 and HT29(US) cells, CAV1 expression, migration and invasiveness increased upon treatment with anti-neoplastic drugs. CAV1 upregulation was mediated by a sequence of events including activation of the MEK/ERK pathway and ROS production. Drug-enhanced migration and invasion of the cancer cells was linked to CAV1 phosphorylation on tyrosine-14 therefore MTX and ET increased CAV1 expression by a pathway involving MEK/ERK activation and ROS production. Increased phosphorylation on tyrosine-14 lead to increased migration and invasiveness of colon cancer cells.

The Effects of Estradiol and Bisphenol A (BPA) on Histone Modifying Enzymes in Ovarian Cancer.

L. Hayes¹, A. Weening¹, L. Morey¹;

¹Biology, Canisius College, Buffalo, NY

Ovarian cancer is the ninth most common cancer but the fifth leading cause of cancer death for women. It has long been known that ovarian cancer growth and development is dependent upon estrogen. Conversely, there is less known about how environmental estrogens influence ovarian cancer development. Estrogenic compounds have been shown to affect the epigenome, yet little is known about the specific mechanisms by which these changes occur. This project studied the effect of Bisphenol A (BPA) and Estradiol on expression of histone modifying enzymes (HMEs) in the SKOV3 and OVCAR3 human ovarian cancer cell models. This study compared the effects of BPA and Estradiol on Set8 (HMT) and Sirt1 (HDAC) expression under physiological conditions. Experiments were conducted

using Estradiol or BPA alone, or in combination with ICI, the estrogen receptor antagonist. . We found differences in the expression pattern of these genes between the two compounds and between the two model systems. These results imply that environmental estrogens potentially influence global gene expression by changing the expression of HMEs. Furthermore, these changes are different depending on the model system analyzed demonstrating a complex effect of these compounds in human ovarian cancer.

The effect of the estrogenic compounds E2 and BPA on the expression of histone modifying enzymes in prostate cancer cell lines.

J. Walczyk¹, A. Affonso¹, K. Burton¹, L. Shaw¹, L. Morey¹;

¹Biology, Canisius College, Buffalo, NY

Prostate cancer continues to be the most commonly diagnosed cancer in males and it is known that exposure to estrogenic compounds can increase the likelihood of developing prostate cancer. The focus of this project was to determine the effect of physiological measurements of two estrogenic compounds, estradiol (E2) and bisphenol A (BPA) on certain histone modifying enzymes (HMEs) in prostate cancer cells. BPA is a known environmental estrogen that has the ability to bind to the estrogen receptor and induce biological activity classifying it as an endocrine disruptor. When activated, the estrogen receptor acts as a nuclear hormone receptor inducing transcription of target genes. The two HMEs studied were SET8, a histone methyltransferase (HMT) and SIRT1, a histone deacetylase (HDAC). Epigenetic regulation has been determined to be an important process in the maintenance of healthy cells and loss of this regulation has been linked to the development and progression of many cancers, including prostate cancer. To determine the role of these estrogenic compounds, LNCaP and PC3 prostate cancer cells were treated with various physiological doses of E2 or BPA alone and in conjunction with ICI, an estrogen receptor antagonist, or Casodex, an androgen receptor inhibitor. Cells were collected 24 hours post-treatment and RNA was isolated and purified. Isolated mRNA was analyzed and used to measure changes in the expression of SET8 and SIRT1 using endpoint PCR. The results of our experiments show that the expression of the two HMEs studied were differentially expressed by E2 or BPA alone as well in combination with ICI. There were distinct changes in expression between the two models as well. We have also demonstrated that expression of SET8 was not altered by treatment with E2 and Casodex, however, expression of SIRT1 was modified under these treatment conditions.

P1931**Board Number: B442****Identifying APC-dependent protein networks in *Drosophila melanogaster* using a complementary genetic and proteomic approach.**M.A. Blundon¹, D.R. Schlesinger¹, A. Parthasarathy¹, E. Kunttas-Tatli¹, B.M. McCartney¹, J.S. Minden¹;¹Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

Wnt signaling is necessary for differentiation in all embryos, from flies to humans. Inappropriate Wnt pathway activation has been linked to a myriad of cancers, most notably breast and colorectal, as well as insulin insensitivity contributing to type II diabetes. The *Adenomatous polyposis coli* (*APC*) tumor suppressor encodes a multifunctional protein that is an essential negative regulator of Wnt signaling by contributing to β -catenin degradation through the destruction complex. In addition, APC functions in many cytoskeletal processes including actin assembly and microtubule network formation. Mutations in *APC* are found in 80% of all sporadic and hereditary colorectal cancers and disruption of APC's Wnt signaling function contributes to colon cancer initiation. While progress has been made in defining the normal functions of APC, controversy and significant gaps in our understanding remain.

We used *Drosophila* to identify novel APC-associated protein networks to more completely define APC's molecular role. APC proteins are conserved between humans and fruit flies, and much of APC biology elucidated in *Drosophila* has translated well to mammals. To understand the comprehensive consequences of loss of APC activity to protein networks, we took a complementary strategy coupling genetics and a proteomic technique called two dimensional difference gel electrophoresis (2D-DIGE). We used 2D-DIGE to detect visible proteomic changes between *wild type* and *APC* mutant embryos prior to the onset of significant zygotic transcription. We identified 16 obvious isoform changes corresponding to 17 proteins that are different between *APC2* null and *wild type* embryos. These isoform changes are likely the result of phosphorylation changes, suggesting that APC may facilitate a kinase or set of kinases that regulates these proteins. We prioritized the protein differences in three tiers by understanding the isoform changes under different mutant and rescue genetic conditions. The majority of the 9 prioritized proteins have been identified by mass spectrometry. Finally, our data support the hypothesis that many of the APC-dependent protein changes are also dependent on deactivation of the destruction complex and/or the accumulation of *Drosophila* β -catenin. Because our experiments are conducted at a time in embryogenesis prior to significant zygotic transcription, and the changes observed are exclusively isoform changes, we predict that these APC dependent protein differences are not the result of transcriptional activation of Wnt target genes. Taken together, this complementary genetic and proteomic approach has revealed novel APC-dependent proteomic changes that may contribute to colon cancer initiation and progression.

P1932**Board Number: B443****Regulation of mammalian pexophagy by oxygen-regulated hypoxia-inducible factors alpha.**M. Schönenberger¹, K.M. Walter¹, M. Horn¹, M. Trötz Müller², M.S. Lucas¹, H. Elsässer³, A.B. Moser⁴, T. Schwarz¹, P.A. Gerber⁵, P.L. Faust⁶, H. Moch⁵, H.C. Köfeler², W. Krek¹, W.J. Kovacs¹;¹ETH Zürich, Zürich, Switzerland, ²Medical University of Graz, Graz, Austria, ³Philipps-University Marburg, Marburg, Germany, ⁴Kennedy Krieger Institute, Baltimore, United States, ⁵University Hospital Zürich, Zürich, Switzerland, ⁶Columbia University, New York, United States

Peroxisomes play a central role in lipid metabolism and their function depends on molecular oxygen. Low oxygen tension or von Hippel-Lindau (*Vhl*) tumor suppressor loss is known to stabilize hypoxia-inducible factors alpha (Hif-1a and -2a) to mediate adaptive responses, but it remains unknown if peroxisome homeostasis and metabolism are interconnected to Hif-a signaling. By studying liver-specific *Vhl*, *Vhl/Hif1a*, and *Vhl/Hif2a* knockout mice we demonstrate a regulatory function of Hif-2a signaling on peroxisomes. Hif-2a activation augments peroxisome turnover by selective autophagy (pexophagy) and thereby changes lipid composition reminiscent of peroxisomal disorders. The autophagy receptor Nbr1 localizes to peroxisomes and is likewise degraded by Hif-2a-mediated pexophagy. Furthermore, we demonstrated that peroxisome abundance is reduced in *VHL*-deficient human clear cell renal cell carcinomas with high HIF-2a levels. These results establish Hif-2a as a negative regulator of peroxisome abundance and metabolism and suggest a mechanism by which cells attune peroxisomal function with oxygen availability.

P1933**Board Number: B444****Novel function of human Swi3 homologues BAF155 and BAF170 in aerobic respiration and tumor suppression.**M. Alam¹, J. Hooda¹, S. Lal¹, A. Shah¹, T.M. Cao¹;¹Molecular and Cell Biology, University of Texas at Dallas, Richardson, TX

The Swi3 human homologues BAF155 and BAF170 are known tumor suppressors. Previous studies have shown that they are essential components of the SWI/SNF chromatin remodeling complex. Importantly, emerging evidence strongly suggests that Swi3 and its human homologues can act independently of the Swi2/Brg1 to serve as a global regulator of aerobic respiration gene expression and oxygen consumption. An analysis of ChIP-Seq data showed that many genes involved in oxidative phosphorylation and mitochondrial respiration are regulated by both BAF155 and BAF170, but not Brg1. Further, in HeLa cells with BAF155 or BAF170 knocked down, the rate of oxygen consumption was significantly increased. Similarly, in yeast, deletion of the SWI3 gene, but not SWI2, caused a dramatic increase in oxygen consumption rate. Additionally, we found that Swi3 nuclear localization, but not Swi2

nuclear localization, requires oxygen. Further analysis showed that the transcription of genes encoding functions involved in oxidative phosphorylation was selectively increased in Δ swi3 cells. Likewise, measurements of mitochondrial respiratory chain complexes showed that their levels were increased in Δ swi3 cells. These results show that Swi3 and its human homologues BAF155 and BAF170 play a central role in the regulation of aerobic respiration genes and cellular bioenergetics. Inhibiting the function of Swi3 and BAF155 and BAF170 would lead to increased aerobic respiration and cellular energy generation. These results reveal a novel function of Swi3 and its human homologues and provide a molecular basis for the tumor suppressing function of BAF155 and BAF170. Experiments are currently underway to further ascertain the function of BAF155 and BAF170 in cellular respiration and tumor suppression.

Glenn Laboratories for the Biology of Aging, Stanford University, Stanford, CA, ⁶London Regional Cancer Program; Children's Research Institute, Western University, London, ON, ⁷Department of Medicine, Stanford University, Stanford, CA, ⁸Department of Biochemistry, Stanford University, Stanford, CA

Reprogramming of differentiated cells to induced pluripotent stem (iPS) cells is a fascinating yet incompletely understood process. Based on the similarities between reprogramming and cancer, we investigated the tumor suppressor Rb in the induction of pluripotency. Here, we show that loss of Rb increases the efficiency of iPS cell reprogramming. Surprisingly, Rb inactivation does not enhance reprogramming by accelerating the cell cycle. Instead, Rb directly binds regulatory regions of many pluripotency genes, including *Sox2* and *Oct4*, and controls the chromatin state of these factors and their targets. Consequently, loss of Rb leads to a slight but widespread de-repression of the pluripotency program, rendering Rb-deficient cells reprogrammable without exogenous *Sox2*. Moreover, *Sox2* was found to critically mediate Rb-induced tumorigenesis. These results identify Rb as a global transcriptional repressor of the pluripotency network, explaining previous reports about Rb's involvement in cell fate pliability. Our observations also implicate factors involved in pluripotency such as *Sox2* in cancers driven by loss of Rb.

P1935**Board Number: B446****Epigenetic downregulation of *SPINT2* in aneuploidy.**H. Zhang¹, H. Li¹, N. Ganem², D. Pellman¹;¹Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, ²Cancer Center, Boston University School of Medicine, Boston, MA

One aspect of genome instability – a hallmark of cancer – is increased rates of chromosome missegregation. Chromosome missegregation leads to aneuploidy, and consequently, the majority of tumors are aneuploid. While whole chromosome aneuploidy is known to impose a significant cost to cellular fitness, post-selection recurrent aneuploidy is thought to confer considerable evolutionary advantages in the context of tumorigenesis. It has been established that the proliferation of aneuploid mammalian cells is limited by a p53-dependent cell cycle arrest. We have identified the epigenetic downregulation of *SPINT2*, a putative tumor suppressor, to be an adaptive mechanism that allows aneuploid cells to bypass the p53-dependent arrest. The degree of *SPINT2* downregulation correlates with the severity of aneuploidy in hTERT RPE-1 cells. Additionally, *SPINT2* downregulation in aneuploid cells is associated with promoter hypermethylation, and its expression correlates with promoter CpG methylation density. Furthermore, depletion of *SPINT2* by RNAi in HCT116 colorectal carcinoma cells leads to proliferating, persistent aneuploid populations after experimentally induced chromosome missegregation. Our results indicate that disruption of *SPINT2* function renders mammalian cells more tolerant of aneuploidy. We aim to elucidate whether *SPINT2* mediates a tumor-suppressing mechanism that is prone to epigenetic misregulation and to understand the role of *SPINT2* in aneuploidy and tumorigenesis.

P1936**Board Number: B447****TM40, a novel target of p53, interacts with p53 and modulates cellular localization and function of p53.**S. Namkoong¹, K. Lee¹, R. Park², J. Park¹;¹Division of Biological science and technology, Yonsei University, Wonju, Korea, ²Yonsei University, Wonju, Korea

The p53 is one of the most important tumor suppressors and its malfunction has been reported in many types of cancer. Normally, the transcription level of p53 targets are decreased in the most common cancers. Here, we report that TM40 is the novel of transcriptional target of p53 and modulates the localization and transcriptional activity of p53. Microarray analysis revealed that TM40 expression is generally decreased in ovarian tumor and western blot analysis showed that depletion of p53 decreased the TM40 expression. Next, we examined the function of TM40 and found that TM40 is involved in transcriptional activity of p53. TM40 expression affects p53 phosphorylation as well as p53 localization. In addition, TM40 interacts with p53 and interferes with p53 dependent transcription. These results

collectively indicate that TM40, a target of p53, regulates the transcriptional activity of p53 by negative feedback mechanism.

Function of TBP-Like Protein (TLP) in p53-Governed Cell Growth Regulation.

R. Maeda¹, H. Tamashiro¹, K. Takano¹, H. Suzuki¹, T. Endo¹, T. Tamura¹;

¹Chiba University, Chiba, Japan

p53 is inactivated in about 50% of all human cancers, and induces growth arrest, DNA repair, or apoptosis in response to cellular stress such as DNA damage. Since p53 inhibits tumorigenesis, p53 is regarded as “the guardian of the genome”. It is well known that p53 interacts with many kinds of proteins and activates its target genes, though, overview of proteins that interact with p53 and their functions are remained unclear. TBP-like protein (TLP), which belongs to the TBP family proteins, regulates the expression of many genes involved in development and cell growth regulation. Previous studies show that TLP interacts with p53 and activates p21 gene expression in a p53-dependent manner, though detail of their molecular mechanisms is unknown. In this study, we investigated the role of TLP in regulation of p53 function. We found that TLP binds to the N-terminal region of p53 and activates p21 transcription in a p53-dependent manner. These observations suggest that TLP acts as a coactivator of p53. TLP over-expression and knock-down resulted in an increase and decrease of p53 protein level, respectively. Because TLP did not affect the mRNA level of p53, we speculated that TLP regulates p53 at protein level. Because p53 is down-regulated by MDM2 through polyubiquitination, we measured the amount of ubiquitin-conjugated p53. As expected, TLP over-expression decreased ubiquitin-conjugated p53. It is known that knock-down of TLP accelerates cell growth and inhibits damage-induced apoptosis. Consequently, it is suggested that TLP potentiates p53 function through stabilizing p53 protein, which subsequently modulates cell growth profiles and apoptosis induction.

Mammalian Glutamine Metabolism Controls Circadian Rhythm through Regulation of Reactive Oxygen Species.

B.J. Altman¹, Z.E. Stine¹, A.L. Hsieh^{1,2}, R.J. Deberadinis³, C.V. Dang^{1,4};

¹Abramson Family Cancer Research Institute, University of Pennsylvania, Philadelphia, PA, ²Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD, ³Department of Pediatrics, University of Texas Southwestern Medical Center, Dallas, TX, ⁴Division of Hematology-Oncology, Department of Medicine, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Circadian rhythms are twenty-four hour physiologic cycles present in all eukaryotes that control a variety of organismal processes, including metabolism. Peripheral clocks such as those present in the liver control metabolic pathways such as glucose metabolism and respiration as well as amino acid metabolism. It has been recently demonstrated that the availability of the metabolite NAD (nicotinamide adenine dinucleotide) can feed back to control circadian rhythm. There is much interest in targeting glutamine metabolism in cancer, but it is still unknown how inhibition of glutamine metabolism affects normal cell physiology, including circadian rhythm. Here we show using U2OS osteosarcoma cells, a commonly-used model of molecular circadian rhythm, that glutamine withdrawal blocked proper circadian oscillation of gene expression. Glutamine withdrawal led to distinct and dramatic changes in circadian gene expression which could be rescued by addition of the cell permeable TCA-intermediate α -ketoglutarate. However, cells withdrawn from glutamine did not show signs metabolic stress or impairment of the mTOR pathway. While alterations to histone modifications possibly stemming from impairment of α KG-dependent enzymes were observed, these did not explain the observed alterations in circadian rhythm. Rather, glutamine withdrawal led to the strong downregulation of several genes involved in reactive oxygen species (ROS) defense and neutralization. Further supporting the importance of ROS in regulation of circadian rhythm, addition of cell permeable antioxidants rescued the disruption of circadian oscillation in the absence of glutamine. Together, these data suggest that glutamine availability and metabolism are critical to support circadian rhythm and gene expression through modulation of intracellular ROS.

P1939**Board Number: B451****Transcriptome Analysis of Psoriatic Epidermis.**

M. Tervaniemi^{1,2}, S. Katayama³, A. Siitonen^{1,2}, J. Vuola⁴, S. Suomela⁵, T. Skoog³, S. Linnarsson⁶, J. Kere³, O. Elomaa^{1,2};

³Biosciences and Nutrition, Karolinska Institutet, Stockholm, Sweden, ⁴Helsinki Burn Center, Helsinki University Central Hospital, Helsinki, Finland, ⁵Dermatology, University of Helsinki, Helsinki, Finland,

⁶Medical Biochemistry and Biophysics, Karolinska Institutet, Stockholm, Sweden

Split thickness skin grafts (STSG), consisting mainly of the epidermis and only a small amount of dermis, were taken from 9 healthy control (C), 5 psoriatic non-lesional (PN), and 6 lesional (PL) patients and subjected to RNA 5'-end sequencing. Total RNA per cell in PL was higher than in the C and PN samples; the data, therefore, was analyzed by using RNA spike-in normalization instead of global normalization. We found only 35 differentially expressed transcripts (DETs) in the PN skin when compared with the controls (FDR < 0.05). 28 of these were up-regulated (FC > 1.5) and only 7 down-regulated (FC < 0.75). Interestingly, 12 of the DETs map to the known *PSORS* loci, of which *PSORS4* was the most represented among the up-regulated ones. 2437 and 3541 transcripts were up-regulated and 2550 and 491 down-regulated in the PL, when compared with the C and PN samples, respectively. Gene set enrichment analysis with the differentially expressed genes (DEG) in PL, revealed enrichment at the *PSORS4* locus. The functional annotation analysis of DEGs highlighted gene ontology groups related to keratinocyte and epidermal cell differentiation, already in the PN samples. Furthermore, PL-DEGs showed enrichment in many of the functional groups previously associated with psoriasis: e.g. innate immunity and cell adhesion. RNA-Seq also enables the identification of different start sites and transcripts from the introns and untranslated regions. Within Top20 up-regulated transcripts from introns and untranslated regions, two are located at the *PSORS4* locus and therefore further highlighting the importance of the region. Comparison of our STSG DEGs with the previous gene expression data from full thickness (FT) psoriatic samples shows considerably less down-regulation, which may be due to the high amount of dermis in the FT samples; the expansion of epidermis in psoriasis leads to decrease in dermal genes. These results indicate that our samples enable direct focusing mainly on the epidermal transcripts. In addition, the sensibility allows a more concrete recognition of the altered signaling pathways; we identified much more altered components in each pathway than previous microarray studies, making it possible to get a better overall understanding about affected pathways and the network between them.

P1940**Board Number: B452****Mitochondrial DNA deletion breakpoints are strongly enriched for G-quadruplex-forming and direct repeat sequences.**B.A. Kaufman¹, D.W. Dong^{1,2};¹Department of Animal Biology School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA, ²Penn Genome Frontiers Institute, University of Pennsylvania, Philadelphia, PA

Mitochondrial DNA (mtDNA) deletions are associated with the aging process and are a major cause of human mtDNA-related diseases. The sequence distribution of mtDNA deletion breakpoints around this circular genome is non-random. Although various mechanisms have been proposed recently, the role of sequence in deletion genesis remains inconclusive. In this study, we used novel and rigorous statistical measures to identify which of the proposed mtDNA sequence motifs are associated with mtDNA deletions.

To that end, we generated lists of six types of mtDNA motifs, including: G-quadruplex (GQ) forming sequences, stem-loop/cruciform (SC) structures, and several repeat sequences (direct, inverted, complementary, and inverted complementary). Those motif lists were then compared against the lists of mtDNA deletions found in healthy tissues or tissues of six clinical categories of diseases. For the full set of mtDNA deletions and for each disease category, we calculated the percentage of mtDNA deletions whose ends lie within 20 nucleic acid bases of either a repeat sequence pair (for each type of repeat motif), or two motif locations (for GQ or SC motifs). These values were compared to those calculated for controls, which were generated by rotating the corresponding motif set to every location along the circular human mtDNA to generate a finite p-value.

In the full mtDNA deletion set, a strong enrichment was detected for both ends being in close proximity to G-quadruplex motifs (p-values less than $10e-12$). Similarly, we found both ends of mtDNA deletions to be enriched near those of a direct repeat (p-values also less than $10e-12$). The mtDNA deletions enriched for these motifs preferentially showed enrichment at both breakpoints simultaneously. None of the other types of motifs produced enrichment of mtDNA deletions. Furthermore, we found that both G-quadruplex and direct repeat motifs were enriched in deletions from Parkinson's disease and healthy tissues. Direct repeat motifs also produced enrichment for tumor and inclusion body myositis. G-quadruplex motifs also produced enrichment for Kearns-Sayre syndrome, Pearsons syndrome, and progressive external ophthalmoplegia.

In conclusion, both G-quadruplex and direct repeats are associated with mtDNA deletions. For different diseases, different deletion formation mechanisms are potentially at work.

1941**Board Number: B453****Analysis of the Zct1 promoter, a key repressor of alkaloid production in *C. roseus*.**J.D. Weaver¹, E.J. Cram¹, C. Lee-Parsons²;¹Biology, Northeastern University, Boston, MA, ²Chemical Engineering; Chemistry and Chemical Biology, Northeastern University, Boston, MA

Because of their stationary existence, plants rely on swift, well-adapted responses to environmental stresses. Plants readily activate secondary metabolism and produce defense compounds in response to these stresses. *Catharanthus roseus* provides a relevant model for studying secondary defense pathways as it produces numerous Terpenoid Indole Alkaloids (TIAs) in response to certain environmental stressors, such as wounding or the presence of a pathogen. Furthermore, several TIAs produced are pharmaceutically valuable, most notably the anticancer drugs vincristine and vinblastine. However, these drugs are very expensive due to their low concentrations in the plant.

In the last two decades, there has been steady advancement in the understanding of TIA biosynthesis, including the sequencing of genes for the biosynthetic enzymes, discovery of transcription factors that regulate biosynthesis, transcriptomic analysis under various conditions, and elucidation of the pathway induced by the plant hormone Jasmonate (JA). JA has been shown to initiate TIA production by inducing expression of a network of transcription factors, including the repressor ZCT, and then expression of the biosynthetic genes. Here, we report the sequencing and analysis of the Zct1 promoter, a key transcriptional repressor of TIA biosynthesis. The full length Zct1 promoter and a series of deletions was used to drive expression of the GUS reporter gene in the Fast Agro-Mediated Seedling Transformation (FAST) method. The minimal promoter and relative importance of the identified elements was determined.

P1942**Board Number: B454****Molecular and functional characteristics of S-like ribonucleases from carnivorous plants.**N. Arai¹, E. Nishimura¹, S. Jumyo¹, K. Kuroda¹, T. Liu¹, T. Ohshima¹;¹Biology, Waseda University, Tokyo, Japan

Expression of S-like ribonucleases (RNases) is usually induced by phosphate starvation, wounding or senescence in plants. However, they are used for digestion of preys in carnivorous plants (Nishimura *et al.*, *Planta* 238, 955-967, 2013). To know molecular and functional characteristics of S-like ribonucleases from carnivorous plants, using the S-like RNases from *Drosera adelae* (sundew), *Dionaea muscipula* (Venus flytrap), *Cephalotus follicularis* (Albany pitcher plant), *Aldrovanda vesiculosa* (waterwheel plant), *Nepenthes bicalcarata* (fanged pitcher plant) and *Sarracenia leucophylla* (white pitcher plant) and those

from “non-carnivorous” plants, we recently performed a comparative study of S-like RNases. This study identified ten positions at which only carnivorous plants show the common usages of amino acid residues. Furthermore, it was revealed in a phylogenetic analysis that the S-like RNases of carnivorous plants form a group beyond the phylogenetic relationships of the plants (Nishimura *et al.*, *Planta* 240, 147-159, 2014). More recently, we have prepared the recombinant *D. adela* S-like RNase DA-I and its variants that have altered amino acid residue(s) at the above-described ten positions. These variants showed altered enzymatic properties, indicating the significance of the amino acid residues conserved among the carnivorous plants. The study of Nishimura *et al.* (2014) also suggested that the magnitude of kinetic parameters for carnivorous plant S-like RNases correlates negatively with the dependency on symbionts for prey digestion. To understand the structural background for this correlation, we are currently performing a detailed analysis on the structure-function relationship of the mutant enzymes.

Whole Exome Sequencing of Radiation Sensitive Patients Reveals Novel/Rare MCM2 Mutations.

X. Liu¹;

¹University of Florida Genetics Institute, Gainesville, FL

The relationship between ionizing radiation (IR) and human health is paradoxical; IR is a potent environmental carcinogen, but at the same time, it is one of the most effective therapeutic agents for the treatment of cancer. A greater understanding of how humans respond to IR exposure, both at the level of the whole organism and at the single cell level can inform the rational design of radioprotective or radiosensitizing agents. Many key features of the cellular and biochemical pathways that respond to IR damage have been elucidated through the study of rare autosomal recessive genetic disorders in humans characterized by hypersensitivity to IR. Prior studies of Ataxia-Telangiectasia (A-T) identified ATM as the critical signaling molecule in the DNA damage response (1), while similar studies of Nijmegen Breakage Syndrome (NBS) identified NBN and elucidated the role of the MRE11-RAD50-NBN (MRN) complex (2;3). Recently, the study of a single patient with RNF168 deficiency (RIDDLE Syndrome) revealed an important and unanticipated role for ubiquitination in the signaling of DNA double strand breaks (DSB) (4). We have studied the genetics of radiosensitivity in humans by focusing on recessive genetic disorders that result in the most extreme IR hypersensitivity phenotypes. During the course of these studies, we have accumulated cell lines from patients referred to us for diagnostic testing for A-T or NBS in whom no mutations in either the ATM or NBN genes could be found after exhaustive screening. These radiosensitive lymphoblastoid cell lines (RS-LCL) constitute a rich and unique resource for exploring and understanding the mechanisms of human cellular radiation hypersensitivity. In the present study, we applied exome sequencing to identify the causative mutations in our panel of RS-LCLs. Exome sequencing data have generated some candidate genes with novel and rare mutations that have not been previously reported; among these are a frameshift mutation in the exon 4 of minichromosome maintenance complex component2 (MCM2), which results in an early stop codon, and a missense

mutation in the exon 9 of MCM2 resulting in a replacement of one amino acid from glycine to arginine. Preliminary data show RS-LCLs harboring MCM2 mutations exhibit impaired colony formation and viability although the expression level of MCM2 mutant protein is comparable to wild type (WT) LCL. Mutant MCM2 protein is able to interact with other MCM members and forms complexes *ex vivo*. Further studies are necessary in order to elucidate the molecular mechanisms underlying the phenotypes of MCM2 mutant cell lines.

Alternative splicing of the PCLO gene is conserved between mice and zebrafish.

D. Fountain¹, L. Knapp², C. Hermerda¹, M. Posner², S.D. Fenster¹;

¹Biology, Fort Lewis College, Durango, CO, ²Dept. of Biology, Ashland University, Ashland, OH

Alternative splicing of genes is a fundamental process in multi-cellular organisms that ultimately leads to greater protein diversity. Conservation of alternative splicing events between orthologous genes of evolutionarily distant species has not been thoroughly examined. Here we investigated alternative splicing patterns between a mammalian species (*Mus musculus* or mouse) and a teleost species (*Danio rerio* or zebrafish) for the piccolo gene (*PCLO*). Piccolo is a multidomain protein with localized expression at presynaptic nerve terminals of neuronal synapses. Previous studies have revealed the presence of two primary alternative spliced transcripts of *PCLO* (a shorter isoform 2 and a longer isoform 1) in mouse brain. Isoform 1 contains two C2 calcium-binding domains (C2A and C2B) whereas the shorter isoform 2 contains only a single C2 domain (C2A). Further analysis of alternative spliced products of the mouse *PCLO* gene revealed additional minor splice variants including transcripts that lack the 27-nucleotide exon 16 found in the C2A domain-coding region. Deletion of exon 16 dramatically alters the calcium binding properties of the C2A domain. Recent studies have indicated that in zebrafish, a gene duplication event led to the generation of two versions of the Piccolo gene (*PCLO-a* and *PCLO-b*). Both genes exhibit striking similarity in genomic organization to their mouse and human homologs. Using RT-PCR analysis, we show that like mouse, both *PCLO-a* and *PCLO-b* from zebrafish can be generated into two primary alternative splice variants. Further analysis of alternatively spliced transcripts for both *PCLO-a* and *PCLO-b* revealed the presence of several minor splice variants including transcripts lacking the conserved 27-nucleotide exon in the C2A domain-coding region. Finally, using real-time PCR, we were able to quantify the gene expression of the two major splice variants in mouse and the four major splice variants in zebra fish. Our results indicate that in adult mouse brain, the longer isoform 1 is expressed at 3-fold higher levels than the shorter isoform 2. In zebrafish, the highest expressed transcript is the *PCLO-b* isoform 1 with this variant showing higher expression than the other three major splice variants (e.g. isoform 2 of *PCLO-b* and isoform 1 and 2 of *PCLO-a*). Our results provide evidence that for the *PCLO* gene both major and minor splicing events are conserved between two evolutionarily distant vertebrate species.

P1945**Board Number: B457****Utility of syntenic relationships of VDAC1 pseudogenes for not only an understanding of the phylogenetic divergence history, but also ascertaining possible pseudogene candidates as genuine pseudogenes.**Y. Ido^{1,2}, T. Yoshitomi^{1,2}, K. Ohkura³, T. Yamamoto^{1,2}, Y. Shinohara^{4,5};

¹Faculty of Pharmaceutical Science, The University of Tokushima, Tokushima, Japan, ²Institute for Genome Research, The University of Tokushima, Tokushima, Japan, ³Faculty of Pharmaceutical Science, Suzuka University of Medical Science, Suzuka, Japan, ⁴Faculty of Pharmaceutical Science, University of Tokushima, Tokushima, Japan, ⁵Institute for Genome Research, University of Tokushima, Tokushima, Japan

The voltage-dependent anion channel (VDAC), present in the outer mitochondrial membrane, is responsible for the free permeation of metabolites smaller than 5000 Da across this membrane; and 3 isoforms of VDAC, i.e., VDAC1, VDAC2, and VDAC3, are expressed in mammals. Our previous study on the transcripts encoding rat VDAC isoforms indicated the possible existence of an mRNA showing structural similarity with rat VDAC1. We assumed this unexpected mRNA would have been formed by transcription of this VDAC1 pseudogene, and so we explored pseudogenes of VDAC1 in the rat genome. As a result, we obtained 16 pseudogenes of rat VDAC1. The possible presence of pseudogenes of mouse and human VDAC was reported earlier, but their detailed characterization has not yet been achieved. To obtain a clue as to how and when pseudogenes of VDAC were formed in mammals, in this study we characterized pseudogenes of rat, mouse and human VDAC1. To identify candidates of pseudogenes of rat, mouse or human VDAC1, after having entered the amino acid sequence of rat, mouse or human VDAC1, the genome database of the target species was screened with tblastn program. As a result of this screening, we identified 16, 15 and 13 pseudogenes, respectively. When we loosened the screening conditions for pseudogenes we identified 4, 2 and 1 sequences, showing lower similarities with the VDAC1 sequence, and referred to them as "possible pseudogene candidates of VDAC1." None of the pseudogenes or pseudogene candidates identified in these genomes retained intron/exon boundaries of genuine genes encoding VDAC1, thus indicating that these sequences had been formed by retrotransposition of VDAC1 mRNA. The most intriguing question regarding studies on pseudogenes is how and when they are formed during the process of evolution. To answer this question, we further conducted synteny analysis of individual pseudogenes. No syntenic combination was observed with pseudogenes of VDAC1 between human and rodent, but 3 combinations were found to show synteny between mouse and rat. In this study, we discovered 3 syntenic pseudogene combinations of VDAC1 between mouse and rat genomes, which synteny was formed before their phylogenetic divergence. The obtained results are also expected to be useful for a better understanding of the molecular evolution of the VDAC genes.

P1946**Board Number: B458****Mechanisms of epigenetic silencing during hippocampal neuronal development.**L. Guajardo^{1,2}, R. Aguilar^{1,2}, B. Van Zundert¹, M. Montecino^{1,2};¹Center for Biomedical Research, Univ Andres Bello-Fac De Ciencias Biologicas, Santiago, Chile, ²FONDAP Center for Genome Regulation, Univ Andres Bello-Fac De Ciencias Biologicas, Santiago, Chile

During hippocampal neuron differentiation, the expression of critical inducers of non-neuronal cell lineages needs to be efficiently silent. Runx2 transcription factor is the master regulator of intramembranous osteoblast differentiation that leads to formation of the craniofacial bone tissue that surrounds and protects the brain in mammalian embryos. The molecular mechanisms that induce Runx2 gene silencing in brain cells and at the same time promote Runx2 expression in pre-osteoblastic precursors have not been explored. Here, we assess the epigenetic mechanisms that mediate osteoblast-specific gene silencing in neurons. In particular, we address the contribution of histone epigenetic marks, histone modifiers (Polycomb- and Trithorax-associated complexes), miRNAs and DNA methylation, on the expression of the Runx2/p57 bone-related isoform as well as its down-stream targets osterix and osteocalcin in hippocampal tissue obtained from rat embryos. Our results indicate that there is an enrichment of repressive chromatin histone marks and of the Polycomb PRC2 complex at the Runx2/p57 and osterix promoter regions. In addition, osterix and osteocalcin promoters exhibit extensive DNA (CpG) methylation. Moreover, we detect the presence of Runx2 mRNA-targeting miRNAs in hippocampal tissue. Silencing of Polycomb H3K27-methyltransferases Ezh2 and Ezh1, as well as overexpression of the Trithorax-subunit Wdr5, result in increased Runx2 mRNA expression. Additionally, we find that the expression of Ezh1 and Ezh2 changes during hippocampal neuron maturation and that a main mechanism to control this differential expression is mediated by miRNAs. Finally, we report that in immature neurons, expression of the Runx2/p57 protein re-activates transcription of early osteoblast-related genes and down-regulates expression of hippocampal genes. Together these results support a model where complementary epigenetic mechanisms efficiently silence osteoblastic genes during neuronal differentiation and at the same time promote the hippocampal phenotype. FONDAP15090007, FONDECYT3140418.

P1947**Board Number: B459****Isolation of Louisiana Crayfish RNA for gene expression investigation.**N. Gillette¹, A.A. Nagengast², I. Vatnick³;¹Biology, Widener University, Chester, PA, ²Biochemistry, Widener University, Chester, PA, ³Biology and Biochemistry, Widener University, Chester, PA

Aquatic ecosystems around the world are constantly polluted by the domestic and agricultural use of common herbicides such as Round-Up and Atrazine. Run-off causes leaching of these chemicals into aquatic ecosystems, exposing all organisms to their harmful effects. We are particularly interested in

understanding the physiological and molecular effects that herbicide exposure has on crayfish, a commercially important food product in the U.S. and in Argentina. Collaborative studies with colleagues at the University of Buenos Aires have shown that crayfish exposed to the active ingredients of herbicides like Round-Up and Atrazine exhibit reduced growth and a metabolic response. Our current extension of this project aims to identify the molecular cause of these affects. Understanding the molecular modification that may be occurring following exposure begins with an understanding of the genes that may be expressed or repressed following herbicide exposure. We started by determining an efficient method of RNA isolation from the hepatopancreas tissue of the Louisiana Crayfish. Following the comparison of two common RNA isolation techniques, we determined that the RNeasy mini prep kit, that utilizes Trizol, is a simpler and more efficient mode of isolating RNA from the Louisiana Crayfish. With viable RNA isolated, we proceeded to perform a microarray with *Drosophila* chips to identify the genes expressed in the hepatopancreas of untreated Louisiana Crayfish. However, abundant hybridization did not occur between isolated RNA and the fly chip. Therefore, we plan to reiterate this procedure and will optimize the isolation of Louisiana Crayfish RNA, so as to produce RNA of greater purity. If successful hybridization occurs when using a fly chip again, we will then utilize this microarray technique with isolated RNA from Louisiana Crayfish exposed to herbicides. This analysis will identify changes in gene expression that may occur following herbicide exposure.

Genetic regulation of the temperature-dependent egg-laying rate in *C. elegans*.

V. Hoelscher¹, K.P. McPherson², S. Lasse³, E. Andersen⁴, M.B. Goodman³;

¹Department of Biology, Barry University, Miami, FL, ²Emory University, Atlanta, GA, ³Molecular and Cellular Physiology, Stanford School of Medicine, Palo Alto, CA, ⁴Molecular Biosciences, Northwestern University, Evanston, IL

In humans, muscle function depends on temperature, but due to genetic complexity, it is difficult to identify genes responsible for this dependence. The genomes of humans and *Caenorhabditis elegans* contain many homologues, enabling *C. elegans* research to provide a blueprint for studying temperature-dependent muscle function in humans. Muscle function can be measured quantitatively in *C. elegans* by tracking egg-laying, since when an egg is laid, the vulval muscles of the worm must contract. These muscles function at different rates across a range of temperatures, meaning that the worms' muscles contract more often at certain optimum temperatures than at others. We have found that the egg-laying rates and optimum egg-laying temperatures also differ among strains of *C. elegans*, despite the presence of only minor genetic differences. By comparing the egg-laying rates and genomic sequences of two phenotypically divergent strains, N2 (Bristol) and CB4856 (Hawaii), we have identified loci within chromosomes IV and X of the *C. elegans*' genome that may affect muscle function. After specific genes of interest are identified in *C. elegans*, homologous genes in humans can be studied for their roles in temperature dependence of muscle function.

P1949**Board Number: B461****The NuA4 and Swr1 chromatin modification complexes are important for RNA splicing.**D. Sprague¹, N. Paripati¹, A. Moazamian², R. Moazamian³, J. Martinez⁴, T.L. Kress¹;¹Biology, The College of New Jersey, Ewing, NJ, ²Biology, Celloxess LLC, Pennington, NJ, ³Celloxess LLC, Pennington, NJ, ⁴Thomas Jefferson Medical College, Philadelphia, PA

The ability to quickly and precisely regulate gene expression is a fundamental biological process of paramount importance to cell survival. Two important steps in gene expression are transcription and splicing. These steps are coordinated to ensure accuracy and efficiency, yet very few proteins that function in this coordination have been identified. Recent high throughput genetic interaction studies using *Saccharomyces cerevisiae* revealed that splicing factors interact with factors that are important for transcription. We have utilized a targeted genetic screen to identify novel interactions between splicing factors and factors that modify chromatin to modulate transcription. Using both qualitative and quantitative growth assays we identified negative genetic interactions between genes encoding splicing factors and both *SWR1*, a component of the Swr1 chromatin remodeling complex, and *HTZ1*, which encodes the variant histone inserted into chromatin by Swr1. In addition, our screen revealed novel negative genetic interactions between splicing factors and *EAF7*, a component of the NuA4 histone acetyltransferase complex. Notably, both the NuA4 and Swr1 complexes function together to regulate transcription. Using quantitative RT-PCR we have shown that mutation of individual components of the NuA4 or Swr1 complexes or Htz1 causes a modest block in RNA splicing and exacerbates the splicing defects observed in a yeast strain lacking a splicing factor, as predicted by our genetic analysis. Taken together, these data support a model in which the NuA4 and Swr1 chromatin modification complexes interact with the splicing machinery to coordinate transcription and splicing.

P1950**Board Number: B462****The Set2 histone methyltransferase is required for efficient RNA splicing.**S. Ucles¹, M. Sorenson², D. Flood¹, S.W. Stevens², T.L. Kress¹;¹Biology, The College of New Jersey, Ewing, NJ, ²University of Texas at Austin, Austin, TX

Proper gene expression involves multiple steps, including RNA splicing where non-protein coding regions of RNA are removed from the RNA transcript. RNA splicing is carried out by the large and dynamic spliceosome, which is comprised of small ribonucleoprotein complexes (snRNPs) that assemble on an RNA molecule in a precise order. Assembly of the spliceosome occurs co-transcriptionally and RNA splicing is tightly coordinated with transcription to ensure precise and efficient gene expression. However, the mechanisms that underlie this coordination are poorly understood. In order to identify proteins that function to coordinate RNA splicing with transcription we carried out a genetic interaction

study using *Saccharomyces cerevisiae*. We identified negative genetic interactions between genes encoding RNA splicing factors and the *SET2* gene, a histone methyltransferase that methylates lysine36 on histone H3 (H3K36) to regulate transcription. Furthermore, we show that mutations that block H3K36 methylation also have negative genetic interactions with splicing factor genes, suggesting that H3K36 methylation is important for RNA splicing. Indeed, we have shown that deletion of *SET2* or point mutation of H3K36 inhibits RNA splicing and exacerbates splicing defects in yeast strains harboring deletions of splicing factor genes. Using chromatin immunoprecipitation, we demonstrate that deletion of *SET2* reduces the association of snRNPs with chromatin. Thus, we provide the first evidence that H3K36 methylation is required for appropriate RNA splicing in yeast and suggest a model in which Set2 or H3K36 methylation help to recruit splicing factors to RNA during transcription.

Mio acts in the insulin-producing cells of the *Drosophila* brain to control feeding and metabolism.

J. Docherty¹, J. Manno¹, J. McDermott¹, J. DiAngelo¹;

¹Department of Biology, Hofstra University, Hempstead, NY

During times of nutrient abundance, animals recognize the availability of nutrients and regulate their intake and storage of these nutrients accordingly. However, the molecular mechanisms underlying nutrient sensing and subsequent changes in behavior and metabolism are not fully understood. The production and secretion of the peptide hormone insulin has been shown to be nutrient responsive and affect metabolism in many different organisms ranging from flies and worms to mice and humans. Our lab has recently shown that *Mio*, the *Drosophila* homolog of carbohydrate response element binding protein (ChREBP), functions in the fat body (the equivalent of liver and adipose tissue of the fly) to control triglyceride storage as well as feeding suggesting that *Mio* may act as a nutrient sensor to coordinate food consumption and metabolic homeostasis. Here, we demonstrate that *Mio* functions in the insulin-producing cells (IPCs) of the fly to regulate feeding and metabolism. Targeted disruption of *Mio* specifically in the IPCs inhibits feeding and alters nutrient storage. Interestingly, *Mio* may be acting in the IPCs by controlling the expression of hormones secreted from these cells as IPC-specific RNAi of *Mio* leads to a decrease in *Drosophila insulin-like peptide (dilp) 2* and an increase in *dilp3* levels. Furthermore, disruption of *Mio* function in the IPCs does not affect *dilp5* or *Drosulfakinin (Dsk* — the *Drosophila* homolog of mammalian *cholecystokinin*) expression. These data indicate that *Mio* functions as a nutrient sensor in the IPCs by controlling insulin-like peptide expression leading to the regulation of feeding and metabolism in accordance with nutrient availability.

P1952**Board Number: B464****Epigenome-wide evaluation of short-term DNA methylation stability in monocytes.**R. Furukawa¹, T. Hachiya¹, H. Ohmomo², Y. Shiwa¹, K. Ono², S. Suzuki³, M. Satoh¹, J. Hitomi⁴, K. Sobue⁵, A. Shimizu²;

¹Division of Biobank and Data Management, Iwate Tohoku Medical Megabank Organization, Iwate Medical University, Shiwa-gun, Iwate, Japan, ²Division of Biomedical Information Analysis, Iwate Tohoku Medical Megabank Organization, Iwate Medical University, Shiwa-gun, Iwate, Japan, ³Department of Physiology, School of Medicine, Keio University, Shinjuku-ku, Tokyo, Japan, ⁴Deputy Executive Director, Iwate Tohoku Medical Megabank Organization, Iwate Medical University, Shiwa-gun, Iwate, Japan, ⁵Executive Director, Iwate Tohoku Medical Megabank Organization, Iwate Medical University, Shiwa-gun, Iwate, Japan

Cytosine methylation in CpG dinucleotides is one of the key epigenetic mechanisms that regulate gene expression. DNA methylation is considered to be a stable, and to define "fields" for producing the transcriptomes that characterize the functional differences of cells and tissues. On the other hand, gene expression patterns are well known to change in response to various stimuli in the body. It remains unclear to what extent short-term dynamics in gene expression involves epigenetic mechanisms, especially DNA methylation. In the present study, we examined the short-time dynamics and stability of gene expression and DNA methylation of monocytes that show relatively low heterogeneity in blood cells. We collected blood 24 times from two healthy volunteers (males in thirties) in three months, obtained CD14^{high}CD16^{low} monocytes using cell sorter (SH800, Sony), and extracted DNA and RNA. Methylation levels of approximately 480,000 CpG probes were measured by Illumina Infinium HumanMethylation450 BeadChip microarrays, and were evaluated by β -values, which are the ratio of the methylated probe intensity and the total signal intensity (ranged from 0 to 100 %). For >97% of CpG probes, the maximum differences of DNA methylation levels between the 24 times were less than 10%. On the other hand, the maximum differences of DNA methylation levels exceed 50% at 81 CpG probes. Next, in order to investigate whether these variations of DNA methylation level affect expression of neighboring genes, we conducted RNA sequencing, and then detected Methylation-Expression associations (MEAs) using a linear regression model and the ANOVA test. Of 341,233 CpG positions located on the promoter or gene body regions, 2,819 (0.83%) were associated with the expression of neighboring genes with a significance level of 0.01. In these MEA CpG positions, the maximum differences of DNA methylation levels exceed 50% at only one CpG probes, and in approximately 96% of the genes detected by MEA analysis, the maximum difference of the $\log_{10}[\text{FPKM}+1]$ were less than 0.3. From these results, the drastic variation of DNA methylation does not seem to contribute much to the dynamic change of gene expression. However, a possibility that small or moderate changes of DNA methylation may affect the gene expression is required to be explored.

P1953**Board Number: B465****Expression Levels of DNA Damage Response Genes in Zebrafish (*Danio rerio*) following Treatment Methylnitrosourea, Doxorubicin, or Ultraviolet light.**J. Woolcock¹, H. Khan¹, K. Joseph¹, E.E. Gestl¹;¹Biology, West Chester Univ, West Chester, PA

While much of the signaling of DNA damage is coordinated through post-translational modification, the expression levels of five genes, ATM, p53, p21, chk1, and chk2 have been examined in zebrafish at different stages of life ranging from two hours to adults (males and females) three years of age. Zebrafish are vertebrate, freshwater fish that grow 3-4 cm in size and are relatively easy to maintain at low costs. Each pair of fish can produce hundreds of eggs biweekly with a generation time of 3 months. The embryos develop ex vivo and are completely transparent during the first week of life, allowing for the observation of internal structures. This study utilized RNA collected from both untreated zebrafish embryos, and embryos treated with Ultraviolet light, N-nitroso-N-methylurea (MNU), or Doxorubicin. The level of mRNA expression from these genes at each stage was determined using quantitative reverse transcriptase polymerase chain reaction (q-RT PCR) and SYBER Green in relation to actin. Both ATM and p21 exhibited high levels of gene expression within untreated samples isolated from older zebrafish such as 3 years of age. Every gene treated with MNU and Doxorubicin increased in expression as the concentration was raised, however, ATM was the only gene that showed an increase in its expression following exposure to ultraviolet radiation. The expression of DNA damage response genes examined in zebrafish will further establish this vertebrate as a model organism to study DNA repair mechanisms.

P1954**Board Number: B466****Evolution of novel response element specificity in the glucocorticoid receptor.**W.H. Hudson¹, E.A. Ortlund¹;¹Department of Biochemistry, Emory University, Atlanta, GA

Specific recognition of DNA response elements by transcription factors is a key step in the regulation of gene expression. Some transcription factors recognize multiple, distinct response elements to mediate transrepression or transactivation of target genes. However, the mechanism by which a single transcription factor can evolve to recognize multiple response elements is unclear. Here, we study the evolution of the glucocorticoid receptor, which recognizes distinct response elements to mediate activation or repression its target genes. The glucocorticoid receptor binds to activating glucocorticoid response elements, or (+)GREs, as a dimer to activate transcription. Alternatively, GR binds to negative glucocorticoid response elements (nGREs) in a monomeric fashion to repress transcription. We demonstrate that, of the extant 3-keto steroid receptors, only the glucocorticoid receptor can bind to and repress transcription in a nGRE-dependent manner, despite the ability of all 3-keto steroid receptors

to bind to and activate gene transcription from (+)GREs. Surprisingly, using ancestral gene reconstruction, we find that nGRE binding and gene repression was a feature of the ancestor of all extant 3-keto steroid receptors. nGRE binding and repression originated as a subfunction of the ancestral 3-keto steroid receptor coincident with (+)GRE binding, and this subfunction was optimized in the evolutionary lineage of the glucocorticoid receptor but lost in the ancestors of the mineralocorticoid, progesterone, and androgen receptors. Further, using x-ray crystallography and other structural biology approaches, we define the structural mechanisms by which the modern-day DNA binding specificity evolved in the glucocorticoid receptor.

Determination of Expression Levels of all 20 DNA Polymerases in Zebrafish (*Danio rerio*) throughout Development and following Treatment with MNU, Doxorubicin, and UV Radiation.

J. Petovic¹, L. Sekela¹, B. Della Fera¹, L. Ver Steeg¹, J. Woolcock¹, M. Miller¹, E.E. Gestl¹;

¹Biology, West Chester Univ, West Chester, PA

Zebrafish like humans contain sixteen DNA polymerases encoded by 20 different genes, the most recent uncovered in 2012. The expression of the DNA polymerases were determined at stages of development throughout the zebrafish (*Danio rerio*) life establishing it as an excellent model for the study of basic biological processes including DNA replication. RNA isolated from zebrafish of varying ages from 2 hours to 3 years old was used for Reverse-Transcriptase PCR to determine the level of polymerase gene expression throughout zebrafish development. All the polymerases were expressed at every stage of development examined. Quantitative RT-PCR was used to determine the relative quantity of polymerase expression by comparison with actin. While polymerase replicative polymerases like polymerase delta1 and delta2 resulted in similar levels in all the developmental stages, polymerases iota and eta were detected at decreased levels, most possibly due to their specialized roles in DNA replication. The expression level of polymerases beta and eta was highest in older stages of zebrafish development. The polymerase expression levels were also examined following exposure of 1-day old zebrafish embryos to the doxorubicin and methylnitrosourea, or ultraviolet radiation. One of the primary results was an increase in the level of polymerase eta expression due to its role in thymine-thymine photoproduct bypass. This completed study of polymerase expression results in a comprehensive model of DNA replication in zebrafish that can be utilized in future research.

P1956**Board Number: B468****GcrA is a global transcriptional regulator promoting open complex formation at methylated promoters in *Caulobacter*.**D.L. Baer^{1,2}, M.T. Laub^{1,2};¹Biology, Massachusetts Institute of Technology, Cambridge, MA, ²Howard Hughes Medical Institute, Cambridge, MA

Global regulators, unlike classical bacterial transcription factors, associate with RNA polymerase (RNAP) prior to binding DNA, and are found at promoters in a sequence non-specific manner. However, the extent of their effect on gene expression and mechanism of action are incompletely defined. Here, we show that GcrA, a major regulator of cell cycle progression in *Caulobacter crescentus* is a global regulator. GcrA forms a stable complex with RNAP holoenzyme through an interaction with σ^{70} , the primary sigma factor. Consistent with this interaction, ChIP-Seq analysis reveals that GcrA is present at nearly all σ^{70} -dependent promoters. Surprisingly, although GcrA is found at σ^{70} -regulated promoters in a sequence non-specific manner, only promoters harboring an extended recognition element that includes a subset of GANTC methylation sites are affected by GcrA. GcrA promotes open complex formation at these methylated promoters by interacting with Region 2 of σ^{70} , the region involved in binding the -10 element during strand separation. Guided by these mechanistic studies, we combine ChIP-Seq and expression profiling to pinpoint the direct GcrA regulon. Our work elucidates a new mechanism for transcriptional regulation and shows how this regulation contributes to a reprogramming of gene expression during a key stage of the cell cycle in *Caulobacter*.

P1957**Board Number: B469****Transcription regulation of LRRK2 by Egr-1 in B lymphocyte.**H. Han¹, H. Li¹, Y. Zou¹, Z. Zhang²;¹Central South University, State Key Laboratory of Medical Genetics, Changsha, China, ² Central South University, State Key Laboratory of Medical Genetics, Changsha, China

The leucine-rich repeat kinase 2 (LRRK2) mutations are the most common genetic cause of autosomal-dominant Parkinson disease (PD) and is also associated with susceptibility to Crohn's disease and leprosy. Currently, pathogenesis of PD caused by the LRRK2 mutations are poorly understood, and the physiological activities of LRRK2 as well as its transcription regulation are still elusive. Here we characterized the 5'-flanking region of the human LRRK2 gene and identified Egr-1 as a transcription regulator of LRRK2, the nine nucleotides GCGTGGGCG located in the 5'-flanking region of the human LRRK2 gene constitute the Egr-1 binding site. Knockdown endogenous Egr-1 reduces LRRK2 transcription in Epstein-Barr virus transformed B lymphocytes. Phorbol 12-myristate 13-acetate (PMA), which caused a rapid induction of Egr-1, can induce LRRK2 gene expression. LRRK2 modulates IL-6 production in PMA activated Epstein-Barr virus transformed B lymphocytes, indicating that LRRK2 takes part in cytokines

production in activated B cells. Moreover, Egr-1/LRRK2 pathway is critical for constitutive Immunoglobulin G(IgG) secretion. These data suggest that LRRK2 regulates immune responses through mediating B cell function and help us to understand the pathophysiological function of LRRK2 in the immune system.

Despite the nucleus' central role in multi-cellular biology, how the cell's proteome is partitioned between nucleus and cytoplasm is still poorly understood. This is mostly due to the difficulty of separating nuclear and cytoplasmic content and the challenge to comprehensively measure relative protein abundance and dynamics. Here, we quantify the nucleocytoplasmic distribution for more than 9000 proteins, with two different methods of quantitative proteomics, using the giant *Xenopus laevis* oocytes, which allow nuclear isolation via microdissection. We find a trimodal distribution, where most proteins localize exclusively to the nucleus or the cytoplasm, while a third subset of proteins is nearly equidistributed. By measuring the physiological protein size in undiluted cytoplasm we show that nearly all partitioned proteins have a physiological size larger than ~100kDa, while physiologically smaller proteins are typically equipartitioned. This suggests that protein assembly plays an important and so far underappreciated role in proteins' retention within a membrane bound organelle. Unexpectedly, we also find multiple examples of large, equipartitioned complexes. By following subcellular protein dynamics upon nuclear export perturbation with Leptomycin B, we provide evidence that these complexes are equipartitioned by active bi-directional nuclear transport. Surprisingly, this perturbation also re-localizes many kinases towards the nucleus, suggesting an intriguing explanation for the efficacy of this drug class in the treatment of various cancers. Thus, we present the first resource for the quantitative nucleocytoplasmic partitioning of a vertebrate proteome, measure its dynamics upon perturbation, shed new light on the mechanisms of subcellular protein localization, and suggest novel mechanisms of action for a cancer therapeutic.

P1959**Board Number: B472****Single Molecule Real-Time (SMRT) Imaging of HIV-1 RNA Modulation by DDX1 in Living Cell.**L. Tu¹, A. Joseph¹, H. Chu², L. Gerace², D. Grunwald¹;¹RNA Therapeutics Institute, University of Massachusetts Medical School, Worcester, MA, ²Department of Cell and Molecular Biology, Scripps Research Institute, La Jolla, CA

Evidence is building that DDX1, a DEAD-box helicase, participates in rev-assisted HIV-1 RNA genome transport processes. We are particularly interested in the spatial and temporal landscape of this rev-RRE and DDX1 interaction in the cell nucleus as well as the binding states. Specifically we aim to understand the life cycle of the HIV-1 genome, beginning at the transcription site of the integrated pro-virus, during intra-nuclear “transport” of the HIV-1 genome (i.e. diffusion to the nuclear periphery) to its appearance in the cytoplasm.

To study HIV-1 RNA and DDX1 interactions in real time in the living cell we engineered an optimized fluorescent cell line which can be used in single molecule microscopy techniques with nanometer and millisecond resolution. This cell line is based on a previously described U2OS derived cell line that harbors 75 stably integrated copies of replication deficient HIV genome labeled using a 24x MS2 cassette (Boireau et al. J Cell Biol. 2007). After selection of a subclonal population of cells that express replication deficient HIV genome, we stably integrated a nuclear pore marker (POM121), a MS2 coat protein, a codon optimized DDX1 and shRNA(s) against endogenous DDX1. All integrated sequences are fused to a fluorescent protein sequence except for the shRNA(s). Cell populations were selected either by fluorescence levels or via antibiotics in case of the shRNA(s). We show that the codon optimized DDX1 can rescue a full depletion of endogenous DDX1. This allows us to modify the amount of labeled, optimized DDX1 relative to endogenous DDX1 and further optimize our cell line for all three fluorescent tags to visualize and track HIV-1 RNA and DDX1 molecules in real-time in living cells by single molecule microscopy.

P1960**Board Number: B473****The mRNA export factor NXF1:NXT1 forms a symmetric binding platform for retroviral RNA export.**S. Aibara¹, E. Valkov¹, J. Katahira², M. Stewart¹;¹MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, ²Graduate School of Frontier Biosciences, Osaka University, Osaka, Japan

The NXF1:NXT1 complex (also known as TAP:p15) is a general mRNA nuclear export factor with homologs from yeast to humans (1). NXF1 contains four domains: RRM (RNA recognition motif), LRR (leucine rich repeat), NTF2L (nuclear transport factor 2-like), and UBA (ubiquitin associated domain) and

forms a tight heterodimeric complex with NXT1 through the NTF2L domain (2). NXF1:NXT1 is thought to facilitate mRNA export using direct interactions with both mRNA and nuclear pore proteins (2).

NXF1:NXT1 also facilitates the rapid nuclear export of unspliced retroviral genomic RNA from simple type-D retroviruses, such as simian betaretrovirus serotype 1 (SRV-1), that contain a constitutive transport element (CTE), a *cis*-acting two-fold symmetric RNA stemloop motif. NXF1:NXT1 mediates the export of CTE-tagged transcripts more efficiently than other transcripts and can also block the export of native mRNAs (3-5). The principal regions of NXF1 involved in RNA binding have been thought to be the RRM and LRR domains and recently a crystal structure has been obtained of them bound to half of the CTE RNA (6) motif. However, how NXF1:NXT1 binds to complete CTE RNA and whether this involves any higher organization of the NXF1 domains remains unknown.

We have obtained a 3.4 Å crystal structure of the LRR and NTF2L domains of human NXF1 complexed with NXT1. Two copies of this complex were present in the asymmetric unit and were arranged to form a domain-swapped dimer, in which the linkers between the LRR and NTF2L domains of each complex formed intimate interactions with the NXT1 of the other complex, generating a two-fold symmetric platform. We have identified residues in this linker and engineered mutants that demonstrate dimer formation is important for the CTE-mediated enhancement of export of CTE-tagged transcripts. Combining complementary structural, biochemical, and ex vivo data, we have developed a plausible model for the recognition of CTE RNA by a symmetric RNA binding platform formed by a domain-swapped dimeric NXF1:NXT1 complex.

Intracellular trafficking of nuclear β -dystroglycan.

R. Mondragon Gonzalez¹, V.G. Jimenez¹, A. Vasquez-Limeta², B. Cisneros¹;

¹Genetics and Molecular Biology, CINVESTAV, Mexico, D.F., Mexico, ²CINVESTAV, Mexico, D.F., Mexico

β -dystroglycan (β -DG) is a transmembrane protein that belongs to the Dystrophin Associated Protein Complex (DAPC). β -DG has been widely described at the plasma membrane (PM), where it confers integrity to the phospholipid bilayer and participates as scaffold for signal transduction. Recently we described the presence of β -DG in the nucleus of different cell lines and characterized its nuclear import pathway, which is mediated by an importin α / β -recognized NLS, localized in the juxtamembrane region

of β -DG. The aim of the present study was to define the intracellular traffic that β -DG undergoes to reach the nucleus. Treatment of C2C12 cells with brefeldin A (BFA) to block endoplasmic reticulum (ER) to Golgi anterograde transport revealed that β -DG requires passing throughout Golgi to be further localized to the nucleus. Biotinylation of plasma membrane proteins and subsequent nuclei isolation showed that β -DG is translocated from PM to the nucleus. Inhibition of endocytic pathway using dynasore resulted in decreased nuclear localization of β -DG, which suggests that endocytic vesicle-dependent retrograde transport is involved in β -DG nuclear translocation. Identification of biotinylated β -DG in a purified endoplasmic reticulum fraction indicated that β -DG reaches this organelle before its nuclear translocation. Overall, our results suggest that β -DG releases from PM via endocytosis and transits through ER as part of its retrograde trafficking to the nucleus.

Molecular determinants of nuclear size in melanoma cancer cells.

L.D. Vukovic¹, D. Levy²;

¹Univ Wyoming, Laramie, WY, ²Department of Molecular Biology, University of Wyoming, Laramie, WY

Pathologists assess changes in nuclear size and morphology to diagnose and stage various cancers. We hypothesize that increases in nuclear size contribute to metastatic capacity by promoting proliferation and/or invasive potential. Some factors that regulate nuclear size have been identified and experiments in *Xenopus* showed that nuclear import rates correlate with nuclear size. The levels of two nuclear import factors, importin α and Ntf2, were shown to be particularly important, modulating the import rate of nuclear lamins. The goal of our study is to quantify differences in nuclear size and the nucleocytoplasmic ratio between normal and cancer cell lines and to determine how the levels of known nuclear scaling factors vary during carcinogenesis. We utilize different stage melanoma cell lines, including primary melanoma (radial and vertical growth phases) and metastatic melanoma, as well as a normal melanocyte cell line as a control. We have quantified large differences in nuclear size between normal melanocytes and three different radial growth phase melanoma cell lines. We also observed a small but statistically significant difference in nuclear size between a vertical growth phase and metastatic melanoma cell line derived from the same patient. Surprisingly, the largest nuclear sizes were consistently observed in radial growth phase primary melanomas. To better understand this result, we are currently measuring nuclear-to-cytoplasmic volume ratios in these cell lines. We observed an inverse relationship between nuclear size and Ntf2 protein levels in whole cell extracts. Normal melanocytes with the smallest nuclei have the highest Ntf2 levels, while radial growth and metastatic melanomas with the largest nuclei have very low levels of Ntf2. These data were confirmed in cells by Ntf2 immunofluorescence staining. All these data suggest that Ntf2 may play a role in nuclear size changes during melanoma progression. To directly test this idea, we will manipulate the levels of Ntf2 in these various cell lines and observe how this impacts nuclear size. We plan to generate stable cell lines in which we can inducibly vary the levels of Ntf2, as well as other nuclear scaling factors. As a proof of principle, we find that knocking down the levels of importin alpha in metastatic melanoma cells leads to

a reduction in nuclear size. We will use our inducible cell lines to examine how altering nuclear size affects cancer cell characteristics such as invasive potential and rates of proliferation and apoptosis.

Nuclear localization of eEFSec and its role in Selenocysteine incorporation.

A. Dubey¹, P.R. Copeland²;

¹Graduate Program in Cell and Developmental Biology, Biochemistry and Molecular Biology, Rutgers Robert Wood Johnson Medical School, Piscataway, NJ, ²Department of Biochemistry and Molecular Biology, Rutgers Robert Wood Johnson Medical School, Piscataway, NJ

Selenoproteins form the bulk of a cell's antioxidant defense system and contain the 21st amino acid, Selenocysteine (Sec). Glutathione peroxidases, thioredoxin reductases and deiodinases are selenoproteins that perform both housekeeping and stress-response functions in the cell. Sec is synthesized from the essential trace element selenium (Se) and is highly reactive. Thus, it is often present in the active site of the above enzymes. The translation of selenoprotein mRNAs itself has a unique mechanism. An in-frame UGA codon, that serves as a canonical termination codon, gets recoded to incorporate Sec. This specialized elongation cycle requires several dedicated and unique *cis* and *trans* acting factors, including the Sec-specific elongation factor called eEFSec. Unlike canonical translation elongation factor eEF1A, eEFSec binds only one species of tRNA -- the selenocystnylated-tRNA^{Sec}, and contains four domains instead of three. Previous studies have highlighted the importance of eEFSec Domain IV for all eEFSec functions during Sec incorporation. However, little is known about the subcellular localization, interacting partners and regulation of eEFSec. This study confirms the nucleo-cytoplasmic shuttling of eEFSec, which is rare for elongation factors as most are predominantly located in the cytoplasm. Additionally, specific residues that allow for nuclear localization as well as nuclear export of eEFSec have been identified. Our data suggest that eEFSec contains a bipartite nuclear localization signal, located in the C-terminus of the protein and a nuclear export signal located in the N-terminus. Moreover, these residues are critical for eEFSec to be able to support Sec incorporation *in vitro*, suggesting that nucleo-cytoplasmic shuttling of eEFSec may be critical to its function. Finally, immunoprecipitation experiments with eEFSec as the bait have identified two nuclear proteins involved in ribosomal biogenesis as eEFSec binding proteins. Thus, a model can be constructed where eEFSec is co-exported from the nucleus in a complex with ribosomal subunits, and that disruption of the residues involved in nuclear localization or export interfere with eEFSec's ability to interact with ribosomes during Sec incorporation. Future work includes determining the nuclear export pathway utilized by eEFSec, as well as the role and regulation of eEFSec localization during selenoprotein biosynthesis.

P1964**Board Number: B477****Beta-Adducin is Phosphorylated in The Nuclei of HeLa Cells by Protein Kinase C.**H.P. Pariser¹;¹Biology, Salem State Univ, Salem, MA

The 87 kDa protein adducin 2b is a cytoskeletal protein responsible for increasing the stability of actin-spectrin networks by behaving as an actin-filament-capping protein in the cytosol. The plasticity of the actin-spectrin network is regulated through the phosphorylation of serine 713 and 726 in the myristoylated alanine-rich protein kinase C (PKC) substrate domain. More recently it has been shown adducin 2b translocates to the nuclei of HeLa cells in response to the cytokine pleiotrophin (PTN) where it has been shown to be phosphorylated at serine 713 and 726. Adducin 2b also becomes associated with centrioles and condensed chromosomes in dividing cells. Here we demonstrate that adducin 2b is a substrate target for PKC when HeLa cell nuclear extract is treated with the PKC activator phorbol 12-myristate 13 acetate (PMA). This result suggests that adducin 2b is regulated in the nucleus and is possibly the mechanism by which adducin 2b associates with nuclear chromatin.

P1965**Board Number: B478****Elucidating mechanisms of nuclear size regulation using cell-free cytoplasmic extracts and microfluidic droplet-generating technology.**J.W. Hazel¹, K. Krutkramelis², P. Jevtic¹, D. Levy¹, J. Oakey², J. Gatlin^{1,3};¹Department of Molecular Biology, University of Wyoming, Laramie, WY, ²Department of Chemical and Petroleum Engineering, University of Wyoming, Laramie, WY, ³Molecular Cellular Life Sciences Program, University of Wyoming, Laramie, WY

Organelles and other intracellular structures must scale with cell size in order to function properly. The functional significance of nuclear size control remains poorly understood, particularly in the context of certain cancers in which the scaling relationship between nuclear and cell size has gone awry. An intriguing possibility is that aberrant nuclear size associated with a disease state might actually be required for cell homeostasis and viability. Elucidating the underlying mechanisms that govern nuclear scaling has proven difficult, due primarily to the lack of experimental approaches capable of precisely manipulating cytoplasmic volume and uncoupling cell size from a developmental or cellular context. To overcome these challenges, we combined microfluidic droplet-generating technology with cell-free *Xenopus* egg extracts. Using this approach, we were able to encapsulate demembrated sperm nuclei in extract droplets and recapitulate nuclear assembly in discrete cytoplasmic volumes. We found that changes in cytoplasmic volume alone, even in the absence of changes in cytoplasmic composition that occur during development and disease progression, could partially explain nuclear scaling as it occurs during development in *Xenopus* embryos. Encapsulated nuclei exhibited asymptotic growth, reaching a volume-dependent steady-state size within two hours post-encapsulation. This is in contrast to

unconfined nuclei, which grew at a constant rate over the same time period. In isovolumetric droplets containing multiple nuclei, nuclear size was dependent upon the total number of encapsulated nuclei. Preliminary results suggest that total nuclear volume is independent of the number of nuclei assembled within a cytoplasmic volume, whereas total nuclear surface area increases with increasing numbers of nuclei. Going forward, this new experimental platform should be of great utility in elucidating the cytoplasmic factors involved in nuclear scaling and will serve as a system to address other important questions of nuclear size regulation.

Over-expression of an export-defective Ltv1 is dominant negative but does not block pre-40S subunit export in *S. cerevisiae*.

J.R. Merwin¹, L. Bogar¹, B. Herken¹, D.E. Lycan¹;

¹Biology Dept, Lewis Clark Coll, Portland, OR

Yeast Ltv1 is a conserved 40S-associated ribosome biogenesis factor that has been proposed to function in small subunit nuclear export. Here we show that Ltv1 has a functional leucine-rich nuclear export signal (NES) at its extreme C-terminus that is both necessary for Crm1 interaction and for Ltv1 export. Over-expression of an Ltv1 lacking its NES (Ltv1 Δ NES) was strongly dominant negative (DN) and resulted in the nuclear accumulation of RpS3-GFP; however, export of the pre-40S was not affected. The dominant negative phenotype of Ltv1 Δ NES over-expression can be suppressed by adding the exogenous PKI NES to Ltv1 Δ NES, showing that Ltv1 must be nuclear to cause the dominant negative phenotype. The DN phenotype could also be suppressed by co-over-expressing RpS3 and its chaperone, Yar1, or by deletion of the RpS3 binding site in Ltv1 Δ NES, suggesting that titration of RpS3 by Ltv1 Δ NES is deleterious in yeast. The dominant negative phenotype did not correlate with a decrease in 40S levels but rather with a reduction in the polysome to monosome ratio, indicating reduced rates of translation. We suggest that titration of RpS3 by excess nuclear Ltv1 interferes with 40S function or with a non-ribosomal function of RpS3.

P1967**Board Number: B480****Simple physical considerations explain the conformational transitions of the FG nucleoporins induced by the nuclear transport factors.**M. Opferman¹, D. Jasnow¹, R. Coalson², A. Zilman^{3,4};¹Physics, Pittsburgh University, Pittsburgh, PA, ²Chemistry, Pittsburgh University, Pittsburgh, PA,³Physics, University of Toronto, Toronto, ON, ⁴Cell and Systems Biology, University of Toronto, Toronto, ON

Nuclear Pore Complex (NPC) is a biological “nano-machine” that controls the macromolecular transport between the cell nucleus and the cytoplasm. It is a remarkable device that combines selectivity with robustness and speed. Unlike many other biological nano-channels, it functions without direct input of metabolic energy and without transitions of the gate from a ‘closed’ to an ‘open’ state during transport. The key aspect of transport is the interaction of the cargo-carrying transport factors with the unfolded, natively unstructured proteins that partially occlude the channel of the NPC and its nuclear and cytoplasmic exits. Mechanistic understanding of the transport through the Nuclear Pore Complex, and in particular its selectivity is still lacking. Conformational transitions of the unfolded proteins of the NPC, induced by the transport factors, have been hypothesized to underlie the transport mechanism and its selectivity. These conformational changes are hard to access in vivo; they have been investigated in vitro generating apparently contradictory results.

We have investigated the biophysical underpinning of these conformational changes, using computational modeling based on the ideas of polymer physics. We show that the differences in the experimentally observed behaviors can be explained by rather general physical factors, such as the attraction strength between the transport factors and the unfolded chains, protein density and the transport factor size. We also show how these general behaviors can be modulated by specific details, such as the aminoacid sequence and the relative arrangement in space of the charged and hydrophobic residues. Finally, we extend the model into a realistic NPC geometry. These results provide new insights into the fundamental principles of transport through the NPC and the control of the behavior of natively unfolded proteins in general.

P1968**Board Number: B481****Establishing a microfluidics platform to watch the deformation of frog oocyte nuclei.**M. Podolski¹, M. Uroz Marimon², M. Kim³, S.K. Tang³, M. Renz⁴;¹Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, ²Department of Biomechanics and Cellular Biophysics, Institute for Bioengineering of Catalonia, Barcelona, Spain, ³Department of Mechanical Engineering, Stanford University, Stanford, CA, ⁴Department of Obstetrics and Gynecology, Albert Einstein College of Medicine, Bronx, NY

Shape and architecture of the mammalian cell nucleus are thought to be maintained by chromatin and nuclear envelope proteins alone. None of the major cytoskeletal proteins, i.e. actin and microtubules, seem to be present in the cell nucleus in considerable amounts. Recently, however, there has been increasing evidence for nuclear actin. This nuclear actin may predominantly exist in its monomeric globular form and may be as such involved in transcription processes. So far, no role for polymerized fibrous actin in the mammalian cell nucleus has been described. It is known, on the other hand, that the actin content in the giant cell nuclei of amphibian oocytes is much higher than in other cell nuclei. The lack of specific export allows the actin to accumulate and consequently polymerize. In frog oocyte nuclei, actin forms a fibrous meshwork morphologically similar to its cytoplasmic counterpart. This actin meshwork may be an inevitable scaffold for the up to 400- μ m measuring frog oocyte nuclei needed for additional mechanical support which cannot be sufficiently provided by chromatin and nuclear envelope proteins alone.

Here, we describe a microfluidics approach to deform frog oocyte nuclei. We provoke cell nucleus deformation by flowing cells through microfluidic channels comprising narrow spaces and orifices. The microfluidic channels used permit high-resolution fluorescence imaging. With these tools, we characterize structural rearrangements of frog oocyte nuclei during and after the imposed deformations.

P1969**Board Number: B482****Cytonuclear transport defect underlies C9ORF72 ALS/FTD neuronal injury in human neurons.**C.J. Donnelly^{1,2}, K. Zhang¹, A.R. Haeusler³, J. Wang³, T.E. Lloyd^{1,4}, R. Sattler^{1,2}, J.D. Rothstein^{1,2,4};¹Neurology, Johns Hopkins University, Baltimore, MD, ²Brain Science Institute, Johns Hopkins University, Baltimore, MD, ³Biochemistry and Molecular Biology, Johns Hopkins University, Baltimore, MD, ⁴Neuroscience, Johns Hopkins University, Baltimore, MD

A hexanucleotide repeat expansion in the C9ORF72 gene has recently been identified as the most common known genetic cause of familial and sporadic amyotrophic lateral sclerosis (ALS) and

frontotemporal dementia (FTD). Recent evidence employing iPS-neurons from C9ORF72 ALS patients suggests that the GGGGCC RNA products transcribed from the repeat expansion form complex G-quartet RNA structures and are neurotoxic. Similar to other repeat expansion disorders (e.g., myotonic dystrophy type I and II), the C9ORF72 GGGGCC_{exp} RNA can sequester nuclear factors, including RNA binding proteins, and we hypothesize that these aberrant interactions are the primary cause of C9ORF72 neurotoxicity. Previous work from our laboratory has indicated that the GGGGCC RNA interacts with RanGAP1, a regulator of Ran-mediated cyto-nuclear trafficking. We have also found that RanGAP1 is a robust suppressor of neurotoxicity in a *Drosophila* model system that overexpresses GGGGCC RNA. Consistent with a RanGAP1 loss-of-function model, both the G4C2 *Drosophila* model and C9ORF72 iPS-neurons show reduced nuclear localization of NLS-containing reporters and that iPS-neurons from C9ORF72 ALS/FTD patients exhibit perturbed Ran protein gradients. The Ran and cytonuclear trafficking deficits observed in C9ORF72 ALS iPS-neurons can be rescued by enhancing neuronal RanGAP1 levels or by treatment with antisense oligonucleotides that target GGGGCC repeat-containing RNAs and small molecules that bind G-quartet RNA structures to prevent any interaction with endogenous proteins. Taken together, these studies strongly support an RNA gain-of-function mechanism underlying C9ORF72 neurodegeneration. Moreover, we show, for the first time, that the toxic GGGGCC_{exp} RNA reduces the nuclear import of classical NLS-containing proteins via an aberrant interaction with RanGAP1. Since cytoplasmic inclusions of predominantly nuclear proteins is the most pronounced pathology in ALS and FTD patient tissue, cytonuclear trafficking deficits might be a common pathway in all ALS/FTD disease pathogenesis.

Nuclear import and DNA damage recognition of Poly(ADP-ribose) Polymerase-2.

A.A. Riccio¹, M.F. Langelier², J.M. Pascal²;

¹Department of Biochemistry and Molecular Pharmacology, Thomas Jefferson University, Philadelphia, PA, ²Department of Biochemistry and Molecular Pharmacology, Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA

Environmental factors and normal genome replication result in DNA damage that must be repaired to ensure the health of an organism. There are many DNA repair pathways that maintain genome integrity, including; single-strand break repair (SSBR), base excision repair (BER), and homologous recombination (HR)[3,10,11]. An essential set of proteins contributing to DNA damage repair is the poly(ADP-ribose) polymerases or PARPs. The PARP superfamily has 17 members, of which PARPs 1, 2, and 3 are DNA damage-dependent PARPs. Upon the recognition and binding of DNA damage, DNA damage-dependent PARPs increase their catalytic activity several fold generating long, branched polymer of poly(ADP-ribose) (PAR). PAR is a highly negatively charged posttranslational modification and the addition of this polymer onto a target protein can modulate structure, function, and the biochemical properties of the target protein. The current body of PARP literature emphasizes the DNA-dependent detection and activation of PARP-1. However, the essential roles of both PARP-1 and PARP-2 are highlighted by the

embryonic lethality of PARP-1-/-PARP-2-/- double knockout mice. PARP-2 is a multi-domain protein composed of an N-terminal region (NTR), a central WGR domain named for the Trp-Gly-Arg motif, and a C-terminal catalytic domain (CAT). In contrast to the homology in the C-terminal regions, WGR and CAT, the NTR of PARP-2 shares negligible sequence homology with other members of the PARP family. We show that the PARP-2 NTR (i) is intrinsically disordered, (ii) is essential for nuclear localization, (iii) is not sufficient or required for localization to cellular sites of DNA damage, and (iv) is required for in vitro DNA binding and activation on a subset of DNA breaks. We have determined biochemically and biophysically that PARP-2 NTR is unique from other PARPs in its intrinsic disorder. A 1.9Å crystal structure of PARP-2 NLS bound to the nuclear transporter, importin α , demonstrates that PARP-2 contains a bipartite NLS motif required for efficient transport into the nucleus. Through live cell microscopy, the crystal structure is verified by monitoring cellular compartmentalization upon disruption of importin alpha cargo binding residues. Interestingly, it is the C-terminal domains of PARP-2 that bind and localize to sites of cellular DNA damage allowing the functions of nuclear import and DNA binding to be partially separable. However, the NTR remains important for fine tuning regulation of catalytic activity and for SSB recognition. Overall, this study highlights the nonredundant roles of DNA damage PARPs and the distinct role of PARP-2 in the DNA damage response.

Nuclear export of β -Dystroglycan.

J. Guadalupe Elizabet¹, B. Cisneros¹, G. Velez Aguilera¹;

¹Genetics and Molecular Biology, CINVESTAV, Mexico, D.F., Mexico

Dystroglycan is an essential component of the Dystrophin-Associated Proteins Complex (DAPC), which maintains the integrity of the sarcolemma and connects the extracellular matrix with the actin cytoskeleton. The DAPC also participates in cell signaling processes. Dystroglycan is composed of α and β subunits, which are associated each other in a non-covalently manner. β -Dystroglycan (β -DG) is a transmembrane protein involved in cell signaling, cell adhesion, and cytoskeleton remodeling. Recently our research group demonstrated that β -DG is transported to the nucleus through a nuclear localization signal (NLS) located in the juxtamembranal region of the protein.

In this study, we present the identification and characterization of a nuclear export signal (NES) in β -DG. In silico analysis identified a putative NES located in the residues 763ILLIAGIIAM772. Treatment of C2C12 cells with leptomycin B, an inhibitor of CRM1 exportin resulted in nuclear accumulation of both endogenous β -DG and GFP- β DG fusion protein, which implies that CRM1 exportin mediates the nuclear export of β -DG. Likewise inactivation of the NES by site-directed mutagenesis caused nuclear accumulation of GFP- β -DG. Finally we demonstrated in vitro interaction of CRM1 exportin with β -DG. Overall, our results suggest that β -DG has a functional NES that is recognized by CRM1 to export the protein from the nucleus to the cytoplasm. The nuclear export of β -DG may be important to modulate its levels in different cell compartments.

Mobility of mRNA in the nucleus as seen by simultaneous 3D single-molecule real time microscopy (3D-SMRT).

C. Smith¹, A. Joseph², S. Preibisch³, S. Stallinga⁴, B. Rieger⁴, R. Singer⁵, D. Grunwald²;

¹RTI, Univ Massachusetts Med Sch, Worcester, MA, ²RNA Therapeutics Institute, University of Massachusetts Medical School, Worcester, MA, ³Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ⁴Quantitative Imaging Group, Delft University of Technology, Delft, Netherlands, ⁵Albert Einstein College of Medicine, Bronx, NY

The ability to image single molecules, such as proteins or RNAs, in the living cell has opened a window for direct visualization of its inner workings. Due to the limited focal depth of conventional light microscopes, however, three-dimensional images must be assembled from a series of images taken along the optical-axis of the microscope over time. The relatively slow acquisition of sequential z-stack images results in a time-difference between the first and subsequent images that limits the accurate 3D recording of rapidly moving single molecules. This can be overcome by simultaneously imaging an entire volume consistent of multiple focal planes.^{1,1a}

Here, we describe simultaneous single RNA-molecule real time (3D-SMRT) microscopy as a way to track the entire distribution of endogenously labeled mRNA within the nucleus of a live mammalian cell. 3D-SMRT microscopy combines the power of multi-focal-plane microscopy with precise registration between fluorescently labeled mRNA, nuclear pore complexes and an intercalating DNA dye that serves as an inherent cellular marker.^{1,2}

By combining redundant geometric local descriptor matching and information entropy based image processing with cell-inherent data we were able to account for aberrations that cannot be accounted for by fiduciary marker-based image registration methods.³ We show that 3D-SMRT microscopy provides exceptional correlation between multiple channels and allows for a quantitative, robust transformation model that globally optimizes image alignment to within half-pixel precision.

P1973**Board Number: B486****New Promising Approach to Karyotype Determination in *Amoeba proteus*.**Y. Podlipaeva¹, S. Demin¹, S. Skarlato¹, A. Yudin¹, M. Berdieva¹, A. Goodkov¹;¹Institute of Cytology, Russian Academy of Sciences, St.Petersburg, Russia

Amoeba proteus-type amebas, the classic model organisms for cell biology studies, are obligatory agamic lower eukaryotes which are characterized by pronounced epigenetic heredity and variability. These unicellular organisms have been under study for about 200 years; however, their chromosome numbers and ploidy level still remain enigmatic. Traditional light and electron microscopical data suggest that the nucleus of *A. proteus* contains about 500 or even more small chromosomes and therefore is likely to be polyploid. Studies of nuclear DNA content during the cell cycle do not shed light on the problem of ploidy because these amebas lack the G₁-phase and the S-phase starts directly after karyokinesis. At the end of the S-phase, the DNA content can increase up to 3.9 times, i.e. the so-called DNA hyper-replication takes place; however, in the G₂-phase DNA is partly eliminated. In mass ameba cultures, one dividing cell can be found per approximately 1000 non-dividing organisms. Thus, the cell cycle synchronization is an important requirement for investigation of the mitotic chromosomes in amebas. In our studies, the *A. proteus* culture, strain B, was synchronized by feeding via pinocytosis on quail egg albumen (Podlipaeva et al., 2013) which allowed: (a) to achieve the high level of cell cycle synchronization; (b) to obtain significant amount of cells at certain mitotic phases, the metaphase in particular; (c) to avoid “background noise” caused by dense food remnants in the digestive vacuoles when amebas were fed with the small ciliates *Tetrahymena*. In our recent experiments, the so-called high-pressure squash technique specifically modified for karyotype studies in amebas allowed to visualize about 23-24 pairs of metaphase chromosomes, which is significantly less than it had been reported for *A. proteus* earlier.

P1974**Board Number: B487****Telomere dysfunction at the nucleotide level: repeat identity in crisis and escape.**. Bennett¹, N. Liu¹, Y. Hu¹, M. Moravec², E. Rodriguez¹, A. Claus², M.C. King¹;¹Department of Cell Biology, Yale University, New Haven, CT, ²Eidgenössische Technische Hochschule Zürich (ETHZ), Institute of Biochemistry (IBC), Otto-Stern-Weg, Switzerland

We have developed a high-throughput sequencing approach that enables us to exactly determine telomeric repeat sequences from tens of thousands of individual *S. pombe* telomeres. To define the molecular changes needed for cells to adopt the alternative lengthening of telomeres (ALT) pathway, we sequenced telomeres from serially cultured cells lacking the telomerase recruitment factor Ccq1. Telomeres from freshly germinated ccq1Δ cells have a highly diverse telomeric sequence content driven by recombination. We find that improved growth, increased telomere length and canonical telomere sequence content in survivors correlates with the derepression of telomeric repeat-containing RNA

(TERRA). Degradation of TERRA in *ccq1Δ* survivors forces a return to a growth crisis. These results suggest that production of TERRA represents a key step in the adoption of the ALT pathway, which has important implications for understanding mechanisms of selection and maintenance of ALT-positive tumor cells.

Dynamic and structural properties of interphase chromatin mapped in vivo with fluorescence correlation spectroscopy and quantitative modelling.

M. Wachsmuth¹, T.A. Knoch²;

¹European Molecular Biology Laboratory (EMBL), Heidelberg, Germany, ²Biophysical Genomics, Dept. Cell Biology and Genetics, Erasmus MC, Rotterdam, Netherlands

The three-dimensional organization of chromosomes of eukaryotic interphase cells is emerging as an important parameter for the regulation of storage, replication and expression of the genome. While a range of techniques like electron microscopy (EM), fluorescence in situ hybridization (FISH), or chromosome conformation capture techniques (3C, 4C, 5C, HiC, or the novel targeted chromatin capture, T2C) have been very successfully used to study chromosomal architecture, many details of structural and especially of dynamic properties remain unresolved. Here, we present a novel approach to dissect intramolecular polymer dynamics from fluorescence intensity fluctuations measured with fluorescence correlation spectroscopy (FCS) to investigate the higher order chromatin dynamics in living cells. Using fluorescently tagged linker histone H1 and core histones H2A and H2B as tracer molecules, we find distinct chromatin relaxation times of ~160 ms for open and ~90 ms for dense chromatin areas, corresponding to radii of gyration of 240 and 300 nm for the topologically independent chromatin units. According to their genomic content of ~1 Mb, these units correspond to the distinct topologically associating domains (TADs) found recently by 3C-derived techniques and to subchromosomal domains seen earlier by FISH and in vivo chromatin labelling. We have also obtained light-sheet microscopy-based FCS maps of chromatin domain dynamics. Based on these results, we have developed a quantitative analytical and numerical model of chromatin dynamics that provides access to mass density, persistence length and topological information of chromatin. It allows to extract these parameters from dynamics and 5C/HiC results, to predict chromatin conformation and distance data, and to identify complex looping as crucial for domain formation. Data and model suggest the existence of several connected loops of ~100 kb each per domain. Especially in combination with the recently developed highly selective T2C method (see abstract T.A. Knoch & M. Wachsmuth, "Determination of the three-dimensional organization of chromatin by modelling-supported targeted chromosomal interaction capture (T2C)"), which provides very good signal-to-noise ratio at high genomic resolution, we present a comprehensive systematic approach for the understanding of chromatin dynamics and its relation to structure as well as for insight into the impact on gene regulation.

P1976**Board Number: B489****The Mechanics of Nuclear Shaping.**Y. Li¹, D. Lovett¹, Q. Zhang¹, R. Kuchibhotla¹, S. Neelam², R. Zhu³, G.G. Gundersen³, R.B. Dickinson¹, T.P. Lele¹;¹Chemical Engineering, University of Florida, Gainesville, FL, ²Biomedical Engineering, University of Florida, Gainesville, FL, ³Department of Pathology and Cell Biology, Columbia University, New York, NY

The nuclei in cultured cells are commonly flat, but how the nucleus becomes flattened during cell spreading remains unclear. To answer this question, we imaged NIH 3T3 fibroblasts with a confocal microscope at different stages of spreading and quantified the shape changes of nuclei. Surprisingly, we find that actomyosin forces, microtubule-based forces and intermediate filaments, as well as the LINC complex, are all dispensable for nuclear flattening. Remarkably, nuclear height correlated tightly with the degree of cell spreading. Independent of the type of cytoskeletal force perturbed, the nucleus is flat unless the perturbation prevents initial cell spreading, or rounds up a spread cell. Our computational model shows that F-actin flow due to polymerization from the apical cortex, together with viscous transmission of stress from the moving cell boundary to the nuclear surface, is sufficient to translate and flatten the nucleus, even in the absence of actomyosin contractility.

P1977**Board Number: B490****Novel nuclear localization and function of the actin bundling protein Fascin.**C.M. Groen¹, T.L. Tootle²;¹Anatomy and Cell Biology, Univ Iowa-Carver Coll Med, Iowa City, IA, ²Department of Anatomy and Cell Biology, University of Iowa Carver College of Medicine, Iowa City, IA

The actin regulator Fascin is a critical factor in a number of developmental processes and disease states, such as neurogenesis and cancer. Fascin's roles in these biological processes have largely been attributed to its activity as a cytoplasmic actin bundler, although more recent work suggests that Fascin also has bundling-independent functions. *Drosophila* oogenesis is an ideal system to uncover the function and regulation of cytoskeletal regulators like Fascin (*Drosophila* Singed). Late stage oogenesis requires dynamic actin remodeling events, which include formation of parallel actin filament bundles. Fascin is required for formation of these actin bundles, and loss of Fascin results in female sterility. While Fascin has previously only been shown to function in the cytoplasm, we find that Fascin acts at new cellular sites during *Drosophila* oogenesis. Fascin exhibits weak localization within the nucleus, a previously unreported phenomenon in any system. As development progresses, Fascin more strongly localizes within the nucleus and subsequently undergoes a dramatic re-localization to the nuclear periphery. This dynamic subcellular distribution suggests that Fascin's localization is developmentally regulated. Indeed, we find that loss of lipid signals called prostaglandins (PGs) alters the subcellular localization of Fascin, likely by modifying Fascin's phosphorylation state. When PG signaling is lost,

Fascin initially exhibits a stronger nuclear signal and becomes progressively less associated with the nucleus. In addition, Fascin fails to re-localize to the nuclear periphery at S13 upon loss of PGs. These data suggest that Fascin has important functional roles in the nucleus, and that these novel activities are regulated by PGs. Indeed, we find that disruption of nuclear Fascin affects nucleolar shape and size. When PGs are lost and Fascin is elevated in the nucleus, the nucleolus becomes greatly enlarged and fragmented. By contrast, when Fascin is lost, the nucleolus becomes much more dispersed and unstructured. Importantly, this is not due to loss of cytoplasmic actin bundle formation, as two other *Drosophila* mutants that lack bundles exhibit normal nucleolar structure. Current efforts focus on further elucidating the mechanism by which PGs regulate Fascin and determining the role(s) of Fascin in the nucleus and at the nuclear periphery, including possible associations with nuclear actin. The novel roles of Fascin in the nucleus and at the nuclear periphery are likely contributing to its activities in other tissues and organisms, including during cancer initiation and progression.

Nucleolar assembly and growth are governed by a concentration-dependent phase transition.

S.C. Weber¹, J. Berry², M. Haataja², C. Brangwynne¹;

¹Chemical and Biological Engineering, Princeton University, Princeton, NJ, ²Mechanical and Aerospace Engineering, Princeton University, Princeton, NJ

Eukaryotic cells exhibit a remarkable degree of spatial organization. In addition to classical membrane-bound organelles, the cytoplasm and nucleoplasm contain membrane-less, liquid-like droplets of RNA and protein, many of which function in regulating RNA metabolism. How such structures assemble and stably persist without a physical boundary holding them together, and how cells might regulate this process, are still unclear. Here, we use quantitative imaging of live *C. elegans* embryos combined with analytical theory and numerical simulations to investigate the assembly and growth dynamics of the nucleolus, a non-membrane bound organelle important for cell size homeostasis. We find that nucleolar components condense into nucleoli only above a threshold concentration and that the final size of the organelle depends linearly on concentration. Furthermore, the growth kinetics of nucleoli are consistent with a phase separation model in which the thermodynamic attraction between nucleolar components results in stable, coherent droplets. Our results suggest that phase transitions could play a general role in functionally organizing the nucleoplasm/cytoplasm and generating organelles of appropriate size.

P1979**Board Number: B492****Visualization of large scale genomic data in single cells uncovers the functional organization of chromosomes.**T.R. Luperchio¹, X. Wong¹, M. Hallstead², R. Ach³, K. Pekrun³, N. Yamada³, K.L. Reddy¹;¹Biological Chemistry and Center for Epigenetics, Johns Hopkins University School of Medicine, Baltimore, MD, ²UC Davis, Davis, CA, ³Agilent Technologies, Agilent Laboratories, Santa Clara, CA

Nuclear structure and scaffolding have been implicated in expression and regulation of the genome. Discrete domains of chromatin exist within the nuclear volume, and are suggested to be organized by patterns of gene activity. The nuclear periphery, which consists of the inner nuclear membrane and associated proteins, forms a sub-nuclear compartment that is mostly associated with transcriptionally repressed chromatin and low gene expression. Previous studies from our lab and others have shown that repositioning genes to the nuclear periphery is sufficient to induce transcriptional repression; these regions of chromatin that come in molecular contact with the nuclear periphery are called Lamin Associated Domains (LADs). Our current work highlights the relationship of LADs, the epigenome and three-dimensional architecture in development and potential disease phenotypes. LADs are dynamic and serve as a mechanism for regulation of specific gene sets during cellular programs and these dynamics are both seen in populations and single cells. We hypothesized that LAD patterns are reflective of and influenced by higher order chromatin structure and that higher order chromatin structure and epigenetic signatures are closely and functionally linked. Visual studies of LAD architecture in single cells using novel oligonucleotide DNA probes underscores these relationships, and also defines a novel compartment at the nuclear periphery where Lamina Associated Domains are restricted.

P1980**Board Number: B493****Increased age is associated with polyploidy and aneuploidy on neuronal nuclei from mouse brain cortex.**T. Gonçalves do Carmo Oliveira¹, H. Ferreira Rodrigues¹, M. Mondin², T. Andrade de Souza¹, F.G. Ghiraldini³, M. Silveira Mello³, A. da Silva Moraes^{1,4};¹Institute of Biomedical Sciences, Federal University of Uberlandia, Uberlandia, Brazil, ²Department of Genetics, Superior Agriculture School Luiz de Queiroz, University of Sao Paulo, Piracicaba, Brazil, ³Department of Structural and Functional Biology, UNICAMP, Campinas, Brazil, ⁴Federal University of Uberlandia, Uberlandia, Brazil

Background Polyploidy, in mammals, is a phenomenon classically observed in hepatic and muscular cells. However, some previous works show evidence of polyploidy, as well as aneuploidies in brain cells from mouse, rats, and humans. It seems to exist a positive correlation between aging and increased ploidy degrees in some tissues. However, attempts to detect age-related changes in ploidy levels in

neural cells have not been conclusive. **Aims** Look for evidences of polyploidy and aneuploidy on cortical neurons from mice and evaluate if such events are influenced by age. **Methods** Neuronal nuclei were isolated from brain cortices from young and aged mice, followed by flow cytometry of propidium iodide-stained nuclei, image analysis of Feulgen-stained nuclei smeared on histological slides, and telomere analysis after FISH. All experiments involving animal handling and care were approved by the Institution's Committee on Ethics for Animal Experimentation. **Results** Both image and flow cytometry analyses provided evidence of both, aneuploidy and polyploidy in neuronal nuclei, as well as an age-related increase in both phenomena. A higher number of telomeric spots per nucleus in neurons from older mice are in accordance to these data. **Conclusion** Present data show evidence of both polyploidy and aneuploidy, and it is possible that the number of polyploid, as well as aneuploid cells, or the number of individual chromosomes in some cells increases with age. We believe that the increased aneuploidy is linked to impaired maintenance of chromosome structure, and may positively correlate with cognitive decline frequently observed in the elderly. The role of increased ploidy in cells from aged individuals is still an unresolved issue, but may correlate positively with the onset of neurodegenerative disorders like Alzheimer's and Parkinson's diseases.

The Biogenesis of Small Nuclear Ribonucleoproteins in *Arabidopsis Thaliana*.

L.Y. Salazar¹;

¹Biology, Northern New Mexico College, Espanola, NM

The nucleus is the center for all inheritable genetic information. Genetic information regulates everything from form and function to the survival and evolution of life. The nucleus contains a number of distinct non-membranous subcompartments called nuclear bodies. Two examples of such compartments are the nucleolus and Cajal bodies. These subcompartments are formed by a unique set of proteins that carry out specific functions. One such protein is the Survival of Motor Neuron protein (SMN). In animals, mutations in this protein have been implicated to the genetic recessive disorder called Spinal Muscular Atrophy (SMA). SMA is the leading disorder for mortality in children under the age of 2 years. SMN is part of a large protein complex, called the SMN Complex, which is essential for RNA splicing in all eukaryotic cells. SMN has been conserved evolutionary through several organisms ranging from humans to mice, flies, worms and plants. However, little is know about the biology of this pathway in plants. The goal of my project is to study the role of SMN during plant development using *Arabidopsis Thaliana* as a model organism system. Specifically, i) I will use genetic and cellular approaches to characterize the effects of *Arabidopsis* SMN (AtSMN) mutants in the biogenesis of different RNAs. ii) I will analyze, in vivo, the localization of the AtSMN protein at the subcellular level in wild type and in different genetic backgrounds. During the last two semesters I have identified four independent mutations on the AtSMN gene using the Polymerase Chain Reaction method. I have been making genetic crosses using different mutants and nuclear fluorescent markers to study the cell nucleus in my AtSMN mutant plants. Currently, I am cloning the AtSMN gene to rescue SMN mutant

flies to demonstrate that *Arabidopsis* is an excellent model to study the underlying basic biology for SMA.

Characterization of the Spindle Assembly Checkpoint in *S. cerevisiae*.

U. Rai¹, V. Thompson², A.M. Tartakoff^{1,3};

¹Departments of Molecular Biology and Microbiology, Cell Biology Program, Case Western Reserve University, Cleveland, OH, ²Department of Biology, St. John's University, Queens, NY, ³Department of Pathology, Case Western Reserve University, Cleveland, OH

The Spindle Assembly Checkpoint (SAC) regulates the metaphase-to-anaphase transition when chromosomes are not properly attached to the mitotic spindle. In *S. cerevisiae*, at the end of G2 phase, the bud is large and the nucleus stretches and divides in two to generate the haploid nuclei of mother and daughter (bud). In this process, the nuclear envelope does not break down. A stable Medial Nuclear Division (MND) intermediate can be imposed by inhibiting activation of the Anaphase-Promoting Complex/Cyclosome (APC/C). We study the effect of SAC using strains in which the APC activator Cdc20 is under the control of a methionine-repressible promoter. Upon arrest, we observe that the nuclear envelope continually extends across the bud neck while chromatin “transits” every 2-10 min between the two domains of the nucleus. During this period (which can last for hours), a short spindle transects the chromatin mass. Moreover, the nucleolus remains attached to the nuclear envelope in the mother cell and the spindle pole bodies repeatedly traverse the bud neck. Especially the latter observation is surprising since the bud neck restricts diffusion of membrane proteins between mother and bud.

3D organization of chromatin in the macronucleus of the ciliate *Bursaria truncatella*.

V.I. Popenko¹, B. Karajan², Y. Ivlev³, J.L. Ivanova¹, S. Skarlato⁴, O. Leonova¹;

¹Engelhardt Institute of Molecular Biology RAS, Moscow, Russia, ²Institute of Cytology RAS, St.Petersburg, Russia, ³Severtsov Institute of Ecology and Evolution RAS, Moscow, Russia, ⁴Institute of Cytology, Russian Academy of Sciences, St.Petersburg, Russia

Ciliated protists contain two morphologically and functionally different types of nuclei in each cell: a germinal functionally inert micronucleus, and a somatic macronucleus, which is DNA-rich and transcriptionally active during vegetative growth. In contrast to genomes of metazoan cells, the macronuclear genomes are represented by sets of relatively short DNA molecules (minichromosomes) either of “gene size” (0.5-25 kb) or of subchromosomal size (from several tens up to several hundred kb). For this reason, ciliate macronuclei are a convenient object to study the peculiarities of chromatin

and nucleolus morphology in the nuclei with noncanonical genome organization. In particular, non-classical nucleolar organization was observed in *Stylonychia lemnae* (“gene-sized” species) and in *Didinium nasutum* (“subchromosomal” species) macronuclei [1-3].

In this work we studied 3D organization of chromatin in the macronucleus of the ciliate *Bursaria truncatella* using electron microscopy (EM), confocal microscopy, and 3D electron microscopic reconstruction on the basis of serial ultrathin sections [4]. The macronuclear *B. truncatella* DNA molecules vary in size from 50 to about 350 kb. EM data show that in interphase macronucleus these DNAs are packed into chromatin bodies 0.06-0.2 μm in size. During encystment or under unfavourable conditions (e.g. starvation) some chromatin bodies increase in size and aggregate, forming long anastomotic chromatin threads 0.1-0.2 μm thick. 3D models showed that such threads are morphologically similar to the chromoneme fibres observed in the nuclei of higher eukaryotes. These processes only occur in specific regions located axially in the central part of *B. truncatella* macronucleus.

Using BrdU label and confocal microscopy we showed that late replicating genes are mainly located in the central regions of *B. truncatella* macronucleus. On the contrary, early replicating genes are at the periphery of the macronucleus, where no aggregation of chromatin bodies occurs. Our data correlate well with the fact that in metazoan nuclei late- and early-replicating genes are located in the heterochromatin and euchromatin nuclear domains, respectively. However, unlike the metazoan nuclei, early-replicating chromatin is located at the periphery of *B. truncatella* macronucleus, whereas late-replicating chromatin – in its central regions. The data obtained show that the architecture of the nuclei with organization of genome in short minichromosomes can differ from that of metazoan nuclei. RFBR grant 11-04-01967.

The DEAH-box helicase Dhr1 Dissociates U3 snoRNA from the pre-rRNA to promote folding of the central pseudoknot.

R. Sardana¹, X. Liu², S. Granneman³, J. Zhu¹, M. Gill¹, D. Tollervey³, C. Correll², A.W. Johnson¹;

¹Univ Texas-Austin, Austin, TX, ²Rosalind Franklin University of Medicine Science, North Chicago, IL,

³University of Edinburgh, Edinburgh, United Kingdom

A central question in ribosome biogenesis is how RNA-RNA and RNA-protein structural rearrangements are coordinated. In eukaryotes, the highly conserved U3 snoRNA base-pairs with the pre rRNA to

coordinate early cleavage and folding events within pre-40S particles. U3 interactions with the 5' ETS region of the pre-rRNA are essential for cleavage at sites A0, A1 and A2, which generate the 20S, an 18S precursor, and separate the large and small subunit precursors. U3 binds multiple sites in the pre-rRNA, bringing distant elements together. In particular, U3 promotes a long-range interaction termed the central pseudoknot (CPK), a universally conserved architectural feature of the small ribosomal subunit. However, binding of U3 is mutually exclusive with folding of the mature CPK structure, necessitating its removal during pre-40S maturation. Here, we provide genetic and physical evidence that Dhr1 is the helicase responsible for U3 displacement. Active site mutations in Dhr1 trapped a novel ~50S particle containing U3 snoRNA, the core SSU Processome factors Mpp10 and Imp4 and 20S and 21S pre-rRNA. These RNAs have undergone U3-dependent cleavage at sites A0 and A1 but are only partially cleaved at site A2. Chemical probing was consistent with U3 snoRNA remaining base-paired with pre-rRNA. UV crosslinking identified Dhr1 binding sites in the 5' region of U3 snoRNA and U29, C39, G47 and A48 as nucleotides that were directly crosslinked to Dhr1. These residues are adjacent to U3 box A, which is believed to bind across the CPK, and to U3 5'-hinge, a sequence that base-pairs to the 5' ETS. Separately, we identified mutations in U3 snoRNA that suppressed the growth defect of a *dhr1* cold-sensitive mutant. The suppressing mutations in U3 mapped to residues 1 through 28, immediately upstream of the Dhr1 binding site. Finally, we show that purified Dhr1 is an active RNA helicase that can displace a model U3 snoRNA-pre-rRNA duplex. Together, these data strongly suggest that Dhr1 promotes the release of U3 snoRNA to promote the formation of the CPK and separation of pre-40S from the early pre-ribosome.

Reproduction of FC/DFC units in nucleoli.

E. Smirnov¹, D. Cmarko¹, T. Mazel², Z. Svindrych³, G.M. Hagen¹, A. Schrofel¹, S. Svidenska³, M. Hornacek¹, M. Skalnikova¹, I. Raska¹;

¹ICBP, Charles University in Prague, First Faculty of Medicine, Prague, Czech Republic, ²Charles University in Prague, First Faculty of Medicine, Prague, Czech Republic, ³Charles University in Prague, First Faculty of Medicine, Prague 2, Czech Republic

Nucleoli are formed on the basis of Nucleolus Organizer Regions (NORs), i.e., the clusters of ribosomal genes coding for the ribosomal particles. FC/DFC units are key structural components of the nucleoli, where rDNA is transcribed, and the transcripts are processed. In the present study we followed cell cycle related changes of these units in vivo using a human sarcoma derived cell line with stable expression of GFP-RPA43 (a subunit of RNA polymerase I, pol I) and RFP-PCNA (the sliding clamp protein). Employing CLEM, we could identify the FC/DFC units previously observed in the live cells also on the thin plastic sections. According to our data, in early S phase, when transcriptionally active ribosomal genes are replicated, the units occasionally divided or lost pol I. Remarkably, although the units multiplied from early to late S phase, their number in that period increased only by about 70%. After the cell division, the units gradually unfolded from the NORs, and around the middle of G1 phase their number in each of

the daughter cells exceeded one half of the number observed in the maternal cell in G2. The peculiar mode of reproduction of FC/DFC units suggests that a considerable subset of ribosomal genes remain transcriptionally silent from late S phase to mitosis, but get activated in the postmitotic daughter cells.

Replication and transcription machineries are efficiently separated in nucleoli.

M. Skalnikova¹, E. Smirnov¹, D. Cmarko¹, Z. Svindrych¹, P. Krizek¹, G.M. Hagen¹, L. Kovacik¹, I. Raska¹;
¹ICBP, Charles University in Prague, First Faculty of Medicine, Prague, Czech Republic

In mammalian cells, ribosomal genes coding for the 18S, 5.8S and 28S rRNAs are transcribed within the nucleolar structures called FC/DFC units (i.e. Fibrillar Centers with adjacent Dense Fibrillar Components). Since these genes are intensively transcribed throughout interphase, some kind of mutual adjustment is needed to avoid collision of the DNA polymerase and RNA polymerase machineries. In this work, we measured correlation of various replication and transcription signals in the nucleoli of HeLa, HT-1080 and NIH 3T3 cells employing a specially devised software for analysis of confocal images. Using a stable cell line expressing GFP-RPA43 (subunit of RNA polymerase I) and RFP-PCNA (the sliding clamp protein) based on HT-1080 cells, we found that replication and transcription signals are more efficiently separated in nucleoli than in the nucleoplasm. Analysis of single molecule localization microscopy (SMLM) images indicated that transcriptionally active FC/DFC units did not incorporate DNA nucleotides. Moreover, comparing distribution of distances between the transcription (FU) and replication (EdU) signals on the one side and between fibrillarin (which is a structural component of DFC) and EdU signals on the other, shows that EdU signals tends to localize closer to fibrillarin than FU signals. Our data indicate that FC/DFC units may provide a structural basis for the efficient separation of replication and transcription in the nucleoli. ¹Chemical and Biological Engineering, Princeton University, Princeton, NJ, ²UT Southwestern, Dallas, TX, TX, ³Department of Biophysics, University of Texas Southwestern Medical Center, Dallas, TX, ⁴Howard Hughes Medical Institute, Dallas, TX

Non-membrane bound intracellular organelles are associated with a wide range of biological functions. Several of these structures have been shown to be enriched with multi-valent molecules and exhibit liquid-like properties that may represent droplets of phase-separated RNA and/or proteins. Little is

known about the molecular interactions driving the assembly, properties, and function of these organelles. Here, we address this question using a model multi-valent protein system consisting of repeats of the Small Ubiquitin-like Modifier (SUMO) protein and a SUMO-interacting motif (SIM). Solutions of these proteins are found to undergo phase separation into liquid-like droplets, both in vitro and within cytoplasmic extracts. We combine microrheology and quantitative microscopy approaches to determine the viscosity, density and surface tension of these droplets. We also utilize fluorescence recovery after photobleaching (FRAP), fluorescence correlation spectroscopy (FCS) and Dextran partitioning experiments to probe the internal structure and molecular dynamics within these droplets. Our results shed light on how the strength of inter-molecular interactions manifests in mesoscale droplet properties, and lay the groundwork for a comprehensive biophysical picture of intracellular RNA/protein organelles.

Spatial relationship between Bdnf alleles and their parent chromosome territories in neurons upon seizures.

A. Walczak¹, M. Pyskaty¹, A.A. Szczepankiewicz¹, B. Ruszczycki¹, G. Wilczynski²;

¹Neurophysiology, Nencki Institute of Experimental Biology, Warsaw, Poland, ²Nencki Inst, Warsaw, Poland

In the interphase nuclei chromatin is organized in the form of chromosome territories. Moreover, it is known that particular genes are non-randomly located in the nuclear space. From the experiments concerning several types of cells, it is known that the position of gene loci in relation to the parent chromosome territory is not stable, and may change upon various conditions (e.g. during differentiation). However, little is known about this phenomenon in differentiated cells such as neurons. Previously, in the rat model of epilepsy, we showed that the localization of Bdnf gene is non-random in hippocampal neurons. In the control neurons, Bdnf alleles were localized at the nuclear periphery in as many as 50,5% of the nuclei, whereas in the nuclei of the stimulated neurons only 27,9% had the Bdnf alleles at the nuclear periphery. To examine the spatial positioning of the alleles in relation to chromosome 3 territory we performed fluorescent in situ hybridization with the chromosome painting probe and the gene-specific probe. The allele was considered located outside the chromosome territory if the distance from its center to the surface of the territory was greater than 350 nm (the microscope resolution averaged in three dimensions). We observed that in the control animals there were 21,74±0,02% of the nuclei with both Bdnf alleles located outside of its parent chromosome territories, 46,52±0,01% of the nuclei with one of the allele located outside its parent chromosome territory and as many as 31,74±0,02% of the nuclei with none of the alleles located outside of its parent chromosome territory. Such an analysis was also performed for the neurons after seizures. Here we observed that 26,95±0,12% of the nuclei had both of the Bdnf alleles located outside of parent chromosome territory whereas 41,84±0,09% of the nuclei had one of the allele located outside of the chromosome territory. We did not observed any difference as far as the nuclei with none of the alleles located outside of the

territory is concerned. The slight but significant difference in the percentage of the nuclei with the alleles outside the chromosome territory suggests that the alleles tend to loop out from their parent territory upon neuronal stimulation. Presented study was supported by the 'Preludium' grant for young investigators financed by Polish National Science Center (grant number 2011/03/N/NZ3/04516).

Vesicle Docking and Fusion

P1989

Board Number: B507

Rab3/rabphilin is present on a subset of vesicles predestined to dock to RIM clusters at the plasma membrane.

N.R. Gandasi¹, S. Barg¹;

¹Institute of Medical Cell Biology, Biomedical Center, Uppsala University, Uppsala, Sweden

Insulin is released by regulated exocytosis, which requires secretory vesicles to be docked at the plasma membrane. The number of release ready vesicles at the plasma membrane is therefore rate limiting for hormone secretion. Stable docking is preceded by a loosely tethered state, and we showed recently that this transition occurs within seconds after arrival of the vesicle by recruitment of syntaxin and munc18 to the docking site. The molecular nature of the tethered state is not known and it remains elusive whether the vesicles tether to a preexisting receptor complex in the plasma membrane or attach to random sites. To answer this we quantified GTP-binding rab proteins and their effectors at the docking site by imaging GFP-tagged proteins using TIRF microscopy. Clusters of the rab3 interacting protein RIM and rabphilin existed at docking sites prior to vesicle tethering and docking. A further increase in RIM fluorescence was seen at vesicles during their maturation into the releasable pool, confirming a role of RIM in priming. Vesicles that successfully docked carried rab3 and rabphilin whereas those that only temporarily tethered did not. In contrast, rab27 and its effector granuphilin were present on both types of vesicles. These results suggest that rab3 and rabphilin act on the incoming granules as signals to initiate the docking process. Since RIM is thus far the only protein found to be enriched at the docking site it may act as a docking receptor for the incoming vesicle.

⁶Cell Biology and Metabolism Program, NICHD, NIH, Bethesda, MD

Cytotoxic T lymphocytes (CTLs) are an integral part of the immune system as they are responsible for destroying virally infected and tumorigenic cells throughout the body. CTL undergo a dramatic reorganization of the actin and microtubule cytoskeletons upon target recognition, facilitating the polarized secretion of a potent cocktail of lytic proteins that induce target apoptosis. These cytolytic proteins are housed in specialized lysosome-related organelles called “lytic granules.” It is known that CTL direct lytic granule trafficking specifically in the direction of the target by polarizing the centrosome to the CTL/target interface. However, how CTL regulate secretion of lytic granules is still unclear. The actin cortical cytoskeleton plays a role in regulating exocytosis in a number of professional secretory cells. It can act as a barrier-- preventing secretory granules from reaching the plasma membrane. We previously showed that actin clears away from the plasma membrane at the interface between the T cell and the target. However, controversy remains as to the role of actin in secretion at the synapse. Using newly developed Lattice Light Sheet Microscopy, we show that actin cortical density is reduced at the synapse within 1 minute after target recognition. We also find that lytic granules cluster at the centrosome prior to its delivery to the synapse. We hypothesize that the rapid formation and maintenance of an area of reduced cortical actin density at the synapse after target recognition could provide a platform to mediate immediate and facile secretion of lytic granules which are delivered to the synapse in conjunction with the centrosome. Supporting this hypothesis, we also note that CTL manipulate the actin cortical cytoskeleton to prevent secretion. Using TIRF microscopy, we show that following secretion of a few granules, actin cortical density dramatically increases at the synapse. Surprisingly, actin cortical density remains reduced at the synapse lacking proteins that are required to secrete lytic granules, indicating that this actin “wall” forms only after lytic granule secretion. Depolymerization of the actin “wall” with low doses of Latrunculin A results in immediate lytic granule secretion. This suggests that this actin wall could be serving as a barrier to prevent sustained lytic granule secretion toward an individual target cell. CTL are serial killers. In order for this to be true, CTL must regulate the number of granules that are secreted in each target encounter. This way, they maintain a complement of granules to be used against subsequent target cells.

Investigating the regulation of pulmonary surfactant secretion using fluorescence microscopy.

A.J. Trexler¹, J.W. Taraska²;

¹NHLBI, NIH, Bethesda, MD, ²NHLBI/NIH, Bethesda, MD

Alveolar type II (ATII) cells are found in the lining of alveolar air sacs in the mammalian lung. One function of these cells is the secretion of pulmonary surfactant, which is a mixture of lipids and protein that reduces surface tension in the lung and helps to maintain functional air exchange. In cells pulmonary surfactant is stored within large vesicles known as lamellar bodies (LBs), and the calcium-

dependent fusion of these vesicles with the plasma membrane is accomplished using the machinery of regulated exocytosis including SNARE proteins and a host of effectors and regulatory partners. We are developing a model system for studying surfactant secretion in A549 cells, a human lung carcinoma line derived from ATII cells and that shares many features with ATII cells. Our approach is to visualize LB fusion and the relative localization of associated proteins in live cells using total internal reflection fluorescence microscopy. Here we focus on two families of calcium-sensitive membrane-binding proteins that are potential regulators of LB fusion: the synaptotagmins and annexins. We find that A549 cells exhibit LB fusion after stimulation using hypo-osmotic shock, which induces cell swelling and membrane stretching, consistent with ATII cell physiological response to breathing and lung expansion. We have not observed evidence that the synaptotagmin isoforms expressed in lung tissue colocalize with sites of LB fusion, suggesting that this protein family may not play a local role in the regulation of LB fusion. However, annexin A7 appears to localize to sites of LB exocytosis concomitant with membrane fusion. Annexin A7 does not appear on the membrane prior to fusion, at our time resolution, and this suggests annexin may not initiate fusion but is involved in a later phase. Interestingly, we observe actin recruitment to sites of LB fusion, and annexins have previously been suggested to mediate actin polymerization at lipid membranes. We are currently investigating this possible relationship and other functions of the annexins in regulated pulmonary surfactant secretion.

Clustering of L-type Ca²⁺-channels promotes exocytosis of individual secretory granules.

P. Yin¹, N.R. Gandasi², M. Riz³, M. Chibalina⁴, M.G. Pedersen³, S. Barg²;

¹Institute of Medical Cell Biology, Uppsala University, Uppsala, Sweden, ²Institute of Medical Cell Biology, Biomedical Center, Uppsala University, Uppsala, Sweden, ³Information Engineering, University of Padua, Padua, Italy, ⁴Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom

Aim:Ca²⁺ entry through voltage gated L-type calcium channels triggers release of insulin-containing secretory granules. Electrophysiological data suggest that channel clustering near docked granules is critical for exocytosis and physiological insulin secretion. A certain number of clustering is thought to be mediated by binding of the α 1 subunit of L-type channels to SNARE proteins through its synaptic protein interaction site (synprint). However, direct evidence for channel clustering near granules is lacking.

Materials and methods:Distribution of the EGFP-labeled Ca²⁺-channel subunit Cav1.2 was imaged together with a granule marker in rat insulin secreting Ins1 cells using TIRF-microscopy. Localized Ca²⁺ influx was imaged using the calcium sensor Ca²⁺ sensor (lyn-GECO-R, membrane-targeted) or Fluo5F in EGTA loaded cells (Ins1, mouse and human pancreatic beta cells). Ca²⁺-currents were quantified using patch clamp and local Ca²⁺-gradients estimated using a deterministic model.**Results:**Cav1.2-EGFP formed clusters on a hazy background that partially colocalized with docked granules. Image analysis indicated specific binding of Cav1.2-EGFP to granules, which was confirmed by Single molecule imaging that

demonstrated reduced mobility of Cav1.2-EGFP near docked granules. This binding was not detectable when the synprint fragment was coexpressed, suggesting that the peptide competes with and uncouples Cav1.2 from the exocytosis machinery. Ca^{2+} -channel clusters formed at granules at least 60 s after their arrival at the plasma membrane, and rapidly dispersed after exocytosis. In depolarized cells, docked granules that exocytosed (responders) carried significantly more Cav1.2-EGFP than those that failed to do so (failures). Visualization of Ca^{2+} -influx indicated localized Ca^{2+} -entry with faster $[\text{Ca}^{2+}]$ increase at responder granules compared with failures or random sites. Modeling of Ca^{2+} -influx confirmed that the observed rates of Ca^{2+} -entry and distribution are consistent with localized Ca^{2+} -influx near granules. The copy number of calcium channels associated with the granule site was estimated by combined fluorescence and current recordings. Common signaling pathways in the pancreatic β -cell do not affect channel clustering. **Conclusions:** In summary, we demonstrate clustering of Cav1.2 channels near a subset of docked insulin granules. This arrangement results in localized calcium entry and selective exocytosis of the associated granules. Channel clustering depends on short term binding via the synprint domain and disrupting this interaction leads to dispersal of the channels away from granules.

Spatial control of H,K-ATPase-containing membrane trafficking and docking by phosphorylation-coupled ezrin-syntaxin 3 interaction.

W. Yao¹, . Suzuki², B. Qin¹, X. Yuan³, H. Takahashi², K. Takeyasu², X. Yao³;

¹Physiology, Morehouse School of Medicine, Atlanta, GA, ²School of Biostudies, Kyoto University, Kyoto, Japan, ³Cellular Dynamics, University of Science Technology of China, Hefei, China

The digestive function of the stomach depends on acidification of the gastric lumen. Acid secretion into the lumen is triggered by activation of a cAMP-dependent protein kinase (PKA) cascade, which ultimately results in the insertion of gastric H,K-ATPases into the apical plasma membranes of parietal cells. A coupling protein is ezrin whose phosphorylation at Ser66 by PKA is required for parietal cell activation (J. Biol. Chem. 2003. 278, 35651-9). However, little is known regarding the molecular mechanism(s) by which ezrin operates in gastric acid secretion. Here we show that phosphorylation of Ser66 induces a conformational change of ezrin which enables its association with syntaxin 3 and provides a spatial cue for H,K-ATPase trafficking. This conformation-dependent association is specific for syntaxin 3 and binding interface and is mapped to the N-terminal region. Biochemical analyses show that inhibition of ezrin phosphorylation at Ser66 prevents ezrin-syntaxin 3 association and insertion of H,K-ATPase into the apical plasma membrane of parietal cells. Using atomic force microscopic analyses, our study revealed that phosphorylation of Ser66 induces unfolding of the ezrin molecule to allow syntaxin 3 binding to its N-terminus. Given the essential role of Stx3 in polarized secretion, our study presents the first evidence in which phosphorylation-induced conformational rearrangement of ezrin provides a spatial cue for polarized membrane trafficking in epithelial cells.

P1994**Board Number: B512****TRIM72/MG53 directly modulates phosphatidylinositol-4,5-bisphosphate 3-kinase signaling to mediate vesicular trafficking during endocytosis and exocytosis.**S. Bhattacharya¹, J. Alloush¹, E. Beck¹, L. Gushchina¹, N.L. Weisleder¹;¹Davis Heart and Lung Research Institute, Ohio State University Medical Center, Columbus, OH

Tripartite motif (TRIM) proteins constitute a family of proteins that all contain a canonical RING finger, B-box and coiled-coil domains which participate in several cellular processes. TRIM72, also known as mitsugumin 53 (MG53), is an essential component of the membrane repair machinery in striated muscles. The TRIM72/MG53 knockout mouse displays compromised muscle membrane repair and *trim72*^{-/-} mice develop myopathy. Due to its essential role in the membrane repair process in striated muscle, TRIM72/MG53 has recently been considered as a therapeutic candidate for the treatment of muscular dystrophy. Following membrane disruption, TRIM72/MG53 translocates to the site of injury to allow resealing of the damaged area. The precise molecular mechanism by which TRIM72/MG53 translocate to the injury site and reseal the damage membrane is clearly not known. Previous studies established that membrane damage increases vesicular trafficking to the site of membrane injury, which is followed by vesicular fusion to patch the damaged portion of the membrane. Previous studies indicate that both endocytosis and exocytosis are important in the membrane repair process, and also that TRIM72/MG53 expression can appear in vesicles that are released from myocytes. In this study we examined the role of TRIM72/MG53 in vesicular endocytosis and exocytosis in C2C12 myoblasts overexpressing TRIM72/MG53. The extent of vesicular endocytosis and exocytosis was measured as internalization of fluorescently tagged dextran and internalization/recycling of fluorescent transferrin using laser scanning confocal microscopy and fluorescence-activated cell sorting (FACS), respectively. Overexpression of TRIM72/MG53 in C2C12 myoblasts increased the total amount of endocytosis of labeled dextran into the myoblasts. Exocytosis as assayed by transferrin internalization and recycling was also increased by expression of TRIM72/MG53. Our recent findings show that TRIM72/MG53 overexpression is sufficient to activate the phosphatidylinositol-4,5-bisphosphate 3-kinase (PI3K) signaling pathway. Therefore, we hypothesized that this TRIM72/MG53 mediated vesicular translocation may be regulated by a PI3K-dependent pathway. To test this hypothesis, dextran uptake and transferrin internalization/recycling were measured in the presence of wortmannin. Wortmannin significantly attenuated dextran uptake and transferrin internalization/recycling in C2C12 myoblasts. To control for any off-target effects of chemical inhibitors, molecular approaches were used to introduce constitutively active PI3K and protein kinase B (AKT) constructs which increased dextran and transferrin trafficking in C2C12 myoblasts similar to TRIM72/MG53. Dominant negative PI3K and AKT constructs prevented TRIM72/MG53 mediated increases in endocytosis and exocytosis. We conclude that TRIM72/MG53 is an important regulator of the PI3K/AKT signaling pathway and positively regulates translocation of vesicles to the site of membrane injury.

P1995**Board Number: B513****The exocyst subunit Sec6 has a role downstream of SNARE assembly.**M.L. Dubuke¹, S. Maniatis², S. Shaffer², M. Munson¹;¹Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, ²Proteomics and Mass Spectrometry Facility, University of Massachusetts Medical School, Worcester, MA

In eukaryotic cells, membrane-bound vesicles carry protein and lipid cargo between intracellular compartments, to and from the cell surface, and to the extracellular environment. A major unanswered question is how vesicle fusion is tightly controlled to prevent premature or inappropriately localized membrane fusion. Two of the conserved families of proteins required for vesicle fusion at the proper target membrane site are the oligomeric tethering complexes and the SNARE proteins. The exocyst is the exocytic tethering complex that regulates polarized exocytosis, and is proposed to tether vesicles to their sites of fusion. Subsequently, the SNARE proteins mediate membrane fusion. Because the exocytic SNARE proteins show little specificity for their binding partners and are not always localized to sites of membrane fusion, SNARE complex assembly must be highly regulated. Previous work from our laboratory demonstrated that, in vitro, the *Saccharomyces cerevisiae* exocyst subunit Sec6 directly binds the plasma membrane SNARE Sec9 and inhibits the assembly of the binary SNARE complex containing Sec9 and the plasma membrane SNARE Sso1. Sec6 and Sec9 also interact in vivo; therefore, we hypothesize that the interaction between Sec6 and Sec9 regulates the assembly of SNARE complexes at sites of exocytosis upon vesicle arrival. In order to elucidate the role of the Sec6-Sec9 interaction in SNARE complex assembly, we used the zero-length crosslinker EDC (1-Ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride) and mass spectrometry analyses to identify the residues required for binding. We monitored the cross-linking reaction over a range of times from 15 to 120 minutes, and identified a patch of residues on Sec9 between the two SNARE helices; these residues were mutated for further analysis. A re-interpretation of our lab's previous data regarding Sec6's inhibition of Sec9-Sso1 complex formation, combined with new data using the Sec9 mutant protein, suggests that Sec6 is capable of binding to both the binary Sec9-Sso1 SNARE complex and the ternary Sec9-Sso1-Snc2 SNARE complex. The mutations in the Sec9 linker are not sufficient to disrupt the Sec6-Sec9 interaction, but are sufficient to disrupt binding of Sec6 to the binary SNARE complex. These results suggest a new role for Sec6 downstream of SNARE assembly.

P1996**Board Number: B514****The Q-SNARE SNAP-47 regulates trafficking of selected VAMPs.**

A. Kuster¹, S. Nola¹, F. Dingli², B. Vacca¹, c. gauchy¹, J. Beaujouan¹, M. Nunez³, T. Moncion³, D. Loew², e. formstecher³, T. Galli¹, V. Proux-Gillardeaux¹;

SNAREs constitute the core machinery for membrane fusion. Vesicular SNAREs localize to different intracellular compartments via largely unknown mechanisms. Here we sought to define the regulatory network of TI-VAMP/VAMP7 by a proteomics approach. We were able to confirm previously described interactions and further identified an interaction between VAMP7 and SNAP-47. We found that SNAP-47 preferentially interacts with VAMPs 4, 7 and 8, and is mainly localized to the endoplasmic reticulum, and ERGIC. Yeast two-hybrid screens pulled out syntaxins with SNAP-23 and -29 but not SNAP-47 as baits which instead interacted with proteins involved in budding and transport. Nevertheless, SNAP-47 was coimmunoprecipitated by syntaxin 5 but also syntaxin 1 when this latter is retained in the ER in the absence of Munc18a. A C-terminally deleted form of the protein was impaired in VAMPs interaction and affected the subcellular distribution of VAMP4 and VAMP7. Silencing of SNAP-47 expression further decreased the localization of VAMP4 in the Golgi apparatus. Overexpression of SNAP-47 inhibited the exocytic activity of pHluorin-tagged VAMP7. We conclude that SNAP-47 plays a role in budding and transport through the early secretion pathway of a subset of v-SNAREs to regulate their post-Golgi functional availability.

P1997**Board Number: B515****The golgin coiled-coil proteins tether vesicles.**

M. Wong¹, S. Munro¹;

¹Cell Biology, MRC Laboratory of Molecular Biology, Cambridge, United Kingdom

A key step in membrane traffic is tethering, which provides initial association between transport vesicles and their target membranes prior to SNARE-mediated membrane fusion. The golgins are one class of putative vesicle tethering factors found on the Golgi apparatus. Their precise functions have been unclear, partially due to redundancy suggested by mild phenotypes of mutant models. In this work, we adopted a relocation strategy to test for sufficiency rather than necessity. Ten golgin proteins were systematically relocated to the mitochondria through substituting their C-termini, which have been shown to confer Golgi localisation, by a mitochondrial transmembrane domain. We found that individual golgins are capable of capturing ER-derived cargos, Golgi residents, or endosome-to-TGN cargos to the mitochondria. Furthermore, ultrastructural studies show striking accumulation of vesicles around mitochondria decorated with particular golgins. Our results demonstrate for the first time in vivo that

golgins are indeed vesicle tethers, and that they exhibit specificity towards different classes of transport vesicles that travel to or through the Golgi.

The HOPS/Class C Vps complex tethers membranes by binding to a Rab GTPase in one membrane and directly via a curvature-sensing motif to a second, highly-curved membrane.

C. Stroupe¹, R. Ho¹;

¹Molecular Physiology and Biological Physics, University of Virginia, Charlottesville, VA

Membrane tethering factors are thought to function by simultaneously binding to two apposed membranes. However, the sites on tethered membranes that are bound by tethering factors in order to form membrane-bridging physical linkages remain unknown. Here, we use liposomes and purified proteins to identify the physical interactions needed for membrane tethering by the HOPS/Class C Vps complex, an effector for the yeast vacuolar Rab GTPase Ypt7p. We find that HOPS can tether two low-curvature membranes using its two Ypt7p binding sites – one in its Vps41p subunit, the other in its Vps39p subunit – to bind a molecule of Ypt7p in each of the apposed membranes. HOPS also can tether a low-curvature membrane to a high-curvature membrane by binding to the low-curvature membrane via Ypt7p and to the highly-curved membrane using a curvature-sensing ALPS motif in Vps41p. A protein construct containing only the Ypt7p-binding site and ALPS motif from Vps41p was unable to tether membranes, while a HOPS complex lacking Vps39p was similarly unable to perform tethering. We therefore conclude that HOPS tethers low-curvature membranes to high-curvature membranes by binding via Vps39p to Ypt7p in the low-curvature membrane, and via its ALPS motif to the high-curvature membrane. These results suggest a model for how HOPS tethers both high-curvature membranes (e.g. small transport vesicles) and low-curvature membranes (e.g. late endosomes/multivesicular bodies) at the large, low-curvature vacuole/lysosome.

Conformational flexibility of GCC185 is required for vesicle tethering at the trans Golgi.

P. Cheung¹, C. Limouse², H. Mabuchi³, S.R. Pfeffer⁴;

¹Department of Biochemistry, Stanford University, Palo Alto, CA, ²Stanford University, Stanford, CA,

³Applied Physics, Stanford University, Stanford, CA, ⁴Department of Biochemistry, Stanford University, Stanford, CA

Membrane trafficking involves the collection of cargo molecules into transport vesicles, movement of vesicles along cytoskeletal tracks, and tethering, docking and fusion of vesicles at a target membrane.

Transport vesicle tethering is perhaps, the least understood process in membrane traffic. GCC185 is a trans Golgi-anchored, coiled coil tethering protein required for maintenance of Golgi structure and the receipt of transport vesicles inbound from late endosomes. GCC185 is predicted to be a highly extended protein, and like most other coiled coil tethers, it contains regions of predicted flexibility that may function as a hinge to bring vesicles into close proximity with target membranes. We have used atomic force microscopy (AFM) to analyze the structure of purified human GCC185 protein. The full-length protein (mean length: ~130 nm) as well as its fragments, appear shorter than expected according to structure prediction algorithms. A clear splaying of the dimeric coiled coil is seen near the middle of GCC185, a feature that can serve as a flexible, central joint within this tethering factor. Proximity ligation experiments revealed that GCC185's N- and C-termini can be detected in close proximity (<40 nm) on the surface of the Golgi in cultured cells; proximity was significantly decreased for deletion mutants lacking the splayed, central region. Using purified GCC185 fragments, we detected direct interaction between the N-terminal 358 residues and a C-terminal domain, consistent with the proximity of these regions, detected in cells. Functional rescue of mannose 6-phosphate receptor trafficking in GCC185-depleted cells required the presence of GCC185's central flexible region; replacement of these sequences with unstructured Gly-Gly-Ser repeats yielded the same, complete rescue of mannose 6-phosphate receptor trafficking seen with wildtype GCC185 protein. These experiments provide a detailed, structural analysis of a trans Golgi-associated coiled coil tether, and demonstrate, for the first time, a requirement for central flexibility in transport vesicle tethering at the trans Golgi.

The syntaxin 31-induced gene, LESION SIMULATING DISEASE1 (LSD1), functions in Glycine max defense to the root parasite *Heterodera glycines*.

S.R. Pant¹, B.T. McNeece¹, J. Jiang¹, P. Niraula¹, A. Krishnavajhala², G.W. Lawrence², V.P. Klink¹;

¹Department of Biological Sciences, Mississippi State Univ, Mississippi State, MS, ²Department of Biochemistry, Molecular Biology, Entomology and Plant Pathology, Mississippi State University, Mississippi State, MS

The membrane fusion genes alpha soluble NSF attachment protein (α-SNAP) and syntaxin 31 (Gm-SYP38) contribute to Glycine max defense to the plant parasitic nematode *Heterodera glycines*. Accompanying their expression is the transcriptional activation of the defense genes ENHANCED DISEASE SUSCEPTIBILITY1 (EDS1) and NONEXPRESSOR OF PR1 (NPR1) that function in salicylic acid (SA) signaling. These results implicate the added involvement of the antiapoptotic gene LESION SIMULATING DISEASE1 (LSD1). Roots engineered to overexpress Gm-α-SNAP, SYP38, EDS1, NPR1, BOTRYTIS INDUCED KINASE1 (BIK1) and xyloglucan endotransglycosylase/hydrolase (XTH) in the susceptible genotype G. max[Williams 82/PI 518671] have induced Gm-LSD1 (Gm-LSD1-2) transcriptional activity. In reciprocal experiments, roots engineered to overexpress Gm-LSD1-2 in the susceptible genotype G. max[Williams 82/PI 518671] have induced levels of SYP38, EDS1, NPR1, BIK1 and XTH, but not α-SNAP prior to infection. In tests examining the role of Gm-LSD1-2 in defense, its overexpression results in reduced

nematode parasitism. In contrast, RNA interference (RNAi) of Gm-LSD1-2 in the resistant genotype G. max[Peking/PI 548402] results in an 3.24-10.42 fold increase in parasitism. The results identify that Gm-LSD1-2 functions in the defense response. It is proposed that LSD1, as an antiapoptotic protein, may establish an environment whereby the protected, living plant cell could secrete materials in the vicinity of the parasitizing nematode to disarm it. After the targeted incapacitation of the nematode the parasitized cell succumbs to its targeted demise as the infected root region is becoming fortified. The results indicate a similar framework may be in place for other agriculturally important root parasitic nematodes.

Cytoskeleton organizes exocytosis “hotspots” in endocrine cells revealed by spatiotemporal analysis of discrete vesicle fusion events.

T. Yuan¹, Y. Zhang², L. Chen¹;

¹Institute of Molecular Medicine, Peking University, Beijing, China, ²National Laboratory of Biomacromolecules, Institute of Biophysics, Chinese Academy of Sciences, Beijing, China

In secretory cells, depolarization induces rapid fusion of secretory vesicles with the plasma membrane, thus releasing neurotransmitters and hormones to mediate important physiological processes (1). Using fluorescent imaging and electrophysiological methods, people have studied the molecular mechanisms underlying vesicle exocytosis. Cytoskeletons have been proposed to regulate transport of vesicles to the plasma membrane (2). The spatial information of the fusion events within a single cell has seldom been systematically investigated due to the lack of a fully automated program to analyze large image datasets. Therefore, how cytoskeletons regulate the spatial profile of fusion sites remains unknown. Here, we performed spatiotemporal analysis of exocytic events recorded from insulin-secreting INS-1 cells under a total internal reflection fluorescence microscope (TIRFM). We statistically prove that individual vesicle fusion events are clustered at “hotspots”. This spatial preference disappears upon pharmacological disruption of either the actin or the microtubular network, which also severely inhibit evoked exocytosis. During long time recording of single cell exocytosis under high glucose stimulation, we observed the changes of exocytosis between different “hot regions”. The results indicate that the biphasic insulin secretion involves the changing of spatial preference of exocytosis over time. By demonstrating that newcomer vesicles are delivered from deep in the cell to the surface membrane and contribute a large proportion of exocytosis, we highlight an unappreciated mechanism, in which the cytoskeleton-dependent transportation of newcomer secretory vesicles instead of the active-zone-like accumulation of pre-docked secretory vesicles organizes exocytosis hotspots in endocrine cells.

P2002**Board Number: B520****Integral membrane protein sorting and degradation is intrinsic to vacuole fusion.**E. McNally¹, C. Brett¹, J. Richard¹;¹Biology, Concordia University, Montreal, QC

Integral Membrane Proteins (IMPs), such as surface receptors and transporters, are essential for signaling and substrate transport across membranes. Consequently, the regulation of IMP expression levels underlies numerous fundamental cellular processes. Therefore, determining how these proteins are degraded is important for a comprehensive understanding of cell physiology. Eukaryotic cells degrade surface IMPs via endocytosis and the Multi Vesicular Body (MVB) pathway, which solves the topological challenge of exposing IMPs to luminal acid hydrolases within the vacuole (or lysosome) for degradation. However, this process does not account for turnover of all IMPs within the cell. For example, it is not understood how IMPs that avoid the MVB machinery, such as vacuole transporters, are degraded. Based on detailed studies of homotypic vacuole fusion, it is known that a portion of the organelle membrane, called the contact zone, is internalized and degraded as a product of the reaction. Thus, we hypothesize that if vacuole IMPs are sorted into the contact zone, then they will be internalized and degraded as a consequence of homotypic membrane fusion. To test this hypothesis in *Saccharomyces cerevisiae*, we monitored transporters during the homotypic vacuole fusion reaction both in vivo and in vitro using time-lapse fluorescence microscopy, a pHulorin-based reporter assay and by Western blotting for products of degradation. We find that most GFP-tagged vacuole transporters are excluded from the contact zone and spared. However, some GFP-tagged transporters tested are actively sorted into the contact zone, internalized and degraded during homotypic vacuole fusion. Importantly, degradation of these IMPs is not affected by mutations that impair the MVB pathway. Ongoing experiments are designed to uncover the mechanisms responsible for labeling and sorting of vacuole IMPs destined for degradation. However, our initial findings confirm the existence of a second, independent cellular pathway responsible for the degradation of intracellular IMPs. Analogous to the role endocytosis in controlling surface IMP levels, this process likely controls the IMP profile that defines organelle identity and function required for normal cellular physiology.

Post-Golgi Trafficking

OVERLAPPING FUNCTIONS OF PI4KII AND PI4KIII β (Fwd) IN DROSOPHILA CELLS.

T. Chorna¹, J. Burgess^{1,2}, J. Tan³, K. Oh⁴, J.A. Brill¹;

¹Cell Biology Program, Hospital for Sick Children, Toronto, ON, ²Molecular Genetics, University of Toronto, Toronto, ON, ³Department of Molecular Genetics, University of Toronto, Toronto, ON, ⁴IRCM, Montreal, QC

Phosphatidylinositol 4-kinases (PI4Ks) synthesize a pool of phosphatidylinositol 4-phosphate (PI4P) that binds and recruits factors required for post-Golgi trafficking. *Drosophila melanogaster* has a single type II enzyme (PI4KII) and two type III enzymes (PI4KIII α and PI4KIII β (Fwd)). Previous studies in our lab have shown that PI4KII and PI4KIII β (fwd) are non-essential since their null mutants are viable. Fwd is localized to the Golgi, where it is required for spermatocyte cytokinesis, but is dispensible for glue granule formation in salivary glands. PI4KII is localized to the Golgi and endosomes and is required during glue granule biogenesis, but is dispensible for spermatocyte cytokinesis. By contrast, PI4KIII α is essential and needed for generating pool of PI4P at the plasma membrane and cortical integrity during oogenesis. Since Fwd and PI4KII localize to the Golgi, we hypothesized that these enzymes might have overlapping functions. Thus, the main objective of our study was to investigate potential redundancy of Fwd and PI4KII in *Drosophila* cells. For our experiments, we used a combination of *Drosophila* genetic tools, immunohistochemical methods and confocal imaging. We found that GFP-Fwd and endogenous or mCherry-tagged PI4KII localize near each other at the Golgi in salivary gland cells and spermatocytes. In fwd PI4KII double mutants, which die as second instar larvae, the Golgi appear smaller and clathrin adaptor AP-1 puncta are not always associated with each Golgi body in salivary gland cells. Double knockdown of fwd and PI4KII by RNAi in *Drosophila* S2 cells displaced a fluorescent PI4P marker (YFP-PH-FAPP) from the Golgi into the cytoplasm, indicating that the two PI4Ks are redundant for synthesizing Golgi PI4P. In addition, fwd PI4KII double mutants showed severe Golgi phenotypes in egg chambers. Moreover, nurse cell membranes, which were not affected in fwd and PI4KII single mutant ovaries, appeared thinner and discontinuous in fwd PI4KII double mutant germ line clones, revealing the redundant roles of these PI4KII enzymes in plasma membrane stability. These results suggest that Fwd and PI4KII together might affect processes controlled by PI4KIII α .

P2004**Board Number: B522****E-cadherin apical sorting by a p200/AP-1/clathrin/RAB-11 pathway during morphogenesis.**G. Gillard¹, M. Shafaq-Zadah², O. Nicolle¹, G. Michaux¹;¹CNRS, IGDR, Rennes, France, ²INSERM U1143-CNRS UMR 3666, Institut Curie, Centre de Recherche, Paris cedex 05, France

Membrane traffic can be divided in two essential steps: sorting between cargos and transport to various destinations. In epithelial cells, a specific sorting event is required to differentially traffic apical and basolateral proteins; while basolateral sorting has been extensively studied, apical sorting mechanisms are still elusive. To characterise apical sorting *in vivo* we choose to examine the apical delivery of E-cadherin (E-cad) in *C. elegans* epidermal cells. A systematic RNAi screen designed to find genes required for the strict E-cad apical localisation identified clathrin, the clathrin adaptor AP-1 and p200/SOAP-1, a physical AP-1 interactor; their loss induced a basolateral localisation of E-cad while the loss of Rab5, Rab11 or the exocyst lead to intracellular accumulation. This phenotype was specific to E-cad since other apical markers and the apico-basal diffusion barrier were unaffected in the epidermis. Surprisingly glycosphingolipids were not required in that process, likely ruling out a role for lipid rafts, the best known apical sorting mechanism, in E-cad apical sorting. We further found that SOAP-1 controls AP-1 localisation which is itself required for Rab11 subapical localisation. Furthermore Rab11 depletion induced a strong loss of the apical E-cad pool. We concluded that SOAP-1/AP-1 control E-cad sorting upstream of its apical delivery via Rab11 endosomes in the biosynthetic and/or recycling pathways. This function of AP-1 in E-cad apical delivery is essential during embryonic morphogenesis, a process controlled by junction rearrangement and driven by acto-myosin contractions: we found that the E-cad basolateral accumulation was correlated in time and space with a strong loss of cell-cell adhesion and a dramatic loss of actin organisation. We therefore propose that a molecular pathway including SOAP-1, AP-1 and clathrin acts upstream of Rab11 to apically deliver E-cadherin in *C. elegans* epidermal cells and control cell-cell adhesion rearrangement during morphogenesis.

P2005**Board Number: B523****Plasma membrane trafficking mediated by a novel polybasic Golgi export signal in the reovirus p14 FAST protein is mediated by Rab11 and AP1.**H. Parmar¹, C. Barry¹, F. Kai¹, R. Duncan²;¹Microbiology and Immunology, Dalhousie University, Halifax, NS, ²Dalhousie University, Halifax, NS

The sorting and trafficking of integral membrane proteins to the plasma membrane is essential for proper cellular function. Our understanding of the pathways and signals involved in regulating this process is incomplete, particularly as it relates to Golgi export to the plasma membrane. The reovirus

fusion-associated small transmembrane (FAST) proteins traffic through the ER-Golgi pathway to the plasma membrane where they cause cell-cell membrane fusion. We undertook an analysis of factors regulating plasma membrane trafficking of the p14 FAST protein. Results indicate that a polybasic motif (PBM) in the cytosolic tail of p14 functions as a novel autonomous Golgi export signal. Alanine substitution of the p14 PBM led to loss of p14 plasma membrane localization and accumulation of p14 in the Golgi complex. Extensive mutagenic analysis indicated that a minimum of three basic residues are required for efficient Golgi export, and that the PBM exerts differential trafficking effects depending on its membrane proximity. Moreover, insertion of the PBM into a Golgi resident protein mediated protein export to the plasma membrane, indicating the p14 PBM is an autonomous Golgi export signal. Co-immunoprecipitation (Co-IP) indicated p14 interacts with activated Rab11 in a PBM-dependent manner, and RNAi approaches revealed Rab11 and adaptor protein 1 (AP1) are both required for efficient p14 trafficking to the plasma membrane. This is the first indication that interaction of activated Rab11 with membrane cargo can sort membrane cargo to AP1-coated vesicles for plasma membrane trafficking, and in the case of p14 this is mediated by a novel tri-basic Golgi export signal.

Biological membranes in eukaryotes contain a large variety of proteins and lipids often distributed in microdomains in plasma membrane and endomembranes. Molecular mechanisms responsible for the transport and the organization of these membrane microdomains along the secretory pathway still remain elusive. Here we show that vesicular SNARE TI-VAMP/VAMP7 plays a major role in membrane microdomains composition and transport. We found that the transport of exogenous and endogenous GPI-anchored proteins was altered in fibroblasts isolated from VAMP7-knockout mice. Furthermore, disassembly and reformation of the Golgi apparatus induced by Brefeldin A treatment and washout were impaired in VAMP7-depleted cells, suggesting that loss of VAMP7 expression alters biochemical properties and dynamics of the Golgi apparatus. In addition, lipid profiles from these knockout cells indicated a defect in glycosphingolipids homeostasis. We conclude that VAMP7 is required for effective transport of GPI-anchored proteins to cell surface and that VAMP7-dependent transport contributes to both sphingolipids and Golgi homeostasis.

P2007**Board Number: B525****Microtubule regulation of insulin packaging and secretion in pancreatic β -cells.**X. Zhu¹, R. Hu¹, D. Yampolsky¹, M. Brissova¹, R. Stein¹, A.C. Power¹, G. Gu¹, I. Kaverina²;¹Vanderbilt University medical center, Nashville, TN, ²Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

Glucose-stimulated insulin secretion (GSIS) from pancreatic β cells maintains glucose homeostasis. The prevailing hypothesis is that insulin secretion by β cells is the result of microtubule-dependent transport, which delivers insulin granules to exocytic sites. In contrast to this common notion, we report that microtubules (MTs) regulate insulin secretion by restraining excessive delivery of insulin granules to the plasma membrane. Using high- and super-resolution microscopy on intact islets, combined with GSIS detection, we found that MTs in functional β cells emerge from the Golgi complex and form a meshwork-like network that anchors insulin granules. High glucose enhances MT dynamic turnover resulting in a less dense network, which is necessary for GSIS. Importantly, the density of MT network is significantly greater in dysfunctional β cells of diabetic mice compared to normal mice. Furthermore, we show that MT depolymerization facilitates delivery of insulin granules to the cell membrane and dramatically enhances GSIS, suggesting that dense MTs withhold granules away from secretion sites, and that glucose induces dynamic MT turnover and makes granules available for GSIS. Moreover, our data indicate that while insulin secretion is facilitated w/o MTs, proinsulin packaging into the granules at the TGN is retarded due to slow proinsulin sorting for entry. These results demonstrate that MTs act as a cellular “rheostat” for precisely metered insulin secretion, which is tuned according to physiological needs by modulating MT density and dynamics. Currently, we are in progress of developing a computational model, which will allow us to simulate relative contributions of distinct MT-dependent mechanisms to balanced insulin secretion.

P2008**Board Number: B526****Formin-mediated traffic control: Involvement of RhoA-mDia1 pathway in regulating the movements of secretory vesicles.**Z. Lieu¹, N. Flores-Rodriguez¹, S. Miserey-Lenkei², A. Mogilner³, A.D. Bershadsky^{1,4};¹Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ²Institut Curie-Centre National de la Recherche Scientifique, Paris, France, ³Department of Biology, Courant Institute of Mathematical Sciences, New York, NY, ⁴Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel

The trafficking of secretory vesicles along microtubule track mediates the transport of cargo proteins or lipids from one intracellular compartment to another. While microtubule-based motor proteins and their associated regulatory machinery are known to be involved in regulating the mobility of secretory

vesicles along microtubule, the role of the actin cytoskeleton, in particular, the formin family of actin nucleators remains poorly understood. Using the secretory cargo, monocyte chemoattractant protein 1 (also known as CCL2), we showed that formin mDia1 and its activator RhoA are involved in regulating the movements of CCL2 vesicles along microtubules. Increasing the activity of RhoA using lysophosphatidic acid or expression of constitutively active RhoA significantly reduces the proportion of moving vesicles, the average anterograde velocity and the total vesicle displacement. These effects of RhoA were shown to be mediated by its immediate downstream target mDia1, a potent activator of actin filament nucleation and elongation. The overexpression of constitutively active mDia1 mutant was by itself sufficient to reduce the mobility of CCL2 vesicles to the levels similar to those observed in RhoA activated cells, suggesting that increased actin polymerization mediated by activated mDia1 restricts the motion of CCL2 vesicles. Several lines of evidence suggest that mDia1 effects on the movements of CCL2 vesicles may be regulated by local actin polymerization rather than overall increase in F-actin in cells. First, live imaging observations demonstrated that formin mDia1, but not mDia2, is transiently localised to CCL2 vesicles. Second, immunoprecipitation experiments demonstrated that mDia1 interacts with the kinesin-1 heavy chain as well as with the components of dynactin complex. Finally, alterations of global F-actin level in cells using actin polymerization-affecting drugs did not result in significant changes in the motility of CCL2 vesicles, as compared to those produced in cells by active mDia1 or RhoA. Taken together, our results are consistent with the hypothesis that mDia1 regulates the kinesin-1-driven movements of secretory vesicles along microtubules by affecting local actin polymerization.

The Arf GEF GBF1 integrates inputs from its product, Arf4•GTP, and the Golgi influx of sensory membrane cargo to activate Arf4 in ciliary trafficking.

D. Deretic¹, J. Wang¹;

¹Surgery/Ophthalmology, University of New Mexico, Albuquerque, NM

One of the outstanding questions in Arf GTPases regulation is the role of protein cargo in their activation. In this study, we show that during ciliary membrane trafficking a functional complex exists between the sensory membrane cargo, rhodopsin, the cognate Arf, Arf4, and the Arf GEF GBF1, which regulates Arf4 activation. The *in situ* Proximity Ligation Assay (PLA) revealed that GBF1 interacts with rhodopsin, Arf4, and the Arf GAP ASAP1 at the photoreceptor Golgi/TGN. The GBF1 GEF activity was essential for the GBF1-rhodopsin-Arf4 interaction, since its selective inhibitor Golgicide A (GCA) caused a significant decrease in all but the GBF1-ASAP1 interactions. GCA specifically inhibited rhodopsin delivery to the cilia. However, in contrast to BFA, GCA had no effect on the Golgi morphology. The GBF1 GEF activity involves the catalytic Sec7 domain. GBF1 also contains conserved regulatory domains: a dimerization and cyclophilin binding (DCB), a homology upstream of Sec7 (HUS), and three homology downstream of Sec7 (HDS) domains. GST-pulldowns of purified rhodopsin were performed with DCB-HUS and Sec7-HDS1, with or without recombinant Arf4 pre-loaded with GTPγS or GDPβS. GST-DCB-HUS pulled down rhodopsin significantly better than GST-Sec7-HDS1, or GST alone, either in the presence or

absence of Arf4, demonstrating a direct rhodopsin-GBF1 interaction. Arf4•GTP preferentially interacted with DCB-HUS, whereas Arf4•GDP interacted with Sec7-HDS1. Thus, GBF1 combines a regulatory binding site within its DCB-HUS domain with a catalytic binding site within the Sec7 domain and acts both as a GEF and an effector of Arf4. The influx of rhodopsin into the Golgi/TGN and Arf4•GTP likely cooperatively activate GBF1 to increase the levels of Arf4•GTP at the Golgi/TGN and optimize budding conditions for ciliary-targeted post-TGN carriers. Notably, the Arf GEF GBF1 and the Arf GAP ASAP1 directly interact with each other, and with rhodopsin and Arf4•GTP, to synchronize Arf4 activation cycles during ciliary receptor trafficking.

Energy-Dependent Regulation of Clathrin Adaptors by the Arf-like GTPase (Arl1).

D. Buelto¹, C. Hung², X. Zhang³, Y. Wang³, M. Duncan⁴;

¹Curriculum in Genetics and Molecular Biology, University of North Carolina, Chapel Hill, NC, ²Biology, University of North Carolina, Chapel Hill, NC, ³Dept. of Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI, ⁴Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

Cellular homeostasis requires adequate levels of glucose. Cells starved for glucose, such as during ischemia, experience severe stress and a reduction in viability. Our lab has discovered an important membrane trafficking response to glucose starvation. During this response, plasma membrane proteins of various types are internalized and delivered to the lytic compartment of the cell, the yeast vacuole. Understanding the regulation of this pathway will be important for shedding light on how cells respond to energy stress. Key regulators of membrane trafficking are obvious candidates, such as Arf GTPases. Similar to Arf1, Arl1 can interact with the clathrin adaptor, Gga2, in its GTP-bound state. Arl1 may therefore be able to recruit clathrin adaptors *in vivo*, however, the role of Arl1 in membrane trafficking has not been well-characterized. These studies provide evidence for a role of Arl1 in the regulation of endosome to vacuole transport during glucose starvation. Using live-cell imaging and western blotting, we demonstrate that Arl1 is required for endosome to vacuole transport of plasma membrane (PM) cargoes during glucose starvation. Apart from proteins, another PM cargo that can be delivered to the vacuole or lysosomes to be degraded and used for ATP generation is lipids. We show that depletion of Arl1 in mammalian cells results in a reduction in lipid droplet size and number during glucose starvation. Similarly, we demonstrate that Arl1 is required for endosomal localization of clathrin adaptors during energy stress. We show that the adaptors themselves are required for endosome to vacuole delivery of PM proteins during glucose starvation. Additionally, using a permeabilized cell assay, we can add ATP and GTP to yeast spheroplasts and stimulate the recruitment of clathrin adaptors to puncta. Previously, we found that GTP synergizes with ATP to recruit adaptors. Our recent data shows that loss of ARL1 eliminates this GTP-ATP synergy. This suggests that Arl1 acts directly in the recruitment of clathrin adaptors, with the help of an unknown ATP sensor. Importantly, loss of ARL1 and subsequent endosome to vacuole transport during glucose starvation leads to reduced ATP recovery and reduced

cell viability. Lastly, we are working to see if the PM to vacuole shunt and the role of Arl1 during glucose starvation are conserved in mammalian cells. Cumulatively, these data point to an energy-dependent role for Arl1 in the regulation of clathrin adaptors at the endosomes and subsequent endosome to vacuole transport. This trafficking step is critical for cell survival during starvation. We propose that, through a mechanism similar to Arf1, Arl1 can recruit clathrin adaptors to the TGN and endosomes during energy stress to promote cell survival.

Mechanism of action of flippase Drs2p in modulating GTP hydrolysis of Arl1p.

F.S. Lee¹, J. Hsu¹, Z. Chen¹, Y. Liu¹;

¹Molecular Medicine, National Taiwan University, Taipei, Taiwan

Small GTPase ADP-ribosylation factors are key regulators of membrane trafficking and their activities are determined by guanine nucleotide-binding status. Arl1p, an ARF-like protein, is responsible for multiple trafficking pathways at the Golgi. The GTP-hydrolysis of Arl1p is stimulated by its GTPase-activating protein Gcs1p, and binding with its effector Imh1p protects Arl1p from premature inactivation. However, the mechanism involved in the timing of Arl1p inactivation is unclear. Here, we demonstrate that another Arl1p effector, lipid flippase Drs2p, is required for Gcs1p-stimulated inactivation of Arl1p. Drs2p is known to be activated by Arl1p and is involved in vesicle formation through its ability to create membrane asymmetry. We found that the flippase activity of Drs2p is required for proper membrane targeting of Gcs1p in vivo. Through modification of the membrane environment, Drs2p promotes the affinity of Gcs1p for the Golgi where it binds to active Arl1p. Together, Imh1p and Drs2p modulate the activity of Gcs1p by timing its interaction with Arl1p, hence providing feedback regulation of Arl1p activity.

The role of phosphatidylserine flippase activity in lateral membrane organization.

H.M. Hankins¹, Y. Yacouba Sere², A.K. Menon², T.R. Graham¹;

¹Department of Biological Sciences, Vanderbilt University, Nashville, TN, ²Department of Biochemistry, Weill Cornell Medical College, New York, NY

An asymmetric distribution of phospholipid species, particularly at the plasma membrane (PM), is a common feature of many eukaryotic cells. Establishment and maintenance of membrane asymmetry requires the activity of flippases that translocate phospholipid substrates from the luminal/extracellular leaflet to the cytosolic leaflet. While the role of flippases in the transverse segregation of phospholipids has been well established, little is known about the role of flippases in lateral membrane organization. The budding yeast PM is organized laterally into a patchwork of “compartments” formed through lipid-

lipid and lipid-protein interactions and marked by specific membrane proteins. In budding yeast there are five flippases (Dnf1p, Dnf2p, Dnf3p, Drs2p, and Neo1p) and there is suggestive evidence that the yeast flippase Drs2p, which has substrate specificity for the aminophospholipids phosphatidylserine (PS) and phosphatidylethanolamine (PE), may have a role in lateral membrane organization. Ergosterol, a core component of lateral membrane domains which normally localizes to the PM, accumulates in internal membranes in *drs2Δ* cells. Membrane proteins which partition into distinct membrane compartments (Pma1p and Can1p) also partially mislocalize to the vacuole in *drs2Δ* cells, further indicating loss of Drs2p flippase activity is disrupting lateral membrane organization. To determine if these defects are specifically due to loss of PS flip, two flippase constructs were used that lose (*drs2*-[QQ->GA]) or gain (DNF1 N550S) the ability to flip PS. *drs2*-[QQ->GA], despite retaining the ability to flip PE, is not able to suppress the ergosterol and membrane protein mislocalization phenotypes of *drs2Δ* cells. In contrast, DNF1 N550S, which gains the ability to flip PS in addition to its normal lysophospholipid substrates, is able to suppress the *drs2Δ* defects. These results suggest that PS flip by Drs2p plays an important functional role in the generation and maintenance of lateral membrane organization and provides new insight into how lateral domains are established in budding yeast.

Structure and function of the N-terminal domains of Sec7/BIG1/2 regulating Arf1-mediated trafficking from the trans-Golgi network.

B.C. Richardson¹, J.C. Fromme²;

¹Cornell University, Ithaca, NY, ²MBG/WICMB, Cornell University, Ithaca, NY

Export of trafficked proteins from the trans-Golgi network (TGN) is an essential function in all eukaryotes, controlled by the small GTPase Arf1. The proximal upstream regulator of Arf1 is the conserved Sec7 (yeast) / BIG1/2 (mammal) / Sec71 (fly) guanine nucleotide exchange factor (GEF), which activates Arf1 specifically at the TGN. This action initiates the terminal cascade of events at the Golgi leading to cargo sorting and vesicle formation with multiple different cargos and cargo adaptors.

Sec7 consists of a single well-characterized catalytic domain responsible for its GEF activity on Arf1, and six similarly sized domains, two N-terminal and four C-terminal to the GEF domain. We recently demonstrated that these latter six domains serve varying and essential functions both to localize Sec7 to its point of action and to regulate its activity negatively when unlocalized and positively when properly localized. Together, the regulatory domains of Sec7 tightly restrict its activity to the trans-Golgi network, ensuring proper maturation and targeting of all transported proteins. However, the mechanistic details of how each domain mediates its autoregulatory functions and its interactions with other proteins remain obscure.

Here, we present the 2.7 Å crystal structure of the two N-terminal regulatory domains of Sec7, representing the first structural model available for regions of Sec7 outside the catalytic domain. The structure identifies a pair of conserved surface regions, one in each domain, mutation of which affects

the activity of Sec7 on Arf1 both *in vitro* and *in vivo*. Paired with small-angle x-ray scattering and multi-angle light scattering data of a suite of Sec7 fragments, this structure provides insight into the nature of dimerization mediated by the N-terminal domains and into the relationship between the catalytic domain and the N-terminal domains.

Defining the assembly determinants and architecture of the yeast exocyst complex.

M.R. Heider¹, C.M. Duffy¹, Z. Hakhverdyan², R. Kalia³, M. Gu³, M. Rout², A. Frost³, M. Munson¹;
¹Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, ²Laboratory of Cellular and Structural Biology, The Rockefeller University, New York, NY, ³Biochemistry, University of Utah, Salt Lake City, UT

The exocyst is a highly conserved, hetero-octameric protein complex, which is proposed to function at the tethering step of exocytosis in all eukaryotes. The classification of the exocyst as a multisubunit tethering complex (MTC) stems from its known interacting partners, polarized localization at the plasma membrane, and structural homology to other putative MTCs. The presence of 8 subunits begs the questions: why are so many subunits required for vesicle tethering and what are the contributions of each of these subunits to the overall structure of the complex? Additionally, are subunit or subcomplex dynamics a required feature of exocyst function? In order to answer these questions, it was critical that we accurately define the subunit connectivity within the endogenous exocyst complex. Using *Saccharomyces cerevisiae* as our model system, we purified intact exocyst complexes under physiological conditions. Regardless of the exocyst subunit used as purification handle, all 8 subunits are stoichiometric. In contrast to early studies of the exocyst, these complexes remained assembled over a wide range of pH and ionic strength conditions, suggesting greater intra-complex stability than previously expected. However, at higher extremes of pH and salt concentration, biochemically stable subcomplexes including Sec10-Sec15 and Sec3-Sec5-Sec6-Sec8 emerged. To further dissect these connections and because most of the exocyst subunits are encoded by essential genes, we used the auxin-inducible degradation (AID) system to selectively and rapidly degrade individual exocyst subunits and monitor the effects on complex assembly. Using the AID system, we identified critical subunits that are required for the overall assembly and for connecting modular subcomplexes. However, given the highly stable assembly of the complex, we hypothesize that any subunit dynamics or complex disassembly require additional factors. To address this hypothesis, we are using the AID system to identify which components within the post-golgi secretory pathway are required for the assembly and disassembly of the exocyst. By selectively depleting GTPases, myosin, and SNAREs and then purifying endogenous exocyst complexes, we will pinpoint the steps in the pathway when these complex rearrangements may occur. Finally, piecing together these subunit connections into the overall structure of the exocyst will provide clues as to how the subunits are poised to capture secretory vesicles. To this end, we visualized its structure for the first time using negative stain electron microscopy. 2D class

averaging reveals an elongated conical structure, and we are currently working to position the individual exocyst subunits within this overall structure.

Trafficking of the Kir2.1 potassium transporter is regulated by the ubiquitin ligase Rsp5 and a select subset of alpha-arrestins in yeast.

A.F. O'Donnell^{1,2}, T. Mackie³, A. Kolb³, A. Dempsey⁴, C. Szent-Gyorgyi⁴, M.P. Bruchez⁴, J.L. Brodsky⁵;

¹Cell Biology, Univ Pittsburgh, Pittsburgh, PA, ²Dept. of Molecular and Cell Biology, University of California at Berkeley, Berkeley, CA, ³Dept. of Biological Sciences, University of Pittsburgh, Pittsburgh, PA, ⁴Molecular Biosensor and Imaging Center, Carnegie Mellon University, Pittsburgh, PA, ⁵Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA

To ensure optimal cell growth and survival, protein composition at the plasma membrane is tightly regulated, with both controlled protein internalization and selective protein targeting to the cell surface in response to environmental changes. To identify factors that regulate this selective protein trafficking, we developed a yeast expression system for the Kir2.1 potassium channel, which maintains potassium homeostasis in heart cells and is thereby critical for cardiac function. By monitoring the growth of Kir2.1 yeast on low potassium medium, Kir2.1 activity at the cell surface can be assessed. Using a high-throughput screening methodology we identified the ESCRTs and retromer complex as novel regulators of Kir2.1 trafficking. We now show that three specific alpha-arrestins – Ldb19/Art1, Aly1/Art6, and Aly2/Art3 – control Kir2.1 trafficking. In marked contrast to the well-described role for alpha-arrestins as endocytic adaptors, these alpha-arrestins promote Kir2.1 trafficking to the cell surface, increasing Kir2.1 activity at the plasma membrane and raising intracellular potassium levels. Consistent with the alpha-arrestin requirement, we also demonstrate that the ubiquitin ligase, Rsp5, and the protein phosphatase calcineurin regulate Kir2.1 plasma membrane targeting. Furthermore, by fusing a single chain antibody to Kir2.1 and employing live cell fluorescence microscopy, we can selectively monitor Kir2.1 cell surface localization or its intracellular distribution, thus providing a complementary tool to delineate the intracellular sorting pathway for this channel. Current work is focused on using the yeast model to define additional factors and regulatory elements required for alpha-arrestin-mediated trafficking of Kir2.1 to the cell surface. Together, these findings identify Kir2.1 as new alpha-arrestin substrate and lay the foundation to further define the molecular mechanisms governing alpha-arrestin-mediated intracellular sorting.

P2016**Board Number: B534****CLATHRIN ADAPTOR AP-1 CONTROL BASOLATERAL SORTING OF THE CHLORIDE CHANNEL 2 THROUGH A SOLE DILEUCINE MOTIF.**E. de la Fuente-Ortega*¹, D. Gravotta*², C. Lagos³, A. Voltage-regulated chloride channel 2 (ClC2) is a polytopic protein ubiquitously expressed in the basolateral membrane of many epithelial cells that function in the regulation of cell volume, ion transport and acid-base balance. As for most chloride channels, the molecular signals and cellular machinery that determine the subcellular distribution of ClC2 are poorly understood. Here, we combined *in silico* modeling, biochemical and cellular approaches to study the mechanisms that control the basolateral localization of ClC2 in polarized MDCK cells. ClC2 exhibit three putative dileucine motifs in its C-terminus, two in cystathionine β -synthase domain 1 (CBS1) and a third motif, previously implicated in basolateral sorting, within the CBS2. Our *in silico* model of ClC2 however revealed that CBS2-motif, TIFS⁸¹²LL, was buried within the dimeric structure of the channel and inaccessible, while CBS1-motifs, ESMI⁶²³LL and QVVA⁶³⁵LL, displayed a higher exposure toward the solvent. Consistently yeast three hybrid assays and *in silico* modeling of AP-1 demonstrated that ESMI⁶²³LL favorably interacted with a highly conserved pocket in the gamma-sigma1A hemicomplex of AP-1. Single alanine mutagenesis of these motifs and trafficking analysis of these mutants in MDCK cells demonstrated that ESMI⁶²³LL acted as a sole basolateral sorting signal. Single and double knockdown experiments indicated that clathrin adaptors AP-1A and AP-1B were individually necessary and sufficient for basolateral localization of ClC2. Our study constitutes the first structure-function analysis of a dileucine-based basolateral sorting mechanism in epithelial cells. Supported by NIH grants EY08538 and EY022165 to ERB, a Chilean government fellowship to EdIF and a PEW Latin American postdoctoral fellowship to GL.

2-deoxyglucose (2DG), a non-metabolizable analogue of glucose thought to block glycolysis, prevents cancerous growth in animal models and in human tumor cell lines. Despite its widespread use and important clinical applications, the mechanism of 2DG action remains unclear. Our study demonstrates that 2DG is a potent inhibitor of yeast cell growth, even when cells are grown in the presence of abundant glucose. Using a comprehensive high-throughput screen, we demonstrate that over-expression of either of the two low-affinity hexose transporters – Hxt1 and Hxt3 – can suppress yeast sensitivity to 2DG. Furthermore, we find that in response to 2DG addition, these transporters are rapidly internalized and trafficked to the vacuole for degradation. 2DG-induced internalization of Hxt1 and Hxt3 requires Rod1/Art4 and Rog3/Art7, members of the alpha-arrestin family of trafficking adaptors. Consistent with a role for Rod1 and Rog3 in mediating cellular response to 2DG, cells lacking these alpha-arrestins are resistant to 2DG and 2DG fails to trigger Hxt1 and Hxt3 internalization and trafficking to the vacuole. Importantly, Hxt1 and Hxt3 internalization in response to 2DG is regulated by the Snf1 protein kinase, the ortholog of which is mammalian AMPK. In the presence of 2DG, Snf1 becomes moderately activated, as indicated by phosphorylation on its activation loop, and selectively phosphorylates Rod1 and Rog3, while other known Snf1 substrates, including the transcriptional repressor Mig1, are not phosphorylated under these conditions. Addition of 2DG not only increases the Rod1 and Rog3 phosphorylation, but dramatically increases the ubiquitination of these alpha-arrestins. We further show that binding to the ubiquitin ligase Rsp5 is required for Rod1- and Rog3-mediated trafficking of the Hxts and induction of 2DG sensitivity. However, while phosphorylation of Rod1 and Rog3 may facilitate their ubiquitination it is not required for ubiquitination as in the absence of Snf1, both alpha-arrestins are ubiquitinated and able to stimulate Hxt internalization. Based on these findings we propose a mechanism for 2DG-induced toxicity in yeast whereby Snf1 becomes activated, triggering phosphorylation and subsequent ubiquitination of the alpha-arrestins Rod1 and Rog3, which in turn induces Hxt1 and Hxt3 endocytosis and trafficking to the vacuole. By reducing glucose transporter levels at the cell surface, 2DG causes a glucose starvation response, even when cells are grown in a glucose-rich environment. Our findings may shed light on the long elusive mechanism of 2DG in inducing cancer cell death.

In vivo imaging reveals that restricted exocytic trafficking drives cell shape changes required for intercalation during chondrocyte stacking.

D.S. Levic¹, E.W. Knapik²;

¹Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN, ²Medicine, Vanderbilt University Medical Center, Nashville, TN

Mechanisms that control cell shape changes and 3D tissue organization play a crucial role in morphogenesis. A striking example occurs during vertebrate cartilage development, when clusters of

small chondrocytes transition to stereotypical rows of elongated cells that build intricate skeletal structures by a process called stacking. Although this process has been observed for nearly a century, the cellular programs that execute chondrocyte shape changes during stacking are largely unknown. Here, using imaging, genetic and cell biology approaches we identify Erc1 as a novel component of the vesicle trafficking pathway that regulates chondrocyte cell elongation *in vivo*.

During stacking, Erc1-deficient cells become hyper-elongated but fail to expand in width, leading to chondrocyte cell death and craniofacial dysmorphology. We show that Erc1 is required to promote orientation of microtubules, and Erc1 depletion results in aberrant microtubule localization at polarized cortical regions of intercalating chondrocytes. These changes in microtubule polarity do not drive cell shape change in an active mode, but instead correlate with vesicle trafficking defects. We observed that this mechanism is engaged exclusively during chondrocyte cell shape changes.

Erc1 depletion leads to accumulation of vesicular structures at the chondrocyte cell cortex as well as the intracellular retention of glycosylated ECM components, suggesting impaired exocytosis. We demonstrate by *in vivo* mosaic analysis and *in situ* imaging in the developing cartilage that Rab8 and Kinesin-1 contribute to Erc1-dependent chondrocyte cell shape changes. Our study identifies for the first time a cellular mechanism of chondrocyte cell shape regulation that drives stacking and organ morphogenesis while utilizing microtubule polarity and vesicle trafficking machinery.

Lipid Binding by Osh4p, an OSBP homologue, is Required for Polarized Exocytosis.

R.J. Smindak¹, D.M. Hyatt¹, R.C. Deutscher¹, K.G. Kozminski²;

¹Biology, University of Virginia, Charlottesville, VA, ²Biology and Cell Biology, University of Virginia, Charlottesville, VA

Polarized exocytosis is an essential cellular process required for diverse events such as polarized cell growth and secretion, and cell migration. The seven-member Osh protein family, the *S. cerevisiae* homologues of the mammalian oxysterol-binding protein (OSBP) family, is required for polarized exocytosis (Alfaro et al., *Traffic*, 2011). Within the Osh protein family, Osh4p (Kes1p) is known to bind and transfer specific lipid species between membranes *in vitro*, however whether lipid binding and transfer by Osh4p is an essential activity *in vivo* has remained elusive (de St. Jean et al., *JCB*, 2012; Georgiev et al., *Traffic*, 2011). Two questions regarding Osh4p function are whether Osh4p regulates non-polarized exocytosis in addition to polarized exocytosis and whether lipid binding by Osh4p regulates its role in polarized exocytosis. First, we show data excluding a role for Osh4p in non-polarized exocytosis as marked by invertase secretion. Further we show that the dominant lethality of the osh4Y97F allele, which encodes a sterol binding null Osh4p, is dependent on the ability of Osh4p to bind phosphatidylinositol-4-phosphate (PI4P) and that Osh4p must be able to bind both sterols and PI4P for polarized exocytosis, marked by Bgl2p, to occur. These studies show that Osh4p is dependent on its

lipid binding activity to function in polarized exocytosis, with PI4P serving as a positive regulator of Osh4p function. These results suggest that other Osh or OSBP family members will be shown to regulate polarized exocytosis or other membrane-membrane contact sites in a lipid dependent manner.

GGA3 modulates the trafficking of G protein-coupled receptors via direct interaction.

M. Zhang¹, C. Li², J. Davis², G. Wu²;

¹Georgia Regents University, AUGUSTA, GA, ²Georgia Regents University, Augusta, GA

The molecular mechanisms underlying the cell surface transport of newly synthesized G-protein-coupled receptors (GPCRs) remain poorly defined. Here, we determined the role of GGA3 [Golgi-localized, gamma-adaptin ear domain homology, ADP ribosylation factor (ARF)-binding protein 3] in the cell surface targeting of alpha2B-adrenergic receptor (AR), a prototypic GPCR. As an adaptor protein for clathrin-coated vesicles, GGA3 modulates the transport between the trans-Golgi network (TGN) and endosomes and its function is tightly controlled by specific interactions of the VHS domain with the acidic LL motifs presented in the C-terminus of cargo molecules. We found that siRNA-mediated depletion of GGA3 significantly attenuated the cell surface expression of alpha2B-AR and arrested the receptor in the Golgi/TGN compartment. Consistent with the reduction in the cell surface expression, the function of alpha2B-AR measured as MAPK activation was markedly inhibited in response to agonist stimulation in cells transfected with GGA3 siRNA. More interestingly, although alpha2B-AR does not possess any acidic LL motifs, it strongly interacted with GGA3 and the interaction domains were subsequently mapped to the VHS domain of GGA3 and the third intracellular loop of the receptor. These data demonstrate an important function for GGA proteins in the Golgi-to-plasma membrane transport of GPCRs which is likely mediated through a non-conventional mechanism.

P2021**Board Number: B539****A phosphorylation-dependent sorting motif restricts presenilin 2 to late endosomes/lysosomes providing a basis for substrate specificity.**R. Sannerud¹, C. Esselens¹, L. Annaert⁵;¹Center for the Biology of Disease, VIB / KULeuven, Leuven, Belgium, ²Subcellular Structure and cellular Dynamics, Institut Curie, Paris, France, ³Switch Laboratory, VIB / KULeuven, Leuven, Belgium, ⁴LiMoNe, VIB, Leuven, Belgium, ⁵KU Leuven and VIB Center for the Biology of Disease, Campus Gasthuisberg, POB 602, OandN4, Room 7.159, Laboratory of Membrane Trafficking, Center for Human Genetics, Leuven, Belgium

Regulated intramembrane proteolysis (RIP) abrogates or initiates downstream signalling by cleaving substrate proteins within their transmembrane domains. γ -Secretase governs such mechanism by targeting >100 type I proteins, including amyloid precursor protein (APP) and Notch. Its activity is confined to a complex comprising presenilin (PSEN), nicastrin, APH-1 and PEN-2. The two homologous (PSEN1&2) and several APH-1 isoforms give rise to complex heterogeneity within the cell of which the functional relevance is largely unexplored. Using biochemical and confocal approaches, we now reveal that, as opposed to the broad distribution of PSEN1/ γ -secretase, PSEN2/ γ -secretase is essentially confined to late endosomes/lysosomes in different cell types including primary hippocampal neurons. Domain swapping and mutational analysis identified a unique N-terminal motif in PSEN2 that directs PSEN2/ γ -secretase to late endosomes through a direct phosphorylation-dependent interaction with the AP-1 adaptor complex. This restricted localisation limits substrate availability for PSEN2/ γ -secretase, providing the first cell biological basis and relevance of complex heterogeneity.

P2022**Board Number: B540****Palmitoylated Ras-driven MAPK signaling and transformation is spatially regulated by plasma membrane microdomains.**J.V. Michael¹, J.G. Wurtzel¹, L.E. Goldfinger^{1,2};¹Department of Anatomy and Cell Biology and the Sol Sherry Thrombosis Research Center, Temple University School of Medicine, Philadelphia, PA, ²Cancer Biology Program, Fox Chase Cancer Center, Philadelphia, PA

This study addresses the spatiotemporal regulation of Ras/MAP kinase (MAPK) signaling and mitogenic and tumorigenic outcomes. Somatic mutations in the Ras-superfamily of small GTPases are highly prevalent in cancers. Activating mutations in Ras (e.g., H-Ras) cause uncontrolled signaling through the MAPK pathway via activation of Raf kinase. After recruitment to the plasma membrane Raf propagates a mitogenic cascade by phosphorylating MEK, leading to ERK-mediated transcription. H-Ras also has been

shown to support induction of tumor angiogenesis. Related-Ras (R-Ras) has a nearly identical sequence with H-Ras, but is unable to drive MAPK signaling. R-Ras is anti-angiogenic and weakly mitogenic, but is not tumorigenic, and activating mutations have not been linked with human cancers. R-Ras can bind Raf *in vitro*, but does not bind *in vivo*. These paralogues have identical effector-binding regions, and differ primarily in the C-terminal domains, which harbor sequence-specific target sites for lipid modifications that direct targeting to distinct plasma membrane (PM) microdomains: H-Ras to lipid raft/non-raft borders, R-Ras to rafts. We hypothesized that the lateral spatial segregation at the PM regulates effector interactions, downstream signaling, and functional effects. We used targeting domain (tD) swap mutants between H- and R-Ras, and assessed the signaling, cellular and tumorigenic effects. Activated R-Ras harboring the H-Ras tD (R-Ras-tH), stably expressed in NIH3T3 fibroblasts, interacted with Raf and propagated MAPK signaling through MEK and ERK phosphorylation in the absence of growth factors. Furthermore, R-Ras-tH stimulated cell proliferation under these conditions, and supported anchorage-independent growth in soft agar, similar to activated H-Ras, indicating induction of a transformed phenotype *in vitro* by the R-Ras-tH. Conversely, H-Ras harboring the R-Ras tD (H-Ras-tR), did not stimulate MEK or ERK phosphorylation, or proliferation, and these cells displayed significantly reduced colony formation in soft agar compared with active H-Ras cells. Thus, access to Raf at the plasma membrane is a critical step for Ras-driven mitogenic signaling and transformation. A tumor xenograft model showed that R-Ras-tH promoted tumor formation whereas R-Ras cells yielded few tumors; however, R-Ras-tH tumors showed no neovascularization, which blunted tumor progression. Both H-Ras and H-Ras-tR xenografts formed very large, highly vascularized tumors. Thus, factors outside of the tDs affect tumor progression distinct from *in vitro* transformation, as H-Ras-tR appears to drive tumorigenesis through a MAPK-independent pathway *in vivo*. Together, these results indicate that the angiogenic function of Ras isoforms is independent of PM microdomain localization.

Cytosolic N-terminal proline-rich domains of MAL2 confer specificity to protein trafficking in polarized hepatic WIF-B cells.

A. Lopez Coral¹, P. Tuma²;

¹Biology, The Catholic University of America, Washington, DC, ²Department of Biology, Catholic Univ America, Washington, DC

Epithelial cells rely on the formation of tight junctions at the plasma membrane to create two major membrane domains, the apical (AP) and basolateral (BL), which separates the external from the internal environments. The establishment and maintenance of these membrane domains are driven by a highly regulated protein trafficking pathway that selectively deliver newly-synthesized AP or BL resident proteins to their respective membrane domains. Polarized hepatocytes use the indirect route to deliver newly-synthesized apical resident proteins from the trans-Golgi network (TGN) to the BL from which they are selectively endocytosed into basolateral early endosomes (BLEE), transcytosed to the subapical compartment (SAC) and finally delivered to the AP. Myelin and lymphocyte protein 2 (MAL2) has been

identified as an important apical protein trafficking regulator of the indirect route in polarized WIF-B cells in at least two stages: from the TGN to the BLEE and from the BLEE to the SAC. More recently, we have determined that MAL2 also regulates constitutive secretion from the TGN to the BL. Our hypothesis is that MAL2 coordinates with multiple binding partners thereby conferring specificity to cargo selection and vesicle targeting to distinct locations. Once the cargo is packaged into discrete vesicles, we propose that sorting specificity may be conferred by interactions of distinct MAL2 binding partners (e.g. rab17 and Ser/Thr kinase 16) with the divergent MAL2 N-terminal domain. Thus, we predicted that the MAL2 cytoplasmic domains mediate interactions with other proteins or lipids that in turn confer specificity to apical sorting/targeting. Interestingly, the MAL2 N-terminus encodes VPPPP and FPAP sequences that resemble the F/L/W/YPPPP recognition sites for EVH1 (enabled, VASP, homology1) motifs present in Ena/VASP proteins, suggesting a possible role of MAL2 in actin dynamics. The N-terminus also encodes a predicted phosphorylated site (ser 17) that may be important in regulating protein-protein interactions. To test our hypothesis, we will overexpress C-terminal FLAG-tagged MAL2 constructs using recombinant adenoviruses in WIF-B cells to allow their detection relative to endogenous MAL2. We will change the VPPPP and FPAP motifs to alanines either alone or together, deleting them individually or together and adding them to the MAL N-terminal sequence. We will also mutate ser 17 to ala or asn (a phospho-mimetic) and analyze their distribution and function in protein trafficking. Finally, we will examine if the C-terminal LRRW in MAL2 mediates lipid association like in MAL. Such careful and rigorous analysis will identify which (if any) of the domains confer specificity of MAL2 binding interactions and subsequent vesicle targeting.

Specific targeting/cellular localization of HCMV tegument protein pUL71 plays a critical role in production of infectious virus particles.

R. . Grabski¹, W.J. Britt¹;

¹Pediatrics-I.D., University of Alabama at Birmingham, Birmingham, AL

The human cytomegalovirus (HCMV), also known as human herpesvirus-5, is a common virus that can cause life-threatening infection in immunocompromised patients. The HCMV UL71 gene product, a component of the viral tegument layer, is a palmitoylated, oligomeric protein that plays a critical role in secondary envelopment of viral particles. Although previously described as non-essential, deletion of pUL71, mutation of palmitoylation sites, or deletion of oligomerization sequences severely impairs production of infectious virus. To explore involvement of pUL71 in viral assembly, we generated a series of C-terminal truncation mutants. Co-localization studies in transfected cells showed that pUL71 has strong preferential localization to the trans-Golgi compartment. At the position 23-26AA of pUL71 we identified a YxxΦ sorting signal responsible for interaction with the μ subunit of Adaptor Protein complex. The mutation of YVLL sequence of pUL71 to alanines (mutant 23A) exhibited a strikingly different phenotype as compared to that of the wild type (WT) protein, with characteristic plasma membrane localization and decreased presence at the Golgi apparatus. Considering the close proximity

of the mutations to the palmitoylation sites of pUL71 we tested incorporation of modified palmitic acid in transiently expressed WT and 23A mutant. The lack of differences in palmitoylation showed that the phenotype of the 23A mutant was caused by the replacement of the YVLL with AAAA. To elucidate the functional significance of the YxxΦ motif in assembly of the virus, a recombinant mutant virus was created. The 23A mutant virus showed extremely slow growth and infectivity rate. The electron microscopy analysis of cells infected with the 23A mutant virus showed accumulation of empty capsids and partially tegumented sub-viral particles in the cytoplasm. Our results indicate the existence of a new functional motif in pUL71 distinct from previously described palmitoylation and oligomerization signals, and one that is vital for localization of pUL71 and its function in HCMV assembly. It is attractive to speculate that tegument protein pUL71 may cycle between trans-Golgi, TGN, endosomes and plasma membrane, compartments that are dramatically modified during the process of infection, in a similar manner to that of envelope glycoproteins of HCMV.

Molecular basis of the phenotypic heterogeneity in congenital sucrase-isomaltase deficiency.

B. Gericke¹, M. Amiri¹, D. Cooper², H.Y. Naim¹;

¹Department of Physiological Chemistry, University of Veterinary Medicine Hannover, Hannover, Germany, ²QOL Medical LLC, Vero Beach, FL

The etiology of chronic, severe and common gastrointestinal symptoms (GI) such as osmotic diarrhea and abdominal pain is oftentimes due to carbohydrate malabsorption triggered by reduced levels of disaccharidase activity at the apical membrane of the enterocytes. Congenital sucrase-isomaltase deficiency (CSID) is a prominent form of carbohydrate malabsorption disorders that is characterized by altered trafficking and functioning of sucrase-isomaltase (SI), the most active intestinal disaccharidase. CSID is commonly detected as a recessive inborn defect that is elicited by mutations in the coding region of SI. Biochemical and cellular analyses of several mutations have established the phenotypes concept of CSID according to the cellular location, intracellular processing and function of SI (for a review see Naim et al., JPGN 2012). While the clinical presentation of CSID in most reported cases is severe, it is worthwhile to investigate whether a mild to severe spectrum of GI symptoms exists in heterozygotes or other less severe genotypes that would occur at a higher frequency in the general population. Here, we investigated the molecular pathogenesis of 14 naturally occurring mutations of the SI gene in patients with a prior diagnosis of CSID and varying enzyme activity levels. (Uhrich et al, JPGN 2012). The mutations were introduced into the cDNA of wild type SI by site-directed mutagenesis and expressed in COS-1 cells. Analysis of the structural and biosynthetic features of the mutants, their cellular localization and enzymatic function revealed three major categories of CSID. The first category is comprised of mutants that are trafficked and processed in a fashion similar to wild type SI and with mostly normal, but varying, levels of enzymatic activity. The second class of mutants revealed delayed trafficking and maturation kinetics as well as reduced enzymatic activities. Finally, the third group of mutants is entirely

transport-incompetent and persists in the ER as mannose-rich, immature and enzymatically inactive proteins that are ultimately degraded, presumably in the proteasome. Notably, the expression of active, wild-type SI proteins is negatively impacted by malformed SI mutants in heterozygotes. The current study supports the existence of heterogeneous forms of CSID that vary in their degree of enzyme activity and clinical severity. These forms are primarily generated by the interaction of two mutants of SI or a mutant SI with its wild type counterpart. Furthermore, variations in the degree of severity are dictated by the malformed structure of SI and its trafficking rate, which may vary in heterozygotes.

Mx1, a large GTPase involved in intracellular transport.

F. Hoff¹, C. Greb¹, E. Hoenig¹, K. Ringer¹, R. Jacob¹;

¹Institute for Cytobiology Cytopathology, Philipps-University of Marburg, Marburg, Germany

The plasma membrane (PM) of polarized epithelial cells can be subdivided into an apical and basolateral domain, both separated by tight junctions. Targeting cargo molecules to their correct site of delivery is provided by a complex intracellular sorting and transport machinery. The analysis of post-TGN (Trans Golgi Network) exocytic carriers for new components involved in apical trafficking revealed the presence of the large GTPase Mx1 on these vesicles in Madin Darby Canine Kidney (MDCK) cells. Mx1 is known so far as an antiviral factor induced by the Interferon system after viral infections. However Mx1 is constitutively expressed in MDCK cells. Interestingly, the intracellular amount of Mx1 increases during early days of epithelial polarization. We could see that this dynamin-related protein associates with cargo vesicles guided to the apical PM. Furthermore, siRNA mediated knockdown of Mx1 significantly reduces the apical delivery of both soluble and membrane proteins. Our recent data show an interaction of this GTPase with the tubulin and actin cytoskeleton in the subapical region of MDCK cells. Fluorescence microscopy data indicate that Mx1 also colocalizes with different motor proteins.

The Role of Sec3p in Secretory Vesicles Targeting and Exocyst Complex Assembly.

G. Luo¹, W. Guo¹;

¹Department of Biology, University of Pennsylvania, Philadelphia, PA

During membrane trafficking, vesicular carriers are transported and tethered to their cognate acceptor compartments before SNARE-mediated membrane fusion. The exocyst complex was thought to target and tether post-Golgi secretory vesicles to the plasma membrane during exocytosis. However, no definitive experimental evidence is available to support this notion. We have developed an ectopic targeting assay in yeast, in which each of the eight exocyst subunits was expressed on the surface of

mitochondria. We find that most of the exocyst subunits were able to recruit the other members of the complex there, and mis-targeting of the exocyst led to secretion defects in cells. On the other hand, Sec3p, but not other members of the exocyst, is capable of recruiting secretory vesicles. Our assay also suggests that both cytosolic diffusion and cytoskeleton-based transport mediate the recruitment of exocyst subunits and secretory vesicles during exocytosis. In addition, the Rab GTPase Sec4p and its guanine nucleotide exchange factor Sec2p regulate the assembly of the exocyst complex. Our study helps to establish the role of the exocyst subunits in tethering and allows the investigation of the mechanisms that regulate vesicle tethering during exocytosis.

Endocytic Trafficking 3

A flow cytometry based mutagenesis screen to identify novel endocytic factors.

K. Wrasman¹, Y. Zhang², M. Khairy¹, B. Wendland¹;

¹Department of Biology, Johns Hopkins University, Baltimore, MD, ²Scripps Research Institute, San Diego, CA

Clathrin-mediated endocytosis involves the coordination of many proteins to uptake nutrients, and respond to extracellular signals. With the plethora of proteins that need to be internalized from the plasma membrane, and the needs of the endocytic machinery to respond to many types of signals, it is unlikely we have identified all the factors involved in endocytosis. Using *Saccharomyces cerevisiae*, we performed an EMS mutagenesis screen to identify novel genes that contribute to endocytosis using an endogenous cargo, the methionine permease protein Mup1 to measure endocytic activity. Mup1 localization was visualized and quantified using a pHluorin (pHI) tag, which is a pH-sensitive GFP variant that is quenched upon delivery to the acidic environment of the vacuole lumen. In cells grown in low methionine conditions, Mup1 accumulates at the plasma membrane, whereas Mup1 is internalized and trafficked to the vacuole in high levels of methionine. We used flow cytometry to enrich for mutagenized cells with elevated fluorescence, where Mup1-pHI failed to traffic to the vacuole following addition of methionine. Over 1000 positive colonies were secondarily screened by microscopy. Defects in endocytosis and trafficking of Mup1-pHI were confirmed in 256 mutants, and these were categorized according to Mup1 subcellular localization. Eight recessive mutants with general endocytic defects (defined as having defects for all endocytic cargos thus far tested) were selected for further characterization, and two of these mutants are truncations of the known endocytic genes, SLA1 and SLA2. We are currently identifying the remaining general endocytic mutants using whole genome sequencing. As expected, some mutants with specific defects in the endocytosis of Mup1 are complemented by LDB19/ART1, a protein known to contribute to Mup1 internalization. Our screen allows us to directly identify endocytic mutants using a high-throughput, phenotype-based approach to study endocytic mechanisms of specific cargo proteins, and to find mutants with altered rates of transit from the plasma membrane to early/late endosomes.

P2029**Board Number: B547****Defining the adaptor function of endocytic protein Syp1.**K. Hoban¹, A. Reider Apel², S. Chuartzman³, M. Schuldiner^{4,5}, B. Wendland¹;¹Department of Biology, Johns Hopkins University, Baltimore, MD, ²Physical Biosciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, ³Department of Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel, ⁴Department of Molecular Genetics, The Weizmann Institute of Science, Rehovot, Israel, ⁵Molecular Genetics, The Weizmann Institute of Science, Rehovot, Israel

Endocytosis is an important cellular process. One class of endocytic proteins is the adaptors, which bind to specific cargos, membranes, and other components of the endocytic machinery. One of the earliest-arriving proteins recruited to sites of clathrin-mediated endocytosis (CME) in yeast is Syp1, a member of the muniscin family of adaptors that includes multiple mammalian homologs.

Syp1 is known to bind Ede1, another early-arriving CME factor, and cargos such as Mid2, via its μ -homology domain (μ HD). However, the molecular mechanisms underlying Syp1's adaptor functions, including the sites on the μ HD necessary for its physical interactions with Ede1 and cargo proteins, as well as the sorting motifs that allow Syp1 to select specific cargos for internalization, have not been determined. Therefore, we aimed to locate the Ede1 binding site on the μ HD and ascertain the mechanisms of cargo recognition. Also, few proteins have been classified as Syp1 cargos; consequently, we sought to identify additional cargos of this adaptor.

Using a collection of alanine scanning μ HD mutants, we isolated an evolutionarily conserved region of the domain's surface that appears important for its physical interaction with Ede1. This construct, in which a seven residue-long sequence of the μ HD is mutated, shows reduced binding to Ede1 in assays such as affinity pull-downs. However, the mutant does bind Mid2, indicating that the mutant μ HD is folding properly and the decreased affinity for Ede1 is due to loss of side chains present in the WT domain.

We also confirm the identity of Mep3, an ammonium permease isolated in a high throughput microscopy screen, as a novel Syp1 cargo using fluorescence microscopy. Mep3-GFP internalization is inhibited in the absence of Syp1; the protein instead accumulates at the plasma membrane. Its endocytosis is also μ HD-dependent, as the introduction of truncated Syp1 lacking this domain fails to internalize Mep3. Similarly, truncation of a portion of the Mep3 cytoplasmic, C-terminal tail prevents its endocytosis in WT cells. This indicates that Mep3 is a novel Syp1 cargo recognized specifically by the μ HD, possibly via a specific sorting motif.

We are searching for this potentially novel endocytic motif involved in Syp1 cargo selection. We predict that a motif present in the cytoplasmic tail of Syp1 cargos such as Mid2 is important for cargo binding to the μ HD. Mutant Mid2 in which a small cytoplasmic segment is mutated to alanines exhibits diminished affinity for the μ HD in pull-down assays. We plan to use our collection of alanine scanning μ HD mutants

to identify the cargo binding site on this domain, complementing our studies to define the sorting motif within cargo proteins.

CALM is an adaptor for Gyating-clathrin coated membranes.

A. Gorin¹, Y. Luo¹, L. Ruggiero¹, J.H. Keen¹;

¹Biochemistry/Mol. Biol., Thomas Jefferson Univ, Philadelphia, PA

We have identified highly dynamic clathrin-coated structures in the endosomal region of mammalian cells, and their rapid but highly localized movement, suggestive of clathrin-coated buds on membrane tubules, led to the term “Gyrating-“ or “G-clathrin” (1). Endocytic cargo such as transferrin can be visualized in G-clathrin downstream of the sorting endosome, and the structures have been implicated in rapid recycling of transferrin, β_1 -integrin and c-met receptor. While the tetrameric TGN and plasma membrane adaptors AP-1 and AP-2 are virtually undetectable in G-clathrin the single chain adaptors GGA1 or GGA3, expressed as fluorescent protein fusions, are almost completely colocalized with G-clathrin. Here we report that another single chain adaptor, GFP-tagged CALM (Clathrin assembly lymphoid myeloid leukemia protein) is also present in G-clathrin. Importantly, endogenous CALM can also be detected in G-clathrin structures followed through fixation. CALM contains an unstructured assembly domain which binds clathrin, and an N-terminal phosphoinositide-binding ANTH domain which has also recently been shown to bind SNARE proteins (2). Consistent with this, we could readily detect GFP-tagged forms of VAMP3, VAMP4 and VAMP8 in G-clathrin. However, SNARE binding is not critical for G-clathrin formation, as G-clathrin persisted in cells over-expressing either CALM mutants lacking SNARE binding or a CALM construct lacking the entire ANTH domain, and all were incorporated into G-clathrin structures. In contrast, expression of the CALM ANTH domain alone was cytosolic (3). G-clathrin also was unaffected by siRNA-mediated knockdown of CALM. However, this treatment abolished appearance of VAMP3 in G-clathrin. As endocytosis of VAMP3 is blocked under these conditions, as previously reported (2), these observations indicate that G-clathrin functions primarily in VAMP3 recycling rather than in biosynthetic transport, and that CALM is not required for G-clathrin formation. Finally, in cells expressing tagged forms of both CALM and GGA1, their presence in G-clathrin appeared mutually exclusive. While structures with GGA1 are primarily Arf6-dependent and are resistant to BFA, those with CALM show substantial sensitivity to BFA. This suggests that G-clathrin, until now defined only by its mobility and clathrin coat, likely exists in structurally and functionally distinct forms in the endosomal regions of cells. Further, our results suggest that G-clathrin is a significant trafficking compartment for other potential CALM cargos.

P2031**Board Number: B549****The use of phospholipase A2 Inhibitors to investigate the localization and trafficking of amyloid precursor protein.**S.K. Boyle¹, N. Belko¹, E.B. Cluett¹;¹Biology, Ithaca College, Ithaca, NY

Evidence from our lab has implicated phospholipase A2 activity in the intracellular transport of LDL-derived free cholesterol in the endomembrane system. The effects of phospholipase inhibitors on the localization of proteins associated with endocytic compartments implicated the early endosome and the Endocytic Recycling Compartment (ERC) in the transport of cholesterol. siRNA knockdown of rab5 isoforms revealed differential effects on the distribution of cholesterol in both control and ONO-treated cells. Using isoform-specific antibodies and immunofluorescence microscopy, treatment with ONO altered the localization of rab5A and rab5B but not rab5C. The ability to alter the distributions of cholesterol and marker proteins associated with specific intracellular compartments suggest that phospholipase A2 inhibitors may be useful in investigating the trafficking and processing of amyloid precursor protein (APP), a normal cellular protein that undergoes complex proteolytic processing. Misprocessing of this protein is associated with Alzheimer's Disease. However, it is still not clear where the different processing events occur in the cell or what causes the misprocessing. Cholesterol is implicated in the onset of AD, and evidence suggests that the amount of cholesterol in the membrane may play a role in the misprocessing of APP. An emerging model suggests that one set of processing steps occur on the plasma membrane, but alternative processing, which can lead to misprocessing, may occur in an intracellular compartment. In CHO cells that have been stably transfected with APP, the protein is found in several different intracellular compartments, which is consistent with existing evidence. Treatment of these cells with ONO significantly changes the distribution of APP. However, APP does not appear to be appreciably associated with cholesterol in the ERC. Knockdowns of rab5 isoforms or rab11 change the distribution of APP suggesting that the protein traffics through the endocytic pathway. Experiments are now underway using immunoblotting and sandwich ELISAs to investigate the processing of the protein in the presence and absence of ONO.

P2032**Board Number: B550****cholesterol trafficking between the plasma membrane and the endocytic recycling compartment.**S. Mao¹, D.B. Iaea^{2,3}, F.R. Maxfield²;¹biochemistry, Cornell University Weill Cornell Medical College, New York, NY, ²Cornell University Weill Cornell Medical College, New York, NY, ³Tri-Institutional Program in Chemical Biology, Weill Cornell Medical College, New York, NY

Cholesterol is an essential constituent of membranes in mammalian cells. The plasma membrane (PM) is the largest cholesterol pool in the cell and contains ~60% of total cellular cholesterol. Cholesterol is also highly enriched in the endocytic recycling compartment (ERC). The abundance and distribution of intracellular cholesterol within membranes are tightly controlled by complex and poorly characterized homeostatic mechanisms. To analyze cholesterol transport between organelles, a fluorescent cholesterol analog dehydroergosterol (DHE) was used. We used fluorescence recovery after photobleaching (FRAP) to measure cholesterol delivery to ERC. Within 30 min after photobleaching, the fluorescence in ERC recovered about 90%. Recovery of DHE fluorescence in the ERC can be described by a single first order rate constant. The recovery $t_{1/2}$ into the ERC is 14.5 ± 1.5 min in U2OS cells. We developed a novel efflux method, in which a large exogenous cholesterol pool from red blood cells (10^9 per ml) rapidly exchanges with DHE at PM. This new method allows for accurate measurement of DHE efflux that can be modeled as a single exponential to characterize sterol transport rates from the ERC to the PM. DHE in the ERC effluxed completely out of cells with a $t_{1/2}$ of 14.9 ± 0.9 min in U2OS cells. Using these experimental improvements in the measurements of DHE trafficking, we accurately measured the effect of intracellular cholesterol level, the role of cholesterol transporters, and the energy-dependent and -independent transport processes in sterol trafficking. High intracellular cholesterol levels increase cholesterol the transport rate constant between the ERC and the PM, while mildly reduced intracellular cholesterol levels do not statistically change the rate constants for cholesterol transport into and out of the ERC. The increased amount of a cholesterol transporter (STARD4) significantly enhances the rate of cholesterol transport between ERC and PM. Energy depletion slightly reduces the rate of cholesterol transport between the ERC and the PM. These results suggest that while there is some contribution from vesicular transport, nonvesicular transport plays the major role in sterol transport between the ERC and the plasma membrane.

CFTR transcytosis in human respiratory epithelia: a constitutive rescue mechanism of basolaterally missorted channel from the biosynthetic and recycling pathways.

A. Bidaud (Bidaud-Meynard)¹, F. Bossard¹, G. Veit¹, G.L. Lukacs^{2,3};

¹Physiology, McGill University, Montreal, QC, ²Physiology, McGill University, Quebec, QC, ³Biochemistry, McGill University, Montreal, QC

Cystic Fibrosis (CF) is caused by mutations in the CF transmembrane conductance regulator (CFTR), a chloride channel in the apical (Ap) plasma membrane (PM) of secretory epithelia. Considering that CFTR density at the Ap PM correlates with the CF disease severity, understanding the cellular/molecular mechanisms that determine the channel delivery to and removal from the Ap PM has fundamental importance. The mechanism responsible for CFTR polarized expression, however, remains poorly defined. Using morphological and biochemical assays, here we show that CFTR undergoes constitutive transcytosis (basolateral-to-apical) in differentiated, filter grown immortalized (CFBE) and conditionally

reprogrammed primary (HBE) human bronchial epithelial cells expressing CFTR. Transcytotic CFTR partly originates from basolaterally delivered channel from a) non-selective Ap and basolateral (Bl) delivery of secretory vesicles (cca. 30%) and b) from reversed or Ap-to-Bl transcytosis (cca. 70%) as a consequence of the limited fidelity of Ap recycling internalized CFTR. A similar trafficking rescue mechanism may be involved in mutations leading to small C-terminal truncations that have been implicated in compromising CFTR polarized expression by disrupting the interaction between the C-terminal PDZ (Postsynaptic density/Disc large/ZO-1)-binding motif of CFTR and NHERF-1, a PDZ-domain containing scaffolding protein. Truncation of the PDZ-binding motif increased internalization and decreased endocytic recycling of the CFTR- $\Delta 6$ mutant without discernible effect on Ap expression and stability in CFBE cells contrary to previous reports. The preserved Ap expression of CFTR- $\Delta 6$ could be explained by its increased transcytosis rate, similarly to that of the wild-type CFTR upon NHERF-1 knockdown and accounts for the lack of CF clinical phenotype in individuals carrying C-terminal truncations. Using morphological, genetic and biochemical tools some unique characteristics of CFTR transcytosis were revealed. Internalized CFTR delivery to contralateral PMs avoids both Ap and Bl recycling endocytic compartments contrary to Transferrin and IgA receptors, but likely involves EEA1 positive early endosomes. On the other hand, microtubule disruption interferes with the transcytosis of multiple cargoes, including CFTR, without interfering with its internalization and recycling. In summary, we have uncovered some of the cellular-molecular mechanisms that contribute to CFTR transcytosis and plays a role in the channel polarized expression in airway epithelial cells by redirecting basolaterally missorted molecules to the apical PM.

Shear Stress Dependent Regulation of Apical Endocytosis in Renal Proximal Tubule Epithelia.

V. Raghavan¹, Y. Rbaibi¹, F. Carattino¹, M.D. Carattino¹, O.A. Weisz¹;

¹Univ Pittsburgh Sch Med, Pittsburgh, PA

The kidney has an extraordinary ability to maintain stable fractional solute and fluid reabsorption over a wide range of glomerular filtration rates (GFRs). Internalization of filtered low molecular weight proteins, vitamins, hormones, and other small molecules is mediated by the proximal tubule (PT) multiligand receptors megalin and cubilin. Changes in GFR and the accompanying fluid shear stress (FSS) modulate acute changes in PT ion transport thought to be mediated by microvillar bending. We recently discovered that FSS also modulates apical endocytosis in PT cells via a mechanosensitive pathway regulated by primary cilia. FSS caused an acute and transient increase in intracellular calcium in cells that preceded the endocytic response. Neither the FSS-stimulated increase in intracellular calcium or apical endocytosis was observed in deciliated cells. Addition of ATP to the medium rescued both responses, suggesting the involvement of purinergic receptors in the signaling cascade. Consistent with this, inclusion of the ATP hydrolyzing enzyme apyrase or the pan-purinergic receptor inhibitor suramin in the perfusion medium blocked the FSS-stimulated endocytic response. Both basal and FSS-stimulated

endocytosis were inhibited by perturbants of clathrin and dynamin function. Additionally, treatment of PT cells with small molecule inhibitors of cdc42 or siRNA mediated knockdown of cdc42 ablated the FSS-stimulated increase in endocytosis. Similarly knockdown of N-WASP or inhibition of Arp2/3 complex-mediated nucleation of branched actin filaments prevented the FSS stimulated endocytic response. Our data suggest that exposure of PT cells to FSS enhances apical clathrin-mediated endocytosis via an actin-dependent pathway that is modulated by activation of Cdc42, N-WASP, and Arp2/3. Studies are underway to determine how the FSS-stimulated increases in intracellular calcium are transduced to increases in endocytosis.

Apical and Basolateral Recycling in Epithelial Cells.

A.E. Perez Bay¹, R. Schreiner², I. Benedicto¹, E. Rodriguez-Boulan³;

¹Ophthalmology department, Weill Cornell Medical College, New York, NY, ²Weill Cornell Medical College, New York, NY, ³Department of Ophthalmology, Dyson Vision Research Institute, Weill Medical College of Cornell University, New York, NY

Epithelial cells mediate vectorial transport of solutes and nutrients, by accurately sorting transporters and receptors to the apical and basolateral plasma membrane (PM) domains. Whereas some sorting occurs in the biosynthetic route, the major sorting of fast recycling receptors, such as Megalin and Transferrin receptor (TfR), occurs in the recycling route. Megalin is an apical recycling receptor responsible for the absorption of ultrafiltrate proteins in the kidney proximal tubule and its mutation in several human genetic syndromes causes proteinuria. TfR is the best-studied basolateral recycling receptor, which mediates iron uptake from the blood. Whereas the basolateral recycling pathway has been extensively studied using several endocytic receptors (i.e. TfR, LDLR, EGFR, etc), the apical recycling pathway is poorly understood. Here we show that apically internalized Megalin recycles successively through WGA-positive apical sorting endosomes, TfR-positive common recycling endosomes (CRE) and Rab11a-positive apical recycling endosomes (ARE) with half-times of 5, 12 and 21 minutes, respectively. Apically internalized Megalin mixes with basolaterally internalized TfR at CRE, suggesting that this is the compartment where sorting of these recycling receptors occurs. Very little is known on the mechanisms that mediate sorting and recycling of Megalin from CRE to the apical PM. Previous work has identified NPXY-like apical sorting signals (Takeda et al., *AJP*, 2003; Marzolo et al., *Traffic*, 2003) and our preliminary results suggest that clathrin is involved. In contrast, basolaterally internalized TfR is known to be sorted at CRE, by the clathrin adaptor AP-1B and clathrin, into a recycling route to the basolateral membrane. In certain epithelia that constitutively lack AP-1B, such as Retinal Pigment Epithelium, and in AP-1B knocked-down MDCK cells, TfR is relocated to the apical surface through a novel transcytotic pathway that involves its apical sorting at CRE by an N-glycan sorting signal and the sorting lectin galectin-4 (Perez Bay et al., *JCS*, 2014) and its transport from CRE to ARE and the apical surface by the kinesin KIF16B, non-centrosomal microtubules and the small GTPase rab11a (Perez Bay et al, *EMBO J*, 2013). In summary, our results describe the complete endosomal itinerary of apically

recycling megalin, provide the first evidence for a role of clathrin in apical sorting in mammalian cells and identify a novel transcytotic pathway for basolateral recycling receptors in AP-1B deficient epithelia.

The Interaction of the Human Papillomavirus type 18 E6 Oncoprotein with Sorting Nexin 27 Modulates Retromer Dependent Cargo Recycling Function.

K. Ganti¹, J. Manzo-Merino², L.M. Banks¹;

¹Tumour Virology, ICGEB, Trieste, Italy, ²Unidad de Investigación Biomédica en Cáncer, Instituto Nacional de Cancerología, Mexico City, Mexico

Human Papilloma viruses are the causal agents of a large number of human malignancies, chief among which is cervical cancer. The continued over expression of the viral oncoproteins E6 and E7 is required for the initiation and maintenance of the neoplasm. Cancer causing HPV types are termed as high risk and a defining feature of the E6 oncoprotein from these types is the presence of a C-terminal PDZ binding motif. This allows the E6 protein to bind to and target various cellular PDZ domain containing proteins for degradation. Recent proteomic studies by Rozenblatt-Rozen et al (2012) and Belotti et al (2013) show that E6 may potentially bind to SNX27, which is a component of the endosomal transport system. Sorting Nexin 27 is unusual in that it is the only sorting nexin known to have a PDZ domain. This PDZ domain is known to facilitate the interaction of SNX27 with various PBM containing cargoes, thus directing their transport through the endosomal system. In this study, we show that SNX27 is a bonafide binding partner of HPV18E6 and this interaction is PDZ dependent. Furthermore, this interaction is conserved across various high risk cancer causing HPV types. We also show that E6 alters the sub-cellular distribution of SNX27 in HeLa cells and disrupts the SNX27-retromer link in a PDZ dependent manner. Analysis of known SNX27 cargoes such as the glucose transporter GLUT1 shows a perturbation in cargo retrieval and transport in the presence of E6. We show that the loss of E6 reduces surface GLUT1 levels in HeLa cells and this loss is reflected in increased lysosomal accumulation as seen in endosomal fractionation studies. We also demonstrate that the loss of E6 re-establishes the interaction between the retromer and GLUT1 in HeLa cells; further supporting the hypothesis that E6 is involved in the perturbation of the SNX27-retromer recycling pathway. Thus, these studies demonstrate a novel function for high risk HPV oncoproteins in the regulation of endosomal sorting pathways.

P2037**Board Number: B555****Defining Cytosolic Components That Regulate Endosomal Membrane Protein Sorting.**M.B. Gireud^{1,2}, S. Reyes^{1,2}, N. Sirisaengtaksin^{1,2}, S. Tsunoda³, A.J. Bean^{1,2,4};¹Neurobiology and Anatomy, University of Texas Health Science Center at Houston, Houston, TX,²University of Texas Graduate School of Biomedical Sciences at Houston, Houston, TX, ³BiomedicalSciences, Colorado State University, Fort Collins, CO, ⁴Pediatrics, M.D. Anderson Cancer Center, Houston, TX

Endocytosis is required for the uptake of essential nutrients from the extracellular environment and to limit the signaling by molecules (e.g. ion channels, receptors) present on the plasma membrane. The endocytic pathway is separated into stages based on cargo movement and identification of morphologically defined compartments. After internalization and transport from early to late endosomes, proteins destined for degradation in the lysosome are internalized into the lumen of late endosomes via membrane invagination and vesicle fission. The resulting organelle, the multivesicular body (MVB), is characterized by a limiting membrane and the presence of internal vesicles. Proteins that are sorted into internal vesicles are subject to degradation while those that remain on the limiting membrane are recycled. To facilitate sorting of proteins into the internal vesicles of the MVB, ubiquitin is added to the membrane protein. Ubiquitin allows for interaction with components of the sorting machinery, a group of cytosolic multi-protein complexes, the endosomal sorting complexes required for transport (ESCRTs), that play a role in protein sorting and internal vesicle formation.

To examine the mechanisms underlying endosomal sorting, we have established a cell-free based assay that measures both MVB formation (ultrastructure) and the sorting of a cargo protein into the endosomal lumen. The sorting event is dependent on cytosolic components, ATP, time and temperature. Since this sorting event is dependent on soluble proteins, we examined the requirements and regulation of endosomal sorting by proteins present in the cytosol. We have undertaken a biochemical examination of cytosolic components by taking advantage of yeast and fly genetics, to understand the regulation of endosomal sorting and MVB biogenesis.

By following the movement of a prototypical membrane protein, the epidermal growth factor receptor (EGFR), we have determined that cytosol obtained from *Drosophila Melanogaster* fly strains and *Saccharomyces cerevisiae* yeast strains are sufficient to support the endosomal sorting of the EGFR with reasonable efficiency (20-40%). Further, cytosol derived from yeast strains deleted of ESCRT-0-III components decreased EGFR sorting into endosomes. The addition of recombinant mammalian ESCRT-0 homologs rescues the sorting defect caused by the absence of these yeast proteins. We have also examined other non-ESCRT cytosolic proteins that regulate the MVB sorting process. Understanding the molecular details of this critical endosomal sorting step will allow a better appreciation of the molecular pathways that ultimately may affect membrane protein signaling.

Retromer is a protein assembly that plays a central role in orchestrating export of trans-membrane cargo proteins from endosomes into recycling pathways destined for the Golgi apparatus and the plasma membrane [1]. Recently, a specific mutation in the retromer component VPS35, VPS35 (p.D620N), has linked retromer dysfunction to familial autosomal dominant and sporadic Parkinson's disease [2, 3].

Here we established that in cells expressing VPS35 (D620N) there is a perturbation in endosome-to-Golgi transport but not endosome-to-plasma membrane recycling, which we confirm and functionally rescue in Parkinson's disease patient cells harboring the VPS35 (p.D620N) mutation [4]. Through comparative stable isotope labeling by amino acids in cell culture (SILAC)-based analysis of wild-type VPS35 versus the VPS35 (p.D620N) mutant interactomes, we establish that the major defect of the D620N mutation lies in the association to the actin nucleating Wiskott-Aldrich syndrome and SCAR homologue (WASH) complex [4,5]. Consistent with this we quantify, using isothermal calorimetry that the affinity of VPS35 (p.D620N) for the WASH complex component FAM21 is decreased by 2.2 +/- 0.5 fold compared to wild-type [4].

In addition, we confirm the interaction between retromer and DNAJC13 [6], a mutation in which, DNAJC13 (N855S), is also linked with Parkinson's disease [7]. Together with evidence that retromer associates with LRRK2 [8] these data highlight retromer-mediated endosome sorting as a new pathway for studying the pathophysiology of Parkinson's disease. Ongoing studies seek to utilize iPSCs and mouse models to further elucidate the role of retromer in dopaminergic neuron function and viability.

P2039**Board Number: B557****Numb Diverts Notch to Late Endosomes to Antagonize Notch Membrane Recycling in Drosophila Sensory Organs.**S. Johnson¹, F.J. Roegiers²;¹Cell and Molecular Biology, University of Pennsylvania, Philadelphia, PA, ²Fox Chase Cancer Center, Philadelphia, PA

Notch signaling is a well conserved signaling pathway that controls a wide variety of developmental functions including cell fate determination and patterning. Errors in the regulation Notch signaling have been implicated in forms of colon cancer and leukemia, as well as other leukodystrophies including CADASIL syndrome. To elucidate Notch signaling regulation, we took advantage of sensory organ differentiation in Drosophila, a process that requires regulation of both Notch activation and inhibition. Sensory organs of Drosophila arise from a pair of cells, one of which must activate Notch signaling, while the other must inhibit signaling. Blockage of Notch signaling in one of the cells requires the presence of Numb, a membrane-associated protein whose mechanism of Notch inhibition is currently unknown. We are working to show that Numb functions through preventing the recycling of the Notch receptor back to the plasma membrane. We show that Numb promotes targeting of full-length Notch to late endosomes. Conversely, Notch levels in early endosomes are equivalent between the Numb positive and negative cells, supporting a model where Numb functions in Notch trafficking at a post-internalization step. Furthermore, we find that Numb itself may localize to recycling endosomes. To evaluate Notch recycling directly, we employed a novel assay that allows for marking of recycled vs. internalized Notch. Using this technique we found that Numb suppresses Notch receptor recycling back to the plasma membrane. Our work will provide new insight into the inhibition of Notch via Numb, which may allow for the creation of new drugs which can function similarly to Numb to regulate Notch activity.

P2040**Board Number: B558****Clathrin Independent Endosomal Trafficking is required for T Cell Conjugate Formation and Activation.**D. Johnson¹, J.M. Wilson², J.G. Donaldson³;¹Univ Arizona, Tucson, AZ, ²Univ Arizona Coll Med, Tucson, AZ, ³Cell Biology and Physiology Center, NHLBI/NIH, Bethesda, MD

The clathrin independent endosomal system is important for cellular homeostasis and specialized modifications of the plasma membrane. We characterized clathrin independent endocytosis (CIE) in the human Jurkat T cell line and compared it other cells. We found that major histocompatibility complex I

(MHCI) was endocytosed separately from the clathrin-mediated endocytic marker the transferrin receptor. Subsequently, MHCI passed through EEA1-positive endosomes, prior to trafficking to LAMP-1 positive vesicles for degradation or to endosomes for recycling back to the plasma membrane. In contrast, another CIE cargo protein, CD98, avoided residence in EEA1 positive endosomes after internalization and was rapidly recycled back to the cell surface. Thus CIE in Jurkat cells is similar to what is observed in other human cell lines.

Two G proteins, Arf6 and Rab22, have been shown to regulate endosomal trafficking and recycling of CIE cargo proteins. They are also required for rearrangement of the cell surface during events like cell spreading. We found that wild type Arf6 co-localized with CIE cargo and Rab22 co-localized with internalized MHCI in resting T cells. To test whether Arf6 or Rab22 activities were required for T cell activation we incubated Jurkat cells with activated antigen presenting cells (APC). Expression of the dominant negative mutants of Arf6 or Rab22 decreased T cell engagement with the APC and reduced actin polarization at the site of the immunological synapse. In addition, there is reduced T cell signaling as indicated by decreased phosphorylated tyrosine at the synapse of cells expressing mutant Arf6. Arf6 and Rab22 dominant negative mutants were also inhibited in their ability to spread when plated on antibody-coated coverslips that cause activation.

Our results confirm that CIE and subsequent endosomal trafficking is a highly conserved process. The clathrin independent endosomal system is used by T cells to redistribute and polarize membranes to the site of activation. Our findings suggest a requirement for Arf6 and Rab22 in mediating membrane trafficking and signaling events at the immunological synapse. Our future goal is to understand how CIE and endosomal trafficking affects T cell signaling and function.

Macronutrient stress modulates antigen trafficking and MHC class II presentation by altering HSC70.

S.N. Deffit¹, J.S. Blum¹;

¹Indiana University School of Medicine, Indianapolis, IN

B lymphocytes exploit macroautophagy to capture cytoplasmic and nuclear proteins within autophagosomes. Autophagosome fusion with lysosomes and endosomes facilitates content proteolysis, with the resulting peptides selectively binding MHC class II molecules which are displayed for recognition by T lymphocytes. Nutrient stress amplified this pathway, favoring increased class II presentation of cytoplasmic antigens targeted to autophagosomes. By contrast, nutrient stress diminished class II presentation of membrane antigens including the B cell receptor (BCR) and cytoplasmic proteins that utilize the chaperone-mediated autophagy (CMA) pathway. While intracellular protease activity increased with nutrient stress, endocytic trafficking and proteolytic turnover of the BCR was impaired. Addition of high molecular mass proteins restored endocytosis and antigen presentation, evidence of tightly regulated membrane trafficking dependent on macronutrient status. Altering the

abundance of the cytosolic chaperone HSC70 was sufficient to overcome the inhibitory effects of nutritional stress on BCR trafficking and antigen presentation. Together, these results reveal a key role for macronutrient sensing in regulating immune recognition and the importance of HSC70 in modulating distinct membrane trafficking pathways during cellular stress.

Alterations in Trafficking and Degradation of FGFR4, a commonly mutated protein in High-Risk Neuroblastoma Cases.

S. Reyes^{1,2}, M.B. Gireud^{3,4}, N. Sirisaengtaksin^{3,4}, P.E. Zage^{5,6}, A.J. Bean^{3,4,7};

¹Department of Neurobiology and Anatomy, University of Texas Health Science Center at Houston, Houston, TX, ²University of Texas Graduate School of Biomedical Sciences, Houston, TX, ³Neurobiology and Anatomy, University of Texas Health Science Center at Houston, Houston, TX, ⁴University of Texas Graduate School of Biomedical Sciences at Houston, Houston, TX, ⁵Department of Pediatrics, Section of Hematology-Oncology, Baylor College of Medicine, Houston, TX, ⁶Cancer and Hematology Centers, Texas Children's Hospital, Houston, TX, ⁷Pediatrics, M.D. Anderson Cancer Center, Houston, TX

Overall survival rates for children diagnosed with high-risk neuroblastoma remain low despite current treatment regimens. Resistance of these tumors to conventional therapies is a major problem and the molecular mechanisms that underlie resistance remain unclear. Growth factor receptors and their signaling cascades have been suggested to cause tumorigenesis and/or metastasis. Therapies targeting these receptors are often effective anti-cancer agents. The fibroblast growth factor receptor 4 (FGFR4) signaling cascade promotes cell division and differentiation. We have observed that expression of a polymorphic FGFR4 correlates with increased mortality in neuroblastoma patients. This polymorphism generates a glycine-to-arginine change in codon 388. It has been linked to aggressive phenotypes in various other cancers and is associated with increased signaling. FGFR4 signaling can be regulated by the endocytic pathway such that the duration and amplitude of receptor signal can be altered by receptor trafficking. Upon ligand binding, FGFR4 is internalized and moves through a series of endosomal compartments prior to being degraded in the lysosome. We hypothesize that the polymorphism (Arg388) interferes with trafficking of this receptor through the endocytic pathway and that sustained signaling from non-degraded receptors promotes neuroblastoma growth. Given the apparent importance of this FGFR4 mutation in neuroblastoma tumorigenesis, and the role that endocytic trafficking can play in receptor signaling kinetics, we explored whether this polymorphism displayed altered trafficking that might underlie enhanced signaling.

We examined (wt) Gly388 and (mutant) Arg388 FGFR4 degradation in SY5Y cells following ligand (bFGF) stimulation. We observed that FGFR4 Arg388 receptors are degraded at a slower rate than wild-type FGFR4 receptors. To understand where in the endocytic pathway the mutant FGFR4 is delayed, we compared the movement of FGFR4s through various steps in the endocytic pathway. For example, we used a cell-free assay that measures movement of membrane proteins into internal vesicles of late endosomes to examine whether wt or mutant FGFR4 are differentially sorted at the late endosome.

Proteins sorted into internal vesicles within late endosome/MVBs are degraded upon fusion with the lysosome and decreased MVB sorting could therefore account for decreased degradation. However, no significant differences in MVB sorting were observed between wild-type FGFR4 and FGFR4 Arg388. Analysis of other endocytic steps whose inhibition could account for decreased FGFR4 Arg388 degradation (e.g. internalization from the plasma membrane, recycling to the plasma membrane, and movement from early endosomes) as well as effects on downstream signaling are ongoing.

Divide and Polarize: The Role of Cytokinesis and Endocytic Transport during Epithelial Cell Polarization.

A. Mangan¹, D. Li^{1,2}, R. Prekeris¹;

¹Cell and Developmental Biology, Univ Colorado Anschutz Medical Campus, Aurora, CO, ²University of Colorado Anschutz Medical Campus, Aurora, CO

Epithelial cells are structurally and functionally polarized to transport specific molecules while maintaining a trans-epithelial barrier. This cellular asymmetry is essential for the proper functioning of epithelial tissues and depends on polarized endocytic transport routes. Additionally, epithelial cells coordinate their polarization with neighboring cells to form an apical lumen, a key step in the establishment of renal and gut architecture, and thereby function. Recent work from several laboratories including ours identified Rab11 and its binding protein FIP5 as major components that regulate apical endosome transport during apical lumen formation. We demonstrated that Rab11/FIP5-containing endosomes (FIP5-endosomes) mediate the formation of apical lumen by targeted delivery of apical lumen proteins, and that FIP5 functions by interacting with sorting nexin 18 and Kinesin-2. It was also shown that targeting of FIP5-endosomes to the apical membrane initiation site (AMIS) is a key step during the initiation and expansion of the apical lumen during formation of MDCK epithelial cysts in 3D tissue culture system. Despite recent advances in our understanding of the mechanisms mediating lumen formation, many questions remains unanswered. How are FIP5-endosomes targeted during apical lumen formation? How do cells establish the site of single apical lumen? In this study we focused on the identification of the machinery that mediates AMIS formation and FIP5-endosomes targeting during apical lumen formation. We identified a new FIP5-interacting protein, cingulin, which is a tight junction protein that localizes to the AMIS. Thus, cingulin is perfectly suited to serve as a tether to mediate FIP5-endosome targeting during apical lumen formation. Importantly, our data demonstrate that AMIS forms around the midbody of the mitotic epithelial cells during late telophase. Finally, we demonstrate that AMIS formation is initiated by Rac1-dependent burst of actin polymerization at the midbody. Based on all these studies we propose a novel hypothesis that AMIS formation around the midbody and FIP5/cingulin-dependent endosome targeting to the midbody during late telophase are the first “symmetry breaking” events leading to the initiation of apical lumen during epithelial morphogenesis.

P2044**Board Number: B562****Novel mechanistic insights into anthrax toxin endocytosis.**S. Friebe¹, L. Abrami¹, F. Van Der Goot¹;¹EPFL, Lausanne, Switzerland

Anthrax is a disease largely caused by the exotoxins of *Bacillus anthracis*. Entry into cells is mediated by one of the two known anthrax toxin receptors. The main receptor is Capillary Morphogenesis Gene 2 (CMG2) also known as ANTXR2, a single pass type I transmembrane protein of unknown physiological function. How these toxins act on cells is well studied, yet the exact initial steps of toxin entry are still poorly understood. We therefore aimed to better understand this complex and fascinating process and to shed light on the physiological role of the main anthrax toxin receptor. For this we identified new potential partner proteins of CMG2 by using several Yeast Two Hybrid screens:

Currently our work is focusing on a kinase and an E3 ubiquitin ligase as well as a protein identified from a genome wide screen for anthrax susceptibility, ARAP3. ARAP3 is a PI3K effector protein and a RhoGAP implicated in integrin regulation and growth factor receptor trafficking. Lastly, the downstream effector of ARAP3, RhoA is a protein known to mediate actin reorganization upon extracellular stimuli.

We could show that all proteins interact with CMG2 by co-immunoprecipitation and have started to pinpoint the interacting domains on the proteins by biochemical and microscopical methods. We also show that interaction between the proteins is constant and not ligand-triggered for all four proteins. To understand the functional implications of these interactions we studied the different steps of anthrax toxin endocytosis. Knockdown of all four proteins did not have an effect on binding of the toxin, yet the effect on later steps of the process was striking. In the absence of the kinase and the E3 ligase, endocytosis of the receptor-toxin complex was almost completely inhibited. This might be due to a lack of phosphorylation and ubiquitination of the receptor after toxin binding in the absence of these enzymes. Knockdown of ARAP3 strongly delayed endocytosis and knockdown of RhoA led to a defect of heptamer formation, a prerequisite for efficient endocytosis. To ensure that these proteins act specifically on CMG2, we looked at entry of Diphtheria Toxin, which also enters cells via clathrin-mediated endocytosis. So far it seems that the proteins are specific for endocytosis of anthrax and are not general regulators of clathrin-mediated endocytosis. By gaining important insights into the endocytosis of anthrax toxin with the help of this small-scale protein network, we also hope to broaden our knowledge about the physiological behavior of its receptor.

P2045**Board Number: B563****Ack1 Overexpression Results in the Interruption of Several Endocytic Pathways and Vesicular Trafficking.**C. Ye¹, L. Guan¹, T. Lin¹, V.E. Prieto-Echagüe², D.A. Brown³, W.T. Miller⁴, A.L. Gucwa¹;¹Biomedical Sciences, Long Island University At Post, Brookville, NY, ²Molecular Human Genetics, Institut Pasteur de Montevideo, Montevideo, Uruguay, ³Biochemistry and Cell Biology, Stony Brook University, Stony Brook, NY, ⁴Physiology and Biophysics, Stony Brook University, Stony Brook, NY

Ack1 is a direct effector of the Rho GTPase member Cdc42, and is amplified and overexpressed in several types of cancers. Its strong implications in tumor progression and metastasis make it of great interest. However, until recently, little was known about this non-receptor tyrosine kinase (NRTK) and its regulation. The NRTK is known to play an integral role in clathrin-dependent internalization and the down-regulation of activated EGFR. We were interested to see whether Ack1 also plays a role in the internalization and trafficking of ErbB2, a member of the ErbB family of growth factor receptors. Treatment of cells in culture with the ansamycin antibiotic, geldanamycin (GA), results in the internalization and degradation of ErbB2 in a clathrin-independent manner. The overexpression of Ack1 disrupted the down-regulation of ErbB2 in GA-treated cells. Cholera toxin uptake, which occurs via lipid raft-dependent mechanisms, was also blocked by its overexpression. We did not find any effect of Ack1 on bulk fluid uptake, as the internalization of high-molecular weight dextran was unchanged. Additionally, we found this effect was not limited to endocytosis; Ack1 overexpression induced the disruption and tubularization of the Golgi apparatus, similar to that seen in Brefeldin A-treated cells. To further investigate the role of Ack1 on the trans-Golgi network, we studied its effect on mannose 6-phosphate receptor (MPR). This receptor binds newly synthesized lysosomal hydrolases in the trans-Golgi network (TGN) and delivers them to pre-lysosomal compartments. A GFP-tagged form of cation-independent MPR (CI-MPR) was sequestered at the plasma membrane when co-expressed with Ack1, suggesting Ack1 may also alter retrograde transport. Taken together, our data suggests the overexpression of Ack1 plays a global and more significant role in endocytosis and intracellular trafficking than previously thought.

P2046**Board Number: B564****FAM21 regulates recycling of SNX27-retromer cargoes to the plasma membrane.**S. Lee¹, J. Chang¹, C.D. Blackstone¹;¹NINDS, National Institutes of Health, Bethesda, MD

The endosomal network controls numerous cellular functions such as signaling, nutrient uptake, and development through balanced trafficking of diverse plasma membrane proteins. After receiving membrane protein cargoes, endosomes sort them into lysosomes for degradation, or else to the trans-Golgi network or plasma membrane for recycling. These pathways are elaborately controlled by the

retromer complex, a multi-subunit complex associated with the cytosolic face of endosomes, along with its interacting proteins. Recently, the retromer complex in association with SNX27, a PDZ-domain-containing SNX protein, has been identified as a major endosomal hub to regulate endosome-to-plasma membrane recycling. Even though the Wiskott-Aldrich syndrome protein and SCAR homolog (WASH) complex, an activator of Arp2/3-mediated actin nucleation in endosomes, has been identified to interact with the SNX27-retromer complex, a specific role for the WASH complex in the recycling pathway has not been elucidated. Here, we have identified the FAM21 subunit of the WASH complex as a direct interacting partner of SNX27. A FERM domain of SNX27 binds to α -helical domains at the N-terminus of FAM21, which are distinct from the binding sites for the VPS35 subunit of the retromer complex. We have also demonstrated that the interaction is required for proper recycling of SNX27-retromer cargoes by distributing SNX27 within an endosomal subdomain to aid export of cargoes to their destination. Thus, we suggest that the WASH complex regulates endosome-to-plasma membrane recycling in collaboration with the SNX27-retromer complex.

The massive exocytosis of synaptic vesicles (SVs) elicited by a potent nerve terminal stimulation is rapidly compensated by bulk endocytosis of SV membranes leading to large endocytic vacuoles. Subsequently, these vacuoles ("bulk" endosomes) disappear in parallel with the reappearance of new SVs. We have capitalized on synapses of dynamin 1 and 3 double knock-out (DKO) neurons, where clathrin-mediated endocytosis is dramatically impaired, to gain insight into the poorly understood mechanisms underlying this process. Massive formation of bulk endosomes was not impaired in these neurons. Conversion of bulk endosomes into SVs during recovery was delayed, but not blocked, even after further clathrin knock-down, showing that this process is independent of clathrin-mediated budding, consistent with the absence of clathrin coats on bulk endosomes. These findings support the existence of a pathway for SV reformation that bypasses the requirement for clathrin and dynamin and demonstrates the plasticity of the SV recycling process.

Molecular insights into zipcode activated cytoplasmic mRNA transport.

H. Shi¹;

¹Dept. of Cell biology, Rockefeller University, New York, NY

Myo4p is one of five distinct myosins of yeast, which is dedicated to cytoplasmic transport of two types of cargos, zipcoded mRNPs and tubular endoplasmic reticulum (tER). Neither cargo binds directly to Myo4p. Instead, She3p serves as 'adaptor' that contains three binding modules, one for Myo4p and one each for zipcoded mRNA and tER. The assembly of a transport-competent motor complex is poorly understood. Here, we report that [Myo4p•She3p] forms a stable 1:2 heterotrimer in solution. In the [Myo4p•She3p] crystal structure, Myo4p's C-terminal domain (CTD) assumes a lobster claw-shaped form, the minor prong of which adheres to a pseudo-coiled coil region of She3p. Because the [Myo4p•She3p] heterotrimer contains only one myosin molecule, it is not transport-competent. By stepwise reconstitution, we found a single molecule of synthetic oligonucleotide (representing mRNA zipcode element) bound to a single tetramer of zipcode binding protein She2p to be sufficient for [Myo4p•She3p] dimerization. Hence, cargo initiates cross-linking of two [Myo4p•She3p] heterotrimers to an ensemble that contains two myosin molecules obligatory for movement. An additional crystal structure comprising an overlapping upstream portion of She3p showed continuation of the pseudo-coiled coil structure and revealed another highly conserved surface region. We suggest this region as candidate binding site for a yet unidentified tER ligand. We propose a model, whereby zipcoded mRNA and/or tER ligands couple two [Myo4p•She3p] heterotrimers and thereby generate a transport-competent motor complex either for separate or co-transport of these two cargos.

Proinflammatory cytokine-induced Tight Junction remodeling through dynamic self-assembly of claudins.

C.T. Capaldo¹, A.E. Farkas¹, C.A. Parkos¹, A. Nusrat¹;

¹Pathology, Emory University, Atlanta, GA

Tight Junctions (TJs) are dynamic, multiprotein intercellular adhesive contacts that provide a vital barrier function in epithelial tissues. TJs are remodeled during physiologic development and pathologic mucosal inflammation, and differential expression of the claudin family of TJ proteins determines epithelial barrier properties. However, the molecular mechanisms involved in TJ remodeling are incompletely understood. Using acGFP-claudin 4 as a bio-sensor of TJ remodeling, we observed increased Claudin 4 Fluorescence Recovery after Photobleaching (FRAP) dynamics in response to inflammatory cytokines.

Interferon gamma (IFN-gamma) and Tumor Necrosis Factor alpha (TNF-alpha) increased the proportion of mobile claudin 4 in the TJ. The claudin 4 PDZ (PSD95/Dlg/ZO-1) motif was required for cytokine-induced changes in dynamics. Upregulation of claudin 4 protein rescued these mobility defects and cytokine-induced barrier compromise. Furthermore, claudins 2 and 4 have reciprocal effects on epithelial barrier function, exhibit differential FRAP dynamics, and compete for residency within the TJ. These findings establish a model of TJs as self-assembling systems that undergo remodeling in response to proinflammatory cytokines through a mechanism of heterotypic claudin binding incompatibility.

From Microdishes to microniches. 3D microenvironmental control around single cells. Application to single cell apico basal polarization and lumenogenesis control.

V. Viasnoff^{1,2}, Q. Li¹, J. Thiery^{3,4}, H. Yu^{1,5,6}, Z. Weng⁷;

¹MBI/DBS, Mechanobiology Institute, Singapore, Singapore, ²UMI3639, CNRS, Singapore, Singapore, ³Biochemistry, NUS, Singapore, Singapore, ⁴IMCB, Astar, Singapore, Singapore, ⁵School of Medicine, NUS, Singapore, Singapore, ⁶IMB, Astar, Singapore, Singapore, ⁷Mechanobiology Institute, Singapore, Singapore

The influence of the microenvironment on cell behavior and fate is increasingly recognized as of key importance. It follows that new techniques to control the 3D environment around cells are key to understand the processes by which cells probe and respond to their microniches. We present here an approach that allow to transform microwells into artificial microniches where the chemical coating, rheological properties and topographical properties can be differentially controlled on the top, sides and bottom of the wells and assembled in a combinatorial way. This technique is also compatible with high and super resolution imaging that allows to probe the dynamics of cell cytoskeleton and regulatory proteins with unprecedented resolution down to the single molecule level in 3D. We exemplify how these bone fide artificial microniches can be used to induce full apico-basal polarization of single epithelial cells and as well as to control intercellular stresses driving the anisotropic growth of intercellular lumens. Other on going applications will also be briefly discussed.

Apical lumen formation in single pluripotent human and mouse embryonic stem cells initiates via establishment of Rho-GTPase dependent intracellular apical membrane initiation site.

K. Taniguchi¹, R. Townshend¹, D. Chue¹, Y. Tsai^{1,2}, C. Harris³, S. Lopez¹, A. Freddo¹, S. Kalantry³, J. Spence^{1,2}, B. Margolis^{2,4}, S. O'Shea¹, D. Gumucio¹;

¹Department of Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI, ²Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, MI, ³Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI, ⁴Department of Biological Chemistry, University of Michigan Medical School, Ann Arbor, MI

Establishment of an apical surface and formation of a lumen is an essential process employed during morphogenesis of epithelial tissues and organs. We have found that single dispersed human embryonic stem cells (hESCs) and human induced pluripotent stem cells (hiPSCs) organize apical and baso-lateral proteins at a peri-nuclear site prior to their first cell division. As the cell divides, this collection of proteins becomes the lumen between the two daughter cells; thus, it functions as an intracellular apical membrane initiation site (intra-AMIS). With further growth, these hESCs and hiPSCs form hollow cysts while maintaining the expression of NANOG and POU5F1. At the one-cell stage, the intra-AMIS structure contains highly distinct apical and baso-lateral compartments. A central apical domain is enriched for EZRIN and aPKC proteins (apical markers), surrounded by ring-shaped ZO1 protein (tight junction), a zone of RAB11 (early endosome) and GM130 (Golgi apparatus), as well as by junctional markers such as E-CADHERIN, β -CATENIN and β 1-INTEGRIN. This clearly shows the presence of intracellular baso-lateral domain in addition to apical. We show that the activation of Rho-mDia and Rac1-Arp2/3 signaling is essential for intra-AMIS formation and consequent patterning of the apical lumen, whereas inhibition of Rho-ROCK-myosin-II signaling promotes lumen formation. Other cell types, such as cultured Caco-2 (human colonic adenocarcinoma) and MDCK.2 (adult canine kidney) cells form intra-AMIS structures that evolve to lumens as well, suggesting that intra-AMIS structures are an important aspect of lumen formation in multiple settings and in multiple species. Like hESCs and hiPSCs, mouse embryonic stem cells (mESCs) also form intra-AMIS structures. Seeking an *in vivo* correlate to this phenomenon, we show that 4-day-old mouse blastocysts display intra-AMIS structures in primitive endoderm, trophoblast and epiblast precursor cells. Together, these data reveal that multiple cell types, including pluripotent human and mouse cells, have propensity to form lumina, and that the organization of the lumen-forming machinery begins with the formation of an intra-AMIS at the one-cell stage.

KLF4 controls epithelial stratification via non-canonical WNT5A signaling.

M. Tetreault¹, D. Weinblatt¹, J.P. Katz¹;

¹GI/Medicine, University of Pennsylvania, Philadelphia, PA

Background: *Krüppel-like factor 4* (Klf4) is a DNA-binding transcriptional regulator highly expressed in gastrointestinal epithelia, specifically in regions of cellular differentiation. In the esophagus, Klf4 is expressed in differentiating cells of the suprabasal and superficial layers. Loss of *Klf4* perturbs normal squamous differentiation pathways and alters squamous epithelial stratification. Wnt5a is a non-canonical Wnt ligand down-regulated by gene expression analyses in *Klf4* conditional knockout mice. Wnt5a is important for the regulation of a variety of cellular functions, such as proliferation,

differentiation, migration, and polarity. We hypothesized that KLF4 controls esophageal epithelial stratification by direct transcriptional regulation of *WNT5A*. **Methods:** We used tissue specific gene ablation to delete *Klf4* in esophagus and sacrificed mice at 3 months of age for analyses. Primary esophageal keratinocytes were isolated for *in vitro* studies of gene regulation, cell migration, and stratification. **Results:** Tissue-specific *Klf4* knockout mice (*ED-L2/Cre;Klf4loxp/loxp*) had altered morphology of cells in the suprabasal and superficial layers. *Wnt5a*, a non-canonical Wnt ligand, was decreased by 3.0-fold on microarray, and we confirmed a 2.9-fold decrease by quantitative real-time PCR. These decreases in *WNT5A* were seen predominantly in the suprabasal layers of *ED-L2/Cre;Klf4loxp/loxp* mice. *Klf4* inducible knockdown with shRNAs in primary esophageal keratinocytes also produced a 30% decrease in *Wnt5a* expression levels. We found marked induction of *Wnt5a* promoter activity by KLF4 in primary esophageal keratinocytes using the luciferase reporter pGL4-*Wnt5a*. Moreover, we also demonstrated KLF4 binding to *WNT5A* by ChIP in human primary esophageal keratinocytes. Primary esophageal keratinocytes with *Klf4* knockdown had decreased polarity during cell migration, which was restored by recombinant *WNT5A*. Furthermore, we demonstrated that human primary esophageal keratinocytes with KLF4 knockdown had evidence of delayed cellular maturation, and defects in stratification in an organotypic 3D cell culture system. Treatment with recombinant *WNT5A* restored proper stratification in 3D cultures with decreased KLF4 expression. Conclusion: KLF4 is a key regulator of esophageal epithelial cell migration and stratification via *WNT5A*.

CRB3 restores epithelial cell shape and actin organization in cancer cells.

E. Loie¹, L. Charrier¹, K. Sollier¹, P. Laprise²;

¹BMBMP, Université Laval, QUEBEC, QC, ²BMBMP, Centre de Recherche sur le Cancer de l'Université Laval - CRCHU de Québec, Québec, QC

BACKGROUND AND OBJECTIVES: Apico-basal polarity is a common feature of epithelial cells. Loss of the polarized architecture of epithelial cells is associated with many pathologies, including cancer. The transmembrane protein CRB3 is an important determinant of the apical domain in epithelial cells. Recently, CRB3 has emerged as a potential tumor suppressor, as it represses tumor growth and metastasis in animal models. However, the molecular mechanisms used by CRB3 to prevent tumor development and progression are unknown. Our goal is to decipher these mechanisms. **METHOD:** HeLa cells, which are devoid of endogenous CRB3, were transfected with a tagged form of CRB3, or truncations of CRB3. The phenotype associated with expression of these proteins was analyzed by biochemistry and cell biology techniques. **RESULTS:** Expression of CRB3 in HeLa cells results in a drastic change in cell morphology and a strong reorganization of the actin cytoskeleton. Cells also show tighter contacts with each other, suggesting an improvement of cell-cell junctions. These changes depend on CRB3 cytoplasmic tail, but do not require the extracellular domain. This indicates that CRB3 probably controls intracellular signaling pathways to trigger actin rearrangements. **CONCLUSION:** Expression of CRB3 in HeLa cells drives important structural changes similar to a mesenchyme-to-epithelial transition

in cancer cells. Expression of CRB3 in aggressive carcinomas could then prevent cancer progression and metastasis. Identification of the mechanisms controlled by CRB3 to limit tumor progression will likely highlight new targets for cancer treatment.

Alternative transcription of Amot80 and Amot130 in response to inflammation in breast cancer.

L.R. Bringman¹, C. Wells²;

¹Indiana University School of Medicine, Indianapolis, IN, ²Department of Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN

The HIPPO signaling pathway is of central importance in controlling the growth of cells in tissues. Conversely, inactivation of HIPPO signaling underlies the progression and promotion of a multitude of cancer types, including breast cancers. HIPPO signaling inhibits the transcriptional co-activator YAP in response to cell-cell contacts and cell polarity. Reduced HIPPO signaling prompts the accumulation of YAP in the nucleus where transcription factors such as TEADs switch on pro-growth, -survival and -invasion programs. YAP is known to be inhibited by members of the Amot family of adaptor proteins. Because Amot proteins also bind the key polarity proteins that drive a differentiated morphology, this directly links YAP inhibition to formation of apical-basal polarity in epithelial cells. Because the Amot gene produces a 130 kDa form (Amot 130) that inhibits YAP and promotes cell polarity and an 80 kDa form (Amot 80), which acts as a dominant negative to promote YAP activation and cell growth, it is important to understand their differential regulation. The balance between expression of Amot80 versus Amot130 is shown to dictate whether breast cells will remain differentiated or undergo dysregulated growth. My analysis of breast tissues finds that total Amot is expressed weakly and localizes to the apical membrane in normal mammary cells. Conversely, Amot expression is significantly higher and localized to intracellular puncta (a hallmark of high Amot80 expression) in human breast cancers, especially in triple-negative forms of this disease. In hormone negative DCIS, Amot expression is high and peri-nuclear, specifically in the more disorganized regions adjacent to stromal areas flooded with inflammatory cells. This led us to examine how Amot transcription is modulated by inflammatory cytokines such as interleukin-6 (IL-6), a canonical activator of STAT3 that is commonly secreted in aggressive breast cancers. Phosphorylation of STAT3 (P-STAT3) by IL-6 activated Janus Kinase (JAK) receptors drives its nuclear accumulation and pro-growth transcriptional effects. Consistently I have found that IL-6 treatment of breast cancer cells increases Amot mRNA levels and immunoblot analysis indicates the differential induction of the Amot isoforms. The overall impact of these studies will be both the enhancement of our understanding of inflammation and growth control in breast cancer as well as a bioassay to measure Amot80 and Amot130 mRNA levels in human tumors. The lack of knowledge regarding the cross regulation between inflammatory signaling, HIPPO signaling, and cell polarity, allows this study to drive novel insights to the undisputed pro-tumorigenic impact of inflammation.

P2055**Board Number: B574****Farnesylated LKB1 regulates cell polarization and invasion through a 3D collagen microenvironment in a kinase-independent manner.**S. Wilkinson¹, A. Marcus²;¹Graduate Program in Cancer Biology, Emory University, Atlanta, GA, ²Hematology and Medical Oncology, Emory University, Atlanta, GA

The tumor suppressor LKB1 is a serine/threonine kinase that serves as a master regulator of cell polarity in epithelial tissue, and is mutated in 30% of non-small cell lung cancer tumors. LKB1 contains a C-terminal farnesylation motif, which allows for post-translational addition of a hydrophobic farnesyl group and insertion into the plasma membrane. Although LKB1 contains a farnesylation motif, the functional significance of this motif is largely unknown. We generated lung cancer cell lines stably expressing GFP-tagged: wildtype LKB1, a farnesylation motif mutant LKB1, and the various domains of LKB1, including the C-terminal domain (CTD, lacking kinase activity) and the CTD containing the farnesylation motif mutant, and then embedded spheroids of these cells in a 3D collagen matrix. Using confocal microscopy and live-cell imaging, we show that lung cancer cells re-expressing wildtype LKB1 acquire a unidirectional polarity, while cells expressing the farnesylation-mutant LKB1 are unable to polarize. Importantly, we show that 3D polarization is regulated through the LKB1 CTD alone, also in a farnesylation-dependent manner. These data indicate that farnesylated LKB1 promotes polarization during 3D motility through its C-terminal domain in a kinase-independent manner. We next sought to identify the role of LKB1 farnesylation in regulating invasion through the 3D collagen microenvironment. After acquiring a unidirectional polarity, cells re-expressing either wildtype LKB1 or the LKB1 CTD invade into the collagen microenvironment. Strikingly, we show that cells re-expressing LKB1 with the farnesylation motif mutation exhibit significantly reduced invasion into the collagen microenvironment, with the few cells invading exhibiting no polarization. Taken together, these data implicate LKB1 farnesylation as critical for promoting cell polarization and potentially providing a mechanism of cell invasion into the collagen microenvironment. This information has the potential to lead to novel information regarding the mechanisms of LKB1 farnesylation in regulating polarization and invasion, ultimately providing new insight into the tumor suppressive function of LKB1.

P2056**Board Number: B575****Adenomatous Polyposis Coli Regulates Epithelial Polarity and 3D Morphogenesis by Mediating FAK/Src Signaling.**A. Lesko¹, J. Prosperi^{1,2};¹Biological Sciences, Harper Cancer Research Institute, University of Notre Dame, South Bend, IN,²Indiana University School of Medicine, South Bend, IN

Adenomatous Polyposis Coli (APC) is a multi-functional protein that is lost or mutated in many epithelial cancers including breast, colorectal, and pancreatic cancer. Although APC is well known as a negative regulator of the Wnt/ β -catenin signaling pathway, it also binds to microtubules and polarity proteins, such as Dlg and Scribble, suggesting functions in regulation of epithelial polarity and cell migration. Our lab has previously determined that the mammary glands of *Apc*^{Min/+} mice demonstrate mis-regulation of epithelial polarity, exhibit early neoplastic changes, and develop more aggressive mammary tumors when crossed to the MMTV-PyMT model of breast cancer. Cells isolated from these tumors activated FAK/Src signaling. Our lab has also shown that APC knockdown in the Madin-Darby Canine Kidney (MDCK) model altered epithelial morphogenesis, resulted in inverted polarity in 3D culture, and up-regulated gene expression of epithelial membrane protein 2 (EMP2). While restoration of the b-catenin binding domain was unable to rescue the phenotype, introduction of either full-length or a c-terminal fragment of APC partially restored these phenotypes. The current studies investigate the Wnt-independent mechanisms by which APC regulates these processes using the MDCK model and primary mammary epithelial cells (MECs) isolated from *Apc* mutant mice. We hypothesize that the c-terminal fragment mediates FAK/Src signaling to regulate 3D morphogenesis and polarity. Treatment of APC knockdown MDCK cells with PP2, a Src kinase inhibitor, or AIIB2, an integrin inhibitor, eliminated the drastic cyst size changes produced by APC knockdown. Furthermore, inhibition of Src partially restored the polarity phenotype in cysts with APC loss. In addition, shAPC-MDCK cells exhibited increased cell migration indicating a role for APC in cell motility. Preliminary data demonstrates that treatment of shAPC-MDCK cells with PP2 and AIIB2 inhibits migration suggesting FAK/Src signaling as a possible mechanism by which APC mediates cell migration. Interestingly, EMP2 has been shown to bind integrin to activate FAK signaling suggesting an interaction in these signaling pathways. Future studies will aim to dissect the role of the c-terminal fragment and further devise the mechanism by which FAK/Src signaling and EMP2 play a role in APC regulating gene expression, cell migration, and polarity and 3D morphogenesis in MDCK cells. Investigating the interactions of APC with several targets such as those in the FAK/Src signaling pathway will help identify key players in the role of APC in Wnt-independent tumor development.

P2057**Board Number: B576****A cytoskeleton-based memory in chemotactic leukocytes.**H. Prentice-Mott¹, Y. Meroz², A. Carlson², M. Levine³, G. Charras⁴, L. Mahadevan², J. Shah¹;¹Harvard Medical School, Boston, MA, ²Harvard School of Engineering and Applied Sciences, Cambridge, MA, ³Biophysics, Harvard University, Cambridge, United States, ⁴London Centre for Nanotechnology, University College London, London, United Kingdom

The directional response of cells to asymmetric chemical environments involves a complex sequence of steps including: gradient sensing, internal polarization and migration. To understand how these modules act to direct cell motion requires quantitative measurements of the cellular response and quantitative control of the external chemical environment. We used microfluidics to generate confining microchannels in which the front and back of the cell can be independently exposed to separate chemoattractant concentrations, which are stable over time. Cells exposed to high, static differences with low background ($C_0=0$ nM, $\Delta C=100$ nM) exhibited persistent polarization, as assessed by PH-Akt asymmetry. Smaller differences ($C_0=0$ nM, $\Delta C=3$ nM) or increased background ($C_0=50$ nM, $\Delta C=50$ nM) resulted in fluctuations between polarized and unpolarized states. The direction of polarization was biased toward the higher concentration. When exposed to uniform concentrations of chemokine ($C_0=0, 3, 10, 100$ nM, $\Delta C=0$ nM), cells exhibited similar polarization fluctuations. Unexpectedly, the direction of polarization for all concentrations except $C_0=0$ was biased towards the initial direction of polarization, indicating a directional “memory”. To further test this, cells were exposed to a controlled dynamic environment, in which a uniform concentration ($C_0=10$ nM, $\Delta C=0$ nM) was first introduced, then changed to no chemoattractant ($C_0=0$ nM, $\Delta C=0$ nM) which caused most cells to depolarize. Subsequent reintroduction of the chemoattractant ($C_0=10$ nM, $\Delta C=0$ nM) after 2 minutes of no chemoattractant caused ~90% of the cells to re-polarize in the same direction as initially polarized. If the chemokine was removed for 10 minutes, this number decreased to ~70%. We measured the decay of internal cellular asymmetries during the no chemoattractant phase and observed dramatic differences in timescales for molecules such as PIP3 and Myosin light chain which were fast (10 seconds), versus the ERM protein moesin (5 minutes). Chemical disruption of the long-lived moesin (NSC668394) or microtubule (colcemid) structures during the no chemoattractant phase, resulted in decreased memory of polarization after reintroduction of the chemoattractant and washout of the drug (60% or 55%, respectively). We developed a phenomenological model incorporating two layers of polarization, a short-lived membrane layer (pm) and a long-lived cytoskeletal layer (pc). The cytoskeletal polarization is driven by the time-integrated pm , while the direction of the membrane polarization is driven by both pc and external concentration differences. This simple model reproduced the observed directional memory. Cells may use this directional memory to navigate the complex chemical environment found in tissues.

P2058**Board Number: B577****TorsinA operates as a membrane-regulated ring-shaped hexameric molecular chaperone within the nuclear envelope during centrosome orientation in migrating fibroblasts.**C.A. Saunders¹, E.M. Smith², Y. Chen², J. Mueller², G.G. Luxton¹;¹Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN, ²Department of Physics and Astronomy, University of Minnesota, Minneapolis, MN

The centrosome is oriented between the nucleus and the leading edge in many migrating cells and contributes to directional cell migration. Recent research shows that torsinA, a AAA+ ATPase found within the Nuclear Envelope (NE), is required for centrosome orientation during directional cell migration. AAA+ ATPases typically function as hexameric ring-shaped molecular chaperones to structurally remodel protein complexes by mechanically unfolding and translocating target proteins through a central pore. TorsinA is an unusual AAA+ ATPase in four ways: 1) it is found within the NE; 2) it is a monotopic membrane-associated protein; 3) it does not possess a recognizable target protein interaction domain; and 4) it lacks arginine fingers that are known to be important for ATP-hydrolysis and oligomerization. Therefore, the molecular mechanism of torsinA-mediated centrosome orientation is currently unknown. To begin to identify this mechanism, we tested the ability of different GFP-tagged torsinA constructs to rescue centrosome orientation in torsinA-null fibroblasts. We find that torsinA-mediated centrosome orientation requires ATPase activity and the ability of torsinA to form a hexameric oligomer with at least three active subunits. We identify two conserved hydrophobic residues (Y128 and Y147) in torsinA that are required for centrosome orientation as potential pore loops, which interact with and translocate target proteins in the central pore of AAA+ ATPases. To determine if torsinA can form hexamers, we developed z-scan Fluorescence Fluctuation Spectroscopy (FFS) in order to measure the oligomeric state of GFP-tagged proteins within the NE of living cells. Using this technique, we show that torsinA is on average a dimer within the NE while the deletion of the N-terminal membrane-association domain results in higher-order oligomeric states consistent with hexamerization. Finally, we show that torsinA lacking the membrane-association domain can still rescue centrosome orientation in torsinA-null fibroblasts. Taken together, our results suggest that torsinA operates as a hexameric ring-shaped molecular chaperone during centrosome orientation and that membrane-association negatively regulates torsinA oligomerization.

P2059**Board Number: B578****TorsinA is required for retrograde actin flow and TAN line assembly during rearward nuclear movement in migrating fibroblasts.**N.J. Harris¹, P. Willey¹, C.A. Saunders¹, G.G. Gundersen², G.G. Luxton¹;¹Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN, ²Department of Pathology and Cell Biology, Columbia University, New York, NY

Actin-dependent positioning of the nucleus at the cell rear is critical for the directional migration of several cell types. We have demonstrated that rearward nuclear positioning is mediated by linear arrays of nuclear envelope membrane proteins composed of nesprin-2G and SUN2, called Transmembrane Actin-associated Nuclear (TAN) lines, which couple the nucleus to actin cables undergoing retrograde flow. Currently, the molecular mechanism of TAN line assembly is unknown. Potential regulators of TAN line assembly are the torsin AAA+ ATPases that reside within the nuclear envelope. Recently, it was shown that torsinA interacts with the KASH domain of nesprin proteins within the nuclear envelope and is important for the localization of nesprins to the nuclear envelope. Since AAA+ ATPases typically function as molecular chaperones that structurally remodel protein complexes, we hypothesized that torsins may regulate the interaction of nesprin-2G and SUN2 during TAN line assembly. Here, we report that of the four mammalian torsins (torsinA, torsinB, tor2A, and tor3A) only torsinA is required for rearward nuclear positioning in migrating fibroblasts. Live imaging of fibroblasts where torsinA function has been inhibited reveals that the nucleus does not move directionally towards the cell rear. We find that torsinA localizes to TAN lines and is required for their assembly, supporting a role for torsinA in the regulation of nesprin-2G-SUN2 interactions. While torsinA inhibition does not negatively affect formation or organization of perinuclear actin cables, it does block retrograde actin flow. Taken together, our results suggest that torsinA controls both TAN line assembly and retrograde actin flow in migrating fibroblasts. Therefore, torsinA is a key regulator of cell polarity in during directional cell migration.

P2060**Board Number: B579****Armcx1, a potential gene of planar cell polarity regulation.**L. Knapp¹, P. Chen¹;¹Department of Cell Biology, Emory University, Atlanta, GA

Planar cell polarity (PCP) is essential in development, tissue morphogenesis, and cell migration. PCP refers to the coordination of cell polarity across a sheet of cells or tissues that utilizes communication between cells leading to a cytoskeletal response. The inner ear, specifically the cochlea's organ of Corti, is a model of PCP. Core PCP proteins have been implicated in coordinating sensory hair cell polarization, leading to uniform orientation of microvilli-derived stereocilia bundles in the organ of Corti. Specifically, membrane proteins Vangl2 along with Frizzled3 and Frizzled6 have been identified as core PCP proteins

required for PCP in the cochlea. How these core PCP proteins regulate morphological polarization is currently unknown. To explore and identify novel components of PCP that may bridge the core PCP proteins and cytoskeletal polarization, we performed a yeast two-hybrid screen to find proteins interacting with the cytoplasmic tail of Vangl2. Armadillo repeat-containing X-linked protein 1 (Armcx1) was identified as a Vangl2-interacting protein. Armcx1 contains armadillo repeats known to mediate protein-protein interactions in cell signaling and cytoskeletal morphogenesis. Down-regulation of Armcx1 mRNA has been linked to carcinomas in which PCP is perturbed. These findings support the hypothesis that Armcx1 may link Vangl2 to cytoskeletal polarization during PCP processes. To determine a possible role for Armcx1 in the PCP of the cochlea, we used in situ hybridization to determine whether its temporal and spatial expression pattern is consistent with a role in establishing PCP in the cochlea. We found that Armcx1 was expressed in the cochlear sensory epithelium, the organ of Corti, during establishment of PCP from embryonic (E) 14.5 to E 18.5 in mice. In addition, Armcx1 is also expressed in the vestibular sensory epithelia during PCP establishment. Together, its expression pattern, its interaction with known PCP proteins, and its associated cellular roles implicate Armcx1 as a potential regulator of PCP in vertebrates. We will further test whether Armcx1 interacts with Vangl2 to regulate cytoskeletal change and test its potential roles in PCP regulation.

Mitotic control of planar cell polarity by polo-like kinase 1.

R. Shrestha¹, K.A. Little¹, D. Devenport¹;

¹Dept. of Molecular Biology, Princeton University, Princeton, NJ

During cell division, polarized epithelial cells require mechanisms to ensure polarity and tissue integrity are preserved as they undergo dramatic structural rearrangements. Planar cell polarity (PCP), which relies on cell communication to align cell polarity across epithelial sheets, is particularly vulnerable during mitosis, as polarity defects can be propagated to neighboring cells. We previously discovered a novel mechanism in the skin epithelium that preserves PCP during mitosis whereby asymmetrically localized, cortical PCP proteins are internalized into endosomes, distributed equally to daughter cells, and recycled to the membrane where polarity is regained. The disassembly and restoration of PCP asymmetry must coincide precisely with cell cycle progression, but the mechanisms controlling PCP dynamics during mitosis are not known. Here we identify Plk1 as a master regulator of PCP dynamics during mitosis. Plk1 interacts with the core PCP component, Celsr1, via a conserved polo-box domain binding motif, localizes to mitotic endosomes and directly phosphorylates Celsr1's endocytic sorting signal. Phosphorylation activates the endocytic motif, allowing AP2 recognition and bulk recruitment of Celsr1 into clathrin-coated endosomes. Inhibition of Plk1 activity blocks PCP internalization, leading to perturbations in PCP asymmetry. Thus, Plk1-mediated phosphorylation of Celsr1 ensures PCP redistribution is precisely coordinated with mitotic entry.

P2062**Board Number: B581****Mitotic membrane turnover coordinates differential induction of the heart progenitor lineage.**C.D. Cota¹, B. Davidson¹;¹Biology, Swarthmore College, Swarthmore, PA

Matrix adhesion can polarize cells by stabilizing signaling enriched membrane domains. While it is known that dividing cells detach from the surrounding matrix and initiate extensive membrane remodeling, the in vivo impact of mitosis on adhesion-dependent signal polarization remains poorly characterized. Here we show that mitotic membrane turnover orchestrates adhesive polarization of heart progenitor induction. We investigate in vivo signaling dynamics in the invertebrate chordate, *Ciona intestinalis*. In *Ciona*, adhesion polarizes Fibroblast Growth Factor (FGF)-dependent induction of the heart progenitor lineage. Through targeted disruption and selective rescue of integrin based matrix adhesion in pre-cardiac founder cells, we show that adhesion promotes localized enrichment of FGF receptors by inhibiting mitotic internalization and degradation. Through mutational analysis of β -integrin subunits, we have experimentally defined the motif required for membrane stabilization and mitotic FGFR retention. Furthermore, targeted manipulations of Caveolin in the heart progenitor lineage indicate that Caveolin-rich membrane domains function downstream of polarized cell-matrix adhesion to retain FGFRs during mitotic rounding. These results support a revised model of adhesion-dependent asymmetric fate induction in which mitotic membrane turnover resets historic, pre-mitotic receptor distribution according to contemporaneous adhesive cues.

P2063**Board Number: B582****SONIC HEDGEHOG SIGNALING CONTROLS GRANULE NEURON MIGRATION IN A RAS-RAF DEPENDENT PATHWAY.**T. Ong¹, D. Solecki²;¹Developmental Neurobiology, St. Jude Children's Research Hospital, Memphis, TN, ²developmental neurobiology, St. Jude Children's Res Hosp, Memphis, TN

Background: Neuronal progenitors in the brain are born in sites known as germinal zones (GZ) where they undergo proliferation and differentiation before migrating long distances to home to their final positions. Developmental cues that control this transition are tightly regulated to ensure proper brain morphogenesis as dysregulation leads to brain malformations, mental retardation and cancer. A major challenge in the field of developmental neurobiology is to delineate the molecular underpinnings that regulate this developmental program. In the cerebellum, cerebella granule neurons (CGN) that fail to exit the external germinal layer (EGL) due to aberrant sonic hedgehog (Shh) signaling continue to proliferate and give rise to Shh driven medulloblastoma (MB). **Results:** Our laboratory have previously

reported that the E3 ubiquitin ligase, Siah2, blocks CGN migration by negatively regulating Par3, a component of the Par complex that is required to recruit the junctional adhesion molecule, JamC to the membrane to initiate cell-cell contacts for GZ exit. Preliminary data show that Shh signaling maintains Siah2 protein expression in a Ras-Raf dependent pathway. We also show a direct correlation between protein levels of active Ras (H and N isoforms) and Siah2, where their levels decrease from post-natal days (P), P4 to P15 respectively. Interestingly, these protein levels remain high in Ptc+/-P18-/- MB cells. In line with these findings are functional studies that show that activation of Shh signaling or gain of function of the Ras-Raf pathway in granule neuron progenitors (GNP) impairs their GZ exit which can be rescued by exogenous expression of Par3 or inhibition of Siah2 function, respectively. **Conclusion:** We propose that Shh signaling negatively regulates Par3 in a Ras-Raf-Siah2 dependent manner, hence blocking CGN GZ exit.

Rab35-dependent axon elongation is negatively regulated by p53-related protein kinase (PRPK).

D. Villarroel-Campos¹, D.R. Henriquez¹, M. Fukuda², C. Gonzalez-Billault³;

¹Biology, Universidad de Chile, Santiago, Chile, ²Tohoku Univ, Miyagi, Japan, ³Faculty of Sciences, Universidad de Chile, Santiago, Chile

The appropriate function of the nervous system relies on the neuronal polarized morphology. Axon elongation is a crucial process through neuronal final shape is achieved, and a mechanism sustained mainly by cytoskeletal dynamics and intracellular trafficking. We previously described that microtubule-associated protein 1B (MAP1B) is required for proper axon outgrowth. The aim of this work is to describe novel MAP1B-interacting proteins which could be involved in axon elongation. We carried out a yeast two-hybrid experiment using MAP1B light chain (LC1) as bait, and detected PRPK as one of the LC1-interacting partners. PRPK overexpression in hippocampal embryonic neurons in culture significantly reduces their axonal length. PRPK-induced phenotype can be rescued by Rab35 overexpression, suggesting that both proteins are functionally related. Noteworthy, axonal defects found in MAP1B knock-out neurons can be recovered by overexpression of either PRPK kinase dead mutant or Rab35 constitutively active. These evidences show that the MAP1B-interacting partner PRPK negatively regulates axon elongation in vitro, in a Rab35-dependent manner.

P2065**Board Number: B584****Oligodendrocyte-innate programs dictate cell shape changes required to form myelin sheaths and account for variation in lengths of CNS myelin sheaths.**M.E. Bechler¹, L. Byrne¹, C. French-Constant¹;¹MRC Centre for Regenerative Medicine, The University of Edinburgh, Edinburgh, Scotland

Myelin internodes are specialized extensions of glial cell plasma membrane spirally wrapped around axons to create a multilamellar sheath. The length of these internodes regulates the speed of axonal signal propagation. This length usually correlates with underlying axon diameters, suggesting the hypothesis that axonal cues regulate the internode properties and instruct the remarkable changes in cell shape required to form a sheath. However, despite decades of work to identify instructive cues, no axonal molecule has been shown to be required for central nervous system (CNS) myelination. Using primary oligodendrocytes cultured with inert microfibers, we tested the alternative hypothesis that myelin sheath formation is an innate property of the oligodendrocyte refined by, but not requiring, axonal signals. Supporting this hypothesis, oligodendrocytes produce internodes of physiological lengths on these microfibers, with compact multi-layered myelin membranes. This oligodendrocyte-innate program can be adapted by specific axonal molecules, with independent regulation of the number and length of internodes. This is distinct from Schwann cells that require axonal cues to differentiate and form compact myelin sheaths. Oligodendrocytes also inherently respond to the physical cue of microfiber diameter, increasing internode length with increased diameters. Surprisingly, we find that oligodendrocytes isolated from distinct CNS regions have differing innate internode lengths. This mirrors the variation in internode lengths found in vivo: spinal cord oligodendrocytes produce longer sheaths than those from cortex. These results indicate the cell shape changes during myelin internode formation are inherently controlled by oligodendrocytes and reveal previously unsuspected differences between oligodendrocytes from different regions of the CNS.

P2066**Board Number: B585****ROCK1 and 2 differentially regulate actomyosin organization to determine cell polarity in fibroblasts and neurons.**K.A. Newell-Litwa¹, M. Badoual², H. Asmussen¹, H. Patel¹, L. Whitmore¹, A.R. Horwitz¹;¹Cell Biology, University of Virginia, Charlottesville, VA, ²Laboratoire IMNC, Univ. Paris-Sud, Orsay, PA

RhoGTPases give shape to the cell by organizing the underlying actin cytoskeleton. As such, they are implicated in polarity underlying normal and cancer cell migration, epithelial polarization, and even the subcellular organization of the polarized dendritic spine, which supports learning and memory. In particular, RhoA-mediated signaling activates non-muscle myosin IIB (MIIB) by di-phosphorylating its regulatory light chain to form actomyosin filament bundles that define the sides and rear of migrating

cells. RhoA also inactivates Rac-driven actin polymerization, via an unclear mechanism, thus segregating the initiation of actin polymerization to the front of the cell to create the leading edge. However, how RhoA coordinates these two processes to drive polarity is unknown. ROCK is the major RhoA effector kinase that activates MIIB to create the cell rear. Yet, it is unclear which ROCK isoform, ROCK1 or ROCK2, is responsible for MIIB activation and Rac inactivation. We examined whether ROCK1 and 2 similarly or separately regulate MIIB activation and Rac inactivation in both front-back migratory cell polarity and dendritic spine polarity. For both systems, we observed a specific role for ROCK1, but not ROCK2, in the di-phosphorylation of myosin regulatory light chain on Thr18 and Ser19. This ROCK1-driven MIIB activation was also necessary for proper microtubule organization. In contrast, ROCK2, but not ROCK1, specifically attenuated Rac activity underlying the formation of the leading edge of the migratory cell and the spine head of the synapse. We hypothesized that ROCK2 regulates Rac activity through a negative feedback mechanism with the actin remodeling protein, cofilin. While Rac activation normally inactivates cofilin by Ser3 phosphorylation; knockdown of ROCK2 decreased levels of Ser3-phosphorylated cofilin. The loss of phosphorylated cofilin resulted in smaller nascent adhesions, which signal through Rac to drive membrane protrusion. However, cofilin inactivation by expression of phosphomimetic cofilin S3D restored adhesion maturation and rescued the morphology of ROCK2-deficient cells. Similarly, cofilin inactivation regulated the size of post-synaptic densities within the spine head. Thus, ROCK1 and ROCK2 regulate distinct molecular pathways downstream of RhoA, and their coordinated activities drive polarity in both cell migration and synapse formation. These results also suggest that the ROCK inhibitor, Y-27632, which indiscriminately targets both isoforms, is inhibiting two different pathways.

Contribution of Reactive Oxygen Species to the Establishment of Hippocampal Neuronal Polarity.

C. Wilson¹, T. Nuñez¹, C. Gonzalez-Billault¹;

¹Faculty of Sciences, Universidad de Chile, Santiago, Chile

Basal production of Reactive Oxygen Species (ROS) by the NADPH (NOX) complex contribute to LTP, memory consolidation and neuronal actin cytoskeleton dynamics. The Rho GTPases Rac1 and Cdc-42 and the actin cytoskeleton are essential for the development of the axo-dendritic compartments. Acquisition of polarity is intimately related with neuronal functions. However, the contribution of ROS during neuronal polarity has not been explored. In this work, we propose that physiological ROS produced by NOX complex contributes to the acquisition of neuronal polarity and axonal growth.

Hippocampal neurons from rat brain embryos (E18.5) were cultured for different times to evaluate whether ROS are involved in the establishment of neuronal polarity. Epifluorescence microscopy was used to assess development of neuronal polarity and axonal length. ROS content and actin dynamics were visualized using the genetically encoded biosensors Hyper and Lifeact, respectively. In addition, FRET biosensors were used to measure local activity of Rac1 and Cdc-42 after NOX inhibition.

The NOX subunits gp91^{phox}, p22^{phox}, p47^{phox} and p67^{phox} were detected in stage 2 and stage 3 hippocampal neurons. NOX complex inhibition (apocynin, gp91ds-tat and transfection of p22^{phox} P156Q (DNp22^{phox})) delayed polarization of hippocampal neurons and decreased axonal length. In addition, DNp22^{phox}-transfected neurons showed a decrease in the number, length and life-time of axonal filopodia. Moreover, the activities of Rac1 and Cdc-42 were also decreased after DNp22^{phox} expression.

Our results suggest that ROS produced by NOX complex contributes to the acquisition of neuronal polarity by regulating actin cytoskeleton. We propose that physiological levels of ROS may be necessary for polarization and maturation of hippocampal neurons.

In vitro interaction of drugs with canalicular lipid transporters.

Z. Mahdi¹, B. Stieger¹;

¹Department of Clinical Pharmacology and Toxicology, University Hospital, Zurich, Switzerland

Background and aims: Canalicular bile formation is maintained by the simultaneous activities of three ABC-transporters: BSEP (Bile Salt Export Pump or ABCB11), ABCB4 (or MDR3) and ABCG5/G8. Dysfunctions in the biliary cholesterol–bile salt–phospholipid secretion (e.g. an increased ratio of cholesterol to bile salts or phospholipids) lead to cholestasis or result in crystallization of cholesterol followed by cholelithiasis. The aim of this project is the development of a cell-based and polarized model system to test the hypothesis that some drugs may induce cholestatic liver disease by specifically interfering with biliary lipid secretion and to identify such inhibitors/stimulators.

Methods: Stably transfected LLC-PK1 cell lines (overexpressing human NTCP, BSEP, ABCB4 and ABCG5/G8) were cultured in the Transwell® system. Detection and polar localisation of the transport proteins was accomplished by immunohistochemistry and Western blots. Functionality and direction of transport were verified using radioactively (e.g. 3H-taurocholate and 14C-cholesterol) or fluorescently (NBD-phosphatidylcholine) labelled substrates. The substrates were added to the basolateral or apical compartments and the amounts transported in the opposite compartment were measured. Albumin was used as an acceptor to stimulate efflux. Lipid secretion into the apical compartment was also chemically analysed by thin-layer-chromatography.

Results: Western blots and immunohistochemistry indicate that the transfected LLC-PK1 cells overexpress all three ABC transporters and that NTCP is overexpressed in the basolateral membrane while BSEP, ABCB4 and ABCG5/G8 are overexpressed in the apical membrane, as is the case in human hepatocytes. Functional transport assays demonstrate that the model cell line displays a vectorial transport of bile salts and phosphatidylcholine from the basolateral to the apical compartment. First experiments with the antimycotic agent itraconazole show slight changes in phosphatidylcholine secretion but a strong induction of ABCB4 expression.

Conclusions: The antimycotic agent itraconazole does not significantly change the amount of phosphatidylcholine secreted but strongly induces ABCB4 expression indicating that itraconazole indeed inhibits phosphatidylcholine secretion in our assay system if the protein amount is considered. This finding is in line with previously published data. Taking this result together with the vectorial transport bile salts and phosphatidylcholine, we have successfully established an in vitro model for canalicular bile salts and lipid secretion. Consequently, we plan to use this model to characterize the effect of additional drugs suspected to interfere with canalicular bile salts and lipid transporters.

The apical polarity of Na⁺,K⁺-ATPase in ARPE-19 cells is regulated by the expression of the β 2 subunit.

L. Shoshani¹, J.A. Lobato¹, J. Bonilla-Delgado², R. Gonzalez-Ramirez³;

¹Physiology, CINVESTAV, Mexico City, Mexico, ²Research Unit, Hospital Juarez de Mexico, Mexico City, Mexico, ³Department of Molecular Biology and Histocompatibility, Hospital General Dr. Manuel Gea González, Mexico City, Mexico

The Na⁺, K⁺ ATPase or sodium pump plays a very important role in the maintenance of epithelial phenotype. This protein is always polarized in epithelia and is crucial for creating and maintaining the electrochemical gradient of Na⁺ and K⁺ as well as the cell volume and osmolarity. In most epithelia, the pump is located in the lateral domain. We demonstrated that the β 1-subunit of the Na⁺, K⁺ ATPase plays an important role in the polarization mechanism as it interacts directly, in the extracellular space with another β 1 subunit localized on a neighboring cell and thus stabilizes the pump in the lateral membrane. However, in the retinal pigment epithelium (RPE) the sodium pump is located at the apical domain. The mechanism of polarization in this epithelium is still unknown. Our working hypothesis is that the apical polarity of the pump in RPE cells is regulated by its β 2 subunit. We got evidences that relate the apical localization of the pump in RPE with the expression of the β 2 subunit, and we are looking for the mechanism by which β 2 subunit regulates the pump polarity. Results: ARPE-19 cells cultured for up to 6 weeks in the presence of ITS acquire the RPE phenotype and express the sodium pump in the apical domain (process termed re-morphogenesis). WB and IF analyses show that the β 2 isoform detected at the apical domain is co-expressed with the α 2 subunit. In order to find out if the β 2 expression is regulated on a transcriptional or translational level, we analyzed as function of time, the mRNAs level of the β subunit isoforms by RTqPCR and the protein expression level by WB. We observed that in the presence of ITS, β 2 mRNAs are increased during re-morphogenesis, as well as the protein level. Silencing the β 2 expression by siRNAs, reduce the apical expression of the pump as gauged by the apical localization of the α 2 subunit. Our results suggest that the apical localization of the pump in ARPE-19 cells depends on the expression of the β 2 isoform and that it is regulated on a transcriptional level. Accordingly, we suggest that the transcription factor Sp1 is involved as it is also expressed in ARPE-19 cells and its amount increases during re-morphogenesis. We therefore expect that silencing Sp1 by siRNA will inhibit the apical localization of the pump (α 2 β 2 complex).

P2070**Board Number: B589****A spatial switch in H,K-ATPase trafficking by *Helicobacter pylori* VacA-elicited phosphorylation of ACAP4.**X. Ding¹, X. Liu², W. Yao², L. Chen³, Y. Zhang¹, X. Yao⁴;¹Medicine, Beijing University of Chinese Medicine, Beijing, China, ²Physiology, Morehouse School of Medicine, Atlanta, GA, ³Beijing University of Chinese Medicine, Beijing, China, ⁴Cellular Dynamics, University of Science Technology of China, Hefei, China

Many cellular processes are orchestrated by dynamic changes in the plasma membrane to form membrane projections and endocytic vesicles. Small GTPase ARF6 is involved in coupling actin dynamics to trafficking of vesicular membranes. Our study demonstrated that ACAP4, ARF6 GTPase-activating protein, governs polarized H,K-ATPase trafficking during parietal cell secretion (J. Biol. Chem. 2010. 285, 18769-80). *Helicobacter pylori* persistently colonize the human stomach and have been linked to atrophic gastritis and gastric carcinoma. Our early study revealed that VacA disrupts apical membrane-cytoskeletal interactions and perturbs parietal cell secretion (J. Biol. Chem. 2008. 283, 26714-25). VacA binds to tyrosine phosphatase PTP- ζ which leads to gastric ulcer (Nature Genetics. 2003. 33, 375-381). However, it is unclear how PTP- ζ operates its downstream signaling events in parietal cells. Here we show that PTP- ζ interacts with ACAP4 and VacA treatment enhances ACAP4 phosphorylation at Tyr733 which rewires cellular signaling for aberrant proton secretion. Our biochemical characterization and cellular imaging analyses show that VacA-elicited phosphorylation of Tyr733 results in re-distribution of ACAP4 to the basolateral membranes. Surprisingly, persistent expression of phospho-mimicking ACAP4 results in recruitment of H,K-ATPase and v-SNAREs to the basolateral domains. The large basolateral expansion elicited by VacA is predicted to recruit membranes from sources not normally targeted to that surface. Significantly, the phosphorylation of Tyr733 was correlated to hypochlorhydria phenotype of clinical VacA-positive patients. In addition, expression of non-phosphorylatable Y733F mutant in ACAP4 knockout mouse parietal cells resumes apical secretion of proton, suggesting that VacA rewires ACAP4 signaling axis by repolarizing parietal cell secretion at basolateral membrane. The results present a previously undefined mechanism by which microbe-host interaction orchestrates a spatial switch of membrane trafficking in gastric parietal cell secretion.

P2071**Board Number: B590****Large, low-complexity MLT1 protein is associated with unique, eyespot-associated microtubules in the green alga *Chlamydomonas reinhardtii*.**T.M. Mittelmeier¹, M.D. Thompson¹, M. Lamb², C.L. Dieckmann¹;¹Molecular and Cellular Biology, University of Arizona, Tucson, AZ, ²Biology, University of Puget Sound, Tacoma, WA

The photosensory eyespot of the unicellular green alga *Chlamydomonas* is found at the equator of the cell in a unique position relative to the two anterior basal bodies and flagella. In response to light, eyespot-initiated signals lead to changes in flagellar stroke patterns and swimming direction, such that the incident light intensity is optimal for photosynthesis. The eyespot comprises components in the plasma membrane, cytoplasm, and chloroplast envelope membranes, and in carotenoid-rich lipid granules associated with thylakoid membranes. Following cell division, the eyespot is assembled *de novo* in each daughter cell adjacent to the D4 microtubule rootlet, one of four rootlets that extend from the basal bodies. During assembly, localization of one or more eyespot components is directed by the D4 microtubules. *mlt1* (multi-eyed) mutant cells contain additional eyespots that are mis-localized to more anterior positions, and localization of both major eyespot photoreceptor proteins is delayed. We used polyclonal antibodies to identify wild-type MLT1 on Western blots and in fixed cells by immunofluorescence. The >300 kDa protein was localized along the D4 rootlet, but not the other three rootlets. MLT1 is absent in *mlt1-1* cells, which have a nonsense mutation near the middle of the *mlt1* coding sequence. Similar to the *Arabidopsis* microtubule-binding protein BPP1 (basic proline-rich protein 1), MLT1 is of low complexity and proline-rich, and has three exclusively basic regions. We are testing the hypothesis that binding of MLT1 to rootlet microtubules via its basic region(s) stabilizes the microtubules and/or promotes microtubule-guided trafficking of eyespot components. MLT1 is also absent in *mlt2-1* mutant cells, which have a phenotype similar to but distinct from *mlt1* cells. Sequencing of the *mlt2-1* genome identified the *MLT2* gene, predicted to encode a large, low-complexity, leucine-rich protein. While eyespot localization is dependent on MLT1 and MLT2, the integrity of the ordered membrane layers of the assembled eyespot is dependent on the MIN1 protein which has an N-terminal C2 domain and a C-terminal LysM domain. Extracellular LysM domains are known to bind bacterial or fungal cell wall components, but the function(s) of intracellular LysM domains is unknown. We observe that cells with changes in highly conserved residues, modeled to be on the surface of the folded MIN1 LysM domain, have “fragmented” eyespots. The data are suggestive that the MIN1 LysM domain is involved in specific interactions that maintain the close apposition of eyespot membrane layers. Further analyses of eyespot proteins will aid our understanding of the functional breadth of a number of widely distributed protein motifs. Support: NSF MCB-1157795 to CD.

P2072**Board Number: B591****Congenital Tufting Enteropathy, a new model for studying intestinal villous morphogenesis.**

J. Salomon¹, J. Schmitz², F. Campeotto², N. Brousse³, J. Magescas⁴, F. Poirier⁴, B. Duvauchelle⁴, B. Ladoux^{5,6}, O. Goulet², L. Veyrier⁴, d. Canioni³, D. Delacour⁴;

¹Institut Jacques Monod- CNRS, Paris, France, ²Université Paris Descartes, Paris Cité, Hôpital Necker Enfants Malades , Paediatric Gastroenterology, Paris, France, ³Université Paris Descartes, Paris Cité, Hôpital Necker Enfants Malades , Pathology Department, Paris, France, ⁴Institut Jacques Monod - CNRS, Paris, France, ⁵Institut Jacques Monod, Université Paris Diderot CNRS, Paris, France, ⁶Mechanobiology Institute, National University of Singapore, Singapore, Singapore

Molecular mechanisms underlying the maintenance of the intestinal villous epithelial layer homeostasis are largely unknown. Congenital Tufting Enteropathy (CTE), (MIM #613217) a rare human cause of intestinal failure, constitutes an interesting working model. It is characterized by aberrant focal stacks of multiple layers of enterocytes, named « tufts » and is due to mutations in the EPCAM or SPINT2 genes. Our study aimed at understanding the cellular functions of EPCAM and SPINT2 in enterocytes and in villous morphogenesis. EPCAM and SPINT2 are located at the lateral membranes and the terminal web in human enterocytes. We analyzed either duodenal biopsies of CTE patients, or stable Caco2 clones depleted for EPCAM or SPINT2. Ultrastructural analyses were performed using transmission electron microscopy. Cell organization, cell differentiation and polarity markers were tested using immunohistology and confocal microscopy analyses. Our results clearly show specific defects in intestinal cell polarity and adhesion in the mutant enterocytes: microvillus atrophy, mislocalization of brush border components, and weakened cell-cell junctions. Although Caco2-depleted cells display a loss of apico-basal polarity, they still formed epithelial monolayers in classical 2D cultures. We thus generated 3D culture supports that recapitulate villus topology and constraints. Placing mutant human enterocytes on synthetic villus cultures revealed strong perturbations in the maintenance and dynamics of the epithelial monolayer, mimicking the tufts observed in CTE patient mucosa. We demonstrated that CTE disorder is characterized by the loss of enterocyte polarity and differentiation. As a consequence, correct cell dynamics along the villous architecture is impaired in mutant enterocytes.

P2073**Board Number: B592****Spontaneous Cdc42 polarization independent of GDI-mediated extraction and actin-based trafficking.**F.O. Bendezu¹, V. Vincenzetti¹, D. Vavylonis², R. Wyss³, H. Vogel³, S.G. Martin¹;¹Department of Fundamental Microbiology, University of Lausanne, Lausanne, Switzerland, ²Department of Physics, Lehigh University, Bethlehem, PA, ³Institut des Sciences et Ingénierie Chimiques (ISIC), Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

How a cell polarizes growth is a fundamental biological question. The conserved Rho-type GTPase Cdc42 is a central player in this process. Activated GTP-bound Cdc42 determines the zone of growth by interacting with effectors necessary for the targeting of secretory vesicles. It is not clear, however, how cells spontaneously polarize to establish a zone of active Cdc42. This symmetry-breaking event is thought to require dynamic Cdc42 recycling off and on the plasma membrane by GDI (Guanine nucleotide Dissociation Inhibitor)-mediated membrane extraction and actin-based vesicle trafficking. Here, we describe the construction of a functional, internally tagged Cdc42-mCherry sandwich (SW) fusion expressed from the endogenous *cdc42* locus in fission yeast. Using pharmacological inhibitors and mutant backgrounds, we find Cdc42 dynamics and spontaneous polarization is maintained largely independent of these proposed recycling pathways. Further strengthening these findings, an engineered Cdc42 allele targeted to the membrane independently of these recycling pathways by an amphipathic helix supports viability and polarizes spontaneously to multiple sites in both fission and budding yeasts. Using Fluorescence Recovery After Photobleaching (FRAP) and Fluorescence Correlation Spectroscopy (FCS), we find that Cdc42 is highly mobile at the plasma membrane. However, mobility is slower at sites of active Cdc42-GTP, which correspond with areas of total Cdc42 accumulation. By contrast, an engineered near-immobile transmembrane domain-containing Cdc42 allele supports viability and polarized activity, but does not accumulate at sites of activity. We propose that Cdc42 activation, enhanced by positive feedbacks, leads to its local accumulation by capture of fast-diffusing inactive molecules at the plasma membrane.

P2074**Board Number: B593****A minimal system to establish microtubule-based cell polarity in vitro.**N. Taberner¹, P. Recouvreux², S. Roth¹, M. Dogterom¹;¹BionanoScience, TU Delft, Delft, Netherlands, ²IBDM - Aix Marseille University - CNRS, Marseille, France

From yeast to fibroblasts, many cell types have a defined polarity that allows them to directionally move, grow or divide. This polarity is typically defined by a polarized distribution of proteins at the cell cortex. We are interested in the emergence of polarity in systems where microtubules are directly involved in its establishment and maintenance by delivering polarity markers to the plasma membrane. We developed two in vitro systems that allow for microtubule-based delivery of proteins to bio-mimetic

cortices. These systems, consisting of elongated micro-fabricated chambers or emulsion droplets, allow for dynamic microtubules to self-assemble and organize in response to interactions with the chamber or droplet boundaries.

In micro-chambers, single events of microtubule-based delivery to a wall are imaged and quantified. Our experiments show that clustering of proteins at microtubule tips (fission yeast's mal3, kinesin tea2, and tip1) enhances prolonged docking of proteins to the wall receptors as opposed to non-clustering proteins (EB analog protein mal3). Moreover, pre-docked clusters at the wall can capture growing microtubule tips enhancing repeated deliveries at the same spot. These observations are very similar to the observation of clustering of polarity markers in living fission yeast cells.

With elongated emulsion droplets the global emergence of polarity in a closed system can be assessed under conditions where proteins can additionally diffuse within the lipid boundaries. With this minimal system we aim to establish the minimal mechanism by which microtubules can establish and maintain cell polarity in living cells. In parallel, we performed experiments in living yeast cells, which suggest that a simple artificial protein that combines membrane affinity with microtubule tip affinity is in principle enough to establish (but not maintain) polarity.

Role of a clutch molecule shootin1 in laminin-induced axon formation.

K. Abe¹, Y. Sakumura^{1,2}, N. Inagaki¹;

¹Grad. Sch. Bio. Sci., Nara Institute of Science and Technology, Ikoma, Japan, ²Sch. Inform. Sci. and Technol., Aichi Prefectural Univ., Nagakute, Japan

Neuron requires correctly oriented axon formation to transmit their signals to appropriate target cells. Axon is directed by asymmetric presentation of soluble and adhesion axon guidance molecules. For example, an extracellular matrix protein laminin contact directs neuronal polarization of retinal ganglion cells to basal lamina in vivo [Owen et al, *Neuron*, 2011]. The growth cone plays a key role in neurite extension to form axon. However, how does laminin affect growth cone and induce directional axon formation remains elusive. Shootin1 mediates a linkage between F-actin retrograde flow and cell adhesion molecule L1-CAM as a clutch molecule at the growth cone and induces traction force for axonal outgrowth [Shimada et al, *J. Cell Biol.*, 2008., Toriyama et al, *Curr. Biol.*, 2013]. As L1-CAM extracellularly interacts with laminin [Hall et al, *J. Neurochem.*, 1997], we hypothesized that axon is induced on laminin by shootin1-mediated linkage between F-actin and L1-CAM. To examine this possibility, we analyzed effect of shootin1 RNAi on directional axon formation of hippocampal neurons cultured on substrates patterned with stripes of laminin and poly-D-lysine. The rate of neurons that formed axon on laminin was significantly decreased by shootin1 RNAi as compared with control. Next, we measured retrograde flow rates of mRFP-actin and EGFP-shootin1 speckles. As L1-CAM binds with laminin, retrograde flow of F-actin and shootin1 would be negatively regulated by laminin on the extracellular substrate. Retrograde flow rates of mRFP-actin and EGFP-shootin1 speckles in the axonal

growth cone on laminin were markedly slower than those on PDL. Because retrograde flow rates of mRFP-actin and EGFP-shootin1 speckles were decreased in the axonal growth cone on laminin, traction force that the axonal growth cone generates would be positively regulated on laminin. To examine this possibility, we performed traction force microscopy. Average stress under the growth cone on laminin was larger than those on PDL. Together, our results suggest that the clutch system involving shootin1 and L1-CAM senses an adhesion cue from laminin and produces traction force for axon formation.

Somal translocation of Retinal Ganglion Cells: a new mode of microtubule involvement in neuronal migration.

J. Icha¹, C. Norden¹;

¹MPI-CBG, Dresden, Germany

Neuronal migration is a key step during brain development and defective neuronal migration can lead to cognitive impairments. Importantly, neuronal migration modes differ depending on tissue context and migratory distances covered. Despite this broad variety however, most mechanistic studies have so far focused on radial glial-guided migration

To get insights into additional neuronal migration modes we investigate the kinetics and molecular mechanisms responsible for retinal ganglion cell (RGC) migration in zebrafish. RGCs are the earliest born neurons in the retina and migration from their apical birthplace to the most basal neuronal layer spans about 50µm. It was proposed that RGCs move via somal translocation but the exact molecular mechanisms of migration are still elusive.

We image migratory processes in the intact embryos using light sheet as well as confocal microscopy at high temporal-spatial resolution. This approach revealed that RGC migration occurs unidirectionally and migratory speeds reach 20 µm/h. To exclude the possibility that somal translocation is a passive process we inhibited nuclear movements of remaining progenitor nuclei. This treatment did not significantly impair RGC migration arguing that it is an active process depending on force generation within the cells. Interestingly, we observe that the centrosomes as well as the Golgi follow the migrating soma during RGC translocation instead of leading it as seen in glia-guided migration. Nevertheless, like in glial-guided migration, both, microtubules and dynein play a role in RGC displacement. Microtubules and dynein are apically enriched during migration, indicating that the force to move cells is generated BEHIND nucleus and soma. This finding revealed the possibility that microtubules push the nucleus, the bulkiest organelle of the cell, in the direction of basal migration and/or prevent re-displacements by acting as an apical barrier. The observation that basal process attachment is crucial for efficient migration underlines this exciting possibility. We currently test this hypothesis further using laser ablation approaches to

explore whether apical and basal processes feature different mechanical properties. We also test the possibility that dynein is important to give rigidity to apical microtubules and thereby stabilizes the apical process.

Overall our study aims to gain a basic understanding of the molecular mechanism involved in somal translocation that will most likely also apply in brain regions beyond the retina. It furthermore shows that neurons can achieve successful migration differently in different scenarios and underlines the fact that neuronal migration has many different flavours several of which still await further exploration.

¹Bryn Mawr College, Bryn Mawr, PA

Synaptotagmin-1 (syt1), a Ca²⁺-binding protein that functions in regulation of vesicle exocytosis at the synapse, is expressed in many types of neurons well before synaptogenesis begins both in vivo and in vitro. We recently demonstrated (Greif et al, 2013) that syt1 plays a role in regulating axon branching and filopodial dynamics in developing embryonic chick forebrain neurons. Overexpression of syt1 increased the formation of axonal filopodia and branches. Conversely, knockdown of syt1 decreased the numbers of axonal filopodia and branches. The mechanism by which syt1 exerts its influence on axon development is unknown. In order to investigate whether syt1 accomplishes its effects on filopodia using a mechanism similar to its role at the synapse, we manipulated Ca²⁺ levels using calcium blockers and calcium ionophores. A 15-minute exposure to the calcium ionophore, A23187, significantly increased axonal filopodia; blockade of calcium channels using La³⁺ or Cd²⁺ decreased filopodia number. These findings are consistent with the well-defined role of Ca²⁺ in filopodial dynamics. Overexpression of syt1 using adenovirus-mediated transfection was coupled with La³⁺ treatment to examine whether blocking Ca²⁺ influx would reverse Syt1-mediated increases in axonal filopodia. Embryonic chick forebrain neurons were transfected with a syt1-YFP construct or GFP. After 48 hrs, cells were treated with La³⁺ or vehicle for 15 minutes. Treatment with La³⁺ reversed the increase in filopodia stimulated by syt1 overexpression. Taken together these data suggest that syt1 regulates the formation of axonal filopodia using its Ca²⁺-binding functions, prior to engaging in its conventional functions at the synapse. Future experiments involve site-directed mutagenesis of syt1's C2 domains, to directly study our hypothesis. This research was supported by grants from Bryn Mawr College.

P2078**Board Number: B600****Fidgetin is a novel microtubule-severing protein that controls neuronal morphology by balancing the stable and labile components of the axonal microtubule array.**L. Leo¹, A. Matamoros², W. Yu³, D. Marena⁴, D. Sharp⁵, P.W. Baas³;¹Neuroscience, Drexel University College of Medicine, Philadelphia, PA, ²Neuroscience/Molecular and Cell Biology and Genetics, Drexel University College of Medicine, Philadelphia, PA, ³Department of Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA, ⁴Biology, Drexel University, Philadelphia, PA, ⁵Albert Einstein College of Medicine, Bronx, NY

The dynamicity of the axonal microtubule (MT) array is defined by stable and labile components. All of the MTs in the axon have a stable domain, and most have a labile domain. MT-severing proteins are important for regulating the axonal MT array by transforming one MT into two, for example to increase the number of MTs at sites of impending branch formation. In order to accomplish this, katanin and spastin (the best studied of the MT-severing proteins) preferentially break MTs in their stable domains, so that each of the two daughter MTs has its own stable domain from which a new labile domain can grow. Theoretically, a MT-severing protein that preferentially breaks MTs in their labile domains would have a very different effect. Specifically, such a severing protein would result in one MT with a stable domain and one without, the latter of which would rapidly and completely depolymerize. In the present study, we have focused on a novel MT-severing protein called fidgetin, which we posit acts in this fashion. The function of such severing would be to pare back the labile domains of the MTs so that they achieve a proportion relative to the stable domains appropriate for meeting the specific challenges neurons face in various stages in their lives. A reduction of such severing activity would result in an expansion of the labile domains, which we posit would be conducive to phenomena such as neuronal polarization. An increase in such severing activity, on the other hand, would reduce the labile domains, which we posit would be conducive to phenomena such as cessation of axonal growth or pruning back of supernumerary axons. In support of these ideas, we have found that reduction in fidgetin levels by siRNA causes cultured rodent neurons to polarize faster, and produce more processes per cell body and longer axons, together with a notable increase in labile MT mass. In developing *Drosophila* embryos, fidgetin reduction in targeted neurons causes axons to grow past their normal targets rather than retract. Previous studies have shown that katanin and spastin target MT regions that have post-translationally modified tubulins characteristic of stable MTs. Our present studies indicate that fidgetin knockdown results in a dramatic decrease in the ratio of acetylated to total tubulin in the neuron, suggesting that fidgetin targets MT regions that are deficient in acetylated tubulin. In support of this, two different experimental approaches for experimentally increasing the acetylation status of the MTs rendered them less sensitive to the effects of fidgetin reduction. Collectively, these results accentuate the importance of the labile MT component in the axon, which has generally received less attention than the stable component.

P2079**Board Number: B601****Fidgetin inhibition is a novel strategy for altering the balance of stable and labile components of the axonal microtubule array to treat nervous system disease and injury.**A. Matamoros¹, L. Leo², D. Jean¹, T. Austin¹, D. Sharp³, W. Yu⁴, P.W. Baas⁴;¹Neuroscience/Molecular and Cell Biology and Genetics, Drexel University College of Medicine, Philadelphia, PA, ²Neuroscience, Drexel University College of Medicine, Philadelphia, PA, ³Albert Einstein College of Medicine, Bronx, NY, ⁴Department of Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA

Effective strategies for treating diseases and injuries of the CNS remain elusive. Recent studies have converged on microtubules (MTs) as a powerful therapeutic target. Neurodegenerative diseases called tauopathies involve the dissociation of tau from MTs in the axon. As a result, MT mass is diminished, and this compromises the axon's ability to maintain proper morphology and organelle transport. Treatments able to correct the MT loss would in theory have profound benefits to patients. Drugs that stabilize MTs have produced encouraging results in preclinical studies on tauopathy, with the same drugs also reported to support regeneration after injury to adult CNS axons. Despite these encouraging results, there are persistent questions as to whether this approach appropriately corrects the MT deficiency. MTs in the axon consist of two domains: a stable domain toward the minus end of the MT and a labile domain toward the plus end. These domains are different from one another in their composition, properties and functions. The labile domains comprise a greater component of the total MT array during development, while the stable domains predominate in adult axons. We have suggested that a better strategy for encouraging an injured adult axon to grow would not be to make the MTs more stable, but rather to promote an increase in the levels of the labile component of the MT mass. In the case of tauopathy, our data suggest that it is the labile component that is most vulnerable to degradation, not the stable component. Therefore, we would question whether notable benefit can be achieved by further stabilizing the remaining MT mass. Here we propose a novel approach aimed at increasing the labile component of the MT mass by suppressing a MT-severing protein called fidgetin. Our data suggest that the normal function of this enzyme is to pare back the labile domains of the MTs, in order to regulate the ratio of the stable and labile MT components of the axon at various stages in the life of the neuron. Our hypothesis is that partially suppressing fidgetin will enable the labile component of the MT mass to swell up, which will restore to the tauopathic axon the MT component that had been lost, and which will make the MT array of the injured adult axon more similar to that of a developing axon, and hence more amenable to growth and regeneration. We will present two sets of experiments on primary cultures of rodent neurons. In the first, we show that fidgetin depletion causes an increase in labile MT mass that is conducive to robust axonal regeneration, even on inhibitory molecules that normally suppress CNS regeneration. In the second, we show that tau depletion results in a loss of labile MT mass that is correctable by fidgetin depletion.

P2080**Board Number: B602****Extracellular nicotinamide protects axons from Wallerian degeneration via multiple pathways in cultured DRG neurons.**S. Tokunaga¹, T. Araki¹;¹PNS, National Ctr Neurology and Psychiatry, Tokyo, Japan

Accumulating evidence suggests delaying axonal degeneration as a possible therapeutic strategy for traumatic and neurodegenerative disorders, including stroke, Parkinson's disease and peripheral neuropathy. Recent studies demonstrated that exogenous application of excess nicotinamide adenine dinucleotide (NAD) or its precursor nicotinamide (Nam), the amide form of vitamin B3, have a therapeutic impact on Wallerian degeneration models, but previous reports demonstrated apparently contradictory results: Wang et. al., showed that application of NAD or Nam at the time of neurite transection *in vitro* can delay neurite degeneration concurrently with increased intracellular NAD and ATP level, while others demonstrated that FK866, a potent inhibitor of nicotinamide phosphoribosyltransferase (Nampt) which synthesizes the substrate for NAD biosynthetic enzyme from Nam, can also delay neurite degeneration concurrently with decreased intracellular NAD. Here we show that excess Nam (≥ 3 mM) application-mediated delay of injury-induced neurite degeneration was unaffected by co-application of FK866 or down-regulation of endogenous Nampt. In contrast, FK866-mediated delay of neurite degeneration was counteracted by Nam (≤ 1 mM) dose-dependently but not nicotinic acid (Na), the acid form of vitamin B3, while Na served as NAD precursor in primary DRG neurons. Our results suggest that the Nam may protect axons independently from Nampt activity, presumably by affecting another enzymatic activity sensitive to FK866.

P2081**Board Number: B603****Nerve Growth Factor Induces Mitochondrial Fission Which is Required for Axon Branching.**L. Armijo Weingart¹, R. Sainath¹, G. Gallo¹;¹Shriners Hospitals Pediatric Research Center, Temple University, Philadelphia, PA

During nervous system development, the formation of branches from axons is essential to the formation of complex neuronal circuitry. In sensory neurons, Nerve Growth Factor (NGF) rapidly (30 min) induces branching through activation of phosphoinositide 3-kinase (PI3K). Recently, mitochondria have emerged as major determinants of the sites of axon branching. However, the mechanism of NGF-induced axon branching remains to be fully elucidated. An understanding of how NGF signaling impacts mitochondria behavior and function during axonal branching is the main goal of our current work. To this end, mitochondria were detected in living axons through labeling with Mitotracker dyes. NGF treatment

decreased the length and increased the number of axonal mitochondria after 15 min of acute treatment, indicative of fission. Consistently, live time-lapse imaging of mitochondria following 5 minutes of NGF treatment revealed mitochondria fission. Direct activation of PI3K using a cell permeable peptide in the absence of NGF copied the effects of NGF. Conversely, inhibition of PI3K using LY294002 blocked the effects of NGF on mitochondria. Inhibition of dynamin related protein 1 (DRP1), a required component of mitochondria fission, using mDivi-1 blocked NGF induced axon branching. Live imaging of axons in the presence of NGF revealed that GFP-DRP1 accumulated at sites of mitochondria fission and endogenous DRP1 was detected in axons through immunocytochemistry. Collectively, these observations indicate that NGF induces mitochondrial fission through a DRP1-dependent mechanism and activation of the PI3K pathway, and that fission is required for NGF-induced branching. The NGF induced fission temporally precedes the formation of branches, consistent with the notion that the fission is required to reorganize the axonal mitochondrial array. In future studies we will further address the mechanistic role of mitochondria fission in the generation of axon branches and the role of PI3K signaling in the induction of fission.

Understanding the Axon Initial Segment Diffusion Barrier at the Nanoscopic Level.

D. Albrecht^{1,2}, H. Ewers¹;

¹Randall Division of Cell and Molecular Biophysics, King's College of London, London, United Kingdom,

²Institute of Biochemistry, ETH Zürich, Zurich, Switzerland

Polarization is a decisive step in neuronal development and once axonal and somatodendritic domains are generated, they persist over the lifetime of an organism. The axon initial segment (AIS), a stretch of 50 – 100 μm in length, bears a specialized cytoskeleton and maintains polarization by restricting the exchange of axonal membrane molecules with the soma. The adaptor protein ankyrinG is essential for the assembly of this diffusion barrier and tethers ion channels and adhesion molecules to the cytoskeleton. However, the structural organization of the AIS and the molecular mechanism, by which protein diffusion is impeded remain unclear. Here, we use novel single molecule localization based superresolution microscopy in primary hippocampal neurons to investigate the molecular architecture of the AIS and to understand the mechanism by which membrane protein diffusion is locally restricted. To do so, we quantify membrane protein diffusion during neuronal polarization in single cells over time by single molecule tracking and correlate these data to the nanoscopic organization of the AIS. We find that the AIS cytoskeleton is organized in a regularly spaced pattern and that coincident with the appearance of this organization during development, the lateral mobility of membrane molecules is locally reduced. Our results clarify the interdependence between cytoskeletal organization and membrane mobility in the axonal plasma membrane.

P2083**Board Number: B605****Mutations in Tau have Differential Effects on the Aggregation and Microtubule Stabilization Properties of its Isoforms.**Y. Mutreja¹, B. Combs², T.C. Gamblin¹;¹Department of Molecular Biosciences, University of Kansas, Lawrence, KS, ²Department of Translational Science and Molecular Medicine, College of Human Medicine, Michigan State University, East Lansing, MI

Tau is a microtubule associated protein found in six different isoforms in neurons. In the diseased state, tau loses its ability to bind and stabilize microtubules and polymerizes to form large aggregates. Various mutations occur in the tau gene leading to a class of neurodegenerative diseases named FTDP-17. These mutations can alter tau's ability to stabilize microtubules and also enhance its ability to aggregate. It has been observed that with many of these mutations, only a subset of isoforms of tau is deposited as aggregates in the patient's brain. Therefore, we hypothesize that these mutations have differential effects on aggregation and microtubule stabilization characteristics of tau in different isoforms. We also sought to determine whether the position of the mutation would differentially affect the underlying biochemical mechanisms of aggregation and microtubule stabilization. We chose to study three different FTDP-17 mutations R5L, P301L and R406W residing respectively in N-terminal, microtubule-binding repeats (MTBR) and C-terminal regions of various isoforms of tau. The extent and kinetics of aggregation induced by arachidonic acid *in vitro* was monitored using laser light scattering, thioflavin S fluorescence and electron microscopy. The aggregation properties of some isoforms were effected more by the mutations than others. Certain isoforms, such as 2N3R and 1N4R were disproportionately affected by mutations in the N-terminal region and the MTBR. The aggregation kinetics of 0N4R were affected more by mutation than the other isoforms. Mutations in the MTBR have a larger effect than N-terminal and C-terminal mutations on the stabilization of microtubules, but also show differences between isoforms for a given mutation. Our results from this study indicates that aggregation and microtubule stabilization of all the isoforms of tau is not affected in same manner and these effects further are dependent on the location of mutation and could provide a biochemical rationale for their different incorporation into aggregates in various diseases in the FTDP-17 class.

P2084**Board Number: B606****Neurite-specific activation of NADPH oxidase in hippocampal neurons overexpressing cellular prion protein or exposed to A β or TNF α .**K.P. Walsh¹, T.B. Kuhn^{1,2}, L.S. Minamide¹, A.E. Shaw¹, S.J. Kane^{3,4}, L.G. Whittington¹, M.D. Zabel³, G.G. Rodney⁵, J.R. Bamburg^{1,4};¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, ²Chemistry and Biochemistry, Univ of Alaska, Fairbanks, AK, ³Microbiology, Immunology, and Pathology, Colorado State University, Fort Collins, CO, ⁴Cell and Molecular Biology Program, Colorado State University, Fort Collins, CO, ⁵Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX

Persistent exposure of neurons to soluble β -amyloid peptide dimer/trimers (A β d/t) or proinflammatory cytokines (TNF α , IL-1 β , IL-6) induce the formation of cofilin-actin rods in a subset of neurons (~23%) and in a subset of neurites (~30%) of those neurons. Rods disrupt synaptic function by blocking transport and/or sequestering cofilin from dendritic spines. Rod formation induced by these agents is dependent on the expression of the cellular prion protein (PrP^C) and the subsequent activation of NADPH oxidase (NOX) and production of reactive oxygen species (ROS) (Walsh et al., PLoS One, 9, e95995, 2014). Overexpression of PrP^C-EGFP in the absence of other treatments induces rods in up to 40% of neurons, but the percentage of neurites forming rods does not change significantly. Here we utilized p47^{PHOX}-roGFP (Pal et al., PLoS One 8, e63989, 2013) as a redox probe for measuring NOX-2 activity in living neurons allowing us to localize ROS to the neurites in which it is produced. We generated adenovirus for expressing the probe in neurons and in some experiments also co-infected neurons with adenovirus for expressing cofilin-R21Q-mRFP, a probe for visualizing cofilin-actin rods but one that does not induce rods through its overexpression (Mi et al., PLoS One 8, e83609, 2013). Our results show that NOX-2 activation and ROS production only occur in a subset of neurites from neurons expressing PrP^C-EGFP, even though the PrP^C-EGFP is relatively uniformly distributed among the neurites. Similarly, neurons treated globally with A β d/t or TNF α only show NOX-2 activity, ROS production and rod formation in a subset of neurites. These findings suggest that although PrP^C levels may limit the overall neuronal rod response to A β d/t or TNF α , some factor downstream of PrP^C is the limiting factor for rod formation and this factor is differentially distributed among neurites. The factor is neither cofilin nor actin, since cofilin-actin rods can be induced in almost all neurons and neurites in a PrP^C- and NOX-independent manner by treatment with excitotoxic levels of glutamate. (Supported in part by NIH AG044812 to JRB).

P2085**Board Number: B607****An unbiased genetic screen using the *Drosophila* wing as a model identifies the essential role of a novel gene, *SAD*, in maintaining axonal integrity during aging.**X. Cao¹, Q. Li¹, X. Teng², Y. Zhu², Z. Ma¹, N.M. Bonini², Y. Fang¹;¹SIOC, IRCBC, Chinese Academy of Sciences, Shanghai, China, ²Department of Biology, University of Pennsylvania, Philadelphia, PA

Axon degeneration is a prominent feature of spinal cord injury and many human degenerative diseases. Studies of the Wallerian degeneration slow (*Wld^S*) mouse indicate that axon degeneration is an active process, however, the underlying mechanisms remain elusive. To identify novel molecular components controlling axonal integrity, it is desirable to perform unbiased, large-scale screening. We have developed a novel model of axon injury using the *Drosophila* wing^{1,2,3}. The fly wing is translucent, allowing us to highlight the axons using fluorescent proteins and to monitor axonal changes in response to traumatic injury and aging in live flies.

Using this model, we have performed forward genetic screens to discover novel genes that can protect the injured nerve or revert the *Wld^S*-mediated axonal protection. We found a mutant line of a functionally uncharacterized gene, which not only diminishes the *Wld^S* protection, but also displays striking age-dependent spontaneous axon degeneration on its own. For this phenotype, we named the mutant: *Spontaneous Axon Degeneration (SAD)*. Further examination reveals massive vacuoles in the brain of aged *SAD* flies, indicating progressive neurodegeneration in the CNS as well. Moreover, the lifespan of the *SAD* mutant is significantly shortened. In addition, aged *SAD* flies have elevated sensitivity to stress such as heat and physical disturbance.

Feature analysis of the *SAD* protein suggests that it may be involved in chromatin remodeling and epigenetic modifications. Ongoing experiments include generating *UAS-SAD* and *RNAi-SAD* transgenic flies to determine the role and molecular mechanisms of *SAD* in maintaining neural integrity during aging. And, our most recent behavior assay results point to a non-cell autonomous mechanism of the *SAD* function in the nervous system. All together, by this study, we hope to provide important foundation for new therapeutic targets of axonal/neural degeneration in acute injury as well as chronic neurological disorders.

P2086**Board Number: B608****Disruption of Intraneuronal Tau by Extracellular Tau Oligomers Containing Individual or Mixed Tau Isoforms.**E.M. Swanson¹, L. McMahon¹, S. Som², G.S. Bloom²;¹Department of Biology, University of Virginia, Charlottesville, VA, ²Departments of Biology and Cell Biology, University of Virginia, Charlottesville, VA

Tau is microtubule-associated protein enriched in the axons of neurons, where its functions include direct binding and stabilization of microtubules and regulation of axonal transport. Tau is found in the central nervous system (CNS) in six isoforms produced by the alternative splicing of a single tau gene, MAPT, with these isoforms characterized by the presence of zero, one or two N terminal inserts, and three or four C-terminal microtubule binding repeats. Neuronal inclusions composed of hyperphosphorylated tau are a major histopathological feature of a series of neurodegenerative disorders known collectively as tauopathies, the most common and well-known of which is Alzheimer's disease (AD). While the clinical and histological presentation of these disorders is heterogeneous, a majority share the following hallmarks: loss of the normal axonal distribution of tau; accumulation of insoluble, fibrillar tau aggregates in neurites and perikarya; synaptic dysfunction; and eventual neuron death. There is also evidence that the majority of these disorders spread through the brain by a prion-like mechanism, in which pathologically misfolded tau is taken up by neurons, confers this pathological phenotype to the endogenous "normal" protein through direct protein-protein contact, and is eventually released by the cell, perpetuating the cycle. Some evidence points to short tau fibrils as being prion-like, but scant attention has been paid to small tau oligomers. Using a new morphometric method for rigorously quantifying tau distributions in cultured neurons, we now demonstrate that externally applied tau oligomers are much more effective than tau monomers or fibrils at disrupting the normal tau distribution in primary cortical neurons, that oligomer potency varies according to tau isoform, and that oligomers made from mixtures of all six CNS tau isoforms are much more potent than oligomers made from individual isoforms. These results raise the possibility that soluble, pre-fibrillar oligomers of mixed tau isoforms account for the prion-like spread of tau pathology in vivo in AD and non-Alzheimer's tauopathies.

P2087**Board Number: B609****Tau hyperphosphorylation in human Alzheimer's Disease (AD) cases: A quantitative histological comparison.**D. Havas¹, B. Kerschbaumer¹, J. Attems², H. Hutter³, B. Hutter-Paier¹;¹QPS Austria GmbH, Grambach, Austria, ²Institute of Ageing and Health, Newcastle University, Newcastle, UK, ³Institute of Cell Biology, Histology and Embryology, Med Univ Graz, Graz, Austria

Alzheimer's Disease (AD) is characterized by neurofibrillary tangle (NFT) pathology. Yet, the tangle reflects an end stage of paired helical filament aggregations that are built much earlier and are typically found in neurofibrillary threads. Furthermore, they consist of a large array of differently hyperphosphorylated Tau (pTau), whereas several phospho-sites were found to be especially related to AD. However, today's histological knowledge about appearance, quantity and location of PHFs with different phosphorylation and in different brain regions during disease progression is rather poor. To elucidate the quantitative distribution of different pTau sites in the AD brain, we analyzed total human Tau, pThr231 as well as pTyr18 Tau in four different cortical brain regions and the hippocampus of each of five AD subjects from three different Braak stages by immunohistochemistry and compared them to the brains of age-matched non-AD controls. In addition ThioflavinS positive NFTs were counted as well. Further markers, especially pSer262 and pSer202/Thr205 will be included. In spite that Tyr18 Tau phosphorylation was published to be an early AD marker, the quantification in the brain rather revealed the drastic load in cortical regions at end stage. The same late stage increase was observed for ThioflavinS positive NFTs and pThr231 Tau positive somata and neurites. However and most importantly both Tyr18 and Thr231 hyperphosphorylation increase much earlier in the hippocampus and are already significant at Braak stages I/II, while NFT formation lags behind. Our findings indicate a special and early vulnerability of the hippocampal formation to Tau hyperphosphorylation at residues Tyr18 and Thr231, which might contribute to the early break-down of memory function in AD subjects. To note, the downstream tangle formation is a sign of the progressive neurodegeneration but turns out to be rather insensitive for the detection of Tau hyperphosphorylation in early AD.

P2088**Board Number: B610****Induced patient neurons as a potential future model system for Alzheimer's disease.**H. Toresson¹, L. Minthon¹, O. Hansson¹, N. Schultz¹, C. Orbjörn², M. Parmar³, U. Pfisterer³;¹Clinical Memory Research Unit, Dept. of Clinical Sciences, Lund University and Skåne University Hospital, Malmö, Sweden, ²Clinical Memory Research Unit, Dept. of Clinical Sciences, Lund University, Malmö, Sweden, ³Wallenberg Neuroscience Center and Lund Stem Cell Center, Department of Experimental Medical Science, Lund University, Lund, Sweden

The underlying mechanisms of Alzheimer's disease (AD) remain unknown. According to the main hypothesis in the field, the amyloid cascade hypothesis, β -amyloid ($A\beta$) is the causing agent and therefore has been the target for massive drug development efforts. Several drug candidates have been tested in phase III clinical trials but so far none has had any clinical effect. These disappointing results highlight the need for intensified research on the disease in humans. We have launched a cell biological initiative within the Swedish BioFinder Study, a large clinical research programme where dementia patients and cognitively healthy elderly are longitudinally phenotyped by e.g. cognitive tests, cerebrospinal fluid (CSF) biochemistry, amyloid-positron emission tomography and advanced magnetic resonance imaging. Additionally, a skin biopsy is taken to obtain fibroblasts.

We have thus far banked fibroblasts from 34 individuals. Preliminary data show that the most efficient way (time, number of cells and induced neuron (iN) conversion efficiency) was to obtain cells from skin explant cultures in 20% serum followed by expansion in defined serum free medium. 12 out of 12 lines tested could be successfully converted to iN cells by growth factor treatment and transduction of the three transcription factors *Ascl1*, *Brn2* and *Myt1l* (under TET-ON transcriptional control) along with the TET-ON transactivator. Several transduced cells adopted neuronal morphology and after 13 days cells expressed the neuronal markers β III-tubulin and MAP-2. Importantly, iN cells also expressed the AD pathology-associated proteins $A\beta$ and the microtubule-associated protein tau. Isoforms of these proteins used clinically as AD CSF biomarkers ($A\beta$ 1-40, $A\beta$ 1-42, and tau (including phosphorylated tau)) were secreted into the medium in measurable amounts.

The value of iN cells as tools to investigate the underlying disease mechanisms in sporadic AD (SAD) will be assessed by two means. The first is comparing iN cell phenotypes from SAD patients with cells from familial AD (FAD) cases with APP, PSEN1 or PSEN2 mutations. The second, and potentially most powerful method for finding unknown disease mechanisms is to perform an unbiased search for correlations between cellular and clinical phenotypes. Our clinical cell biology approach makes it possible to compare cells from cognitively healthy individuals without clinical signs of AD pathology to healthy or AD cases with a long clinical history of AD pathology. Importantly, this human cell biology approach to AD takes the clinical heterogeneity of dementia diseases into account and thus paves the way for future personalised treatment.

P2089**Board Number: B611** **α -Synuclein Modulates Amyloid- β Induced Ectopic Cell Cycle Re-entry of Neurons.**S.S. Thomas¹, G.S. Bloom²;¹Department of Biology and Neuroscience Graduate Program, University of Virginia, Charlottesville, VA,²Departments of Biology and Cell Biology, University of Virginia, Charlottesville, VA

The defining histopathological features of Alzheimer's disease (AD) are extracellular plaques that comprise amyloid- β (A β) peptides and intraneuronal neurofibrillary tangles made from the neuron-specific, microtubule-associated protein, tau. Normal neurons remain post-mitotic through tight regulation of their cell cycle machinery, but in AD and Parkinson's disease (PD), cell cycle proteins are aberrantly activated, causing the normally quiescent neurons to re-enter the cell cycle. Neurons that re-enter the cell cycle progress at least into S-phase, yet instead of dividing they eventually die. In typical cases of AD, approximately 30% of frontal lobe neurons are lost, and aberrant cell cycle re-entry (CCR) may account for as much as 90% of this neuronal death. Similarly, abnormal activation of cell cycle markers, DNA synthesis, and cell cycle related neuron death have been reported to occur in PD. Despite a large body of evidence demonstrating CCR in AD and PD, many questions regarding the underlying mechanism remain unanswered. Previous work from our lab established that amyloid- β oligomers (A β O) induce ectopic neuronal CCR through a mechanism dependent on tau phosphorylation at Y18, S409 and S416 (Seward, et al. J Cell Sci 126: 1278-1276). Using primary mouse cortical neuron cultures as experimental models, we now report that A β O also promote a tau-dependent increase in endogenous α -synuclein, which accumulates in Lewy bodies in PD and in many cases of AD as well. Furthermore, overexpression of the pathogenic A53T, E46K, or A30P mutations of human α -synuclein induces ectopic neuronal CCR independently of A β O, with the A30P mutation generating the most robust response. In contrast, reduction of endogenous α -synuclein using shRNA ameliorates A β O-induced tau phosphorylation at S409 and S416, and consequently prevents neuronal CCR. Taken together, these data implicate α -synuclein as a novel modulator of ectopic neuronal CCR in AD and PD.

P2090**Board Number: B612****Triple miRNA Shank knockdown shows that Shank-cortactin interactions control actin dynamics in neuronal spines and synapses.**H.D. MacGillavry¹, J.M. Kerr², N.A. Frost³, T.A. Blanpied^{4,5};¹Cell Biology, Utrecht University, Utrecht, Netherlands, ²NINDS, NIH, Bethesda, MD, ³Psychiatry, UCSF School of Medicine, San Francisco, CA, ⁴Department of Physiology, Univ of Maryland Sch of Med,Baltimore, MD, ⁵Program in Neuroscience, Univ of Maryland Sch of Med, Baltimore, MD

Proper functioning of the brain relies on the rapid and efficient transfer of signals across neuronal synapses. However, we have little understanding of the molecular mechanisms that establish and modulate the molecular architecture at the postsynaptic density (PSD) and thereby shape the efficiency of synaptic signal transmission. The family of Shank scaffolding molecules (comprising Shank1, 2 and 3) are core components of the PSD that via multiple protein interaction domains link surface glutamate receptors to other scaffolding molecules within the PSD, as well as to the actin cytoskeleton via diverse actin-binding proteins. However, determining the function of Shank proteins in neurons has been complicated because the different Shank isoforms share a very high degree of sequence and domain homology. Therefore, to control Shank content while preventing potential compensatory effects, we developed a miRNA-based knockdown strategy to reduce the expression simultaneously of all synaptically targeted Shank isoforms in hippocampal neurons. Using this approach, we achieved a strong (>75%) reduction in total Shank protein levels at individual dendritic spines, prompting a ~40% decrease in mushroom spine density. Furthermore, miRNA-based Shank knockdown reduced spine actin levels and increased sensitivity to the actin depolymerizing agent Latrunculin A, an effect restored by re-expression of full-length miRNA-resistant human SHANK2. Interestingly, a SHANK2 mutant lacking the proline-rich cortactin binding motif (SHANK2-dPRO) was unable to rescue these defects, suggesting that Shank-cortactin interactions are required for the maintenance and stability of the spine actin cytoskeleton. Furthermore, Shank knockdown reduced cortactin levels in spines and increased the mobility of spine cortactin as measured by single-molecule tracking PALM, suggesting that Shank proteins recruit and stabilize cortactin at the synapse. Consistent with this model, we found that Shank knockdown significantly reduced spontaneous remodeling of synapse morphology, a phenomenon dependent on actin dynamics, that could not be rescued by the SHANK2-dPRO mutant. We conclude that beyond their role as stable scaffolding molecules within the PSD, Shank proteins are key intermediates between the synapse and the spine interior that, via cortactin, permit the actin cytoskeleton to dynamically regulate synapse morphology and function.

Molecular Mechanisms of Neuroprotection in a Drosophila Model of SCA5.

L.C. Keller¹, S. Alabsi²;

¹Biological Sciences, Quinnipiac University, Hamden, CT, ²Biomedical Sciences, Quinnipiac University, Hamden, CT

Spinocerebellar ataxias (SCAs) encompass a large heterogeneous group of late-onset progressive neurodegenerative disorders that result in uncoordinated motor function. Currently, no effective treatments or therapeutics exist to cure these devastating diseases. To facilitate the understanding and eventual treatment of SCAs, it is imperative to gain molecular insight into the processes that drive neurodegeneration. Our strategy is to use *Drosophila* as a model system to explore SCA5. We have identified a pro-degenerative signaling system that responds to mutations in the neuronal spectrin/ankyrin skeleton and ultimately results in the activation of a cysteine-aspartic protease

(caspase) that is both necessary and sufficient for motoneuron and synaptic degeneration (Keller et al., 2011). When any one of seven independent genes in this pro-degenerative signaling system is deleted the progression of neurodegeneration in *Drosophila* is slowed. The identification of genetic perturbations that can protect against degeneration highlight the importance of these signaling molecules as potential therapeutic targets for treatment of neurodegenerative diseases such as SCA. A preponderance of experimental data suggests that protein quality control mechanisms are intimately involved in disease progression of many SCAs, including SCA5. Preliminary data from my lab indicate that components of the conserved autophagic protein degradation machinery are involved in pro-degenerative signaling and removal of these components can protect against degeneration. This research is focused on elucidating new approaches to suppress neurodegeneration in our *Drosophila* model of SCA5 with the goal of discovering novel targets for future therapeutics.

The adhesion-GPCR CELSR3 promotes axonal fasciculation in the embryonic zebrafish.

A. Ciprian¹, F. Sherine¹, A.L. Dell^{1,2};

¹Department of Biology, St. Francis College, Brooklyn, NY, ²Department of Neuroscience, University of Pennsylvania, Philadelphia, PA

Using the zebrafish retinotectal projection as a model system, we previously showed that GPCR signaling is required for axon guidance during normal development. Retinal ganglion cell (RGC) axons that express a dominant negative G-protein subunit $G\alpha S$ fail to cross the midline and misproject to the ipsilateral tectum. $G\alpha S$ promotes expression of the axon guidance receptors Nrp1a and Nrp1b, helping retinal axons cross the midline, likely via cAMP-dependent signaling. This suggests a mechanism by which advancing growth cones can respond to local signals that upregulate cAMP and thereby ready themselves for the next guidance cue they encounter. However which GPCRs and ligands contribute to this process is still unknown. We identified CELSR3 as a candidate by analyzing GEO datasets to find GPCRs expressed in the right time and place to direct growing axons in the visual system. CELSR3 is a member of the adhesion-GPCR with a characteristic a long n-terminal tail decorated with adhesion motifs including EGF-, leucine-rich, and cadherin repeats as well as Ig domains. In the zebrafish retina, CELSR3 is expressed in amacrine cells as well as RGCs. CELSR3 mutants fail to carry out a optokinetic response (OKR) but have not been analyzed for guidance defects. We assessed CELSR3^{-/-} embryos response to the dark flash behavioral paradigm and examined the trajectory of RGC axons by lipophilic dye labeling. We find that CELSR3^{-/-} retinal axons can cross the midline but are defasciculated (4/30 projections $p=0.03$). This result suggests that CELSR3 may primarily function as an adhesion molecule to maintain axonal bundling during neuronal tract formation.

Role of the endoplasmic reticulum during *Legionella pneumophila* infection.

V. Ramabhadran¹, K. Kotewicz¹, E. Haenssler¹, R. Isberg^{1,2};

¹Molecular Biology and Microbiology, Tufts University School of Medicine, Boston, MA, ²Howard Hughes Medical Institute, Boston, MA

Legionella pneumophila is an aerobic bacterium that is the causative agent of Legionnaire's disease. Upon inhalation, the bacteria are internalized by alveolar macrophages, where they replicate. The bacterium's type IV secretion system (T4SS), Dot/Icm, releases over 300 proteins into the host cytosol. These proteins are required for the establishment of the *Legionella* containing vacuole (LCV) and replication. Although it is thought that the LCV acquires membrane by hijacking endoplasmic reticulum (ER) derived vesicles, the exact role of various ER domains during infection is still unknown. Here, we show that *Legionella pneumophila* closely interacts with ER tubules during the early stages of infection. We find that reticulon 4 (Rtn4), a mammalian protein that localizes specifically to the tubular domains of the ER, is mono-ubiquitinated by a family of secreted bacterial effectors, known as SdeA-C. The mono-ubiquitination of Rtn4 leads to the formation of detergent-resistant, immobile Rtn4 aggregates around the LCV. Our live-cell imaging studies suggest that ER tubules form a cage-like structure around the internalized bacterium. Formation of this cage occurs within minutes of infection and may play a role in the establishment of the LCV. Depletion of multiple reticulon families negatively affects *Legionella* intracellular growth in Cos7 cells suggesting that ER tubules might play an important role in the establishment of the LCV. Based on these data, our hypothesis is that the LCV also acquires membrane by interacting with ER tubules rather than solely hijacking ER-derived vesicles. We use genetic manipulation of the *Legionella* genome, gene knockdown, enzymatic profiling of SdeC, and live and high resolution microscopy to test our hypothesis. Our studies will fundamentally change our understanding of how *Legionella pneumophila* establishes a niche to replicate within host cells and will open up new avenues for examining other pathogen-containing vacuoles.

P2094**Board Number: B617****Investigating the genetic pathway driving ER dynamics in *Drosophila melanogaster*.**S.A. Beyeler¹, B.E. Riggs², A.Q. Sims¹, H. Hoffman¹;¹Biology, San Francisco State Univ, San Francisco, CA, ²biology, San Francisco State Univ, San Francisco, CA

The endoplasmic reticulum (ER) is the largest organelle in the cell and recently has been shown to change its shape and localization throughout the cell cycle, experiencing the most dramatic changes during mitosis. It has been suggested that these dynamic changes are the result of the homotypic fusion and fission events of the ER. A prior study has shown that homotypic fusion is mediated by integral membrane GTPase Atlastin (Atl), however the pathway driving these dramatic rearrangements is poorly understood. Here we are investigating the interaction between Atl and the integral membrane ER shaping proteins Reticulon-1 (Rtnl1) and Lunapark (Lnp) in *Drosophila melanogaster*. Our hypothesis is that Atl is regulating the interactions between Rtnl1 and Lnp in a GTP dependent manner mediating homotypic fusions events. To investigate our hypothesis we created 3 different transgenic *Drosophila* lines containing Gal4-UAS mediated RNAi inhibition of Atl, Rtnl1, and Lnp. Each line was driven in the *Drosophila* compound eye and examined for a phenotype. Expression of Atl-RNAi displayed a rough eye phenotype in 70% of the progeny, while expression of Rtnl1 and Lnp did not exhibit a phenotype in the eye. Based on our preliminary findings, we plan to examine Rtnl1-RNAi and Lnp-RNAi in combination with Atl-RNAi and examine the compound eye for either an enhancement or suppression of the rough eye phenotype. These results would indicate that Rtnl1 and Lnp are in the same pathway as Atl, and provide the bases for a modifier screen of the *Drosophila* genome.

P2095**Board Number: B618****Novel ER shaping proteins Pex30 and Pex31 are involved in pre-peroxisome vesicle biogenesis.**A.S. Joshi¹, W. Prinz²;¹NIDDK, NIH, Bethesda, MD, ²NIDDK, National Institutes of Health, Bethesda, MD

The peripheral endoplasmic reticulum (ER) forms a network of flat sheet-like cisternae and highly dynamic interconnected tubules that extend through out the cell. Reticulons and reticulon-like proteins are required to maintain this structure. *S. cerevisiae* has three of these proteins: Rtn1p, Rtn2p, and Yop1p. Interestingly, in cells missing these proteins (*rtn1rtn2yop1delta*) the peripheral ER is mostly converted to sheets. However, a few ER tubules are still found in these cells, suggesting that there may be additional ER tubulating proteins. A novel genetic screen was designed to identify the proteins that tubulate ER in *rtn1rtn2yop1delta*. We found that overexpression of Pex30p and Pex31p restores ER

tubules in *rtn1rtn2yop1delta* suggesting that Pex30 and Pex31 are ER tubulating proteins. Like reticulons and Yop1p, Pex30p and Pex31p are localized mainly in the peripheral ER and absent from nuclear membranes. Unlike reticulons and Yop1p, both Pex30p and Pex31p contain dysferlin domain of unknown function. We show that this domain is required for ER membrane tubulation. Our studies also establish that dysferlin domain is functionally conserved from humans to yeast. In *S. cerevisiae*, Pex30p and Pex31p maintain the number and size of peroxisomes respectively. Mature peroxisomes are derived from pre-existing vesicles known as pre-peroxisomal vesicles (PPV). While the origin of PPV is not known, a recent study show that Pex14p containing PPV are present even in *pex3atg1delta* cells. We investigated whether ER tubulating proteins play a role in PPV biogenesis. We found a significant increase in Pex14p containing vesicles in *rtn1rtn2yop1pex30pex3atg1delta* cells indicating that ER tubulating proteins negatively regulate PPV formation. Taken together, our results suggest that ER shaping proteins are essential for tubulating a subdomain of ER involved in PPV biogenesis. The mechanism of PPV formation remains to be investigated.

Investigating the Role of Myosin 18A in Golgi Morphology.

K. Bruun¹, J.R. Beach², S. Murugesan³, K. Remmert⁴, J.A. Hammer⁴;

¹Department of Biology, St. Joseph's University, Philadelphia, PA, ²CBPC, NIH/NHLBI, Bethesda, MD,

³NIH\NHLBI, Bethesda, MD, ⁴LCB, NIH/NHLBI, Bethesda, MD

Class 18 myosins are closely related to conventional class 2 nonmuscle myosins (NM2) but surprisingly lack intrinsic motor activity. Previous work has shown that M18A binds the Golgi protein GOLPH3 to stretch and shape the Golgi apparatus (Dippold et al., Cell, 2009), although it remains unclear how “motorless” M18A could provide the force necessary to accomplish this task. Recent work from our and Jim Seller’s labs has shown both in vitro and in live cells that M18A co-assembles with NM2 into mixed bipolar filaments. Therefore, M18A may serve to link these hybrid NM2 filaments to the Golgi apparatus, allowing NM2 motor activity to then drive changes in Golgi morphology. The goals of the current study were (i) to use high resolution and super-resolution microscopy to image M18A, NM2, the actin cytoskeleton, and the Golgi apparatus during steady-state and dynamic processes, and (ii) to reexamine the functional role played M18A in determining Golgi shape and size. Using standard Golgi reporters and fluorescently-tagged M18A, we showed that M18A localizes to some extent to the Golgi at steady-state. Additionally, we commonly observed enrichment of actin filaments near the Golgi apparatus. To suppress or eliminate M18A expression, we utilized lentiviral-mediated shRNA knockdown in HeLa cells (HeLa-M18A-KD) and CRISPR-mediated knockout in Rat2 fibroblasts (Rat2-M18A-KO). Surprisingly, we observed no obvious differences in Golgi localization or distribution in KD and KO cells at steady-state relative to control cells. To investigate further, we utilized Brefeldin A (BFA), a small molecule that induces Golgi dispersal, to determine if M18A plays a role during a more dynamic Golgi process. Specifically, we localized M18A and actin during Golgi recovery following removal of BFA. Preliminary results suggest that there is a delay in the recovery of normal Golgi architecture in HeLa-

M18A-KD cells. Moreover, live-cell imaging showed that the localization of M18A and actin on the Golgi apparatus may be enhanced during the recovery process. Overall, therefore, our data suggest that M18A is not important for Golgi morphology at steady-state, but may play a significant role during dynamic Golgi movements, such as those that occur during cell migration or following cell division.

Identification of Rab41 effectors implicated in Golgi organization and trafficking.

S. Liu¹, B. Storrie²;

¹Univ Arkansas Med Scis (UAMS), Little Rock, AR, ²Physiology and Biophysics, Univ Arkansas Med Scis (UAMS), Little Rock, AR

By homology, Rab6a, Rab6a', Rab6b, Rab6c and Rab41 can be grouped together in Rab VI subfamily with Rab6a/a' and Rab41 sharing 80% over much of the protein. Rab6a/a', collectively referred to as Rab6, is the most abundant Golgi Rab protein and localizes to the trans-Golgi cisternae and TGN membranes. Neither depletion nor overexpression of GDP-locked Rab6 results in disruption of the Golgi ribbon and in epistasis experiments, co-depletion of Rab6 suppresses ZW10/RINT1- or COG-dependent Golgi disruption. By electron tomography, Rab6 depletion induces an accumulation of COPI- and clathrin-coated vesicles that is accompanied by an increase in Golgi cisternal number and cisternal continuity. In sum, Rab6 may be more important to Golgi associated membrane trafficking than to Golgi organization. In striking contrast, both Rab41 depletion and overexpression of GDP-locked Rab41 cause Golgi fragmentation into a cluster of punctate elements, suggesting that Rab41 has an active role in maintenance of Golgi ribbon organization. Here, our goal has been to identify the Rab41 effectors producing this phenotypic contrast. To identify how Golgi organization is regulated by Rab41, we screened for Rab41 effectors using the yeast two-hybrid assay. Approximately 5.6×10⁶ yeast transformants were screened from which 265 colonies were isolated under stringent conditions. Following PCR reactions and restriction digestion, 155 non-repetitive hits were isolated and sequenced. 8 putative Rab41 membrane trafficking or vesicle transport effectors were identified. Significantly, none of the 155 hits overlapped with any published Rab6 effector. Syntaxin-8, dynactin subunit 6 and kif18A were selected for further study as candidate effectors of Golgi organization and trafficking. Comparative yeast two-hybrid experiments indicate a preferential interaction of syntaxin-8, dynactin subunit 6 and kif18A with GTP- versus GDP-locked Rab41. Co-immunoprecipitation experiments are in progress to test the interactions of these putative Rab41 effectors with GTP- versus GDP-locked Rab41. More importantly, our studies show that, if dynactin subunit 6 or syntaxin-8, but not kif18A, were depleted using siRNA, the Golgi apparatus displayed a Rab41 knockdown phenotype, i.e., the Golgi apparatus was disrupted into a cluster of punctate Golgi elements. This strongly suggests that, in contrast to Rab6, Rab41 may act directly to regulate Golgi organization through dynactin/dynein recruitment and indirectly through syntaxin-8 dependent membrane trafficking.

P2098**Board Number: B621****A Trans-Golgi Specific Delay in Cargo Transport Is Sufficient to Explain Increased Golgi Cisternal Number in Rab6-Depleted Cells: A Test of a Delayed Cisternal Progression Model.**L. Dickson¹, S. Liu¹, B. Storrie²;¹Univ Arkansas Med Scis (UAMS), Little Rock, AR, ²Physiology and Biophysics, Univ Arkansas Med Scis (UAMS), Little Rock, AR

Rab6 is the most abundant and studied Golgi-associated Rab protein, and is located predominantly at the exit or trans side of the Golgi apparatus. Knockdown of Rab6 results in a selective dilation of the trans-Golgi network (TGN), an accumulation of trans/TGN proximal COPI- and clathrin-coated vesicles, and an increase in Golgi cisternal number¹. These changes in Golgi organization are accompanied by a delay in cargo transport between the Golgi apparatus and plasma membrane¹. We hypothesized that this phenotype could be the outcome of a trans-Golgi/TGN specific delay in COPI-dependent Golgi recycling and hence a delay in cisternal progression. Here, we tested a key prediction of this model, namely, there should be a trans-Golgi specific delay in cargo transport through the organelle. Taking VSV-G-GFP as a model cargo protein, we determined the kinetics of cargo transport relative to cis, medial, trans and TGN46 markers using confocal fluorescence line scanning. Our results showed that cargo in Control and Rab6-depleted cells moved at a similar rate through the initial Golgi compartments (cis and medial). Cargo exit from both the medial Golgi and TGN occurred with similar rapidity, ~3 min. However and importantly, VSV-G transport between the medial Golgi and TGN was selectively delayed, 30 min versus 10 min for Control. Co-localization experiments with trans Golgi markers GalT and SialylT show that the delay was trans Golgi-specific. Taking the delay in cargo transport as an indicator of delayed cisternal progression, we propose that the observed increase in cisternal number with Rab6 knockdown is the predictable consequence. Experiments that test whether the “inserted” Golgi cisternae are trans-specific by Immunogold labeling are in progress. Results are being further validated by biochemical assays of protein glycosylation.

Supported in part by NIH grant R01 GM 092960 and a minority student supplement.

P2099**Board Number: B622****Quantitative analysis of Golgi size changes during interphase in mammalian cells.**A. Sin¹, R.E. Harrison¹;¹Department of Biological Sciences, University of Toronto Scarborough, Toronto, ON

During the cell cycle, organelles and genetic materials need to be duplicated to ensure there is sufficient cellular content for daughter cells. As the Golgi complex plays an essential role in the biosynthetic pathway for all living cells, a fundamental question in cell biology is whether Golgi duplication occurs in mammalian cells. Although this process has been studied in parasitic protozoa, yeast, plants and insects, findings from such research may not be directly applicable to mammalian cells due to the substantial differences in Golgi morphology amongst the species. As careful, extensive research has already been performed on Golgi dispersal and inheritance during mitosis in mammalian cells, the aim of our study is to understand the growth of the mammalian Golgi complex prior to mitosis and elucidate the underlying mechanisms that control this process. Through the use of flow cytometry, we have shown that the mammalian Golgi complex has increased structural protein and enzyme contents as the cell cycle progresses, doubling its levels at late G2. Through 3D reconstruction and volumetric analyses after confocal microscopy, it is observed that the cis-, medial- and trans- cisternae concomitantly double in volume at late G2. To investigate the possibility of cell cycle control on Golgi growth, pharmacological agents were used to prolong specific cell cycle phases for 24 and 48 hours. Our results show that synchronized cells had significantly higher Golgi protein levels than those unsynchronized suggesting a lack of checkpoints that prevent indefinite Golgi growth. Interestingly, cell cycle synchronized cells were significantly larger in cell size than those unsynchronized establishing a correlation between Golgi size and cell size. We aim to further investigate the connections between these parameters in our future studies.

P2100**Board Number: B623****Monoubiquitination regulates Golgi membrane dynamics in the cell cycle.**X. Zhang¹, S. Huang¹, Y. Wang¹;¹Dept. of Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI

Partitioning of the Golgi membrane into daughter cells during mammalian cell division occurs through a unique disassembly and reassembly process. Several converging lines of evidence have suggested that monoubiquitination plays an essential role in the regulation of post-mitotic Golgi membrane fusion. Monoubiquitination, as a regulatory signal, occurs during mitotic Golgi disassembly and is required for subsequent Golgi reassembly. The AAA ATPase p97 and its adapter protein p47 are involved in membrane fusion during post-mitotic Golgi reassembly. The p97/p47 complex binds to monoubiquitin through the UBA domain of p47, and this interaction is required for p97-mediated Golgi membrane

fusion. Proteasome activity is not involved in either Golgi disassembly or reassembly. We have identified a Golgi-localized ubiquitin E3 ligase HACE1 which is involved in mitotic Golgi disassembly; reduced HACE1 activity in human cancer such as Wilms' tumor results in fragmented Golgi. We have also discovered the p97/p47 binding protein VCIP135 as a deubiquitinating enzyme whose activity is required for post-mitotic Golgi reassembly. VCIP135 activity is regulated by phosphorylation in the cell cycle; it is inactivated by phosphorylation in metaphase and activated upon dephosphorylation in telophase. Recently, we have identified the substrates on the Golgi membranes whose ubiquitination and deubiquitination are regulated by HACE1 and VCIP135 in the cell cycle. These data suggest that cycles of addition and removal of ubiquitin to and from substrates regulate Golgi membrane dynamics during cell division.

Essential role of Golgi-derived microtubules in Golgi positioning and function at the mitotic entry.

M. Fomicheva^{1,2}, D. Yampolsky¹, K. Frye¹, V. Magidson³, E. Kolobova¹, E. Smirnova², A. Khodjakov³, X. Zhu¹, I. Kaverina⁴;

¹Vanderbilt University medical center, Nashville, TN, ²Lomonosov Moscow State University, Moscow, Russia, ³Wadsworth Center, Albany, NY, ⁴Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

In interphase vertebrate cells, the microtubule (MT) minus end-directed motor dynein localizes to Golgi membranes and organizes them into a single complex in the proximity of the centrosome. This mechanism is thought to facilitate proper partitioning of the Golgi membranes in mitosis, and Golgi complex reassembly in the daughter cells. Yet, the exact mechanism(s) responsible for segregation of the Golgi during cell division remain unclear. It has been proposed that the Golgi membranes split into two groups and move apart with the separating centrosomes during transition from G2 to mitosis. This view has been recently challenged by the finding that dynein dissociates from the Golgi in late G2, breaking the connection to the centrosome. To discriminate these conflicting ideas, we followed the movements of the centrosome and Golgi in human cells via high-resolution multi-dimensional microscopy, and assessed the distribution of the Golgi membranes by a newly-developed computational approach. We found that late in G2, Golgi stacks redistributed independently of the centrosome separation. However, Golgi stacks did not scatter randomly in the cytoplasm, but slid alongside the nuclear envelope approaching even distribution around the nucleus. Furthermore, we detected extensive nucleation of MTs at the Golgi at this cell cycle stage. Specific elimination of Golgi-associated MT nucleation by a number of alternative approaches prevented Golgi redistribution around the nucleus, indicating that Golgi-derived MTs were essential for this process. We also found that Golgi redistribution required recruitment of dynein to the nuclear envelope, which normally occurs in late G2/prophase. Together, our data indicate that redistribution of the Golgi stacks at the G2-mitosis transition is driven by nuclear envelope-localized dynein that acts along the Golgi-derived MTs. A

corollary of this mechanism is that Golgi-derived MTs are responsible for equal segregation of Golgi membranes between the daughter cells. Indeed, we found that Golgi distribution in proliferating cell populations became irregular upon depletion of Golgi-derived MTs. Additionally, we propose that the described mechanism of Golgi redistribution in prophase serves to properly position Golgi-associated membrane coat protein complexes (COPI), which are essential for nuclear envelope breakdown.

Differential Expression, Sorting and Segregation of Golgi Localized Proteins during Germ Cell Differentiation in the Testis.

L. Hermo¹, C.E. Au¹, E. Byrne¹, J. Smirle¹, A. Fazel¹, P. Simon¹, R. Kearney¹, P. Cameron¹, C. Smith¹, H. Vali¹, J. Fernandez-Rodriguez¹, K. Ma¹, T. Nilsson¹, J.J. Bergeron¹;

¹McGill University, Montreal, QC

Germ cell differentiation in the testis is accompanied by dramatic changes in Golgi apparatus structure and function. These coincide with mitosis of spermatogonia, meiosis of spermatocytes, acrosome formation by early spermatids, and Golgi migration in late spermatids undergoing extensive changes in plasma membrane and cell shape remodeling. Protein based mechanisms are lacking since the protein complement of germ cell Golgi apparatus during these modifications is unknown. To address this, abundant proteins were characterized quantitatively by tandem mass spectrometry of germ cell Golgi fractions isolated from adult rat whole testis homogenates. From 1318 proteins assigned to 22 functional categories, antibodies were generated or obtained to 20 of these proteins. The most abundant was GL54D, a protein of unknown function not previously uncovered but shown here to be a Golgi localized type II integral membrane glycoprotein and germ cell specific. A further protein of unknown function, TM9SF3, was a new Golgi marker for both somatic and germ cells, with 2 other TM9 protein family members predicted as Golgi markers based on extensive organelle sub-fractionation. Besides GL54D and TM9 family members, there were 240 characterized proteins of unknown function enriched in germ cell Golgi fractions. During acrosome formation, different Golgi localized proteins were segregated to Golgi apparatus or were shared with the forming acrosome. The former retained Golgi identity as the Golgi apparatus migrated away from the acrosome after its formation with the latter Golgi proteins remaining trapped in the acrosome. Based on the maturation model for acrosome formation, such segregation is unexpected. During acrosome formation, a subset of Golgi localized molecular chaperone and protein-folding enzymes were uncovered to handle the enormous biosynthetic load. Spermatocytes and spermatids during and after acrosome formation were associated with specific Golgi proteins along with others expressed throughout differentiation. Also unexpected was the finding of a burst and selectivity of expression of Golgi localized proteins to the terminal step 19 spermatid enriched in unstacked flattened cisternae of previously unknown function. When the selective expression and localization of the 20 Golgi localized proteins were compared with 30 proteins characteristic of PM, endosome, ER, coat and cytosol, organelle based molecular signatures for all 63 morphologically distinct germ cells were uncovered. In this way, a marker-based resource with insight

from the cognate protein functions has been established to uncover new mechanisms and proteins in Golgi membrane trafficking and fate during differentiation.

Golgi defects in Alzheimer's disease.

G. Joshi¹, Y. Chi¹, Z. Huang¹, Y. Wang¹;

¹Dept. of Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI

Golgi fragmentation occurs in neurons of patients with Alzheimer's disease (AD), but the underlying molecular mechanism causing the defects and the subsequent effects on disease development remain unknown. In this study, we examined the Golgi structure in APP^{swe}/PS1 Δ E9 transgenic mouse and tissue culture models. Our results suggest that A β accumulation leads to Golgi fragmentation by activating cdk5, which in turn phosphorylates GRASP65 and perhaps other key proteins critical for maintaining Golgi morphology. Significantly, rescue of Golgi structural defects by inhibiting cdk5 or by expressing nonphosphorylatable mutants of GRASP65 reduces A β secretion by elevating non-amyloidogenic APP cleavage. These results reveal Golgi fragmentation as an important mechanism through which A β may exert its toxic effects. A major potential unrecognized source of A β toxicity may be that it compromises Golgi integrity and perturbs the proper trafficking and processing of many proteins essential for neuronal function. We hypothesize that in AD, A β accumulation promotes Golgi defects, which in turn accelerate APP trafficking and A β production; this deleterious feedback circuit would impair the integrity of the secretory pathway and thereby compromise neuronal cell function. Our study provides a molecular mechanism for Golgi fragmentation and its effects on APP trafficking and processing in AD, suggesting Golgi as a potential drug target for AD treatment.

Blocking iron release alters the behavior of transferrin-containing endosomes in epithelial cells.

A. Das¹, M.M. Barroso¹, A.B. Mason², M.J. Gastinger³;

¹Cardiovascular Sciences, Albany Med Coll, Albany, NY, ²Biochemistry, University of Vermont School of Medicine, Burlington, VT, ³Bitplane Inc., South Windsor, CT

Intracellular iron transport occurs by the binding of two iron molecules to transferrin, which is then internalized upon binding to the transferrin receptor and subsequent clathrin-mediated endocytosis. Upon endosomal acidification, iron is released from the transferrin-transferrin receptor complex and is finally taken up by the mitochondria, which is the principal site of iron-sulfur clusters synthesis and iron incorporation into haeme group. However, the mechanism at the basis of the endosomal iron transfer to mitochondria remains poorly understood. Recently, it has been established that iron can be

transported via a direct interaction (“kiss and run”) between transferrin-containing endosomes and mitochondria. To characterize these “kiss and run” events we have employed time-lapse live-cell TIRF microscopy to simultaneously track fluorescently labeled transferrin-containing endosomes and mitochondria in epithelial cells. Spatio-temporal endosomal parameters such as endosomal speed and distance from mitochondria have been derived using the image analysis software Imaris. We found that a transferrin-containing endosome generally shows significantly reduced speed during its interaction with the mitochondrion (the “kiss” phase) and increased speed during the “run” step of the “kiss and run” event. The role of iron release from transferrin on the behavior of transferrin-containing endosomes and on their ability to interact with mitochondria was investigated using a single point transferrin mutant, which cannot release iron during endocytic acidification. Blocking iron release increased the half-life of the “kiss” phase of transferrin-containing endosome-mitochondria interactions to 416ms compared to 216ms when using wild-type transferrin. Interestingly, we also found that blocking iron release leads to significantly higher endosomal speeds of mutant transferrin containing endosomes (mean speed = 0.58 μ m/s) than that of wild-type transferrin endosomes (mean speed = 0.46 μ m/s). These results suggest that blocking iron release affects endosome-mitochondria interactions resulting in longer interactions with mitochondria as well as increased endosomal speed of transferrin-containing endosomes. In order to address the mechanism underlying the effect of iron release on endosomal speed, we will investigate the role of intra-endosomal milieu such as pH, or extra-endosomal cytoskeletal elements such as actin and tubulin. In the future, we also plan to study the functional relevance of transferrin-containing endosomes and mitochondrial “kiss and run” interactions in cancer cell lines owing to their naturally enhanced iron requirements, altered endocytic pathways, and mitochondrial metabolisms.

P2105

Board Number: B628

The unconventional Myosin Vc is crucial for the transport of cargoes and Rab32/38 from early/recycling endosomes to maturing platelet dense granules in megakaryocytes.

F. Martin¹, J. Bultema², S.M. Di Pietro³;

¹Department of Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO,

²University of Colorado, Colorado Springs, CO, ³Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Mutations of Rab38 in mice and rats result in phenotypes consistent with the mouse models of Hermansky Pudlak Syndrome (HPS), characterized by pigmentation deficiencies and bleeding disorders. HPS is caused by defects in the biogenesis of melanosomes and platelet dense granules, two lysosome related organelles (LROs). Platelet dense granule biogenesis takes place in megakaryocytes and depends upon Rab38 and its close homolog Rab32 for sorting and transport of cargoes to the maturing organelle. We initially identified Myosin Vc (Myo5c) as a protein that directly interacts with Rab32 and Rab38, and characterized its involvement in melanosome biogenesis. Here we show that disruption of the

Rab32/Rab38/Myo5c interaction results in sequestering of Rab32, Rab38 and platelet dense granule cargoes into enlarged early endosomal structures. These structures are marked by Rab5; participate in recycling pathways as demonstrated by co-localization with the transferrin receptor; and appear to be “locked” into a dead-end state as evidenced by fluorescent live-cell microscopy. Characterization of Rab32/38 constitutively active and inactive mutants revealed that the interaction with Myo5c is GTP-dependent. Knockdown of Myo5c function using a *dominant negative (DN)* Myo5c construct consisting of the coiled-coil and globular tail region showed that transport of Rab32 and Rab38 to maturing dense granules is dependent upon wild type Myo5c. Further, Myo5c is absolutely required for transport of cargoes to dense granules as revealed by the failure of known dense granule components (VMAT2, SLC35D3) to co-localize to dense granules in cells transfected with *DN* Myo5c. Last, we investigated the relationship with another Rab32/38 binding partner involved in LRO biogenesis, Varp. Our experiments show that *wild type* Myo5c is anti-correlated with the Rab32/38 effector and endocytic recycling protein Varp; however, knockdown of Myo5c function using *DN* Myo5c results in sequestering of Rab32/Rab38, Varp, dense granule cargoes and *DN* Myo5c at early/recycling endosomes. We propose a handoff mechanism for Rab32/38 marked vesicles from Varp at early endosomes to Myo5c for subsequent transport and delivery to maturing platelet dense granules.

VAMP7 trafficking in melanosome biogenesis: tubular transport into and out of melanosomes.

M.K. Dennis¹, C. Delevoye², A. Acosta-Ruiz¹, G.G. Hesketh³, P. Luzio⁴, D.J. Owen⁴, G. Raposo², M.S. Marks¹;

¹Pathology and Laboratory Medicine, University of Pennsylvania Children's Hospital of Philadelphia, Philadelphia, PA, ²Institut Curie, Paris, France, ³Lunenfeld-Tanenbaum Research Institute, Mt Sinai Hospital, ON, ⁴Cambridge Inst Med Res, Cambridge, England

Melanosomes are lysosome related organelles (LROs) that coexist in pigmented cells alongside classical endolysosomes. Melanosomal membrane proteins are directed towards maturing melanosomes via membranous transport carriers derived from early endosomal domains, but neither the machinery that mediates fusion of the transport carriers with melanosomes nor a defined pathway for recycling of machinery components to the site of origin for additional rounds of transport are known. To address these unknowns, we focused on VAMP7 as a candidate vSNARE for melanosome transport. VAMP7 has been implicated in melanosome biogenesis because it localizes in wild-type melanocytes primarily to melanosomal membranes at steady state (unlike other endosomal VAMPs), and because depletion of VAMP7 results in mistrafficking of melanosomal cargoes and hypopigmentation. To determine the pathway through which VAMP7 is targeted to melanosomes, we first assessed the subcellular localization of GFP-VAMP7 in melanocytes from mouse models of Hermansky-Pudlak syndrome, in which melanosomal maturation is impaired. Whereas GFP-VAMP7 localized nearly exclusively to pigmented melanosomes in wild type melanocytes, it overlapped nearly completely with syntaxin 13

(STX13) in early endosomes of BLOC-1-deficient cells, analogous to melanosome cargoes like TYRP1. Upon transient rescue of BLOC-1-deficiency, GFP-VAMP7 exited endosomes in mCherry (mCh)-STX13-labeled tubules, and accumulated in nascent STX13-negative structures with features of early stage melanosomes. This suggests that VAMP7 is targeted to melanosomes in STX13-containing endosomal tubules towards maturing melanosomes and is likely the vSNARE on the BLOC-1-dependent cargo transport pathway. To assess VAMP7 recycling from melanosomes, we exploited live cell imaging of tagged VAMP7 in wild-type melanocytes. A second population of tubules labeled by GFP-VAMP7 but not by mCh-STX13 were frequently detected, often emerging from GFP-VAMP7-containing melanosomes. VARP, a scaffolding protein that maintains VAMP7 in an inactive conformation, was largely localized at steady state to puncta that were associated with melanosomes and that were enriched in the tissue-restricted RAB protein, RAB38. By live imaging, tubules labeled by VARP-GFP overlapped with those labeled by mCh-VAMP7 and were frequently detected departing from melanosomes. As expected for recycling structures, these tubules lacked melanosomal cargoes such as TYRP1 and were discrete from the anterograde STX13-positive tubules. These data support a role for VARP in recycling VAMP7 from melanosomes following cargo delivery. Because VARP is a RAB38 effector and overlaps with RAB38 on melanosomal domains, we speculate that RAB38 also functions on this recycling pathway.

A cluster of isolation membrane-associated tubules represents a part of omegasome during final steps of autophagosome formation.

S. Waguri¹, T. Uemura¹, M. Yamamoto¹, A. Kametaka¹, Y. Sou², A. Yabashi¹, A. Yamada¹, H. Annoh¹, S. Kametaka¹, M. Komatsu²;

¹Dept of Anatomy and Histology, Fukushima Med Univ Sch of Med, Fukushima, Japan, ²Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan

Recent findings have suggested that autophagic isolation membrane (IM) originates from a domain of endoplasmic reticulum (ER) called “omegasome”. However, its fine structure and detailed positional relationships to the ER and IM during autophagosome formation remain unclear. In the present study, we used *Atg3*-deficient mouse embryonic fibroblasts (MEFs) expressing a marker of omegasome, GFP-tagged double FYVE domain-containing protein 1 (GFP-DFCP1), and found that GFP-DFCP1 was localized on tubular or vesicular elements adjacent to the IM rims by correlative light and electron microscopy and immuno-electron microscopy. Moreover, we developed a fixation protocol for electron microscopy (EM) using a mixture of paraformaldehyde, glutaraldehyde, and osmium tetroxide as a primary fixative, for clear-cut detection of IM and associated vesicular or tubular structures. By EM analyses including serial ultra-thin sections and electron tomography, we observed a cluster of thin tubular structures between the IM edges and ER, part of which were continuous with IM and/or ER. These IM-associated tubular structures (IMATs) were observed in several cell lines and MEFs deficient for *Atg5*, *Atg7*, or *Atg16L1*, but not in *FIP200*-deficient cells, suggesting that they are relevant to earlier events in

autophagosome formation. Taken together, our findings indicate that IMATs represent a part of omegasome during completion steps of autophagosome formation.

Phylogenetic conservation and subcellular localization of apicomplexan SNAREs.

D. Ouologuem¹, D.S. Roos¹;

¹University of Pennsylvania, Philadelphia, PA

Apicomplexan parasites are highly polarized eukaryotic cells, with an endomembrane system that includes a minimal ER and Golgi apparatus, and a multitude of distinctive membranous organelles. Dense granules, micronemes and rhoptries are secretory organelles associated with parasite-specific functions, including motility, host cell attachment and invasion, and establishment of a specialized niche for survival within the infected host cell (the parasitophorous vacuole). The Inner Membrane Complex (IMC) consists of a patchwork of Golgi-derived flattened vesicles underlying the parasite plasma membrane and associated with a cytoskeletal scaffold; this assemblage is required for partitioning parasite organelles during cell division. In order to further understand the organellar biogenesis and trafficking, we have identified and partially characterized *Toxoplasma* and *Plasmodium* SNARE proteins (soluble N-ethylmaleimide-sensitive factor adaptor protein receptors). 25 SNAREs are predicted from the *T. gondii* genome, and 24 from the *P. falciparum* genome, and these proteins can be grouped into conventional R/Qabc-SNARE subclasses. Phylogenetic reconstruction, comparison with well-characterized human and fungal SNAREs, and subcellular localization permits identification of clear orthologs for most SNAREs involved in the early secretory pathway (ER/Golgi/TGN trafficking), but not those associated with trafficking to the plasma membrane, lysosomes, etc. Several unusual SNAREs were also identified in the Apicomplexa, including some that localize to the parasite plasma membrane, rhoptries, or uncharacterized cytoplasmic vesicles. This study highlights the divergence of the late secretory pathway in apicomplexan parasites, and provides a map of SNAREs likely to participate in trafficking to both conserved and distinctive organelles.

New Automated Methods to Quantitate Lipid Droplet Number, Fluorescence and Total Volume from Fluorescence Images.

S. Dejgaard Yilmaz¹, J.F. Presley²;

¹Department of Anatomy and Cell Biology, McGill University, Montreal, QC, ²McGill University, Montreal, QC

Lipid droplets are the major organelle for intracellular storage of triglycerides and cholesterol esters. Generally, automated segmentation and quantitation of lipid droplets in fluorescence images of cells has

relied on thresholding-based or watershed methods. We describe here a novel three-stage hybrid method in which candidate lipid droplets are initially identified by thresholding and then tested for circularity. Circular structures are accepted immediately as lipid droplets, while non-circular structures are considered candidate clusters, which are segmented using a watershed algorithm. A unique feature of this method is that the circularity measure can be used as a quality control for the overall segmentation of either stage. The same method can, in principle, be applied with modifications to the estimation of the total lipid droplet volume within a cell. However, as the volume of smaller lipid droplets are difficult to determine accurately by light microscopy, we apply an alternate approach of automatically identifying and fitting the volume of large lipid droplets in calibration images taken parallel to experimental images and identically stained with volume dyes (e.g., Nile Red or Bodipy) and imaged. We describe quantitatively the accuracy of determination of volume of lipid droplets using this method, with respect to factors that must be taken into account, including the degree of reproducibility of staining, the effects of variation in lipid droplet composition and effects of lipid droplet size with respect to several common dyes.

Rapid color changes in the chameleon sand tilefish, *Hoplolatilus chlupaty*.

M. Goda¹, Y. Fujiyoshi¹;

¹Nagoya Univ, CeSPI, Nagoya, Japan

The chameleon sand tilefish, *Hoplolatilus chlupaty*, inhabits areas off the coast of Philippines and Okinawa islands in Japan at the depth of 30 to 70m below the surface of the sea. It is well known to hobbyists, scuba divers and zoologists that color of the trunk of the sand tilefish changes from blue to red within less than one second. For this reason, this species also called “flashing tilefish”. In this study, our optical and electron microscopic observations revealed that the coloration and color changes of the chameleon sand tilefish were generated by interference phenomenon of incident light occurred in dermal iridophores. The cytoplasm of the iridophores contained stacked, very thin reflecting platelets, resembling damselfish-type iridophores, but the platelets were arranged and distributed in the limited area nearby the cell membrane. The color changes of the sand tilefish are inordinately fast for fish iridophores, which have been reported to take several seconds or minutes. To investigate the motile activities of the iridophores, we performed pharmacological examinations with scales from trunk of the chameleon sand tilefish. An elevation of K⁺ ions in the perfusing medium gave rise to rapid color changes of the iridophores from blue to red. While acetylcholine did not influence the state of the iridophores, norepinephrine aroused color changes toward reddish color very effectively. The action of norepinephrine on the iridophores was effectively blocked by alpha-adrenergic blocking agent, phentolamine. These results suggest that adrenergic stimulation is a cue to control the motile activities of the iridophores of the chameleon sand tilefish.

P2111**Board Number: B634****The Keap1-Nrf2 redox pathway alters mitochondrial morphology through induced proteasomal degradation of the mitochondrial fission protein Drp1.**T. Shutt¹, M. Geoffrion², R. Screatton³, R. Milne², H.M. McBride⁴;¹Medical Genetics, University of Calgary, Calgary, AB, ²University of Ottawa Heart Institute, Ottawa, ON,³University of Ottawa, Ottawa, ON, ⁴McGill University, Montreal, QC

Mitochondria, best known for their ability to generate both energy and reactive oxygen species also play important roles in many cellular functions. Various signals can affect mitochondrial morphology by altering the balance between fission and fusion events, ultimately influencing metabolic output and sensitivity to cell death. For example, mitochondrial hyperfusion occurs rapidly following several types of cellular stress, in a process described as Stress Induced Mitochondrial Hyperfusion (SIHM). Mitochondria with a hyperfused morphology are refractive to mitochondrial autophagy and provide protection against apoptotic triggers, suggesting that SIHM may play an important protective role during the early stages of cellular stress. This study examines mechanisms regulating mitochondrial shape in response to oxidative stress. We recently demonstrated a role for oxidized glutathione in the direct activation of the mitochondrial fusion machinery, providing a mechanistic link between oxidative stress and fusion. However, questions remain about the persistence of the fused mitochondrial state and whether fission may also be negatively regulated. As part of a genome-wide screen to find novel factors modulating mitochondrial morphology, we identified Keap1. Under normal conditions, Keap1 promotes the ubiquitination and degradation of several target proteins, including the transcription factor Nrf2 (NFE2L2) a key regulator of the cell's antioxidant response. Given that Keap1 is a redox-regulated protein controlling the cellular response to stress and its knockdown results in a hyperfused mitochondrial network, we characterized this novel pathway using a combination of approaches. Although mitochondrial fusion was not activated with Keap1 siRNA, accumulation and nuclear translocation of Nrf2 resulted in a significant decrease in the levels of the mitochondrial fission protein Drp1, explaining the hyperfused mitochondrial network. We then showed that the transcription factor activity of Nrf2 influences mitochondrial morphology by promoting the expression of proteasome proteins and ultimately increasing the degradation of Drp1. Rather than the acute increase in mitochondrial fusion previously described in response to oxidative stress, this novel pathway occurs on a timescale of hours to days to prolong the hyperfused phenotype, thereby protecting the cell from apoptosis until the stress has been neutralized. In summary, we have identified a novel role for the Keap1/Nrf2 redox pathway in maintaining a fused mitochondrial network following cellular stress.

P2112**Board Number: B635****A direct interaction between actin filaments and the dynamin-like GTPase Drp1 supports dual roles for the actin cytoskeleton during mitochondrial fission.**A.L. Hatch¹, H.N. Higgs²;¹Dartmouth College, Hanover, NH, ²Dartmouth-Geisel Sch Med, Hanover, NH

As a dynamic network, mitochondria routinely change morphology in response to different cellular demands and stresses. In this regard, mitochondrial fission and fusion serve several roles: to distribute mitochondria appropriately in dividing or polarized cells; working as a quality control mechanism to help eliminate damaged mitochondrial segments; and even as a component of apoptotic pathways. Defective mitochondrial fission/fusion is found in patients with neurological disorders such as Charcot-Marie-Tooth disease (CMTD), Alzheimer's, Huntington's, and Parkinson's disease. The dynamin-like GTPase Drp1 is a key component of the fission machinery that provides contractile force needed for mitochondrial fission, but a key unanswered question is how Drp1 gets recruited to the mitochondrial outer membrane (OMM). While a number of Drp1 "receptors" have been identified on the OMM, there is also evidence that a mitochondrial pre-constriction step is required prior to Drp1 action. We have shown that actin filaments contribute to this pre-constriction step through the formin INF2, additionally requiring myosin II. INF2 is an endoplasmic reticulum (ER)-bound actin polymerization factor, and mutations in INF2 lead to CMTD. Still, how do actin filaments and pre-constriction lead to Drp1 recruitment? Here, we show that Drp1 binds directly to actin filaments with high affinity. Drp1 binds evenly along the length of the actin filament (shown by electron microscopy), but the interaction is highly dynamic (shown by TIRF microscopy). Actin filament binding increases Drp1's GTP hydrolysis activity, suggesting that actin binding promotes productive Drp1 oligomer assembly. In mammalian cells, Drp1 mutants defective in actin binding do not rescue mitochondrial fission defects induced by endogenous Drp1 suppression. From these results, we propose that actin filaments serve two roles during mitochondrial fission: 1) to provide the force for OMM pre-constriction; and 2) to recruit Drp1 at fission sites through direct binding. In the first role, we propose that actin filaments generate force for pre-constriction with myosin II in a manner similar to cytokinesis. In the second role, actin filaments act as a "co-incidence detector", along with Drp1 receptors such as Mff, Fis1, MiD49, and MiD51. Co-incidence detection of two signals (in this case actin filaments + a Drp1 receptor) is widely used in cells to tightly control activation of important processes. We further propose that other molecules, such as cardiolipin, may serve as independent co-incidence detectors for Drp1 in a similar manner to actin.

P2113**Board Number: B636****Mitochondrial network topology in the absence of fission and fusion dynamics.**M.P. Viana¹, I.A. Mueller¹, C. Goul², S. Rafelski²;¹Developmental and Cell Biology, University of California Irvine, Irvine, CA, ²Developmental and Cell Biology, University California-Irvine, Irvine, CA

Mitochondria form interconnected networks that are constantly reshaped by fission and fusion dynamics. The underlying topological properties of these networks and how fission and fusion together quantitatively contribute to these properties are unclear. We applied an updated version of our MitoGraph method to quantify the topology of mitochondrial networks in budding yeast. We grew cells in microfluidic chambers with constant fresh media in such a way that the cells stopped dividing but continued to grow. This experimental setup permits mitochondrial networks to be at a steady state; because cells are no longer dividing, we avoid effects of the cell being polarized during cell division. We grew cells both in respiring and non-respiring conditions. We found that the number of networks edges and the total mitochondrial content, expressed in terms of the network length, are strongly correlated in both respiring and non-respiring media. This suggests that there is a typical length for edges in mitochondrial networks, similar to what is observed in other types of planar networks. We also investigated the mitochondrial network topology of $\Delta fzo1\Delta dnm1$ yeast cells, which lack the main proteins responsible for mitochondrial fission and fusion. Surprisingly, although networks in these fission/fusion double mutant cells look different by eye, we found no clear topological differences in non-respiring conditions. The only difference we found was that the surface density of mitochondrial tubules was greater in the fission/fusion double mutant cells in respiring conditions and so was their average interconnectivity. To identify the key rules required to generate the topology of mitochondrial networks we simulated many artificial networks generated by different sets of rules and then compared them to the experimentally measured ones. We found two features critical for generating realistic mitochondrial networks both for wild-type and fission/fusion double mutant cells. First, the networks must consist of nodes with only one or three neighbors in a given proportion and second, nodes that are closer to each other in space must be preferentially connected. We conclude that cells in the absence of fission and fusion still generate mitochondrial networks with very similar basic topological properties to wild-type cells, suggesting that there may be processes beyond fission and fusion that determine how mitochondrial networks are generated in yeast cells. We are now using more sophisticated measurements to determine how the visual differences between wild-type and double mutant cells arise.

P2114**Board Number: B637****High-Throughput drug discovery of novel inhibitors of secretion.**A. Satoh¹, H. Suzuki¹, Y. Honjo², Y. Nishina¹;¹Okayama Univ, Okayama, Japan, ²Hiroshima University, Hiroshima, Japan

Finding new candidate molecules with medicinal properties normally depends on serendipity or investment of time and resources. For example, massive chemical library screenings have successfully identified several new drug candidates. To increase the chances of finding such candidates, we used pooled substrates as starting materials. The pools of substrates, respectively consisting of 11 chemicals and 1 catalyst, underwent multiple chemical reactions, resulting in pools of reactants. These pools were tested in cell-based biological assays for cytotoxicity and secretion. One of the pools was not toxic but exhibited secretion inhibition; therefore, we isolated a compound from the pool showing inhibitory activity. As expected, the compound, termed bis-indole 45, disrupted the Golgi without affecting microtubules. Bis-indole 45 was then compared with known secretion inhibitors, Brefeldin A (BFA) and Golgicide A (GCA), in the following tests. BFA and GCA inhibit secretion by inhibiting the function of an Arf-GEF, GBF1, upon freezing Arf and GBF1 on membranes. Bis-indole 45, however, did not exhibit such an effect. GBF1 recruitment to the Golgi membrane is thought to be mediated by the golgin tether p115 and the small GTPase Rab1. Exogenous expression of a dominant negative mutant of Rab1 but not p115 disrupted GBF1 localization to the Golgi in a manner similar to bis-indole 45. These results suggest that bis-indole 45 inhibits secretion by inhibiting GBF1 recruitment to the Golgi through Rab1. As exemplified in this study, drug screening using pooled substrates can be a powerful and useful method for high-throughput drug discovery.

P2115**Board Number: B638****Quantifying Cell Membrane Morphology Changes with a Biophysical Membrane Model.**R. Tourdot¹, R. Bradley¹, R. Natesan², R. Radhakrishnan²;¹Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA, ²Bioengineering, University of Pennsylvania, Philadelphia, PA

Organelle shapes are defining characteristics of different types of cells and can help regulate their function, with endosomes and the Golgi apparatus being examples of biological topologies with tightly controlled shape and curvature. A special subset of membrane-recruited proteins has recently been shown to sense and/or induce curvature in the bilayer: such proteins include BAR domain containing proteins and the ENTH domain containing proteins. Emerging research has revealed that these curvature-inducing proteins play a role in several critical cell processes ranging from their incorporation into endocytic pits, and localization to sites of invadopodia formation *in vivo*. Mathematical models relating membrane-protein interaction to membrane morphology can provide physical insight into the

driving forces governing curvature induction and morphological changes in the cell membrane. These models of cell membrane elasticity have been used previously to describe the biconcave shape of red blood cells, and large-scale morphological changes of the cell membrane such as cell division. Our work focuses on applying a sub-cellular (mesoscale) model based on the Helfrich formalism for cell membranes to a curvature inducing protein system, and utilizing it in concert with a suite of computational free energy methods to define the free energy landscape of cell-membrane morphology changes. In particular, our model provides novel insight into the critical density of proteins needed for membrane tubulation in invadopodia formation, and the interplay between local tension and curvature generation in vesicle nucleation in endocytosis. Our research finds that protrusions are considerably longer and more stable under low tensions, and these results corroborate recent experimental results comparing cells cultured in 2D and 3D media, where cells in 3D matrices are found to have lower tension and more prominent cell protrusions.

Understanding the factors regulating size and shape of dynamic organelle: an holistic approach.

D. Bhattacharyya^{1,2}, M. Bhave¹;

¹Tata Memorial Centre, Advanced Centre for Treatment, Research and Education in Cancer (ACTREC), Kharghar, Navi Mumbai, India, ²Neurobiology, University of Chicago, Chicago, IL

Size and shape control mechanisms of dynamic organelles are of fundamental importance in basic cell biology. More over several such organelles are known to alter their size and shapes during normal physiological processes as well in diseases especially in cancerous cells and this underlies the importance of the subject. We are presently studying the Golgi apparatus and Nucleus size and shape control mechanism using a combination of cell biology and mathematical modeling. Recently we have shown that the size control mechanism of Golgi apparatus possibly being regulated by altering the cisternal maturation kinetics by ARF1 in budding yeast. Using a genome wide screening approach we have identified several other factors affecting Golgi size. Combining advanced imaging techniques with mathematical simulation based methods we have identified few potential mechanisms through which such regulatory mechanisms may operate. Our results indicate that although size and shape control mechanism may differ for different organelles however there are definitive possibilities of mechanistic similarities in such processes.

P2117**Board Number: B640****Nucleolar size scaling through *C. elegans* growth and development.**S. Uppaluri¹, S.C. Weber¹, C.P. Brangwynne¹;¹Chemical and Biological Engineering, Princeton University, Princeton, NJ

The nucleolus is a non-membrane bound organelle that is the site of ribosome biogenesis and is therefore strongly linked to protein translation and cell growth. Requirements for protein translation vary greatly during *C. elegans* development - from a single-celled embryo through four larval stages to adulthood. How nucleolar size and function varies in the context of multicellular growth remains poorly understood.

We have shown that in the early reductive embryonic cell divisions, nucleoli scale with cell size. Upon hatching and through subsequent larval development we find again that nucleolar size scales with cell size. Altering growth rate, as well as ultimate cell size, through environmental and genetic perturbations leads to the same 'universal' scaling. To elucidate the biophysical mechanism governing nucleolar size, we utilize a custom microfluidic platform to instantaneously change cell volume and nucleolar component concentration. Consistent with a simple phase transition model we find that increasing organelle component concentration leads to larger nucleoli. These results point to a cell-size sensing mechanism through which organelle size is regulated.

P2118**Board Number: B641****A dynamin-like ER-shaping protein and FIT proteins regulate lipid droplet biogenesis in yeast.**N. Ojha¹, V. Choudhary¹, W. Prinz¹;¹NIDDK, National Institutes of Health, Bethesda, MD

Lipid droplets (LDs) are ubiquitous neutral lipid storage organelles. LD biogenesis occurs in the ER but is not well understood. FITs are a conserved family of proteins that have been implicated in LD biogenesis. Yeast has two FIT proteins, called Scs3p and Yft2p. We found that a mutant lacking Scs3p and the dynamin-like GTPase Sey1p have a dramatic growth defect. Sey1p is an orthologue of atlastins and facilitates ER-ER fusion. Cells missing Scs3p and Sey1p were found to have a significant increase in the number of lipid droplets and at least a two-fold increase in neutral lipids, suggesting that these cells may have altered LD biogenesis. Remarkably, we found that LDs in these cells were wrapped by a membrane. We ruled out that these membranes are derived from autophagy but instead are part of the ER. LDs in cells missing Scs3p and Sey1p appear to bud towards the lumen of the ER instead of into the cytosol, which may account for the aberrant membrane wrapping. Together, our findings suggest that Sey1p and Scs3p proteins regulate LD number and LD biogenesis, perhaps by facilitating LD budding from the ER.

P2119**Board Number: B642****Analysis of mitochondrial proteins and their effect on mitochondrial dynamics in *Dictyostelium discoideum*.**L. Woods¹, B.G. Schimmel¹, G.W. Berbusse¹, K. Naylor¹;¹Biology, University of Central Arkansas, Conway, AR

Mitochondrial morphology is maintained by two distinct membrane events -fission and fusion. Altering these conserved processes can disrupt mitochondrial morphology and distribution, thereby disrupting the organelle's functionality and impeding cellular function. In higher eukaryotes, these processes are mediated by a family of dynamin-related proteins (DRP's). In the lower eukaryotes, for instance *Dictyostelium discoideum*, mitochondrial fission and fusion have been implicated but not yet established. To understand the overall mechanism of these dynamics across organisms, we developed an assay to identify fission and fusion events and measure organelle velocity in *Dictyostelium* and to assess the involvement of the mitochondrial proteins, CluA, and two DRPs, DymA and DymB. Using laser scanning confocal microscopy to observe real time movement of fluorescently labeled *Dictyostelium* mitochondria, we show that lower eukaryotes mediate mitochondrial fission and fusion. In *Dictyostelium*, these processes are balanced, occurring approximately 1 event/minute. Quantification of the rates of fission and fusion in *cluA*-, *dymA*-, or *dymB*- strains established that the DRP's are not essential for these processes. Rates of fission and fusion were significantly reduced in *cluA*- cells, indicating that CluA is necessary for maintaining both fission and fusion. Interestingly, loss of DymA significantly increases the velocity of organelle movement within the cell though it does not alter the number of mitochondria moving; while loss of CluA has no effect on velocity, it instead decreases the number of organelles that are motile.

We have successfully demonstrated that *Dictyostelium* mitochondria undergo the dynamic processes of fission and fusion. The classical mediators of membrane dynamics, the DRP's, are not necessary for these dynamics though DymA does affect motility, whereas CluA is necessary for both processes and decreases the percentage of motile organelles. This work contributes to our overall understanding of mitochondrial dynamics and ultimately will provide additional insight into the evolution of these processes.

P2120**Board Number: B643****VAMP7 is a biogenesis of lysosome related organelles complex-1 (BLOC-1) cargo required for pigmentation in melanocytes.**A. Acosta-Ruiz¹, M.K. Dennis¹, R.A. Linares¹, C. Delevoye², G. Raposo², M.S. Marks¹;¹Pathology and Laboratory Medicine, University of Pennsylvania Children's Hospital of Philadelphia, Philadelphia, PA, ²Institut Curie, Paris, France

Melanosomes are lysosome related organelles (LROs) within which melanins are synthesized and stored in pigmented cells. Resident proteins are delivered to nascent melanosomes from early endosomes via membranous transport intermediates in a process that requires Biogenesis of Lysosome Related Organelles Complex-1 (BLOC-1) - a protein complex comprised of subunits that are absent in a subset of patients with Hermansky-Pudlak syndrome. The machinery that mediates fusion of these intermediates with maturing melanosomes is not known. As potential fusion machinery components, we focused on VAMP7 and syntaxin13 (STX13), because depletion of either of these SNARE proteins results in hypopigmentation. In normal pigmented melanocytes at steady state, STX13 localizes to early endosomes and tubules that contact maturing pigmented melanosomes, and VAMP7 localizes primarily to the melanosomes themselves. We thus initially proposed a model wherein BLOC-1-dependent, STX13-positive, endosomal carriers fuse with VAMP7-positive early stage melanosomes. We first found that in BLOC-1-deficient pallid melanocytes, STX13-positive endosomal tubules fail to form, consistent with a critical role for STX13-positive endosomal carriers in protein delivery to melanosomes. However, in these cells a GFP-VAMP7 fusion protein was completely retained within mCherry-STX13-positive endosomes rather than in early stage melanosomes as predicted by our initial model; following "rescue" with myc-tagged Pallidin, GFP-VAMP7 localization was restored to newly pigmented melanosomes that segregated from mCherry-STX13-labeled endosomes. These data suggest that VAMP7 is in fact a cargo of the BLOC-1 pathway and of the STX13-containing transport intermediates. To further test this model, we utilized a novel assay to visualize early events in melanosome biogenesis without the confounding effects of predominant steady state localization to mature melanosomes. We transiently rescued BLOC-1 expression in pallid melanocytes by transfection with myc-tagged Pallidin and monitored changes in the localization of coexpressed GFP-VAMP7 and mCherry-STX13 at various time points following transfection. As predicted by our model, the number of GFP-VAMP7-containing structures that segregated from mCherry-STX13-labeled structures increased over time. Moreover, at intermediate time points following transfection, GFP-VAMP7 could be observed by live cell imaging to traffic within mCherry-labeled tubules towards nascent VAMP7+ puncta. These data support a model wherein BLOC-1-dependent endosomal carriers that contain STX13 and VAMP7 fuse with early stage melanosomes in a process required for pigmentation. We propose that VAMP7 functions as the vSNARE for this fusion event.

P2121**Board Number: B644****ENDOPHILIN RAPIDLY BENDS MEMBRANES TO PROMOTE ENDOCYTOSIS.**K.R. Poudel¹, J. Bai¹;¹Fred Hutchinson Cancer Research Center, Seattle, WA

Synaptic Vesicle (SV) endocytosis is responsible for generating synaptic vesicles at the presynaptic terminals. To sustain high-frequency brain activities, endocytosis must act rapidly to regenerate SVs, which prevents vesicles from depletion. Endophilin is a synaptic protein that plays critical role in promoting SV endocytosis. Endophilin contains a Bin–Amphiphysin–Rvs (BAR) domain that has been shown to bend flat membranes into highly curved tubules in vitro. Our recent findings demonstrate that the membrane-bending activity is required for endophilin's function in vivo. Here, we perform biophysical analyses to investigate molecular mechanisms for endophilin to generate membrane curvature. Our preliminary results show that the endophilin BAR domain is an active membrane bender instead of a passive sensor. These results will help us to understand how endophilin acts to support SV endocytosis in neurons.

P2122**Board Number: B645****Three dimensional architecture of Extended-Synaptotagmin-mediated ER-plasma membrane contact sites.**R. Fernandez-Busnadiego¹, Y. Saheki¹, P. De Camilli¹;¹Department of Cell Biology, Howard Hughes Medical Institute, Program in Cellular Neuroscience, Neurodegeneration and Repair, Yale University School of Medicine, New Haven, CT

Growing evidence suggests that the close apposition between the endoplasmic reticulum (ER) and the plasma membrane (PM) plays important roles in Ca²⁺ homeostasis, signaling and lipid metabolism. The Extended Synaptotagmins (E-Syts/Tricalbins in yeast) are ER-anchored proteins that mediate the tethering of the ER to the PM. E-Syt cytoplasmic domains comprise an SMP domain followed by five C2 domains in the case of E-Syt1 and three C2 domains for E-Syt2/3. Here, we used cryo-electron tomography to study the 3D architecture of E-Syts-mediated ER-PM contacts at molecular resolution. We show that, in vitrified frozen-hydrated mammalian cells overexpressing individual E-Syts, ER-PM distance (19-22 nm) correlates with the amino acid length of the cytosolic region of E-Syts (i.e. the number of C2 domains). We further show that the levels of cytosolic Ca²⁺ regulate ER-PM distance at E-Syt1-dependent contacts sites. E-Syt-mediated contacts displayed a characteristic electron-dense layer between the ER and plasma membranes. In contrast, at STIM1-Orai1-mediated contacts the gap between ER and PM was spanned by filamentous structures perpendicular to the membranes. These two types of ER-PM contacts were also observed in the native context of untransfected neurons. Thus, our results define specific ultrastructural features of E-Syts-dependent ER-PM contacts and reveal their

structural plasticity, which may impact on specific E-Syt functions and the cross-talk between the ER and the PM.

Regulated by mitochondrial fusion dynamics, lipid droplets serve as central fatty acid conduit to supply mitochondria with fatty acids for oxidation during nutrient stress.

A. Rambold¹, S. Cohen², J. Lippincott-Schwartz²;

¹Max-Planck-Institute-IE, Freiburg, Germany, ²Cell Biology and Metabolism Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD

Cells must adapt their metabolism to changing nutrient and environmental conditions in order to survive. One key adaptation occurs during nutrient deprivation when cells reprogram their metabolism from glucose to mitochondrial fatty acid oxidation for maintaining cellular energy levels. Although it is well known that endogenous fatty acids act as major energy substrate during nutrient stress, from where and how such fatty acids are mobilized and selectively trafficked to mitochondria without causing damage to membranes and acting as toxic bioactive lipids is a major question. Using a novel imaging based approach to visualize fatty acid trafficking in live cells in combination with metabolic profiling experiments, we revealed that lipid droplets, specialized lipid storage organelles, serve as selective conduit to direct fatty acids into mitochondria for oxidation. We found that fatty acid recycling by bulk autophagy of cellular membranes helped replenish lipid droplets with fatty acids, increasing lipid droplet number over time. From lipid droplets, fatty acids were subsequently liberated by cytoplasmic lipases, and efficiently transferred into mitochondria. Surprisingly, we found that this transfer step required mitochondria to both be localized near lipid droplets and highly fused. Mitochondrial fusion increased the connectivity to lipid droplets and promoted mitochondrial fatty acid distribution and oxidation. When mitochondrial fusion was prevented in cells lacking the major fusion proteins mitofusin 1 or optic atrophy protein 1, fatty acids neither homogeneously distributed within mitochondria nor became efficiently metabolized. Instead, these morphodynamic defects caused massive alterations in cellular fatty acid routing. Not only were non-metabolized fatty acids redirected to and stored in lipid droplets, they became excessively expelled from cells. Together this study highlights the importance of coordinated organelle dynamics to direct cellular fatty acid flow and oxidation during nutrient stress. Given that fatty acids and their derivatives play important roles in regulating cellular signaling cascades in metabolism and inflammatory responses, future work studying the multi-organelle controlled fatty acid flux system described here might be of high potential for contributing to our understanding of the pathophysiology of lipid-associated diseases, such as obesity, diabetes, cancer and inflammatory disorders.

P2124**Board Number: B647****Mastoparan causes mitochondrial permeability transition not by interacting with specific proteins, but by interacting with the phospholipid phase.**T. Yamamoto¹, M. Ito^{1,2}, K. Kuwahara^{1,2}, K. Kageyama^{1,2}, K. Yamashita³, Y. Takiguchi², H. Terada⁴, Y. Shinohara^{5,6};

¹Institute for Genome Research, University of Tokushima, Tokushima City, Japan, ²Faculty of Pharmaceutical Sciences, University of Tokushima, Tokushima City, Japan, ³School of Dentistry, University of Tokushima, Tokushima City, Japan, ⁴Faculty of Pharmaceutical Sciences, Niigata University of Pharmacy and Applied Life Sciences, Niigata City, Japan, ⁵Faculty of Pharmaceutical Science, University of Tokushima, Tokushima, Japan, ⁶Institute for Genome Research, University of Tokushima, Tokushima, Japan

Mitochondrial permeability transition causes the release of various proteins from mitochondria, and the released proteins trigger subsequent steps of apoptosis and necrosis. Permeability transition is believed to result from the formation of a proteinaceous pore, but the molecular mechanisms have not yet been revealed. The mastoparan peptide is a tetradeca-peptide isolated from the venom of wasp. Mastoparan is known as an inducer of the mitochondrial permeability transition. Although mastoparan was suggested to interact with a proteinaceous target in mitochondria to induce this transition, the action sites of mastoparan have not yet been investigated. To clarify whether specific interactions of mastoparan with receptors or enzymes are associated with the induction of this permeability transition, we here examined the effects of D-isomeric peptides, which were synthesized by using D-amino acids assembled in endogenous (inverso mastoparan) and reverse (retro-inverso mastoparan) orientations. When we added inverso mastoparan to isolated mitochondria, the peptide caused the permeability transition in a partially cyclosporin A-sensitive manner at lower doses and in a cyclosporin A-insensitive manner at higher ones. The action manners and the potencies of inverso mastoparan were close to those of parent mastoparan, indicating that the targets of mastoparan for induction of the permeability transition were neither receptors nor enzymes in the mitochondria. Retro-inverso mastoparan also had the same effect on the mitochondria as mastoparan, but the potencies of the effect were weaker. Not only on mitochondria but also on phospholipid vesicles, mastoparan and inverso mastoparan showed massive permeabilization effects at the same potencies, but retro-inverso mastoparan showed weaker ones. These results indicate that mastoparan interacted with the phospholipid phase of the mitochondrial membrane, not with specific proteins, to induce the permeabilization in cyclosporin A-sensitive manner and -insensitive manners.

P2125**Board Number: B648****Lipid-mediated interactions of the mitochondrial presequence translocase.**K. Malhotra¹, N. Alder¹;¹Molecular and Cell Biology, University of Connecticut, Storrs, CT

Following the original endosymbiotic event, nearly all of the genes that encode mitochondria-resident proteins have been transferred to nuclear DNA. As a result, the biogenesis of mitochondria is dependent on the efficient import of nuclear-encoded proteins to its different sub-organellar compartments, carried out by the protein translocases present in its two membranes. The inner membrane of mitochondria is a highly protein-rich biomembrane, where the lipid molecules are known to modulate protein structure and function, hence affecting mitochondrial processes. This is probably best exemplified by cardiolipin, the signature phospholipid of mitochondria, which regulates numerous mitochondrial functions, from ATP production to cell death. The Translocase of the Inner Mitochondrial Membrane 23 (TIM23) mediates both the transport of nuclear-encoded precursor proteins across the inner membrane and the lateral integration of membrane proteins. The initial steps during precursor protein transport are largely mediated by the interaction between the central component of the TIM23 Complex, Tim23, and its receptor partner, Tim50. The lipid dependence of the functional interactions of subunits within this translocase have largely remained unknown. Using the Tim23 channel reconstituted into soluble nanoscale bilayers (nanodiscs) and site-specific chemical crosslinking, we show for the first time that the interaction between the co-receptor Tim50 and the channel region of Tim23 protein, is mediated by cardiolipin. To confirm the cardiolipin-dependent interactions of the mitochondrial preprotein translocase seen in this model-membrane system, we employ a host of cardiolipin variant yeast strains, to study interactions between Tim23 and Tim50 within active mitochondria. Further, by performing liposome binding studies combined with Molecular Dynamics simulations, we show that the soluble domain of Tim50 interacts specifically with cardiolipin containing membranes, and specific residues in the β -hairpin loop are required for mediating the interaction. Moreover, our study suggests that the interaction between Tim50^{IMS} and cardiolipin is accompanied by secondary structural changes in the soluble domain of the co-receptor. By allowing the study of membrane proteins using solution-based biophysical techniques combined with *in organello* and *in silico* work, this system offers unprecedented insights into the early stages of Tim23-mediated protein import.

P2126**Board Number: B649****Proper inheritance of mitochondrial content is maintained in budding yeast cells with mitochondrial dysfunctions.**I.A. Mueller¹, M.P. Viana¹, S. Rafelski²;¹Developmental and Cell Biology, University of California Irvine, Irvine, CA, ²Developmental and Cell Biology, University California-Irvine, Irvine, CA

The inheritance of mitochondria from mother to bud is asymmetric and highly regulated in budding yeast, *Saccharomyces cerevisiae*. The mitochondrial-volume-to-cell-volume ratio (mitochondrial volume ratio) is higher in buds compared to mothers at the time of division and is normally maintained independent of the mother's mitochondrial content. Mitochondrial inheritance depends not only on the redistribution of mitochondria between mother and bud but also on mitochondrial biogenesis. Mitochondrial biogenesis requires mitochondrial membrane potential, an indicator of mitochondrial functionality, for protein import into the organelle. Consequently, mitochondrial function should play a pivotal part in proper mitochondrial inheritance, but the exact role of mitochondrial function in mitochondrial inheritance has yet to be investigated. We sought to determine whether mitochondrial dysfunctions of different severities impact mitochondrial inheritance in budding yeast. Mitochondrial dysfunctions were introduced by deletion of cytochrome c oxidase subunit 6 (Δ COX6), inducing loss of respiratory function, or by deletion of mitochondrial DNA polymerase MIP1 (Δ MIP), resulting in loss of respiratory function and ultrastructural alterations. Live-cell, 3D light microscopy images of fluorescently labeled mitochondria of wild type, Δ COX6 and Δ MIP cells were analyzed using our quantitative imaging analysis (MitoGraph) approach to determine mitochondrial tubular width and content at the time of division. Visually, the mitochondrial network morphology in Δ COX6 cells is "wild type-like", while the mitochondrial network of Δ MIP cells is characterized by regionally collapsed and clustered tubules. Mitochondrial tubules are 3% narrower in Δ COX6 cells and 7% narrower in Δ MIP cells compared to wild types ones, suggesting ultrastructural alterations occur in both deletion mutants but are more pronounced in Δ MIP cells. Mitochondrial volume ratio is higher in Δ COX6 and Δ MIP buds compared to their mothers, and more importantly the mitochondrial volume ratio of mutant buds is maintained compared to wild type buds at the time of division. This suggests that asymmetric, actively regulated mitochondrial inheritance is not affected in cells with loss of mitochondrial respiratory function and ultrastructural alterations. Interestingly, the total mitochondrial volume ratio of Δ COX6 cells (mother and bud) is lower compared to wild type cells despite the mitochondrial volume ratio of the bud being maintained, implying problems in mitochondrial biogenesis in Δ COX6 cells. Further studies will determine why total mitochondrial volume ratio is reduced in Δ COX6 but not in Δ MIP cells, even though Δ MIP cells should have more severe alterations in organelle functionality and thus biogenesis.

P2127**Board Number: B650****Extracts from *Alpinia galanga* mediate mitochondria dynamics.**C. Lo¹, C. Chiu², C. Chang²;¹Department of Food Science, National Chiayi University, Chiayi, Taiwan, ²The Institute of Biotechnology, National Tsing Hua University, HsinChu, Taiwan

Mitochondria are highly dynamic organelles with continuous fission and fusion. The dynamics of mitochondria is linked to mitochondrial function and cell metabolism. More and more evidence has indicated that mitochondria dynamics respond to different environmental stress. *Alpinia galanga* has been used as a food spice as well as folk medicine. Curcuminoids purified from *A. galanga* were known to have cytotoxic effects on human leukemic cells and may induce apoptosis through a combination of mitochondrial and endoplasmic reticulum stress pathways. Thus, we aim to clarify whether the extracts from *A. galanga* affect mitochondrial dynamics. Our results demonstrated that treating cervical cancer cells with curcuminoids from *A. galanga* changed mitochondrial morphology and function. These results suggest that curcuminoids from *A. galanga* can be used to further dissect the regulatory pathways of mitochondria dynamics.

P2128**Board Number: B651****Ordered partitioning and constant replication ensure mitochondrial DNA maintenance.**R. Jajoo¹, M.P. Viana², S. Rafelski³, M. Springer¹, J. Paulsson¹;¹Department of Systems Biology, Harvard Medical School, Boston, MA, ²Developmental and Cell Biology, University of California Irvine, Irvine, CA, ³Developmental and Cell Biology, University of California-Irvine, Irvine, CA

Mitochondrial DNA (mtDNA) is located in the mitochondrial matrix and is essential for normal eukaryotic cell function. Like nuclear DNA, mtDNA cannot be created *de novo* and must be accurately replicated and partitioned at each cell division. Unlike nuclear DNA, mtDNA has an endosymbiotic origin, varies in copy number, and does not encode its own replication machinery, complicating its maintenance. Here we uncover the partitioning and replication strategies of mtDNA in the fission yeast *Schizosaccharomyces pombe* by counting mtDNA clusters (nucleoids) in single dividing cells. We find that nucleoids are segregated with half the error expected by “random” binomial partitioning, ensuring that most cells have similar numbers of mitochondrial nucleoids and that mtDNA is rarely lost by any cell. By measuring nucleoid partitioning in mutants that divide asymmetrically, we find that this accuracy is achieved by evenly distributing mitochondria throughout the cytoplasmic volume. Finally, by counting nucleoids at the beginning and end of the cell cycle, we show that the nucleoid replication rate is independent of the number of nucleoids present. Therefore, it appears that mitochondrial nucleoids

avoid the instability inherent in self-replication by ceding replication control to the host cell. In total, mtDNA avoids being lost through a combination of ordered partitioning and constant replication.

Novel mitochondria-microtubule crosstalk regulates mitochondrial biogenesis and morphology.

V. Jayashankar¹, J. Aiken², S. Rafelski³, J.K. Moore⁴;

¹University California-Irvine, Irvine, CA, ²Univ Colorado Sch Med, Aurora, CO, ³Developmental and Cell Biology, University California-Irvine, Irvine, CA, ⁴Cell and Development, University of Colorado School of Medicine, Aurora, CO

Mitochondrial homeostasis requires a complex coordination of biogenesis, organization, function, dynamics, and inheritance. Here we identify novel regulation of mitochondrial homeostasis mediated by cross talk with tubulin proteins. We previously conducted a genome wide screen to identify genetic interactions for mutants of yeast α - and β -tubulins that lack negatively charged carboxy-terminal tail regions (CTTs), which project from the microtubule surface. We uncovered a number of mitochondrial genes, including genes involved in biogenesis, morphology, and inheritance. This suggested a role for tubulin CTTs in regulating mitochondrial homeostasis; especially surprising because the actin network in yeast drives mitochondrial transport. To test the hypothesis that tubulin CTTs are important for mitochondrial homeostasis, we imaged live mutant yeast cells using spinning-disk confocal microscopy and quantified the mitochondrial networks in 3D using our MitoGraph image processing method. We found that mutants lacking α -CTT contain fewer, less branched mitochondria resulting in a 20% decreased mitochondrial to cell volume ratio compared to WT cells. This suggests that α -CTTs are required to maintain mitochondrial content, most likely by regulating mitochondrial biogenesis pathways. α -CTT mutant cells also display wider, swollen mitochondrial tubules in respiring cells. This suggests that α -CTT mutant cells may have altered internal ultrastructure organization, which we are verifying by electron microscopy. These phenotypes are unique to α -CTT – mutants lacking β -CTT contain normal mitochondrial content, but have misshapen and occasionally aggregated tubules. Furthermore, cell growth rate and mitochondrial membrane potential are not affected in respiring α -CTT mutant cells, indicating that mitochondria remain functional, despite defects in content and morphology. To define the role of α -CTT in mitochondrial biogenesis and morphology, we examined the sequence features of α -CTT that are necessary for function. We find that α -CTT function can be rescued by mutants that lack negatively charged residues in α -CTT or by replacing α -CTT with the longer, and more negatively charged, β -CTT. These data suggest that α -CTT function depends on the length of the tail, but not its charge. We are currently investigating the molecular mechanisms behind tubulin-CTT regulation of mitochondrial biogenesis and morphology.

P2130**Board Number: B653****Regulation of Mitochondrial Release from Microtubules during Cell Division.**J. Chung^{1,2,3}, J.A. Steen², T.L. Schwarz^{2,3};¹Biological and Biomedical Sciences, Harvard Medical School, Boston, MA, ²The F.M. Kirby Neurobiology Center, Boston Children's Hospital, Boston, MA, ³Department of Neurobiology, Harvard Medical School, Boston, MA

During mitosis, daughter cells depend on proper inheritance of both chromosomes and organelles. Cytoskeletal rearrangement during mitosis is therefore accompanied by changes in organelle behavior and organelle interactions with the cytoskeleton. The mechanism behind ER, Golgi apparatus, and nuclear envelope regulation have been examined, but to date, the mechanism behind mitochondrial redistribution and inheritance remains unknown. During interphase, mitochondria move along microtubules via a motor-adaptor complex, consisting of Miro (also called RhoT1/2), which localizes to the mitochondrial outer membrane; the adaptor protein Milton (also called Trak1/2); and the conventional Kinesin-1 Heavy Chain and Dynein motors. During interphase, most of a cell's mitochondria are therefore closely associated with microtubules. However, as the cell enters mitosis, the mitochondria detach from microtubules and do not appear to associate with either the spindle apparatus or astral microtubules. In HeLa and COS cells, mitotic mitochondria reside primarily in a ring towards the periphery of the cells, do not overlap the spindle, and remain unattached to microtubules until late in anaphase. We have found that mitochondrial disassociation is a consequence of the detachment of the kinesin and dynein motor proteins from their adaptors Miro and Milton. Attaching motors onto mitochondria independent of Miro and Milton mislocalizes the mitochondria onto the mitotic spindle, subsequently causing mitochondrial inheritance and spindle orientation defects. Furthermore, *in vitro* kinase and phosphatase assays determined that motor release is caused by CDK1 phosphorylation of mitochondrial proteins. An attractive target may be the motor adaptor Milton. We have found that Milton is highly phosphorylated and consequently exhibits a cell-cycle dependent band shift on western blots. Milton phosphorylation is a likely trigger for the shedding of the motor proteins from the mitochondrial surface and consequent dissociation of mitochondria from mitotic microtubules. The dissociation of mitochondria from mitotic microtubules is likely to be important for proper inheritance of chromosomes and mitochondria.

P2131**Board Number: B654****Inner membrane fusion mediates spatial distribution of axonal mitochondria.**Y. Yu¹, H. Lee¹, J. Suhan¹, G. Yang¹;¹Carnegie Mellon University, Pittsburgh, PA

The morphological and motility dynamics of mitochondria are striking. It is thought that mitochondrial motility is important for mediating the spatial distribution of the organelle in neurons. However, whether and, if so, how morphological dynamics play a role in mediating axonal mitochondrial distribution is unclear. To address this question, we analyzed the relations between mitochondrial inner membrane fusion and the spatial distribution of axonal mitochondria. We used *Drosophila* larval motor neurons axons as the model system. We collected time lapse images of mitochondria in proximal and distal axon regions. For each mitochondrion, we characterized its movement and shape, which allowed us to perform correlation analysis between the two dynamic processes. We found that knockdown of mitochondrial inner membrane protein dOpa1 led to fragmentation of both stationary and moving mitochondria, with stationary mitochondria affected more substantially. We characterized mitochondrial morphological dynamics in larval motor neuron axons, confirmed that mitochondria underwent frequent fusion and fission in axons. Loss of dOpa1 blocked axonal mitochondrial fusion and reduced fission. Furthermore, we analyzed mitochondrial shape, movement and localization in different regions along the axon. We found that dOpa1 deficiency disrupted spatial distribution of axonal mitochondria. Mitochondria failed to localize to the distal axon regions, but accumulated in the proximal axon regions in dOpa1 knockdown axons. Together, our data revealed a strong connection between mitochondrial inner membrane fusion and spatial distribution.

P2132**Board Number: B655****TRPM2 channels regulate organelle zinc homeostasis and mitochondrial fragmentation.**N. Abuarab^{1,2}, J. Li¹, L. Jiang¹, A. Sivaprasadarao¹;¹Multidisciplinary Cardiovascular Research Centre, School of Biomedical Sciences, University of Leeds, Leeds, United Kingdom, ²College of Medicine, King Saud Bin Abdulaziz University for Health Science-National Guard Hospital, Jeddah, Saudi Arabia

Mitochondria play a central role in oxidative stress induced cell death. By increasing the production of reactive oxygen species, such as H₂O₂, oxidative stress causes mitochondrial fragmentation and apoptosis. Here we hypothesised that Transient Receptor Potential Melastatin 2 (TRPM2) channels play a role in mitochondrial fragmentation. The rationale behind this is the previous evidence that TRPM2 channels are activated by H₂O₂ and conduct ions (Ca²⁺ and Zn²⁺) that affect mitochondrial health and cell survival. To test our hypothesis we have used human umbilical vein endothelial cells (HUVECs). Using FluoZin-3, we demonstrate the presence of free Zn²⁺ in lysosomes, but no detectable free Zn²⁺ in

other compartments of the cell. Exposure of HUVECs to H₂O₂ (1 mM) or high glucose (33 mM) conditions led to lysosomal membrane permeability (LMP), resulting in a marked decrease in lysosomal Zn²⁺ and, interestingly, redistribution of Zn²⁺ to mitochondria. The resultant rise in mitochondrial Zn²⁺ led to extensive mitochondrial fragmentation, mitochondrial outer membrane permeabilisation and cell death. Importantly, release of lysosomal Zn²⁺ was dependent on Ca²⁺ entry through the plasma membrane TRPM2 channels. Silencing of TRPM2 channels with siRNA prevented intracellular Zn²⁺ redistribution, mitochondrial fragmentation and cell death. We found that H₂O₂ causes mitochondrial fragmentation by promoting the recruitment of dynamin-related protein 1 (Drp-1, a mitochondrial fission protein) to mitochondria. TRPM2 siRNA and the Zn²⁺ chelator, TPEN (N,N,N',N'-tetrakis (2-pyridinylmethyl)-1,2-ethanediamine), inhibited Drp-1 recruitment as well as mitochondrial fragmentation. Taken together, our data imply a novel mechanism for how oxidative stress leads to excessive mitochondrial fragmentation and cell death: The mechanism involves activation of TRPM2 channels leading to increased Ca²⁺ entry, translocation of lysosomal Zn²⁺ to mitochondria, Drp-1 recruitment to mitochondria, mitochondrial fragmentation and finally cell death. The physiological relevance of TRPM2 role was established by the demonstration that TRPM2 siRNA inhibits mitochondrial fragmentation in human endothelial cells induced by hyperglycaemic (diabetes) conditions. Since mitochondrial fragmentation is associated with several age-related chronic illnesses including neuronal (Alzheimer's, Parkinson's), cardiovascular (atherosclerosis, myocardial infarction) and metabolic/inflammatory (diabetes) disorders, our results reveal TRPM2 channel as a novel target that could be explored for therapeutic intervention of age-related illnesses.

The work is funded by King Saud Bin Abdulaziz University for Health Science-National Guard Hospital and the British Heart Foundation.

Cardiolipin phase transition induced by Dynamin-related protein 1 promotes mitochondrial membrane fission.

N. Stepanyants¹, P. Macdonald¹, R. Ramachandran¹;

¹Physiology and Biophysics, Case Western Reserve University, Cleveland, OH

Cardiolipin is a unique, dimeric phospholipid essential for mitochondrial dynamics in eukaryotic cells. Here, using model membranes and a variety of novel fluorescence spectroscopic and microscopic techniques, we show that the mitochondrial fission GTPase, dynamin-related protein 1 (Drp1) associates with sequestered but uncomplexed cardiolipin molecules at the mitochondrial surface and reorganizes them in a nucleotide-dependent manner upon helical self-assembly. We demonstrate further that Drp1-mediated cardiolipin reorganization results in the lipid's rapid phase transition from a lamellar phase to the non-lamellar, inverted hexagonal phase. GTP-dependent cardiolipin phase transition effected by Drp1 results in the formation of localized membrane constrictions that become predisposed for fission. We propose that Drp1 thus catalyzes mitochondrial division.

P2134**Board Number: B657****Spire1C promotes actin- and ER-mediated mitochondria constriction and fission.**U. Manor¹, S. Bartholomew², H. Higgs³, J.A. Spudich², J. Lippincott-Schwartz^{4,5};¹Cell Biology and Metabolism, NIH/NICHD, Bethesda, MD, ²Stanford University, Stanford, CA,³Department of Biochemistry, Geisel School of Medicine at Dartmouth College, Hanover, NH,⁴Physiology Course at Marine Biological Laboratory, Woods Hole, MA, ⁵Cell Biology and Metabolism Program, NICHD, NIH, Bethesda, MD

Mitochondria must regularly undergo fission in order to maintain proper cellular health; impaired mitochondria fission can lead to a plethora of diseases ranging from cancer to neurodegeneration. The molecular mechanism by which mitochondria fission is coordinated with the rest of the cell remains unclear, although a role for actin polymerization has been previously implicated. Recent work suggests that the endoplasmic reticulum (ER) induces mitochondria constriction as a necessary step for mitochondria fission; it is thought that this constriction enables Drp1, a dynamin-related GTPase protein, to oligomerize into a helical ring around mitochondria and induce membrane scission at these constriction sites. This model was corroborated by later work, which showed that the actin-polymerization activity of the ER-anchored formin protein INF2 enhances mitochondria constriction and fission. However, the specific mechanism by which INF2 and actin is recruited to and activated at mitochondria fission sites is unknown. Here we show that a previously undiscovered alternate splice isoform of the actin-nucleating, formin-binding Spire protein localizes to mitochondria. Using structured illumination microscopy and the fluorescence protease protection assay (FPP), we show that this novel isoform, Spire1C, localizes to the mitochondrial outer membrane. Using the FPP assay, we also show that the exon unique to this isoform inserts through the mitochondrial outer membrane with the N-terminal side facing the cytoplasm, and the C-terminal side facing the mitochondrial lumen, and that it binds to cardiolipin. We also found that Spire1C N-terminal KIND domain binds to the C-terminal half of INF2 in vitro, and that removing the KIND domain from Spire1C strongly inhibits mitochondria constriction and fission, whereas overexpression of Spire1C enhances constriction and fission. Disrupting Spire1C actin-nucleating ability similarly disrupts mitochondria fission. While overexpression of a Spire1C KIND domain deletion mutant results in decreased association between mitochondria and the ER, overexpression of full length Spire1C increases association between ER-anchored INF2 and mitochondria. Interestingly, overexpression of the KIND domain deletion mutant did not disrupt Drp1 localization to mitochondria, suggesting that the prior step of constriction is required for proper Drp1-mediated mitochondria fission. These results strongly suggest that Spire1C facilitates coordination of the ER and actin to enhance mitochondria fission. These results show, for the first time, that two halves of an actin-regulatory complex can reside at the interface between the membranes of two different organelles, thereby presenting a novel mechanism by which cellular organelles can communicate with and shape one another via the actin cytoskeleton.

P2135**Board Number: B658****Dynamin-related protein 1 (Drp1), inhibited by its A-insert, utilizes mitochondrial fission factor (Mff) as a GTPase-activating protein (GAP).**P. Macdonald¹, N. Stepanyants¹, L. Lehman¹, A. Baglio^{1,2}, R. Ramachandran¹;¹Physiology and Biophysics, Case Western Reserve University, Cleveland, OH, ²Case Western Reserve University, Cleveland, OH

Eight different isoforms or splice variants of the mitochondrial fission GTPase, dynamin-related protein 1 (Drp1) arise from alternative splicing of its single gene-encoded pre-mRNA transcript. Of these, the longest isoform of Drp1 bears a unique stretch of amino acid residues within its GTPase domain termed the "A-insert", whose function is yet not known. By comparing the properties of this neuronally enriched isoform with that of the ubiquitously expressed Drp1 isoform in which this sequence is absent, the role of the A-insert in Drp1 function is revealed. Utilizing a variety of biochemical and biophysical measures, we find that the A-insert auto-inhibits Drp1's helical self-assembly as well as cooperative GTPase activity over mitochondrial membranes, without impairing GTP binding, thus necessitating the requirement for an external GTPase-activating protein (GAP) to relieve this auto-inhibition. The MOM-integrated Drp1 adaptor protein, mitochondrial fission factor (Mff), fulfills such a role by selectively, and potently, stimulating the longest Drp1 isoform's GTPase activity independent of its interaction with the consensus mitochondrial target lipid, cardiolipin (CL). Thus, Mff functions selectively as a GAP for A-insert-auto-inhibited Drp1.

P2136**Board Number: B659****Mitochondrial remodeling protein Opa1-like influences *Drosophila* epithelial tissue homeostasis and stem cell maintenance.**S. Banerjee¹;¹Department of Biological Sciences, Tata Inst Fundamental Res, Mumbai, India

Mitochondrial remodeling proteins with conserved functions in regulating fusion and fission, have a role in implicating cellular/tissue homeostasis and are thus of immense interest. Mitochondrial remodeling proteins like Dynamin related protein-1 (Drp1), Mitofusin-2 (Mfn-2) and Optic atrophy1 (OPA1) have been shown to be involved in cellular homeostasis and stem cell differentiation. I'm interested in understanding the implication of changes in mitochondrial morphology has on tissue homeostasis. Here, using proteomics approach, we identified bonafide and unknown interactors of *Drosophila* Optic atrophy1-like (Opa1-like) such as *Drosophila* Mitofilin (dMitofilin), Mitochondrial assembly regulatory factor (Marf), Rhomboid-7 (Rho-7) along with novel interactors like Mortalin ortholog (Hsc70-5). Further, we showed how Opa1-like influences mitochondrial morphology through interaction with

'mitochondria-shaping' proteins like Marf (Mitofusin ortholog in *Drosophila*) and dMitofilin. Depletion of *hsc70-5* in peripodial cells, yields fragmented, dysfunctional mitochondria (with Opa1-like being proteolysed) that were susceptible to degradation leading to induced lysosome-mediated cell death. Similar phenotype was observed in *hsc70-5* knockdown precursor stem cells (AMPs-Adult Midgut Progenitors) of larval gut which were reversed by changing the mitochondrial morphology via manipulation of mitochondrial remodeling proteins. To understand the significance of death of AMPs that bring about altered tissue behavior and homeostasis, I investigated the role for mitochondrial remodeling proteins in maintaining adult midgut stem cell niche. *Drosophila* adult midgut homeostasis is maintained by Intestinal Stem Cells (ISCs) that divide to form diploid progenitors known as enteroblasts (EBs) which further differentiate into enteroendocrinal (ee) cells and enterocytes (ECs). Depletion of those proteins that regulate mitochondrial morphology and metabolism in ISC/EB cells resulted in fragmented mitochondria with increased number of ee cells and clustered EBs, a hallmark of Notch activity deficient gut. Moreover, these depletions led to increased ROS-induced hyper-proliferation of ISCs along with hyper-activation of EGFR signaling and early-onset of intestinal hyperplasia. Both hyper-proliferation and hyper-activation of EGFR requires Yorkie function. Finally, using genetic epistasis and clonal analysis, I demonstrated that Opa1-like gain of function reverses the cytological dysregulation through change in mitochondrial morphology. Thus, mitochondrial role in the maintenance of adult fly gut stem cell niche cross-talks with that of Notch and Hippo-EGFR pathways. These findings uncover a role for mitochondrial remodeling leading to cell growth/death in tissues.

Structure and dynamics of Miro, a target for PINK1/Parkin signaling of mitochondrial autophagy.

S.E. Rice¹, J. Klosowiak¹, S. Park¹, K.P. Smith¹, M.C. Gonzalez¹, P.J. Focia², D.M. Freymann²;

¹Department of Cell and Molecular Biology, Northwestern University, Chicago, IL, ²Biochemistry, Northwestern University, Chicago, IL

The outer mitochondrial membrane protein Miro is a highly conserved calcium-binding GTPase that is a key player in regulating mitochondrial shape, movement, organelle interactions, and degradation. We solved and published an X-ray crystal structure of a *Drosophila* Miro fragment containing the EF hand and C-terminal GTPase domains (termed EF-cGTPase). This is the first protein structure containing interacting EF hand and GTPase domains. The structure reveals putative PINK1 kinase phosphorylation sites and Parkin-ubiquitinated sites in and near the interface between Miro's EF hand region and the C-terminal GTPase domain. We have new data suggesting that this interface is highly dynamic. While full-length constructs of both *Drosophila* Miro and human Miro-1 are monomeric, an isolated fragment of the human Miro-1 C-terminal GTPase (cGTPase) forms a homo-dimer. We observed this homo-dimer formation using analytical SEC-MALS, SAXS, and in new X-ray crystal structures that our lab has solved. Interestingly, the interface between the dimerized cGTPase proteins is in the same region as the EF hand-GTPase interface in our previous EF-cGTPase structure. It is possible that the EF hand/C-terminal

GTPase interaction and/or dimerization of the C-terminal GTPase may protect Miro from ubiquitination until it becomes phosphorylated by PINK1 kinase. These data are beginning to provide a structural basis for Miro-dependent PINK1/Parkin signaling of mitochondrial autophagy.

The mitochondrial peptidase subunit alpha defines PINK1 alternative mitochondrial import route.

K. Grenier¹, N. Shahrzad¹, J. Xiong¹, S. Nobile¹, M. Kontogianna¹, E.A. Fon¹;

¹Neurology and Neurosurgery, McGill University, Montreal, QC

PINK1, a Parkinson's disease associated gene encoding a mitochondrial kinase, in concert with *Parkin*, another PD gene that encodes an E3 ubiquitin ligase, mediate the autophagy of damaged mitochondria. Loss of the mitochondrial membrane potential, defects in mitochondrial import and the activation of the mitochondrial unfolded protein response are stimuli that lead to PINK1 stabilization on the outer mitochondrial membrane, which in turn recruits Parkin from the cytosol to the mitochondria in order to initiate mitophagy. In healthy cells, PINK1 is processed by multiple proteases in the mitochondria followed by proteasomal degradation in the cytosol by the N-end rule pathway. However, the specific manner and route by which PINK1 is imported and degraded remains to be clarified. We have recently shown that PINK1 also accumulates at the mitochondrial outer membrane following the partial depletion of the catalytic, β subunit of the mitochondrial processing peptidase (MPP). Indeed, MPP β knockdown recapitulates the main features of PINK1/Parkin-dependent mitophagy induced by chemical uncouplers. Here, we report that PINK1 contains an N-terminal MTS that is processed directly by MPP both *in vitro* and *in vivo*. Moreover, we show that the regulatory subunit MPP α , is required for PINK1 insertion and accumulation at the outer mitochondrial membrane both upon MPP β knockdown and mitochondrial depolarization but is not necessary for canonical PINK1 import to the inner mitochondrial membrane. Taken together, our works positions MPP α as a key regulator of PINK1 import, required to divert PINK1 to the outer mitochondrial membrane and to initiate parkin-dependent mitophagy in response to insults that compromise mitochondrial health.

P2139**Board Number: B662****Parkin regulates the activity of MiTF/TFE transcription factors independent of mTORC1 during mitophagy.**C. Nezhich^{1,2}, A.I. Fogel¹, C. Wang¹, R.J. Youle¹;¹NINDS, NIH, Bethesda, MD, ²MRC Mitochondrial Biology Unit, University of Cambridge, Cambridge, United Kingdom

Loss-of-function mutations in the mitochondrial kinase PINK1 and the cytosolic E3 ligase Parkin cause the majority of early-onset familial Parkinson's disease cases. Together, PINK1 and Parkin regulate a quality-control pathway, termed mitophagy, which selectively eliminates damaged mitochondria by autophagosome-dependent lysosomal degradation. Coordinated expression of autophagy and lysosomal genes is regulated by the transcription factor TFEB; however, TFEB has yet to be linked to mitophagy. Because mitophagy requires robust lysosomal function, we sought to understand the molecular link between mitophagy and lysosomal biogenesis. Here, we show that during mitophagy TFEB translocates from the cytosol to the nucleus, where it is active, in a PINK1 and Parkin-dependent manner. Unlike during starvation-induced autophagy, this activation of TFEB was independent of mammalian target of rapamycin complex I (mTORC1) inhibition. To examine whether TFEB was required for mitophagy we generated TFEB null cells using CRISPR-mediated genomic editing. Unexpectedly, these cells exhibited no defect in mitophagy and, contrary to previous studies that used RNAi to decrease TFEB levels, genomic elimination of endogenous TFEB also had no apparent effect on lysosomal morphology. Exploring the potential for compensation for TFEB loss by other members of the MiTF/TFE transcription factor family (MITF, TFEC, and TFE3), we observed Parkin-dependent nuclear translocation of MITF and TFE3 during mitophagy, similar to TFEB. We generated single knockout cell lines for the remaining MiTF/TFE family members and found that each exhibited a partial mitophagy defect that was further enhanced when two or more MiTF/TFE family members were knocked out in the same cell line. This indicates that members of the MiTF/TFE family coordinately participate in mitophagy. Our identification of PINK1 and Parkin as novel regulators of MiTF/TFE family member activation, via a unique pathway that works independently of mTORC1, illuminates a much more dynamic regulation of their activity than previously appreciated and provides new insight into the molecular mechanisms that link mitophagy and lysosomal biogenesis.

P2140**Board Number: B663****PINK1 is a ubiquitin kinase.**L.A. Kane¹, M. Lazarou¹, A.I. Fogel¹, Y. Li¹, K. Yamano¹, S.A. Sarraf¹, S. Banerjee¹, R.J. Youle¹;¹NINDS, NIH, Bethesda, MD

PINK1 is a gene mutated in certain autosomal recessive early onset forms of Parkinson's disease (PD). During the decade since its identification, it has been shown to be a mitochondrial kinase whose

abundance is controlled by mitochondrial membrane potential. Low mitochondrial membrane potential, signaling an unhealthy organelle, causes the accumulation of PINK1 on the outer mitochondrial membrane. This results in the recruitment of Parkin, a cytosolic E3 ubiquitin ligase that is also mutated in early onset PD. Parkin then induces the recruitment of both the proteasome and machinery responsible for autophagy, thus facilitating turnover of damaged mitochondria. The substrates of PINK1 have been a source of debate and many substrates have been suggested in the literature, including Parkin itself. Using an unbiased proteomic approach, we have now identified that PINK1 directly phosphorylates ubiquitin (Kane, *et al. J. Cell Biol.* 205, 143-153 (2014)). This phosphorylation occurs specifically on Ser65 of ubiquitin and mirrors PINK1's known phosphorylation of the ubiquitin-like domain of Parkin. Phospho-Ser65 ubiquitin binds to Parkin and activates its E3 ligase activity *in vitro*. Overexpression of a non-phosphorylatable mutant ubiquitin blocks Parkin translocation to damaged mitochondria *in vivo*. This is the first identification of a ubiquitin kinase and the first reported function for phospho-ubiquitin. Phosphorylation of ubiquitin in this clinically-relevant mitochondrial pathway opens the potential for a broader cellular signaling role for ubiquitin post-translational modification.

Deoxynucleoside salvage and compartmentalization in regulating mitochondrial deoxynucleoside triphosphates levels.

C. Hsiung¹, V. Kamath¹, E.E. McKee¹;

¹Foundational Sciences, College of Medicine, Central Michigan University, Mount Pleasant, MI

Mitochondrial DNA depletion diseases have been identified, in which there is a failure in maintaining mitochondrial biogenesis due to deficiencies and/or mutations of deoxynucleotide salvage pathway enzymes. However, little is known concerning the role of the salvage pathways in regulating deoxynucleosides (dNs) metabolism and deoxynucleoside triphosphate (dNTP) pool sizes, particularly in tissues that are not replicating nuclear DNA and are much more dependent on the salvage pathway. Mitochondrial dysfunction has been associated with a variety of anti-cancer and anti-viral nucleoside analogs that may adversely affect the salvage pathway in non-replicating tissues. The role of protein transporters in moving precursors, intermediates and products of dNTP synthesis is still largely unknown. The purpose of this study is to determine the role of exogenous deoxynucleoside concentration on the size of dNTP pools and the compartmentation of these pools in isolated intact rat heart mitochondria. To accomplish this goal, freshly isolated rat heart mitochondria were incubated at 30°C for 60 minutes with increasing concentrations of tritium-labeled or unlabeled deoxynucleosides. After incubation, mitochondria were separated from the medium by centrifugation. In some cases, mitochondria were further fractionated into membrane and soluble fractions through repeated freezing and thawing. The synthesis of the labeled deoxynucleotides was measured by separation using UPLC and an in-line liquid scintillation counter. The synthesis of dNTPs from unlabeled deoxynucleosides was measured in a modified template driven dNTP assay. Results obtained from current investigation

indicated that the mitochondrial level of TTP and dGTP present were highly sensitive to the exogenous thymidine and deoxyguanosine concentration respectively while the level of dCTP and dATP were insensitive to the exogenous deoxycytidine and deoxyadenosine concentration respectively. Thymidine was the preferred substrate over deoxycytidine for thymidine kinase (TK2) and deoxyguanosine was the preferred substrate over deoxyadenosine for deoxyguanosine kinase (dGK). Further, thymidine was much preferred over TMP as substrate for the synthesis of TTP. The TTP synthesized appeared to equilibrate readily with the medium, while surprisingly, dGTP, being 90% of the total dNTP pools, was highly concentrated inside the mitochondria and remained with membrane fraction on mitochondrial breaking. In conclusion, regulation of the salvage pathway in supporting mitochondrial dNTP pools appears to be compartmentalized and different to each deoxynucleosides.

Calorie restriction: Effects of oxidative and nitrosative stress at the mitochondrial level.

A. Saavedra-Molina¹, M. Clemente-Guerrero¹;

¹Instituto de Investigaciones Químico-Biológicas, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mich., Mexico

Calorie restriction (CR) is an experimental manipulation without malnutrition that is known to extend the lifespan of a number of organisms including yeast, worms, flies, rodents and non-human primates. In addition, CR has been shown to reduce the incidence of aging-related disorders (for example, diabetes, cancer and cardiovascular disorders) in mammals. The mechanisms through which this occurs have been unclear. The aim of this project is to determine the effects of a prenatal and perinatal calorie restriction in rats on oxidative and nitrosative stress in liver mitochondria. Female Wistar rats of 200-300 g of body weight were used and were caged individually and maintained in a 12:12 (light:dark) cycle at a 22 +/- 2 °C. The control groups were fed ad libitum and restricted animals received daily 50% of control animal's food intake (50% calorie restriction). After two weeks of treatment the female rats were caged with males for one week and mating was confirmed by the presence of spermatozoa in a vaginal smear. Pregnant rats were submitted to calorie restriction during the course of gestation and during lactation period, pups were calorie restricted too. At the age of one, three and five months the animals restricted were measured and weighed before the sacrifice by decapitation. The liver was immediately processed to isolate mitochondria. Results obtained showed variation depending the age-development of the rats. An increase on mitochondrial nitric oxide and lipoperoxidation in the perinatal and postnatal stages were observed, as well as peroxynitrite synthesis, respect control. Presence of antioxidants as glutathione and glutathione reductase activity were measured. Both antioxidants measurements were decreased both in pre and postnatal stages. These results suggest that CR has negative control over oxidative and nitrosative stress in the perinatal stage. Acknowledgements: The authors appreciate the partial economic support of the grant of CIC-UMSNH (2.16).

P2143**Board Number: B666****Mitochondrial dynamics in astrocytic processes during secondary pathology in an *in vitro* model of transient ischemic stroke.**J.C. O'Donnell^{1,2}, J.G. Jackson¹, M.B. Robinson^{1,2};¹Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, ²Pharmacology, University of Pennsylvania, Philadelphia, PA

Astrocytes are the most abundant cell type in brain. They are responsible for clearing extracellular glutamate, the predominant excitatory neurotransmitter, from the synapse to maintain crisp signaling and prevent excitotoxicity. In forebrain, the astrocytic glutamate transporter, GLT-1, is responsible for the vast majority of glutamate uptake. Mitochondria are invested throughout fine astrocytic processes where they colocalize with GLT-1. We recently discovered physical and functional interactions between GLT-1, multiple glycolytic enzymes, and mitochondria. We also found that mitochondria in astrocytic processes are retained near glutamate transporters and synapses. Our data suggest that this distribution is regulated by neuronal glutamate release, astrocytic glutamate uptake, and reversal of the Na⁺/Ca²⁺ exchanger. Mitochondria can support glutamate uptake by providing ATP and buffering ions, and a portion of transported glutamate is oxidized in mitochondria to generate energy in these compartments.

Mitochondrial dysfunction and excitotoxicity from failure of astrocytic glutamate uptake are at the core of delayed cell death that occurs after a transient ischemic insult. Aside from inducing hypothermia, this secondary pathology is currently untreatable. The goal of this project is to quantify changes in astrocytic mitochondrial distribution during the secondary pathology period in an *in vitro* model of stroke. To do so we have employed transient oxygen glucose deprivation (OGD) in organotypic hippocampal slice cultures biolistically transfected to fluorescently label astrocytic mitochondria. In ongoing experiments we have observed a loss of mitochondria in astrocytic processes in response to OGD that precedes the peak of delayed neuronal cell death common to this model and to stroke *in vivo*. In preliminary experiments, cyclosporin A, which increases mitochondrial capacity for calcium buffering, reduced cell death and attenuated the loss of mitochondria in astrocytic processes after OGD. Preliminary observations also provide evidence for increased mitophagy (a mechanism for degradation of dysfunctional mitochondria) in astrocytic processes after OGD. Further investigation of the mechanisms underlying the loss of astrocytic mitochondria after transient OGD could provide new therapeutic targets for the currently untreatable secondary pathology following transient ischemic stroke.

P2144**Board Number: B667*****In vivo* tissue-wide synchronization of mitochondrial metabolic oscillations.**N. Porat-Shliom¹, Y. Chen², A. Shitara¹, M. Tora¹, O. Harding¹, A. Masedunskas¹, R. Weigert¹;¹NIDCR, NIH, Bethesda, MD, ²NCI, NIH, Bethesda, MD

Little is known about the spatio-temporal coordination of mitochondrial metabolism in multicellular organisms *in situ*, and how oxidative phosphorylation adapts to rapid changes in energy demand during processes such as membrane trafficking. To address this issue we investigated how mitochondrial metabolism is modulated during GPCR-stimulated exocytosis in the acinar cells of salivary glands (SGs) in live rats. Specifically, we developed a method to follow the dynamics of the mitochondrial metabolic activity in live rodents that is based on the use of intravital two-photon microscopy to determine NADH levels (the main substrate of the electron transport chain, ETC) and mitochondrial potential. Unexpectedly, we discovered that mitochondrial metabolism undergoes rapid and spontaneous oscillations in SGs under basal conditions (period: 10-15 sec), in contrast with what reported in *ex vivo* or *in vitro* model systems where transient metabolic oscillations are observed only after agonist stimulation. These oscillations are regulated by reactive oxygen species but are insensitive to modulations in the levels of intracellular Ca²⁺. Most notably, we found that mitochondria *in vivo* behaves as a network of functionally coupled oscillators, which maintain a high level of coordination throughout the tissue. Indeed, mitochondria in different acini oscillates with the same period and phase, and their coordination is disrupted by blocking the activity of gap junctions. Finally, we observed that β -adrenergic stimulation, which stimulates regulated exocytosis, transiently halts NADH oscillations and increases mitochondrial potential, thus generating the ATP necessary to complete secretion. The mechanism regulating this process will be discussed in here. In conclusion, the ability to measure and characterize metabolic oscillations through NADH emission *in vivo*, has revealed novel aspects of cellular metabolism that have not been appreciated in reductionist model systems, and will open new avenues to study mitochondrial metabolism and tissue energetics at a cellular, subcellular, and tissue scale both under physiological and pathological conditions.

Characterization of the zebrafish family of Trak proteins.

L.B. Stone¹, K.A. Oonk¹, C. Reddig², E. Nickoloff³, D.C. Weiser⁴, S. Walsh²;

¹Rollins College, Winter Park, FL, ²Biology, Rollins College, Winter Park, FL, ³Center for Translational Medicine, Temple University, Philadelphia, PA, ⁴Univ of the Pacific, Stockton, CA

Mitochondria serve as the site of oxidative phosphorylation and can move to areas that possess high energetic needs within a cell. This movement is necessary to maintain basic metabolic functions, and disruption of this motility often results in cell death. In fruit flies and mammals, Miro, an outer mitochondrial membrane protein, and Trak, a kinesin adaptor protein, comprise one protein complex that regulates mitochondrial trafficking along microtubules. Our research aims to determine the role of the zebrafish Trak family of proteins. Through sequence homology, we have identified three zebrafish Trak proteins: zTrak1, zTrak2, and zTrak1-like. When expressed in COS7 cells, both human Trak1 and Trak2 are mitochondrial. However, in COS7 cells, zTrak1 does not localize to the mitochondria, yet zTrak2 does. A chimeric protein containing the N-terminus of zTrak1 and the C-terminus of human Trak1 relocated to the mitochondria, indicating that the C-terminus of hTrak1 is sufficient to direct

mitochondrial localization, and the C-terminus of zTrak1 is likely responsible for its cytosolic localization. Given the low amino acid conservation among these paralogs, these zebrafish proteins might have different cellular functions, and we are currently exploring the role of these proteins in vivo using antisense morpholino oligonucleotides and RNA in situ hybridization in developing zebrafish embryos. Taken altogether, this research will lay the foundation for studies in the role of mitochondrial motility during vertebrate development.

Reconstitution of Apoptotic Cell Engulfment to Decipher an Ancient Signaling System.

A. Williamson¹, R. Vale¹;

¹University of California, San Francisco, San Francisco, CA

Apoptosis is crucial during development and for maintaining healthy adult tissues. However, the appearance of apoptotic cells is normally rare: dying cells are efficiently recognized, internalized, and digested by phagocytes (a process termed corpse clearance). Since inefficient corpse clearance leads to inflammation and further tissue damage, a mechanistic understanding of how engulfment works and how the process can be activated may spur development of rational therapies for inflammatory diseases.

Elegant genetic work has identified the components of an ancient signaling system conserved across flies, worms and mammals that drives engulfment. However how these factors work together to drive the process remains unclear. We have reconstituted apoptotic cell engulfment by a *Drosophila* pathway driven by the receptor Draper and kinase Shark. Expression of Draper in cultured cells converts inept phagocytes into efficient engulfing cells. Recognition and engulfment of apoptotic cells or physiological mimics is rapid and specific.

A clue to the mechanism of Draper and Shark may lie in the signaling pathway that triggers T cells. In the latter case, the T cell receptor complex (TCR) works with a kinase ZAP-70 at the membrane. Both apoptotic cell engulfment and T cell triggering occur at sites of membrane-membrane contact two cells and require actin. Furthermore the molecules that drive each process bear remarkable similarity. We have shown that Shark, like ZAP-70, is recruited to the plasma membrane during signaling. Similar to TCR and ZAP-70, Draper and Shark form clusters at the plasma membrane that undergo retrograde flow, indicating that functional properties of the signaling systems are conserved between these divergent pathways.

We have established a live cell imaging platform to interrogate the contribution of specific molecules towards efficient engulfment; in particular we hope to understand how the Draper pathway interfaces

with downstream actin machinery. As a similar system has been proposed to function in mammalian cells, we look forward to extending our findings from *Drosophila* to other organisms.

Amyloid β -Induced Activation of mTOR at the Plasma Membrane Leads to Neuronal Cell Cycle Re-Entry: a Seminal Step in Alzheimer's Disease Pathogenesis.

A. Norambuena¹, L. McMahon¹, E.J. Kodis¹, E.M. Swanson¹, H.K. Wallrabe¹, S.S. Thomas², D. Baerthlein¹, X. Zhou³, J. Zhang³, S. Oddo⁴, G.S. Bloom⁵;

¹Department of Biology, University of Virginia, Charlottesville, VA, ²Department of Biology and Neuroscience Graduate Program, University of Virginia, Charlottesville, VA, ³Department of Pharmacology and Molecular Sciences, Johns Hopkins University, Baltimore, MD, ⁴Department of Basic Medical Sciences, University of Arizona College of Medicine, Phoenix, AZ, ⁵Departments of Biology and Cell Biology, University of Virginia, Charlottesville, VA

Mechanistic Target of Rapamycin (mTOR) plays a major role in cell metabolism by sensing availability of resources, such as growth factors and amino acids, and integrating the resulting signals to control cell growth and proliferation. These functions involve finely tuned regulation of mTOR activity at specific membrane locations, and mTOR dysregulation has been implicated in cancer and Alzheimer's disease (AD).

AD is characterized by the accumulation in brain of two types of insoluble deposits, extracellular plaques composed of amyloid- β (A β) peptides and intraneuronal neurofibrillary tangles comprising the microtubule-associated protein, tau, and by massive synaptic dysfunction and neuron death. Ironically, a large fraction of neuron death in AD occurs after the normally post-mitotic neurons ectopically re-enter the cell cycle. We recently reported that neuronal cell cycle re-entry (CCR) results from a process by which soluble A β oligomers (A β Os) stimulate PKA, fyn and CAMKII to catalyze site-specific tau phosphorylation (Seward, et al. 2013. J Cell Sci 126:1278). We now describe further details of the CCR pathway, including a novel and essential role for mTOR.

Ki-67 and Cyclin D1 expression, or BrdU uptake were used to identify cultured WT mouse neurons that respectively had exited G0, were in G1, or had entered or completed S-phase after exposure to A β Os. CCR was prevented by knockdown of NCAM, Gas, RalA, Rac1 or eIF4E, or reducing the activity of mTORC1 or mTORC2 by respective knockdown of raptor or rictor. Pharmacological inhibition of mTOR or Rac1, or exposure of neurons to a cell permeable peptide that blocks Rac1 binding to mTOR also prevented CCR. By using a genetically encoded mTORC1 activity reporter (Zhou, et al. Cell Metab *in revision*) we detected A β O-induced mTOR activation at neuronal cell membranes, but not in lysosomes. Reducing Rac1-dependent translocation of mTOR to plasma membrane (PM) domains and forcing mTORC1 association to lysosomes also prevented CCR. In vivo studies showed that CCR marker expression in cortical neurons of Tg2576 AD model mice was strongly suppressed in animals with

genetically-reduced mTor activity. Finally, we found that this Rac1-modulated mTOR signaling controls *in vitro* and *in vivo* tau phosphorylation at S262, which is also necessary for neuronal CCR.

A β O_s thus initiate two pathways that together lead to mTOR dysregulation and are obligatory for ectopic neuronal CCR. One pathway mistargets Rac1-mTOR complexes to the PM, and the other leads from G α s and NCAM to activation of fyn, PKA and CaMKII, which then respectively phosphorylate tau at Y18, S409 and S416. The CCR requirement for tau phosphorylation at S262 establishes that regulation of tau and mTor by each other integrates the two pathways.

BAG-1 differentially regulates intermediate filament-based Hsp70 chaperoning of aPKC in intestinal cells under pro-inflammatory signaling.

A. Mashukova¹, R. Forteza², P.J. Salas²;

¹College of Medical Sciences, Nova Southeastern University, Fort Lauderdale, FL, ²Department of Cell Biology, University of Miami Miller School of Medicine, Miami, FL

Atypical protein kinase C (aPKC) plays an essential role in the establishment of epithelial polarity and tight junction assembly. aPKC acquires inactive conformation after normal activity and can be rescued from ubiquitinylation and degradation by Hsp-70- and intermediate filament-dependent mechanism. We have shown previously that aPKC was strongly downregulated by TNF-alpha-mediated signaling in intestinal epithelial cells and also *in vivo* during intestinal inflammation. Furthermore we have demonstrated that decrease of aPKC levels under pro-inflammatory conditions was mediated through inhibition of Hsp70 chaperoning activity, resulting in failure of the aPKC rescue machinery. The goal of this work was to identify the molecule (or molecules) responsible for Hsp70 inhibition under TNF-alpha stimulation. First, we conducted a transcriptome PCR screen detecting chaperones and co-chaperones and compared mRNAs from control and TNF-alpha treated Caco-2 cells (human colon carcinoma). Subsequent validation experiments allowed us to focus on BAG-1, a multi-functional protein that assists Hsp70 in nucleotide exchange but also blocks its activity at higher concentrations. We found that BAG-1 isoform BAG-1M was upregulated up to 3 fold in human Caco-2 cells following stimulation with TNF-alpha. In addition, BAG-1M levels increased up to 6 fold in mouse enterocytes following treatment with dextran sodium sulfate (DSS) to induce colitis. BAG-1M, but no other isoform, was found to co-purify with intermediate filaments. To test the effect of BAG-1M on Hsp70 chaperoning activity we employed a well-established chemically denatured luciferase refolding assay. Addition of BAG-1M to the assay reaction within the range of concentrations found in epithelial cells resulted in significant inhibition of Hsp70 chaperoning activity in the intermediate filament fraction. To determine if the findings observed *in vitro* also apply to the living cells, we have performed both overexpression and knockdown of Bag-1M in Caco-2 cells using lentiviral transduction. Overexpression of BAG-1M decreased levels of phosphorylated aPKCs, similar to TNF-alpha stimulation. In contrast, knockdown of BAG-1 abolished the TNF-alpha-induced decrease of phosphorylated aPKC. Overall, we conclude that BAG-1M mediates inhibition of Hsp70 chaperoning activity during epithelial inflammatory response.

P2149**Board Number: B673****Optogenetic modulation of Raf/ERK and PI3K/AKT pathways in PC-12 cells - understanding the temporal dimensions of antiapoptotic pathways against oxidative stress.**Q. Ong¹, K. Zhang^{1,2}, S. Guo¹, L. Duan¹, E.A. Collier¹, B. Cui¹;¹Chemistry, Stanford University, Stanford, CA, ²Molecular and Cellular Biology, University of Illinois at Urbana-Champaign, Urbana, IL

Intracellular optogenetics offers chemical biologists an unprecedented new set of tools in manipulating and probing signaling pathways with spatiotemporal precision. We have utilised the light protein-interaction pair, CRY2PHR and CIBN, to elicit Raf and AKT recruitment to the plasma membrane via blue light controllably, with reversible dissociation under dark conditions. This optogenetic toolkit is being applied to study how Raf/ERK and PI3K/AKT pathways act as protective mechanisms to the cells under oxidative stress (hydrogen peroxide and singlet oxygen generation), with greater understanding towards their temporal dimensions.

P2150**Board Number: B674****The MLK3-mediated positive feedback loop is a crucial factor in cellular responses to reactive oxygen species.**C. Hwang¹, H. Lee¹, K. Cho¹;¹Department of Bio and Brain Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea

Reactive oxygen species (ROS) play a central role in the regulation of numerous cellular processes. It is known that opposite cellular response such as proliferation or cell cycle arrest/apoptosis can be made depending on ROS concentration. However, it remains unclear how such different cellular response can be determined through a complex signaling network. In this study, we found that extracellular signal-regulated kinases (ERKs) and c-Jun N-terminal kinases (JNKs) coordinate ROS-dependent cellular response determination. ERKs mediate proliferation at low ROS concentration, whereas JNKs mediate cell cycle arrest/apoptosis at high ROS concentration. From mathematical simulations combined with biochemical experiments, we found that mixed lineage kinase 3 (MLK3)-mediated positive feedback loop balances the signal flow for proliferation and cell cycle arrest/apoptosis, which results in contrasting cellular response determination. Cells treated with an MLK3 inhibitor or MLK3 shRNA showed increased viability at high ROS concentrations through higher ERKs activation and lower JNKs activation than control cells. Taken together, our systems biology analysis and biochemical studies provide new insight into the mechanism underlying how ROS-dependent cellular response is determined.

P2151**Board Number: B675****Anti-inflammatory Effects of Heparin on Vascular Endothelial Cells are Dependent on Dual-Specificity Mitogen-Activated Protein Kinase Phosphatase-1.**S.N. Farwell¹, J.B. Slee^{1,2}, L.J. Lowe-Krentz³;¹Lehigh University, Bethlehem, PA, ²Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA,³Biological Sciences, Lehigh University, Bethlehem, PA

Heparin is widely-used as an anti-coagulant as part of treatment for increasingly prevalent cardiovascular and pulmonary diseases. Anti-proliferative effects of heparin on vascular smooth muscle cells (VSMCs) have been well documented and involve both the down-regulation of the mitogen-activated protein kinase (MAPK) intermediate Erk and the up-regulation of dual-specificity MAPK Phosphatase-1 (MKP-1). Heparin has been also shown to exhibit potent anti-inflammatory properties on vascular endothelial cells (ECs) in vitro, but the molecular mechanism(s) by which heparin accomplishes this remain unclear. We examined heparin's effects on primary macrovessel ECs. We tested the hypothesis that heparin's effects are also at least partially dependent on increased MKP-1 expression in ECs. We show that heparin decreases tumor necrosis factor (TNF) α -induced activation of stress-activated protein kinases (SAPKs) c-Jun N-terminal kinase (JNK) and p38 through western blotting and immunofluorescence assays. Using knockdown strategies, we show these effects are partly dependent on MKP-1. Heparin-induced decreases in TNF α -induced actin stress fiber production also require an MKP-1 induction, as shown through quantitative fluorescence microscopy. An advanced understanding of heparin's anti-inflammatory effects is crucial to identify novel heparin responsive targets and to develop and improve therapeutic strategies. Exploiting heparin as a drug with anti-inflammatory actions is an important direction to pursue in both cardiovascular research and clinical settings. Support from NIH award HL54269 to LLK.

P2152**Board Number: B676****Metabolic control of Ca²⁺/Calmodulin-dependent protein kinase II (CaMKII)-mediated Caspase 2 suppression by the B55 β /protein phosphatase 2A (PP2A).**B. Huang¹, C. Yang¹, J. Wojton¹, N. Huang¹, C. Chen¹, E.J. Soderblom¹, S. Kornbluth¹;¹Duke University Medical Center, Durham, NC

High levels of metabolic activity confer resistance to apoptosis. Caspase 2, an apoptotic initiator, can be suppressed by high levels of nutrient flux through the pentose phosphate pathway (PPP). This metabolic control is exerted via inhibitory phosphorylation of the caspase 2 pro-domain by activated Ca²⁺/Calmodulin-dependent protein kinase II (CaMKII)(1). We show here that metabolic activation of CaMKII depends, in part, on dephosphorylation of CaMKII at novel sites (T393/S395) and that this is

mediated by metabolic activation of protein phosphatase 2A (PP2A) in complex with the B55 β targeting subunit. This represents a novel locus of CaMKII control and also provides a mechanism contributing to metabolic control of apoptosis. These findings may have implications for metabolic control of the many CaMKII-controlled and PP2A-regulated physiological processes, as both enzymes appear to be responsive to alterations in glucose metabolized via the PPP.

Functional interaction network of the conserved NDR kinase Orb6.

C. Chen¹, I. Suarez², D.J. Wiley², G. D'Urso², F. Verde¹;

¹Department of Cellular and Molecular Pharmacology, University of Miami Miller School of Medicine, Miami, FL, ²University of Miami Miller School of Medicine, Miami, FL

Cell polarization is the common feature of a variety of different cell types and is fundamental to many cellular processes, including cell differentiation, cell motility and cell fate determination. Defects in cell morphogenesis are linked to diseases such as cancer, developmental defects and neuronal disorders. The conserved NDR kinase Orb6 controls cell morphogenesis in different organisms, ranging from yeast to neuronal cells. In mammals, NDR kinase is also thought to function as a tumor suppressor. Our lab has previously shown that the conserved NDR kinase homologue in fission yeast, Orb6 kinase, plays a key role in maintaining polarized cell growth at the cell tips by spatially restricting the localization and activity of Cdc42 GTPase.

To identify novel functional targets of NDR kinase Orb6, we used an ordered fission yeast gene deletion library to perform a genome-wide screen for gene functions that display synthetic lethality or suppression interactions with an inhibitor-sensitive Orb6 kinase mutant. This innovative screen further refined the screen results using computational, mass spectrometry, and 2-hybrid analysis approaches. Refined gene candidates fall into four major functional groups, including morphogenesis, nutritional response, transcriptional and translational control. Of particular interest are novel genetic, functional and physical interactions of Orb6 kinase with conserved protein complexes involved in the control of transcription and heterochromatin gene silencing.

P2154**Board Number: B678****An endoplasmic reticulum lipid phosphatase regulates plasma membrane lipid metabolism.**E.J. Dickson¹, J.B. Jensen¹, O. Vivas¹, B. Hille¹;¹Physiology and Biophysics, University of Washington, Seattle, WA

Phosphoinositides are a family of low-abundance phospholipids located on the cytoplasmic leaflet of cellular membranes that maintain cell structure, cell motility, membrane trafficking, ion channel functions and also play key roles in signal transduction. Phosphatidylinositol (4,5)-bisphosphate (PI(4,5)P₂) is the signature phosphoinositide of the plasma membrane. How is PM PI(4,5)P₂ sourced? We have reported that plasma membrane PI(4,5)P₂ levels are supported by at least two, continuously supplying, precursor pools of PI(4)P, one in the plasma membrane itself, and the other in the Golgi. How is plasma membrane PI(4,5)P₂ regulated? Many lipid phosphatases and kinases are needed for the maintenance of each cellular phosphoinositide pool; we focused our attention on an integral membrane lipid 4-phosphatase enzyme localized to the endoplasmic reticulum (ER), Sac1. It has the ability to reduce the precursor source of PM PI(4,5)P₂, namely PI(4)P. Using a variety of optical (confocal, TIRF, super-resolution microscopies), protein dimerization, and electrical (ion channel recordings) techniques, we have discovered that Sac1 aggregates in puncta, intimately apposed to the plasma membrane in endoplasmic reticulum–plasma membrane (ER-PM) contact sites in tsA-201 cells. Based on FRET measurements between Sac1 and a plasma membrane marker, Sac1 is within 10 nm of the plasma membrane. What causes Sac1 to aggregate in ER-PM contact sites? Multiple lines of evidence suggest a role for the cortical ER protein, extended synptotagmin-2 (E-Syt2). Quantitative super-resolution imaging analysis reveals strong correlation between Sac1 and E-Syt2 distributions. Overexpressing or knocking down E-Syt2 increased or decreased the abundance of Sac1 in close proximity to the PM, respectively, and lead to alterations in plasma membrane PI(4)P and PI(4,5)P₂ levels. Activation of G-protein coupled receptors to deplete plasma membrane PI(4,5)P₂ causes a dynamic redistribution of Sac1 puncta away from the plasma membrane. The reaggregation of Sac1 back into ER-PM contacts is dependent on the rate of PI(4,5)P₂ resynthesis. Similar results were observed in superior cervical ganglia neurons. Thus, the intimate organization of ER Sac1 next to the plasma membrane gives it the unique ability to act as a cellular ‘thermostat’ controlling plasma membrane PI(4)P and PI(4,5)P₂ levels and with that many plasma membrane proteins.

Supported by a grant from the NIH National Institute of Neurological Disorders and Stroke R37NS008174 and the Wayne E. Crill Endowed Professorship.

P2155**Board Number: B679****Distinct patterns of phosphatase activation and subcellular localization impact the kinetics of interferon-gamma signaling in CNS neurons.**C. Brown¹, A. Stahl¹, C. Stotesbury¹, K. Sweeney¹, G. Rall², W. Rose¹;¹Department of Biology, Arcadia University, Glenside, PA, ²Immune Cell Development and Host Defense Program, Fox Chase Cancer Center, Philadelphia, PA

The immune cytokine interferon-gamma (IFN-g) plays an essential role in the elimination of numerous central nervous system (CNS) viral infections. The cellular response to IFN-g, mediated by JAK/STAT signal transduction, involves the upregulation of genes that result in the establishment of the antiviral state, and is controlled by multiple negative feedback mechanisms. However, whether these control mechanisms, previously characterized in non-neuronal cells, operate similarly in CNS neurons has not been well-characterized. Our lab previously demonstrated that the control of the neuronal IFN-g pathway is distinct from that in non-neuronal cells, as the duration of STAT1 phosphorylation and IFN-g responsive gene expression in IFN-g treated neurons was markedly extended as compared to mouse embryonic fibroblasts (MEF). We also showed that compared to MEF, STAT1 dephosphorylation was delayed in IFN-g treated neurons, providing a mechanism for the extended kinetics of neuronal STAT1 phosphorylation. The current study investigated the expression and subcellular localization of two STAT1 phosphatases, TC45 and SHP-2, to address the hypothesis that mislocalization of these phosphatases could result in the observed delay in neuronal STAT1 dephosphorylation. Although no differences in overall expression levels of TC45 were observed between neurons and MEF, neurons demonstrated an approximately 3-fold lower level of SHP-2 activation as compared to MEF, regardless of IFN-g exposure. To examine the subcellular localization of these phosphatases, neurons and MEF were exposed to IFN-g, and nuclear and cytoplasmic fractions were purified at 1, 24, and 48h post-IFN-g treatment. Our results showed that while SHP-2 was found strictly in the cytoplasmic fraction of both cell types, TC45 was found only in the cytoplasmic fraction of the neurons, whereas it was equally distributed between nuclear and cytoplasmic fractions in MEF. These results indicate that neurons (but not MEF) lack TC45 in the nucleus, which provides a likely explanation for the observation that neuronal STAT1 is not dephosphorylated as rapidly as it is in MEF. Understanding the control of the IFN-g response in CNS neurons will ultimately aid in the characterization of antiviral immune mechanisms of the CNS.

P2156**Board Number: B680****A-Kinase Anchoring Proteins, Phosphorylated-Akt/PKB and Phosphodiesterase-4A: Players in Schwann Cell Proliferation.**A.L. Asirvatham¹, K. Spears¹, R. Stahl², D. Carey²;¹Biology, Misericordia Univ, Dallas, PA, ²Geisinger Health Center, Weis Center for Research, Danville, PA

Proliferation of Schwann cells in the peripheral nervous system is dependent upon the heregulin/neuregulin family of growth factors secreted by neurons. The stimulation of Schwann cell division by heregulin occurs in a synergistic fashion only if pathways involving cAMP are also triggered. The molecular mechanisms involved in the synergistic modulation of Schwann cell proliferation by heregulin and cAMP pathways are unknown. Previous studies have shown that A-Kinase anchoring proteins (AKAPs) of the cAMP/PKA signaling pathway play a key role in Schwann cell division. Treatment of neonatal Schwann cell cultures with SiRNA oligos synthesized against AKAP150 and AKAP95 exhibited a significant reduction in cell growth, expression of AKAPs and the cell survival signal, Akt/Protein kinase B. Based on these studies it was hypothesized that the expression of AKAP95 and AKAP150 along with the expression of phospho-Akt/PKB and the cAMP-terminating enzyme, PDE4A would increase when Schwann cells were treated with heregulin, forskolin or heregulin + forskolin. Immunoblot analysis revealed that heregulin treatment of Schwann cells increased the protein expression of AKAP95 and phosphorylated-Akt while forskolin treatment caused an upregulation in the levels of AKAP 150, PDE4A and Akt. To corroborate the results from immunoblot analysis, immunofluorescence experiments in Schwann cells were conducted, which revealed that in comparison to control, cells treated with heregulin and heregulin + forskolin exhibit distinct colocalization patterns for AKAPs and Akt while cells treated with forskolin show colocalization for AKAPs and phospho-Akt. These preliminary observations suggest that a relationship between expression of AKAP proteins and phosphorylation of Akt along with PDE4A may be necessary to mediate mitogen-stimulated Schwann cell growth.

P2157**Board Number: B681****Novel substrates of Rho kinase in the heart.**Y. Yura¹, T. Bando², M. Amano¹, K. Kaibuchi³;¹Cell Pharmacology, Nagoya University School of Medicine, Nagoya City, Japan, ²Cell Pharmacology, Nagoya University School of Medicine, Nagoya, Japan, ³Nagoya University School of Medicine, Nagoya, Japan

Rho kinase/ROCK/ROK is highly expressed in the cardiac muscle and is activated in failing heart. However, the substrate and function of Rho kinase in the heart have not been reported so far. We previously developed a novel proteomic approach for screening of protein kinase substrates by combining mass spectrometry and affinity column chromatography of catalytic domain of protein kinase. Using this method, we searched for novel substrates of Rho kinase in the rat heart tissue, and

more than 200 candidate substrates were obtained. We then confirmed that some of these candidate substrates including cardiomyopathy-related gene products were really phosphorylated by Rho kinase in vitro. Among them, we focused on ANKRD1/CARP. ANKRD1 has been reported to play a critical role in the maintenance of sarcomere integrity and transcriptional regulation of cardiac genes dependent on its subcellular localization. We further searched for the binding partners whose interactions are affected by phosphorylation state of ANKRD1. Among the known partners, transcriptional factor YB-1 preferentially bound to non phosphorylated ANKRD1 rather than phosphorylated one. In addition, we also found that 14-3-3 proteins specifically associated with phosphorylated ANKRD1. These results suggest that Rho kinase modifies the ANKRD1 function by regulating its transcriptional activity and subcellular localization through the phosphorylation.

Exploring signaling through TAK1 during SAN development.

C. Awgulewitsch^{1,2}, S. Legros², M. Doss², Y. Dai², A. Foley²;

¹Biology, College of Charleston (Honors College), Charleston, SC, ²Bioengineering, Clemson-MUSC, Charleston, SC

Following a myocardial infarction, cardiomyocytes in the damaged heart tissue are replaced by collagen and fibroblasts. This structural change leads to a decrease in cardiac function and also arrhythmia. One developing treatment option for this damaged tissue is the cellular transplantation of cardiac cells derived from pluripotent cells such as embryonic stem (ES) cells. However, this therapy will require a deeper understanding of the mechanisms that determine cardiac cell fates. Previous work in the Foley lab has shown that early cardiac formation is dependent upon intracellular signaling between the endoderm and mesoderm, mediated by antagonists of the canonical Wnt/ β -Catenin signaling pathway and activators of the Nodal signaling pathway. TGF β -activated kinase (TAK1), which is located directly upstream of the Wnt antagonist NLK, is thought to be critical for cardiac differentiation toward the sinoatrial node (SAN) fate. We hypothesize that SMAD-independent TGF β signaling through TAK1/p38/JNK or TAK/NLK pathways influences formation of the heart inducing endoderm and indirectly to direct SAN differentiation within the myocardium. This study focused on the role of TAK1 in mouse ES cells. Mouse ES cells were transduced with the TAK1 gene and the TAK1 ES cells were then differentiated as embryoid bodies (EBs). Western blots compared protein content of different signaling markers of TAK1 cells to unmodified ES cells. Continuous TAK1 mRNA overexpression and the effects on patterning were assessed by qRT-PCR. Markers for the endoderm and the sinoatrial node were significantly upregulated while cardiac contractile proteins were downregulated. In addition we found TAK1 cells alter the expression of Jnk and NLK in ES cells. Therefore, we have determined that TAK1 overexpression could be directing pacemaker differentiation by acting through one or both of these downstream targets.

P2159**Board Number: B683****Activin-Beta/TGF-Beta signaling in skeletal muscle controls insulin signaling and metabolism to influence final body size.**L. Moss-Taylor¹, M. O'Connor¹;¹Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN

Body size is tightly regulated during development to maximize adult fitness. In *Drosophila*, final body size is mainly determined by the growth rate and the duration of growth during juvenile stages; once maturation occurs, body size is set. The rate of growth is determined by insulin-like peptide (dilp) signaling and metabolism, while the duration of growth is regulated by prothoraciotropic hormone (PTTH) and ecdysone. Manipulation of these pathways alters final body size by either accelerating or delaying the onset of metamorphosis. Skeletal muscle is known to coordinate tissue and body growth during development, influencing final size. Levels of insulin signaling in skeletal muscle proportionately affect body and organ size, but what influences muscle-specific insulin signaling and how the muscle coordinates tissue growth are unknown.

We are investigating the newly identified role that the TGF-Beta ligand Activin-Beta plays in regulating *Drosophila* body size and timing of metamorphosis. We have found that mutations in dActivin-Beta (dAct-Beta) cause accelerated pupariation and reduced final body and organ size. To determine how Act-Beta affects size and timing, we first looked at which cells express Act-Beta and found expression in the Insulin Producing Cells (IPCs), neuroendocrine cells and motor neurons. Overexpression of Activin-Beta in either neuroendocrine cells or motor neurons increases body size. Muscle-specific knockdown of the TGF-Beta signaling transducer/transcription factor *dSmad2* reduces body size, indicating muscle is a target tissue of the Activin-Beta signal. Additionally, levels of phospho-dSmad2 are reduced in skeletal muscle samples of Activin-Beta mutants and increased in animals overexpressing Activin-Beta from motor neurons. Levels of phospho-S6K are correlated with phospho-dSmad2 levels, suggesting TGF-Beta signaling in muscle regulates muscle-specific insulin signaling. Because insulin signaling controls metabolism, we used GC/MS analysis to identify and quantify levels of metabolites in whole-larval samples of Activin-Beta mutants. We found intermediates of the energy-producing steps of glycolysis and lactic acid are reduced, indicated reduced flux through glycolysis. Overall, this indicates neuronally-derived Activin-Beta signals to the skeletal muscle to regulate levels of insulin signaling and subsequent glycolysis. We will identify downstream targets of dSmad2 using skeletal-muscle RNAseq and test potential target genes using tissue-specific knock-downs to determine how TGF-Beta signaling influences insulin signaling and how the muscle coordinates body growth and final organ size.

P2160**Board Number: B684****Understanding the mechanisms of cellular growth control with: (1) the Rose Rosette Virus in plants and (2) Angiotensin II controlled Hippo signaling in mammals.**J. Adler¹, C. Wells²;¹Brescia University, Owensboro, KY, ²Department of Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN

Rose Rosette Virus: Various cultivars of Rose are currently under attack by the Rose Rosette Virus. This emerging virus is threatening the existence of many Rose cultivars, by inducing rapid proliferation leading to the death of the plant. The Adler laboratory is currently interested in growth control of these plants and any differences between the unaffected and those infected with the virus. We hypothesize that the virus is working through a mechanism that promotes aggressive uncontrolled growth, and we are exploring the role that this virus may be playing to hijack growth control pathways, similar to those seen in mammalian cancer cells.

Angiotensin II: Mammalian cellular growth is controlled by microenvironmental signals in serum under both normal physiological settings and during cancer progression. Importantly, the effects of several of these microenvironmental signals are mediated by the activities of the tumor suppressor protein kinases of the Hippo pathway. Canonically, Hippo protein kinases inhibit cellular growth through the phosphorylation and inactivation of the oncogenic transcriptional co-activator Yes-Associated Protein (YAP). In the Wells laboratory, we defined an alternative mechanism whereby Hippo protein kinases induce growth arrest via the phosphorylation of the long isoform of Angiotensin II (Amot130). Specifically, serum starvation is found to activate the Hippo protein kinase, Large Tumor Suppressor (LATS), which phosphorylates the adapter protein Amot130 at serine-175. Importantly, wild-type Amot130 potently inhibits epithelial cell growth, unlike the Amot130 serine-175 to alanine mutant, which cannot be phosphorylated at this residue. The growth-arrested phenotype of Amot130 is likely a result of its mechanistic response to LATS signaling. Specifically, LATS activity promotes the association of Amot130 with the ubiquitin ligase Atrophia-1 Interacting Protein 4 (AIP4). As a consequence, the Amot130-AIP4 complex amplifies LATS tumor suppressive signaling by stabilizing LATS protein steady state levels via preventing AIP4-targeted degradation of LATS. Additionally, AIP4 binding to Amot130 leads to the ubiquitination and stabilization of Amot130. In turn, the Amot130-AIP4 complex signals the ubiquitination and degradation of YAP. This inhibition of YAP activity by Amot130 requires both AIP4 and the ability of Amot130 to be phosphorylated by LATS. Together, these findings significantly modify the current view that the phosphorylation of YAP by Hippo protein kinases is sufficient for YAP inhibition and cellular growth arrest. Based upon these results, the inhibition of cellular growth in the absence of serum more accurately involves the stabilization of Amot130 and LATS, which together inhibit YAP activity and epithelial cell growth.

P2161**Board Number: B685****Tight control of PP2A holoenzyme biogenesis and catalytic subunit recycling.**Y. Xing¹;¹Oncology, University of Wisconsin-Madison, Madison, WI

The function of metalloenzyme protein phosphatase 2A (PP2A) relies on proper formation of diverse heterotrimeric PP2A holoenzymes, comprising common scaffold and catalytic (PP2Ac) subunits and a variable regulatory subunit. Holoenzyme assembly is highly regulated by carboxymethylation of PP2Ac. Our previous study demonstrated that the enzymatic reaction of PP2A methylation is highly responsive to PP2A activation via a direct binding of PP2A methyltransferase to the dynamic PP2A active site (Mol. Cell. 2011, 41(3):331-42). Our recent studies showed that PP2A holoenzyme biogenesis requires PP2Ac stable latency and activation. We showed that the entire protein fold of PP2Ac is highly dynamic and tends to partially unfold in the absence of catalytic metal ions, which renders α 4-binding that involves the inner structure of PP2Ac near the active site. α 4-binding leads to an allosteric relay of conformational changes that perturbs the scaffold subunit binding site at the opposite surface. This unique mode of α 4-binding underlies important mechanisms for stable latency of PP2Ac as well as dissociation of PP2A holoenzymes and recycling of PP2Ac in response to cell signaling. Due to the flexible nature of the apo-PP2Ac, the protein fold of apo-PP2Ac needs to be stabilized by PP2A phosphatase activator (PTPA) via broad contacts with the structural elements surrounding the PP2A active site, which stabilizes the PP2Ac active site in a conformation that could bind catalytic metal ions. PTPA-binding also defines a combined ATP-binding pocket that orients ATP phosphoryl groups to bind directly to the PP2Ac active site. This allows ATP to modulate the metal-binding preferences of the PP2Ac active site and drastically enhances binding of Mg²⁺ by 10,000-fold, which is crucial for acquisition of pSer/Thr-specific phosphatase activity. Consistent with the activation chaperone function of PTPA and activation-dependent PP2A methylation, PTPA stimulates both PP2A phosphatase activity and methylation. Collectively, our studies showed that PP2A stable latency, activation, methylation, and holoenzyme assembly are elegantly coordinated by conformational switches of PP2Ac, underlying novel mechanisms for tight control of PP2A function and regulation in context of cellular signaling.

P2162**Board Number: B686****Real-time Dynamics of the Purinosome Governed by AMPK-associated Signaling Network.**D.L. Schmitt¹, S. An²;¹Chemistry and Biochemistry, Univ Maryland- Baltimore County, Baltimore, MD, ²Chemistry and Biochemistry, Univ Maryland Baltimore County, Baltimore, MD

The objective of this study is to determine if signaling networks associated with AMP-activated protein kinase (AMPK) implicate purinosome dynamics in cancer cells. Human *de novo* purine biosynthesis is a ten-step process catalyzed by six enzymes, using phosphoribosyl pyrophosphate to produce inosine monophosphate. These enzymes have previously been found to compartmentalize together in the cytoplasm upon purine depletion; forming a transient metabolic complex termed the “purinosome.” Recently, there has been growing interest in elucidating signaling networks associated with purinosome dynamics to understand the biological significance of purinosome assembly in cells. Although a metabolic intermediate of purine biosynthesis, 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR), is a well-characterized allosteric activator of AMPK, human *de novo* purine biosynthesis has not yet been explored as part of AMPK-mediated signaling circuits. In this study, we have investigated the effect of AMPK activation on purinosome dynamics by monitoring green fluorescent protein-tagged formylglycinamide ribonucleotide synthase (FGAMS-GFP) as a purinosome marker under fluorescence live-cell microscopy. Dynamic clustering of purinosomes is observed in ~70% of HeLa cells by the addition of AICAR. Subsequently, we reveal that the biguanides, metformin and phenformin, also induce clustering of FGAMS-GFP in ~79% and ~75% of HeLa cells, respectively. These data support our hypothesis that AMPK controls purinosome assembly as a mean to maintain cellular energy homeostasis. We will continue to delineate the coupled network between the purinosome and AMPK in various cancer cell lines by fluorescence live-cell microscopy in combination with established biochemical assays. As *de novo* purine biosynthesis has been a validated target of cancer therapeutics, we envision that a greater understanding of purinosome dynamics, especially in response to cellular energy needs, possesses high potential to be translated into better chemotherapeutic intervention.

P2163**Board Number: B687****Regulation of IP6K2 activity by TRAF2.**H. Rahman^{1,2}, G.J. Miller²;

¹Department of Biology, The Catholic University of America, Washington, DC, ²Laboratory of Biochemistry and Structural Biology, Department of Chemistry, The Catholic University of America, Washington, DC

Overexpression of inositol hexakisphosphate kinase-2 (IP6K2) sensitizes multiple cancer cell lines to the apoptotic effect of IFN- α 2, IFN- β , TNF α , γ -irradiation and other apoptotic inducing agents, while its knockdown confers resistance to these stressors. IP6K2 binds to tumor necrosis factor receptor associated factor-2 (TRAF2), which serves as an adapter protein for the TNF-receptor superfamily and interleukin-1 receptor and is a major mediator for the regulation of cell survival and cell death for these receptors. Two short amino acid motifs (SXXE) in IP6K2 have previously been shown to be responsible for TRAF2 binding, which inhibits phosphorylation of TAK1 and AKT, thereby inhibiting NF- κ B activation and promoting apoptosis. Our objectives are (1) to characterize the interaction of each IP6K2 motif with TRAF2, (2) determine the impact of this interaction on IP6K2 catalytic activity and (3) determine the structural basis of this interaction.

P2164**Board Number: B688****Analysis of secreted protein kinase substrates.**A. Sreelatha¹, K. Orth¹, J. Dixon², V. Tagliabracci²;

¹Molecular Biology, University of Texas Southwestern Medical Center, Dallas, TX, ²department of pharmacology, UC San Diego, San Diego, CA

Kinases mediate protein phosphorylation of intracellular and secreted proteins to regulate various cellular processes. Until recently, the kinases that phosphorylate secreted proteins were unidentified. One member of the atypical secreted protein kinase family, Fam20C phosphorylates the S-x-E/pS motif of over 100 secreted proteins. Genetic diseases such as Raine syndrome that result from Fam20C mutations highlight the importance of Fam20C phosphorylation of secreted protein. Further analysis of Fam20C substrates reveal that it also regulates wound healing and lipid homeostasis. Using bioinformatics, biochemistry and genetics we study the substrates of Fam20C kinases and the role of phosphorylation on substrate function.

P2165**Board Number: B689****Mechanisms and functional consequences of T cell microclusters**X. Su¹, J. Ditlev², E. Hui³, J. Rumpf³, S. Banjade², J. Taunton³, M.K. Rosen^{4,5}, R. Vale³;¹Department of Cell and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA, ²University of Texas Southwestern Medical Center, Dallas, TX, ³University of California, San Francisco, San Francisco, CA, ⁴Department of Biophysics, University of Texas Southwestern Medical Center, Dallas, TX, ⁵Howard Hughes Medical Institute, Dallas, TX

The assembly of higher-order protein structures has been suggested to promote signaling whereas a clear cause-and-effect relationship has been difficult to establish, largely due to limited knowledge about how these structures are formed. To investigate the mechanisms and functional properties of membrane-bound signaling clusters, we developed an in vitro reconstitution system in which signaling clusters are assembled from individual purified components on synthetic supported lipid bilayers. We found multivalent protein-protein interactions can drive the cluster formation of LAT, a signaling hub protein that recruits multiple downstream effectors for TCR signaling. LAT clusters enrich Sos1(RasGEF), PLCg1(Phospholipase), and Nck1(connecting to actin polymerization). Clustering renders resistance to dephosphorylation of LAT by protein tyrosine phosphatase, which suggests a mechanism of how clustering might maintain TCR signaling. In addition, we found two adaptor proteins Grb2 and Gads are redundant and competitive for clustering LAT. Finally, through reconstituting a signaling pathway from TCR triggering to LAT clustering, and to actin polymerization, we showed LAT cluster nucleates actin filaments and promotes membrane-proximal actin network formation. Together, we propose TCR triggering induces a phase transition of LAT complex that promotes downstream signaling.

P2166**Board Number: B690****Identification of Novel Oncogenic Drivers in Cancer Cell Lines Through a Systems Pharmacology Approach.**N. Sakur¹, N. Salmen¹, M.Y. Fink¹;¹LIU Post, Brookville, NY

Oncogenes drive cancer cell growth and identification of novel candidate oncogenes is a necessary step for developing new drugs. Integration of data from genomic, proteomic, and literature findings, in cancer cell lines, can generate models of altered signaling networks in different cancer types and subtypes. Several large-scale systems biology studies have screened cancer cell lines for drug sensitivity. In this study, systems-level network models of cancer cell lines have been generated and, based on these models, drug sensitivity predictions have been made. These predictions were then compared to known sensitivities from published studies. The results identified unexpected interactions between cell

line networks and drugs. The ZR-75-30 breast cancer cell line displayed sensitivity to sorafenib, a multi-kinase inhibitor, that targets several receptor tyrosine kinases and RAF. This reported sensitivity has been confirmed and the specific target and pathway affected in ZR-75-30 cells is currently being explored.

The role of Sp1 in p21^{CIP1} regulation in B-Raf^{V600E} cancer.

M. Karkhanis¹, J. Park²;

¹Biochemistry, Medical College of Wisconsin, Milwaukee, WI, ²Biochemistry, Med Coll Wisconsin, Milwaukee, WI

We have previously reported that mortalin, an Hsp70 family chaperone, can suppress p21^{CIP1} expression in certain B-Raf^{V600E} cancer cells. We observed that mortalin depletion in B-Raf^{V600E} cancer cells results in p21^{CIP1}-mediated cell cycle arrest in a MEK-ERK dependent manner. We thus proposed that mortalin upregulation is a potential mechanism for certain B-Raf^{V600E} cancer cells to bypass growth arrest caused by aberrant MEK-ERK activation. Interestingly, mortalin depletion could induce p21^{CIP1} expression independently of p53 in certain B-Raf^{V600E} cancer cells. In this study, we investigated the mechanism by which mortalin regulates p21^{CIP1} expression. Using luciferase reporter truncation analysis, we have identified a proximal p21^{CIP1} promoter region responsive to mortalin depletion in p53 mutated cancer cells. Interestingly, when Sp1 transcription factor-responsive elements in this region were mutagenized, the p21^{CIP1} promoter reporter was no longer responsive to mortalin depletion. Consistent with this, our ChIP analysis revealed that mortalin knockdown could induce Sp1 binding to p21^{CIP1} promoter in a MEK-ERK dependent manner. Furthermore, RNA interference of Sp1 substantially attenuated p21^{CIP1} expression induced by mortalin depletion in these cells. In summary, our data demonstrate that, in B-Raf^{V600E} cancer cells, Sp1 can regulate p21^{CIP1} transcription even in the absence of wild type p53. This study suggests that Sp1 may have an important role in p21^{CIP1} regulation in certain cancer types.

Pseudophosphatase MK-STYX regulates RhoA signaling, and enhances branching in PC12 cells.

D.A. Banks¹, B.M. Flowers¹, S.D. Hinton¹;

¹Biology, College of William Mary, Williamsburg, VA

The pseudophosphatase MK-STYX (mitogen activated kinase phosphoserine/threonine/tyrosine binding protein) is a member of the dual specificity MAPK phosphatases (MKP) that is catalytically inactive due to mutations in its active site (HCX5R to FSX5R). Previously, we reported that MK-STYX induces neurite-like outgrowths in PC12 cells and enhances the effects of NGF stimulation by dramatically increasing the

number of neurites. Furthermore, MK-STYX induced neurite formation in the presence of a MEK inhibitor, suggesting that MK-STYX exerts its effects independently of the extracellular signaling related kinase ERK pathway. RhoA activity assays showed that MK-STYX decreases RhoA activation, whereas knockdown of MK-STYX increased RhoA activation- suggesting that MK-STYX is a regulator of RhoA signaling. Here, we further investigate the role of MK-STYX as a regulator of RhoA signaling by examining MK-STYX's effects on cofilin, a RhoA downstream effector. Cofilin is an actin binding protein that depolymerizes actin, resulting in cytoskeletal reorganization. MK-STYX did not alter cofilin expression but did alter its phosphorylation. Phosphorylated cofilin (p-cofilin) stabilizes actin filaments, causing persistence of neurites and continued growth. MK-STYX caused an increase in phosphorylated cofilin over time after NGF stimulation, whereas, levels of p-cofilin in control cells stayed consistent over time. Furthermore, p-cofilin decreased when MK-STYX was knocked down with shRNA. Throughout the course of these experiments, we noticed that cells overexpressing MK-STYX developed more neurites, which appeared to branch. To address whether MK-STYX induced a distinct branching pattern in PC12 cells, we scored cells to categorize the neurites branching pattern. Initially, cells were scored for the presence of neurites greater than 20 μm . Cells with at least one extension meeting this criterion were scored for primary (extension from cell body) and secondary neurites (extensions from primary neurite). Cells not stimulated by NGF but expressing MK-STYX showed a slight shift in overall distribution of primary and secondary neurites compared to the control. NGF stimulated cells overexpressing MK-STYX showed a greater shift in distribution of both primary and secondary neurites compared to the control. These data demonstrate that MK-STYX causes branching, which is regulated by the Rho GTPases such as RhoA, in PC12 cells. Taken together these data provide more substantial evidence for MK-STYX as a regulator of RhoA signaling and neuronal differentiation.

Board Number: B693

Characterization of a novel yeast gene, *XRR1*, which confers resistance to the antifungal rapamycin and whose protein may be localized to stress granules.

M.J. Swede¹, V. Rivera¹, R. Suwal²;

¹Health Sciences, Long Island University, Post, Brookville, NY, ²Biomedical Sciences, Long Island University, Post, Brookville, NY

Cell cycle arrest in response to the macrolide antifungal agent rapamycin (sirolimus) in the yeast *S. cerevisiae* is mediated through the binding of FKBP12 protein (FPR1p) with rapamycin, forming a complex with the TOR1 and TOR2 proteins. Deletion mutations in the *FPR1* gene and specific point mutations in *TOR1* and *TOR2* genes, which prevent interaction with the FKBP12-rapamycin complex, result in a resistance to rapamycin phenotype. We have characterized a novel gene, *XRR1* (exhibits Rapamycin Resistance), whose null mutant exhibits temperature sensitive resistance to rapamycin. The *XRR1* gene product was shown via a systematic yeast two-hybrid analysis (Uetz *et al*, 2000) to physically interact with FKBP12 (FPR1p). The *XRR1* gene exhibits sequence homology to the A1pp (Macro) domain

specific for binding ADP-ribose. This domain is found in the C-terminus of the mammalian macroH2A histone variant.

Characterization of the *XRR1* gene suggests a role in the rapamycin resistance pathway. We have observed that the *XRR1* null mutation results in an eight-fold increase in growth in the presence of 100 ng/ml rapamycin at 37°C after six hours of growth compared to five-fold increase at 30°C. Wildtype isogenic strains exhibit only a 2.8 fold increase of growth under the same growth conditions.

The *XRR1* gene product may be localized to stress granules under conditions of nutritional stress. Microscopic imaging of Xrr1p-GFP indicates three subcellular distribution patterns under normal growth conditions: we have observed uniform cytoplasmic staining and staining in which the vacuolar staining is excluded in the majority of the cells observed, and punctate cytoplasmic staining in a small percentage of cells. However, under conditions of glucose starvation, we observed an increase in the punctate staining pattern and a concomitant reduction in cytoplasmic staining. This phenomenon does not appear to occur under conditions of physical stress, as we do not see an increase in punctate staining after a of 42°C heat shock.

Calcineurin Interacting Protein works as a Modulator of tax-6 Signaling Pathway.

H. Jung¹, S. Lee¹, J. Ahnn²;

¹BK21Plus BDR Team, Hanyang Univ, Seoul, Korea, ²Hanyang Univ, Seoul, Korea

Calcineurin is a serine/threonine phosphatase regulated by Ca²⁺-binding calmodulin. Calcineurin consists of two subunits, catalytic subunit A (TAX-6) and regulatory subunit B (CNB-1). Calcineurin substrate candidates of *C.elegans* have been screened by yeast two-hybrid assays. We found that CNP-2 interacted with the catalytic domain of TAX-6. The CNP-2 is expressed in head neurons, posterior intestine, spermathecal valve, spermatheca-uterus valve and cell junction/ membrane in spermatheca. In males, the CNP-2 is expressed in spicule retractor muscles, rays and at the end of fan, which are mating behavior-mediated organs. Also, CNP-2 is required in the ovulation, arrangement of eggs, ray structure and mating behaviors. CNP-2 seems to be critical in the mating efficiency and sperm activation. We are currently investigating the roles of *cnp-2* in *tax-6* pathway, regarding IP3 signaling.

P2171**Board Number: B695****Regulation of body size in C.elegans via counteracting between phosphatase and kinase.**T. Choi¹, S. Lee¹, J. Ahn²;¹BK21Plus BDR Team, Hanyang Univ, Seoul, Korea, ²Hanyang Univ, Seoul, Korea

Calcineurin, Ca²⁺/calmodulin-dependent serine/threonine phosphatase, has been reported to function in body size regulation in *C. elegans*. We confirmed neuronal function of calcineurin is important cue in the regulation of body size. RNAi screening to identify kinases which counteract with calcineurin activity revealed 33 kinases that rescued the phenotype of small body size in *tax-6(lf)* background. Among the positive candidates, we found *mbk-2* which encodes one of two *C. elegans* members of the Dual-specificity Yak1-Related Kinase (DYRK) family proteins partially rescued the body size of *tax-6(lf)*. One of the candidates target gene, *oma-1* RNAi also showed partial rescue of *tax-6(lf)*. We are doing experiments to elucidate the underlying working mechanisms.

P2172**Board Number: B696****High Glucose-Induces Oxidative Stress in HEK-293 Cells.**E. Bradshaw¹, G. Beggs¹, M. Cartafalsa¹;¹Biology, Florida Southern College, Lakeland, FL

Approximately 366 million people worldwide are affected by diabetes. A long-term complication of diabetes mellitus is kidney disease, also known as diabetic nephropathy. To date, the underlying causes of diabetes-induced kidney failure are not well understood but recent evidence points to mitochondrial dysfunction. In models of diabetic nephropathy, there is increased mitochondrial stress, which is associated with kidney cell death. In this study, HEK-293 cells were treated with 25mM glucose and ATP production and oxidative stress was assessed with an ATP assay and TBARS assay, respectively. HEK-293 cells treated with 25mM glucose for 24 hours increased ATP production as well as lipid peroxidation compared to control. These data indicate high glucose conditions influence the mitochondria in this cell type. To determine the molecular mechanism for high sugar environment changes in ATP production and oxidative stress, we examined the mTOR pathway. Recent clinical data implicates the Akt/mTOR pathway in diabetic patients with kidney disease. Preliminary western blot evidence shows that dextrose increases phosphorylation of p70S6 kinase in HEK-293 cells. This effect is inhibited by rapamycin, an inhibitor of the mTOR pathway. Thus, these data suggest mTOR may play a role in the increased ATP production and oxidative stress induced by a high sugar environment.

P2173**Board Number: B697****Regulation of DAG Lipase Activity – Implications for ‘On-Demand’ Endocannabinoid Signalling.**R.L. Markwick¹, E. Williams¹, M. Maresca², P. Singh¹, F. Howell¹, G. Williams¹, P. Doherty¹;¹Wolfson CARD, King's College London, London, England, ²Astra Zeneca, Molndal, Sweden

Diacylglycerol lipases (DAGL α and β) are key enzymes in the biosynthesis of 2-AG, the major endocannabinoid (eCB) in the brain. 2-AG acts on CB1 and/or CB2 receptors and DAGL-dependent eCB signalling regulates a large number of responses including axonal growth during development, as well as neurogenesis and retrograde synaptic plasticity in the adult (Oudin *et al.*, 2011). The enzymes also play a major role in driving pathogenic inflammatory responses via a DAGL/MAGL pathway that generates AA as a precursor to prostaglandin synthesis. DAGL antagonists are being developed as novel therapeutics based on their ability to regulate eCB-mediated signalling and/or inflammatory responses. The DAGLs appears to display ‘on-demand’ synthesis, generating increasing amounts of 2-AG in response to cellular messengers. Based on homology modelling and analysis of phosphoproteomic databases we have postulated that a phosphorylation dependent displacement of an intramolecular regulatory loop “activates” DAGL α/β activity by allowing access of the natural substrate DAG to the active site of the enzyme (Reisenberg *et al.*, 2012). We will report a cellular assay to measure DAGL α function. This assay measures DAGL-dependent activation of the CB1 receptor, reporting on physiologically relevant DAGL α activity in a cell. Evidence for phosphorylation-dependent activation of DAGL α , required for eCB signalling, and use of CRISPR/Cas9 System to systematically ‘switch off’ endogenous DAGL α , will be presented.

P2174**Board Number: B800****Analysis of the Regulatory Mechanism by which Shear Stress and Stretch Force Induce Nitric Oxide Production in Endothelial Cells.**J. Wang^{1,2}, K. Kobayashi-Kato¹, M. Hagiwara¹, N. Ishida¹, K. Matsushita^{1,2};¹Oral Disease Research, National Center for Geriatrics and Gerontology, Nagoya, Japan, ²National Center for Geriatrics and Gerontology, Obu, Aichi, Japan

Blood vessels are subjected to constant mechanical forces from blood pressure and flow, which cause internal stresses (endothelial shear stress and circumferential wall stress, respectively). The mechanical

forces not only cause morphological changes of the endothelium and blood vessel wall but also trigger biochemical and biological events. Physiologic shear stress and stretch force exert vasoprotective effects via nitric oxide (NO) and provide a homeostatic oxidative balance. Perturbation of these mechanical forces can disturb biochemical homeostasis and lead to vascular remodelling and possible dysfunction. It is known that these distinct biological endpoints are caused by some common biochemical pathways. However, little is known about the difference of biological pathways evoked by shear stress and by stretch force. In this study, we focused on NO production induced by shear stress and by stretch force and compared the regulatory mechanism of these stimuli with the NO production in endothelial cells. We examined NO production induced by short (30 sec -10 min) exposure of endothelial cells (HUVECs) to laminar shear stress and sustained stretch force. A high level of NO was produced and peaked at 1 min and 4 min after exposure to shear stress in HUVECs. On the other hand, a low level of NO was produced at 30 sec after exposure to stretch force. Chelation of intracellular Ca²⁺ with BAPTA-AM completely abolished the phosphorylation of Akt and eNOS and the production of NO induced by shear stress, whereas BAPTA-AM suppressed only half of the phosphorylation of Akt and eNOS and NO production induced by stretch force and, conversely, complete depletion of Ca²⁺ in the culture strongly enhanced NO production by HUVECs. These results suggest that the regulatory mechanism by which endothelial cells produce NO depends on the type of stress and that the role of Ca²⁺ signal in NO production may differ with stimulation from shear stress and stimulation from stretch force. The results may be useful for understanding the responses of blood vessels to internal vessel stresses induced by blood pressure and flow.

A Novel Role for Wiskott - Aldrich syndrome Protein (WASP) in the Regulation of Macrophage Nanotubes.

K. McCoy-Simandle¹, D. Cox^{1,2};

¹Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ²Albert Einstein College of Medicine, Bronx, NY

Macrophages are known to interact with tumor cells, pathogens, lymphocytes endothelial cells, and many other cell types via small molecule intermediaries. However, traditional soluble means of communication do not account for all macrophage interactions suggesting other means of communication. Recently discovered tunneling nanotubes (TNTs) are membranous channels that connect different cells together. These connections are thin and may be up to several cell diameters long. These structures occur in many immune cells in vitro and in vivo allowing for transfer of signals, vesicles, and organelles. Even pathogens can use these TNTs to transfer from cell to cell. Due to their length and the ability to form networks of TNTs, cell signals can be propagated over vast distances quickly and without interaction with extracellular fluid. Because these structures have no known

markers and are sensitive to light exposure, shearing force, and chemical fixation, little is known about the formation of these structures in macrophages. In this study, TNTs are characterized in macrophages by in vitro live cell imaging which minimizes TNT breakage. Live visualization of the membrane was achieved by either staining with the fluorescent membrane label, FM1-43FX, or by expression of a fluorescent protein targeted to the plasma membrane using a CAAX motif. Interestingly, macrophages polarized to either the pro-inflammatory or pro-tumorigenic states, using LPS or IL-4, show increased number of TNTs. Formation of TNTs was also investigated when actin-polymerization, PI3 kinase or Src kinase pathways were blocked. Moreover, it was determined that Wiskott-Aldrich syndrome protein (WASP) regulates formation and stabilization of TNTs. Depletion of WASP by shRNA in a macrophage cell line greatly reduces formation of these structures. Furthermore, while phosphorylation of WASP was minimally required for the formation of these structures, it was important for TNT stability. These results reveal a novel role of WASP in macrophage TNT formation. Interestingly, they also suggest that some of the immune deficiencies observed in patients with Wiskott-Aldrich syndrome may be due to the decreased number of TNTs. More research will need to be done to find potential ways to manipulate TNTs therapeutically.

Minding the GAPs: A novel RhoGAP family of RPEL proteins as target for regulation by G-actin.

J. Diring¹, S. Mouilleron², R. Treisman¹;

¹Signal Transduction and Transcription Laboratory, CRUK London Research Institute, London, UK,

²Protein Structure Unit, CRUK London Research Institute, London, UK

Small GTPases of the Rho family control the dynamics of the cytoskeleton through multiple effector proteins that regulate the assembly, activity and turnover of actin-based structures, thereby controlling cell adhesion, morphology and motility in response to extracellular signals. Activation of these GTPases lead to the accumulation of filamentous actin (F-actin) through both filament stabilisation and de novo polymerisation, with concomitant depletion of cellular levels of monomeric actin (G-actin). RPEL proteins are a novel family of G-actin-binding proteins, which are able to sense fluctuations in cellular G-actin concentration, and respond to maintain cytoskeleton homeostasis and remodelling. Two families of RPEL proteins have been described: the MRTF family, which couples gene transcription to F-actin availability, and the Phactr family, which coordinates actomyosin crosslinking with F-actin level.

We identified two novel RhoGAP subfamilies of RPEL proteins, among which Arhgap12 has been the focus of our study. Our data show that Arhgap12 is a GTPase activating protein towards the small GTPase Rac1. It regulates the remodelling of the actin cytoskeleton, cell motility and invasion. Moreover, direct binding of G-actin regulates its subcellular localisation and inhibits its activity by competing with Rac1 binding. Structural studies and point mutation analyses indicate that actin interacts both with the RPEL motif and with a conserved sequence embedded in the GAP domain. We

propose that Arhgap12 orchestrates a homeostatic feedback loop to coordinate G-actin level to the activation of Rac signalling.

Development of a proof-of-concept small molecule inhibitor of MgcRacGAP identifies new potential functions of MgcRacGAP in cell division and signaling.

A. van Adrichem¹, A. Fagerholm², L. Turunen¹, A. Lehto¹, J. Saarela¹, A. Koskinen², G. Repasky¹, K. Wennerberg¹;

¹Institute for Molecular Medicine Finland FIMM, Helsinki, Finland, ²Chemistry, Aalto University, Espoo, Finland

The MKLP1/MgcRacGAP/Ect2 protein complex is well-established as a core regulator for initiation and progression of cytokinesis. Interestingly, it also appears to be involved in oncogenesis through a cytokinesis-independent mechanism where overexpression drives invasiveness, epithelial-to-mesenchymal transition and chromosomal segregation aberrations. Furthermore, MgcRacGAP is reported to be essential for nuclear translocation of STAT transcription factors, including STAT3, which is a well-known promoter of oncogenesis and cancer drug resistance. Small molecule modulators of MgcRacGAP would be very valuable research tools for the detailed study of the many apparent roles of MgcRacGAP. Therefore, we developed a biochemical high throughput screen for identification of inhibitors of MgcRacGAP and screened 370,000 compounds. From this campaign, we identified the first publicly described small molecule RhoGAP inhibitor. This compound (MINC1) showed selective biochemical inhibition of MgcRacGAP at low micromolar concentrations. Cellular treatment with MINC1 resulted in inhibition of proliferation and increased frequencies of multinucleation, in agreement with it being a cytokinetic inhibitor. Surprisingly, we also observed collapsed mitotic spindles that resembled a failure at prophase/pro-metaphase similar to a PLK1-inhibited phenotype. Since MgcRacGAP is a substrate of PLK1, this indicates that MgcRacGAP may also play a role in PLK1-regulated mitotic processes. In agreement with MgcRacGAP regulating cellular polarity and invasion, treatment with MINC1 or siRNA-mediated knockdown of MgcRacGAP caused a strong inhibition of MDA-MB-231 breast cancer cell line matrigel invasion. Finally, based on previous published reports proposing that the MgcRacGAP-Rac1 complex plays a vital role in STAT family transcription factor nuclear translocation, we examined the capability of MINC1 to disrupt STAT signaling. Surprisingly, we instead found that both MINC1 treatment and siRNA-mediated knockdown of MgcRacGAP caused an activation of STAT3 and STAT5B signaling in several cell lines, suggesting that the proposed role of MgcRacGAP in STAT family transcription factor function may not be generally applicable. In conclusion, we have identified MINC1, a small molecule inhibitor of MgcRacGAP. This compound represents the first described selective small molecule inhibitor of a small G-protein GTPase activating protein. We utilized this inhibitor to study the function of MgcRacGAP in cell division and in other biological contexts with both expected and unexpected results. Ongoing work is focused on optimizing the compound to allow further detailed studies of the role of MgcRacGAP.

P2178**Board Number: B804****Investigating Rho GTPase Pattern Formation During Wound Repair: The Role of RhoGAP1/8.**N. Davenport¹, W. Bement^{1,2,3};¹Graduate Program in Cellular and Molecular Biology, University of Wisconsin-Madison, Madison, WI,²Department of Zoology, University of Wisconsin-Madison, Madison, WI, ³Laboratory of Cell and Molecular Biology, University of Wisconsin-Madison, Madison, WI

The ability to respond to physical damage is an essential and evolutionarily conserved feature of single cells and tissues. The Rho family of GTPases has been shown to coordinate the cytoskeletal rearrangements needed to reestablish the integrity of the plasma membrane and underlying cortex in response to cell damage. The precision with which Rho and Cdc42 are activated and maintained in distinct activity zones throughout the healing process suggests the involvement of multiple Rho GTPase regulators at the wound. To date, a candidate screen for guanine nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs) involved in regulating Rho GTPase activity at the wound has identified a single wound regulator. By continuing the candidate screen, we have identified two additional GAPs, RhoGAP1 and RhoGAP8, as potential wound regulators. While initially labeling early and recycling endosomes in resting cells, eGFP-tagged RhoGAP1 is recruited between the zones of active Rho and Cdc42 in *Xenopus laevis* oocytes upon wounding. These results have been confirmed by the discovery of endogenous RhoGAP1 at wounds via immunofluorescence microscopy. Targeting of RhoGAP1 to wounds is mediated by its C-terminal region which contains both a GAP domain and a proline-rich region. Reduction of active Rho due to overexpression of untagged RhoGAP1 and alteration of GTPase activity zone position by dominant negative RhoGAP1 supports a hypothesis that RhoGAP1 acts as an enzymatic barrier to promote proper GTPase zone segregation throughout wound repair. We have shown that RhoGAP1 and RhoGAP8 colocalize at single-cell wounds which, in addition to previously reported evidence of their interaction, suggests they may form a complex to regulate Rho GTPase activity. We have also used both RNAi and morpholinos to effectively knockdown proteins in *Xenopus* embryos 24 hours post-fertilization. Knockdown of RhoGAP1 in embryos appears to increase the amount of cytoplasmic F-actin in cells. Further, wounding of *Xenopus* embryos causes 3XeGFP-RhoGAP1 to be displaced from its punctate, junctional localization to become diffuse and cytoplasmic. This displacement appears to follow an intracellular Ca²⁺ increase and precedes increases in both active Rho and F-actin at cell-cell junctions, suggesting RhoGAP1 may regulate a key step in reorganizing the actin cytoskeleton during the multicellular wound response.

P2179**Board Number: B805****A Novel GEF Independent Role of P-Rex1 in GPCR Trafficking.**M.J. Baker¹, E. Maunders¹, H.C. Welch¹;¹The Babraham Institute, Cambridge, United Kingdom

P-Rex proteins are a family of guanine nucleotide exchange factors (GEFs) for the Rho GTPase Rac. They use their GEF function to catalyse the release of GDP from Rac, thus allowing GTP to bind transforming Rac into its active GTP bound conformation. It has been well established that the GEF function of P-Rex1 mediates membrane ruffling and cell migration, as well as reactive oxygen species production. All known cellular responses to P-Rex1 activity are as a result of Rac signalling, often involving actin filament reorganisation. Therefore, there are no known GEF independent roles of P-Rex1. Furthermore, P-Rex proteins are known to be important for tumour growth and metastasis in several types of cancer including prostate, breast and melanoma.

The role of P-Rex family members in trafficking has not been studied in great detail to date, however, there has been work published which suggests that P-Rex1 has roles in vesicle trafficking. This includes evidence to suggest roles for P-Rex1 in trafficking of the GLUT4 transporter¹. We therefore decided to investigate a potential role of P-Rex1 in stimulation dependent GPCR internalisation, in an effort to identify the function of P-Rex1 in trafficking.

During this study we have identified a GEF independent function of P-Rex1 in membrane trafficking. This novel function of P-Rex1 is the first GEF independent function to be identified. Using fixed cell immunofluorescence imaging we show that overexpressed P-Rex1 has an inhibitory effect on the internalisation of a GFP tagged GPCR and that this function of P-Rex1 does not require its GEF activity. We also identify the domains of P-Rex1 that are required for this inhibitory role as part of a first step to deciphering the mechanism behind this exciting and new role of P-Rex1.

P2180**Board Number: B806****Cdc42 Activation is Necessary for Sustained Oscillations of Ca²⁺ and PIP₂ in RBL Mast Cells Stimulated by Antigen.**D.A. Holowka¹, M.M. Wilkes¹, B. Baird¹;¹Chemistry and Chemical Biology, Cornell University, Ithaca, NY

Antigen stimulation of mast cells via FcεRI, the high-affinity receptor for IgE, triggers a signaling cascade that requires Ca²⁺ mobilization for exocytosis of secretory granules during the allergic response. To characterize the role of Rho GTPases in FcεRI signaling, we utilized a mutant RBL cell line, B6A4C1, that is deficient in antigen-stimulated Cdc42 activation important for these processes. B6A4C1 cells exhibit

severely attenuated Ca²⁺ oscillations in response to antigen, and these are restored to wild type RBL-2H3 levels by expression of constitutively active Cdc42 G12V or by a GEF for Cdc42, DOCK7. Ca²⁺ oscillations are not restored when the C-terminal di-arginine motif of active Cdc42 is mutated to di-glutamine, demonstrating a role for these basic residues in this Rho family function. Antigen-stimulated FcεRI endocytosis, which occurs independently of stimulated Ca²⁺ influx, is also defective in B6A4C1 cells, and Cdc42 G12V reconstitutes this response as well. Thus, activation of Cdc42 occurs prior to and is critical for antigen-stimulated pathways leading separately to both Ca²⁺ mobilization and receptor endocytosis. Accounting for these downstream functional consequences, we show that Cdc42 G12V reconstitutes antigen-stimulated oscillations of phosphatidylinositol 4,5-bisphosphate (PIP₂) at the plasma membrane in B6A4C1 cells, pointing to Cdc42 participation in the regulation of stimulated PIP₂ synthesis as a key functional role for this Rho family GTPase in mast cells.

Rac1-dependent activation of Cdc42 during CSF-1 response by macrophages.

V. Miskolci¹, H. Park¹, L. Hodgson¹, D. Cox^{1,2};

¹Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ²Albert Einstein College of Medicine, Bronx, NY

Rac1 and Cdc42, members of the Rho family of small GTPases, are central regulatory hubs of actin cytoskeleton rearrangement required during directed migration. It was previously reported that genetic deletion of Rac1 had no significant effect on macrophage chemotaxis, although a range of abnormalities were observed both in cell morphology and behavior. These results suggest that some compensatory action may occur, possibly by other Rho family members via increased or re-localized activity. To address these potential scenarios we used FRET-based Rho GTPase biosensors, as they can detect dynamic changes both in the levels and localization of Rho GTPase activity. We found that Cdc42 activity was elevated in response to CSF-1 but not significantly localized at F-actin-rich protrusions in a murine macrophage RAW 267.4 cell line, whereas Rac1 activity was highly localized at these same protrusions. However, there was no detectable alteration in Cdc42 activity or localization following reduction of Rac1 levels using shRNA. Surprisingly, shRNA-depletion of Rac1 in these cells produced inhibitory effects on CSF-1 – mediated Cdc42 activation, suggesting a previously unknown potentiation effect by the Rac1 signaling axis. This new regulatory mechanism of Rac1 activating Cdc42 is not due to defects in CSF-1 receptor expression or signaling, since CSF-1 stimulation resulted in similar levels of receptor tyrosine phosphorylation in control versus Rac1-depleted macrophages. We report here a novel signaling mechanism in which Cdc42 activation is dependent on Rac1, and we hypothesize that a Rac1 – activated GEF targeting Cdc42 is involved in the CSF-1 stimulation pathway in macrophages.

P2182**Board Number: B808****AMPylation of Rho GTPases disrupts multiple host signaling processes.**A.R. Woolery¹, X. Yu², J. LaBaer², K. Orth¹;¹Molecular Biology, University of Texas Southwestern Medical Center, Dallas, TX, ²Biodesign Institute, Arizona State University, Tempe, AZ

Rho GTPases are frequent targets of virulence factors as they are keystone signaling molecules in many processes. Modifications of their switch-1 loop are known to be a potent method of disabling the actin cytoskeletal machinery, but Rho GTPases are also important for many other signaling pathways. We attempted to broaden the understanding of the consequences of switch-1 loop modification in downstream signaling using AMPylation by the *Vibrio parahaemolyticus* type three secreted effector VopS. Using infection models, biochemistry and versatile self-assembled microarrays, several novel effects of Rho GTPase AMPylation were identified. We found that multiple signaling interactions of GTPases were inhibited, including NFκB, MAP kinase, the Inhibitor of Apoptosis proteins (IAP) and the phagocytic NADPH oxidase system (NOX2.) Phosphorylation of IκB^α and JNK kinase was inhibited in a VopS-dependent manner during infection with *Vibrio parahaemolyticus*. VopS also sequestered p65 in the cytosol during infection, while removal of VopS allowed robust translocation. AMPylation also prevented the generation of superoxide by the phagocytic NADPH oxidase complex. Furthermore, the interaction of GTPases with the E3 ubiquitin ligases cIAP1 and XIAP was hindered, leading to decreased degradation of Rac and RhoA during infection. Finally, we screened for novel Rac1 interactions using a nucleic acid programmable protein array (NAPPA) and discovered that Rac1 binds to the protein C1QA, a protein known to promote immune signaling in the cytosol. Interestingly, this interaction was disrupted by AMPylation. In addition to these findings, we also adapted NAPPA to use fluorescent probes to screen for novel substrates of protein transferases, including AMPylation. We conclude that modification of the switch-1 loop by VopS and other toxic proteins is a multifaceted virulence mechanism that counters several host immunity strategies.

P2183**Board Number: B809****Rac1 orchestrates transcriptional and post-transcriptional regulation of matrix remodelling during fibroblast-mediated matrix contraction.**H. Li¹, V. Tovell¹, D. Paull¹, D. Simpson², P.T. Khaw¹, M. Bailly¹;¹Department of Cell Biology, UCL Institute of Ophthalmology, London, United Kingdom, ²Centre for Experimental Medicine, Queen's University, Belfast, United Kingdom

Fibrosis is a major cause of morbidity in humans, with over 40% of all death in the developed world attributable to some form of fibrotic disease. In the eye alone, tissue contraction and scarring are involved in the pathogenesis or failure of treatment of virtually all major blinding diseases. However, the molecular mechanisms underlying fibrosis and scarring are still poorly understood. We previously

identified Rac1 as one of the major player underlying fibroblast-mediated tissue contraction, and showed that an early transient treatment with Rac1 inhibitor NSC23766 is sufficient to block long-term matrix remodelling and tissue contraction *in vitro* and *ex-vivo*. We have now performed a genome wide microarray analysis in primary human conjunctival fibroblasts during contraction *in vitro* with/without treatment with NSC23766. We have found that the cells undergo dramatic shift in gene expression during the early stages of contraction, akin to a wound activation profile, with over 3000 genes changing expression from day 0 to day3, in which a specific gene profile including matrix metalloproteinases (MMP) 1, 3 and 10, inflammatory molecules and cytokines are significantly up-regulated. This “activation” profile recedes when the contraction slows down at day5, with most of the genes changing back in the opposite direction from day3 to day 5, and the gene profile of later contraction is linked to long-term fibrosis with gene expressions found in common with a few human ocular fibrotic diseases. Transient treatment with the Rac1 inhibitor resulted in an almost complete abrogation of the activation phase, with the cells assuming a day5 resting cell profile. In addition, we showed that whilst Rac1 inhibition did not affect the mRNA expression of most MMPs upregulated during contraction, it lead to a significant reduction in overall MMP activity, in accordance with the previously observed reduction in matrix degradation. This suggests that blocking Rac1 activation during the early stages of contraction is sufficient to fully prevent the cells from entering the contractile pathway as a whole, as Rac1 appears to mastermind a complete wound healing response by acting both at the transcriptional and post-transcriptional level.

Rac3 promotes invadopodia maturation and matrix degradation.

S.K. Donnelly¹, J. Bravo-Cordero¹, J.S. Condeelis², L. Hodgson²;

¹Albert Einstein College of Medicine, Bronx, NY, ²Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Metastasis is responsible for ninety percent of all cancer related deaths. One of the first steps in the metastatic cascade is the local invasion of tumor cells into the surrounding tissue. Invadopodia are actin-based protrusions that mediate the extracellular matrix degradation necessary for the invasion of tumor cells. Therefore deciphering the mechanisms of invadopodia regulation is critical to furthering our understanding of cancer cell dissemination. A number of studies have implicated the small GTPase Rac3 in tumor cell invasion but its mechanism of action has not yet been elucidated. Despite the similarity of Rac3 and the better-studied Rac1, there is also evidence to suggest that these isoforms have different functional roles. Rac1 has recently been shown to regulate the disassembly of invadopodia. We now show that, in direct contrast to Rac1, Rac3 regulates the maturation of invadopodia in two breast cancer cell lines, MtlN3 and MDA-MB-231. As Rac1 and Rac3 share 93% sequence homology, traditional approaches are not optimally suited to precisely define the spatial and temporal dynamics of Rac3 activation at invadopodia. Thus we have generated and validated a novel single-chain FRET-based Rac3 biosensor. Preliminary results suggest that there is a transient activation of Rac3 at invadopodia. Taken

together our data suggests that Rac3 functions as a molecular switch that regulates the transition of invadopodia from precursor to mature structure.

Board Number: B811

Cell invasion through basement membrane requires multiple GTPases and is initiated by CDC-42 directed invadopodia formation.

M.R. Clay¹, L.R. Lilley Lohmer¹, J.W. Ziel¹, Q. Chi¹, D.R. Sherwood¹;

¹Biology Department, Duke University, Durham, NC

Basement membrane (BM) is a thin, dense, sheet-like extracellular matrix that underlies epithelia, endothelia, and enwraps muscle and adipose tissues. Cell invasion through BM occurs during development and physiological processes, and inappropriately in cancer metastasis. Extrinsic signaling cues play key roles in inducing invasion, but how these signals regulate the cellular machinery and behaviors that promote invasion remains poorly understood. A key barrier in understanding how extrinsic cues direct invasion is the challenge of experimentally examining the dynamic interactions between invasive cells, BM, and the tissue being invaded *in vivo*. Anchor cell (AC) invasion in *C. elegans* is an experimentally tractable model to uncover mechanisms controlling cell invasion *in vivo*. To identify new genes required for AC invasion, we performed a sensitized genome-wide RNAi screen and found that the Rho GTPase *cdc-42* promotes AC invasion. In response to extracellular signals, CDC-42 can be activated to regulate processes related to cell invasion, such as cell polarity and cytoskeletal organization. Here we show that animals null for *cdc-42* have defects in AC invasion and display a highly penetrant delay in initial breach of the BM. An unknown cue secreted from the vulval precursor cells controls the timing and initiation of invasion, but the molecular pathways downstream of this cue have not been identified. Using site-of-action and genetic analyses, we show that CDC-42 functions in the AC downstream the vulval cue. While *cdc-42* has been identified as a regulator of cancer invasion *in vitro* how CDC-42 is localized, activated, and functions in BM breaching is unknown. A genetically encoded biosensor for active CDC-42 shows that CDC-42 is strongly activated at the site of BM breach, and that active CDC-42 colocalizes with highly dynamic F-actin structures called invadopodia, which are responsible BM breaching in AC invasion. RNAi knockdown of *cdc-42* resulted in a significant reduction in invadopodia number. These results suggest *cdc-42* is downstream of the vulval cue and initiates BM breaching by promoting invadopodia. Interestingly, an additional extrinsic signaling pathway functions in the AC involving the netrin receptor (*unc-40*) and its effectors, the Rac GTPases *ced-10* and *mig-2*. UNC-40 and the Rac GTPases direct formation of a large invasive protrusion after the vulval cue initiates BM breach via CDC-42 and invadopodia. Altogether, our data suggest that multiple, independent cues are required to direct cell invasion through BM (a coincidence system). We speculate that such systems exist to precisely control the site and timing of cell invasion—an essential but potentially destructive biological process.

Signaling Networks Governing Cell Migration

A Cell Life under Confinement: how immune cells manage to move, squeeze and survive.

H. Thiam¹, M. Raab¹, M. Le Berre¹, Y. Liu¹, M. Piel¹;

¹UMR 144, Institut Curie, Paris, France

The quest to understand how the mechanical and geometrical environment of cells impacts their behavior and fate has been a major force driving the recent development of new technologies in cell biology research. Despite rapid advances in this field, many challenges remain in order to bridge the gap between the classical and simple cell culture plate and the biological reality of actual tissues. In tissues, cells have their physical space constrained by neighboring cells and extracellular matrix. In the recent years, we have developed simple and versatile devices to precisely and dynamically control this confinement parameter in cultured cells. I will present results we obtained on the effect of confinement on cell migration focusing on two questions: how modulating confinement and adhesion of slow mesenchymal migrating cells can make them switch to a fast amoeboid like migration behavior and how cells can squeeze their nucleus when migrating through small gaps. I will conclude presenting intriguing results showing that large deformations of migrating cells induce strong damages to their nucleus raising the question of how immune cells such as dendritic cells can combine high motility and long term survival.

TRIM9 regulates DCC trafficking and FAK activity during developmental axonal plasma membrane expansion.

C. Winkle¹, S. Gupton²;

¹Neurobiology, University of North Carolina, Chapel Hill, NC, ²Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC

During neuronal development, growth cones at the tips of axons branch and extend toward postsynaptic targets. This involves dramatic expansion of the plasma membrane and requires regulated delivery of new plasma membrane material. The axon guidance cue Netrin-1 and its receptor DCC promote exocytosis, attractive growth cone turning and axon branching at least partially through the activation of the non-receptor tyrosine kinase FAK. We identified the E3 ubiquitin ligase TRIM9 as a novel regulator of exocytosis, axon branching and axon guidance. We show that TRIM9 directly binds the cytoplasmic tail of DCC within the same domain bound by FAK. Using neurons isolated from

embryonic mouse cortex, we demonstrate that genetic loss of TRIM9 disrupts DCC trafficking, activation of FAK, the frequency of exocytic vesicle fusion, and the density of axon branching. TIRF microscopy and surface biotinylation assays indicate that following Netrin-1 stimulation, DCC clusters and accumulates in the plasma membrane and is subsequently endocytosed and degraded. In TRIM9^{-/-} cortical neurons, DCC fails to cluster in the plasma membrane and does not get degraded following Netrin-1 stimulation. Whereas clustering is rescued by expression of GFP-TRIM9, structure function studies indicate that the ubiquitin ligase domain of TRIM9 is not required for clustering, but is necessary for Netrin response. Although total DCC protein is reduced in TRIM9^{-/-} neurons, a higher proportion of DCC localizes at the cell surface. These defects in DCC trafficking are associated with hyperphosphorylation of FAK at Y397, an increased exocytic frequency and exuberant axon branching in TRIM9^{-/-} neurons. Pharmacological inhibition of FAK rescues the aberrant exocytosis and axon branching in TRIM9^{-/-} neurons and blocks Netrin-dependent increases in exocytosis and branching in wildtype neurons. Interestingly, the exuberant branching of TRIM9^{-/-} axons in vitro was also observed in vivo within the corpus callosum and correlated with increased callosal thickness. We have crossed TRIM9^{-/-} and FRNKlox mice to determine if inhibition of FAK blocks the exuberant axon branching and corpus callosum thickening defects found in vivo. Results from cortical explant assays indicate TRIM9 also functions during axon outgrowth toward an asymmetric Netrin source. We are using a membrane-targeted GFP driven by the Tau promoter to define the axonal projection defects in TRIM9^{-/-} mice in vivo. We conclude that TRIM9 regulates DCC trafficking and FAK activation to control vesicle fusion and plasma membrane expansion during Netrin-dependent axon responses.

Characterizing new genes regulating cell-substrate adhesion to discover novel regulatory mechanisms of cell motility.

T.J. Lampert¹, P. Devreotes²;

¹Johns Hopkins University, Buffalo, NY, ²Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

The model organism Dictyostelium has greatly facilitated our understanding of the signal transduction and cytoskeletal pathways that govern cell motility. Cell-substrate adhesion is a target of many chemotaxis signaling events and it can be used to screen for cells that have defects in cell migration. In fact, cells lacking PTEN, a negative regulator of cellular extensions, adhere strongly to the surface. This leads to reasoning that other regulators of migration would also effect adhesion, a screening method was devised and isolated overly adherent mutants from a pool of mutagenized cells. Restriction enzyme mediated insertion (REMI) mutagenized cells, comprising more than 50000 insertions, yielded about 100 mutated cell lines with the desired phenotypes. The mutation sites in 20 of the strains have been mapped and many of the phenotypes are similar to those of PTEN knockout cells. The extent of increased adhesion, cell motility, directed migration, cell shape, and new filamentous actin at the periphery are all parameters that have been examined in these new overly adhesive cell lines. The

degree in which these parameters have been effected and the correlations between these changes is providing novel insights into the networks controlling cell motility. Many of these genes have human homologs with unknown functions. Therefore, the future study of this new group of regulators of adhesion and motility genes in Dictyostelium will not only advance the knowledge of cell migration in amoeboid cells but elucidate the functions of novel human genes with potential disease relevance.

Synthetic manipulation of PIP2 levels and PIP2-associated chemotactic signaling dissection in Dictyostelium.

Y. Miao¹, T. Inoue², P. Devreotes³;

¹Biological Chemistry, Johns Hopkins University, Baltimore, MD, ²Cell Biology, Johns Hopkins University, Baltimore, MD, ³Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

PIP2 is linked to many key chemotactic players, but our understanding of its roles in chemotactic signaling is very limited due to technical difficulties. The idea that the localized decrease of PIP2 level initiates chemotactic signaling events has been around for years, but has never been tested in a direct manner with traditional methods. In order to illuminate the roles of PIP2 and further explore the features of the chemotactic signaling network, I used the chemically-induced dimerization (CID) system, which allows the rapid inducible translocation of cellular proteins, to synthetically manipulate PIP2 level and dissect the signaling events. I have successfully accommodated CID in Dictyostelium, an excellent model system to study eukaryotic chemotaxis. In my current data, after I synthetically recruited the PIP2-specific 5-phosphatase Inp54p to the plasma membrane, the PIP2 biosensor PHplc δ fell off the membrane and the cells robustly oscillated between a spreading and a crunching morphology. Cells with the spreading morphology, but not the other one, may have further lowered PIP2 levels indicated by PTEN localization, clearly activated chemotactic signaling events as shown by Ras and PIP3 biosensors, and highly elevated F-actin along the periphery. Further, cells still carried out this response when PIP3 production was diminished by the PI3K inhibitor LY. Based on these results, we propose that PIP2 serves as an inhibitory role on Ras; when PIP2 levels are decreased, the chemotactic signaling network containing PKBs is activated following Ras activation. Also based on previous evidence, we propose that PI5K activation is downstream of PKBs activation, which brings up PIP2 levels to a certain degree and leads to the crunching morphology after cell spreading following the synthetic Inp54p recruitment. I will further use this system to dissect the PIP2-initiated signaling and feedback loops, as well as their roles in cell polarity and chemotaxis. Together the results of these experiments should shed light on the unsolved roles of PIP2 in chemotaxis and contribute to our further understanding of the chemotactic signaling network.

P2190**Board Number: B817****The adaptor proteins Crk and CrkL regulate T cell adhesion and selectively promote migration to sites of inflammation.**Y. Huang¹, M. Karimi², T. Park¹, N. Roy¹, T. Curran¹, T. Kambayashi², J.K. Burkhardt¹;¹Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia Research Institute, Philadelphia, PA, ²Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA

Effector T cell migration into inflamed sites greatly contributes to local inflammation and disease severity in inflammatory diseases, including GVHD. T cell migration into such sites depends heavily on regulated adhesion and migration, but the signaling pathways that coordinate these functions downstream of chemokine receptors are largely unknown. Using conditional knockout mice, we have found that T cells lacking the adapter proteins Crk and CrkL exhibit reduced integrin-dependent adhesion, chemotaxis, and diapedesis across an endothelium. Our studies reveal significant functional redundancy of the two closely related proteins. We show that Crk proteins coordinate with C3G and CasL to activate the integrin regulatory GTPase Rap1. Importantly, Crk proteins are required for effector T cell trafficking into sites of inflammation, but not for migration to lymphoid organs. This unique differential migration of Crk/CrkL-deficient T cells has important therapeutic implications, since T cells lacking Crk proteins can carry out graft-versus-leukemia responses with minimal graft-versus-host disease. Our studies show that Crk family adaptor proteins selectively regulate T cell adhesion and migration at effector sites, and identify these proteins as important novel therapeutic targets.

P2191**Board Number: B818****Coagulation factor IX regulates cell migration and adhesion in vitro.**A. Mamiya¹, H. Kitano¹, T. Ishikawa¹, Y. Fujiwara¹, M. Yoshida¹, . Kokubun¹, C. Hidai¹;¹Nihon Univ Sch Med, Tokyo, Japan

Introduction : Coagulation factor IX (F9) is thought to circulate in the blood as an inactive zymogen before being activated in the coagulation process. The effect of F9 on cells is poorly understood. This study aimed to evaluate the effects of intact F9 and its cleavage fragments on cell behavior. Materials & Methods : A431 cells (derived from human squamous cell carcinoma), Pro5 cells (derived from mouse embryonic endothelial cells), Cos7 cells, and human umbilical vein endothelial cells (HUVEC) were utilized in this study. The effects of F9 and its cleavage fragments on cell behavior were investigated in several types of experiments, including wound-healing assays and modified Boyden chamber assays. To investigate intercellular or cell-matrix adhesion, immunohistochemistry was employed. Results : The effect of F9 depended on its processing; full-length F9 suppressed cell migration, increased adhesion to matrix, and enhanced intercellular adhesion. In contrast, activated F9 enhanced cell migration,

suppressed adhesion to matrix, and inhibited intercellular adhesion. the effect of F9 appears to be nonspecific with regards to cell type, as the effect was demonstrated in cells of diverse origin (i.e., epithelial [A431], endothelial [pro5], and mesenchymal [cos7]). An activation peptide that is removed during the coagulation process was found to be responsible for the activity of full-length F9, and the activity of activated F9 was localized to an EGF domain of the F9 light chain. Our data indicated that the activation peptide inhibited the activity of the EGF domain on cells. Conclusion: We found that in addition to its role in the coagulation process, F9 has several novel effects on cells. Full-length F9 has a sedative effect on cells, which is counteracted by activated F9 in vitro. Thus, F9 may play roles before, during, and after the coagulation process.

⁴Department of Anatomy, Physiology and Pharmacology, School of Vet. Medicine, St George's University, True Blue, Grenada, Grenada

We have investigated the dose-response effects DBP on histo-morphometric parameters and ultrastructure of the seminiferous tubules of adult male Japanese quails (*C. japonica*). A total of ninety (90) pre-sexed, 10-week old male quail birds were randomly divided into six experimental groups: The control group (n=15) received a dose of 1 mL/kg of corn-oil (control), or intragastric daily dose of 1, 10, 50, 200, 400 mg DBP/kg/bw (dissolved in corn oil), for a period of 30-day. At study termination, the testes excised from both control and treatment groups and were further evaluated using a computer-aided histometric and ultra-structural (TEM) techniques. Our results showed a generalized significant decrease in the diameter and epithelium thickness (height) of the seminiferous tubules occurring predominantly in the high dose (200mg- and 400mg) groups as compared to median (50mg) or low dose (1mg- and 10mg) groups. Ultra-structurally, a dose-dependent degenerative changes in earlier germ cell series, and being significant at the high dose level, were evident. Necrotic round spermatids were prominent in sub luminal part of the seminiferous tubules amidst apparently normal elongated spermatids. A few spermatogonia were necrotic, and a few empty spaces, probably vacated by necrotic early spermatocytes or spermatogonia, were encountered. Few spermatogonia showed degenerative changes with morphological characteristics of apoptosis-- including shrinkage of cytoplasm and increased nuclear blebbing, occurring mainly in high doses (i.e. 200- and 400mg DBP) groups. Sertoli cells appeared foamy in consistency because they are laden with lipid droplets. Dense bodies were also conspicuous and very importantly, the mitochondria were swollen and showed a disrupted matrix. In

addition, Leydig cells were few and showed numerous lipid droplets (scattered throughout the cytoplasm), multivesicular bodies and giant whorl-like smooth endoplasmic reticulum. In conclusion, the present data indicate that DBP(pubertal) exposure produced dose- and parameter-dependent, histometric and sub-cellular alterations in the seminiferous tubules, thereby affecting the adult spermatogenesis. It is evident that DBP pronounced male reproductive toxicities in testes might likely be due to its anti-androgenic effect on reproduction, resulting from increased damaged to earlier spermatogenic series, Sertoli and Leydig cells. The potential negative implication on the reproductive biology, particularly in those avian species, that are vulnerable to EDCs are further discussed.

High glucose reduces migration and viability of human periodontal ligament cells.

M.M. Monteiro¹, A.R. Tempestini-Horliana², M.F. Santos³;

¹Cell and development biology, University of São Paulo, São Paulo, Brazil, ²Department of Stomatology, University of São Paulo, São Paulo, Brazil, ³Cell and development Biology, Univ Sao Paulo, Sao Paulo, Brazil

Background: Impaired oral wound healing and increased incidence of periodontal diseases are complications of Diabetes Mellitus (DM). DM impairs the migration of dermal fibroblasts, contributing to deficient healing, and some microRNAs (miRs), such as miR-221 and miR-222, are affected by DM and might be involved in cellular functions. **Aim:** to evaluate the effects of the *in vitro* exposure of human periodontal ligament (PLC) cells to high glucose on growth, death, migration, actin cytoskeleton and the expression of miR-221 and miR-222. **Methods:** cells were obtained from premolar teeth of 3 young humans under orthodontic treatment, and cultured under low (LG, 5mM) or high (HG, 25mM) glucose for 7 days before the assays. **Results:** Cell number was reduced by 33% in HG cells, compared to LG, mostly due to a 3x increased in cell death (TUNEL assay). Cell adhesion on fibronectin was reduced by 40% after 20 minutes of plating, and by 30% after 1 hour. Cell spreading after 1h was reduced by 35%. HG cell migration (transwell assay) was reduced by 54%. HG cells showed increased circularity when compared to LG (> 0.5 vs. 0.2, respectively). The expression of miR-221 and miR-222 was increased by 2x in HG cells. **Conclusion:** High glucose negatively affects PLC, reducing migration and viability, thus potentially affecting the progression of periodontal disease and healing after periodontitis treatment, as well as the response to orthodontic treatment. miR-221 and miR-222 were upregulated by HG in those cells and might be involved in some of these events. **Support:** FAPESP, CAPES, PRP-USP (NAPmIR).

P2194**Board Number: B821****High Glucose concentration reduces cellular contractility and tension forces in NIH3T3 fibroblasts, contributing to the impaired migration in 2D and 3D substrates.**M.E. Almeida¹, M. Badoual², M. Lamers³, A.R. Horwitz⁴, M.F. Santos⁵;¹Cell and Development Biology, University of Sao Paulo, Sao Paulo, PA, ²Laboratoire IMNC, Univ. Paris-Sud, Orsay, PA, ³Morphological Sciences, Universidade Federal Do Rio Grande Do Sul, Porto Alegre- RS, PA, ⁴Cell Biology, University of Virginia, Charlottesville, VA, ⁵Cell and development Biology, Univ Sao Paulo, Sao Paulo, Brazil

Background: Long-term complications of Diabetes Mellitus include impaired wound healing and fibroblast migration and extracellular matrix (ECM) remodeling are essential for this process. We have previously shown that fibroblasts migration is reduced under high glucose conditions as well as the maturation of cellular adhesions to the ECM. Another feature of those cells is the long rear and less stress fibers, which suggest impaired myosin II activity. During migration, the contraction of the cell body generates tension on the substrate through cell adhesions, which is important for adhesion maturation. Aim: To study the effects of a high glucose concentration on fibroblast contractility and its potential contribution to the impairment of migration. Methods: NIH3T3 fibroblasts were exposed to physiological (5mM, LG) or high (25mM, HG) glucose concentrations and submitted to different analyses on two-dimensional (2D) fibronectin and three-dimensional (3D) collagen/fibronectin substrates. F-actin arrangement and the expression and distribution of the myosin regulatory light chain (MRLC), myosin isoforms IIA (MIIA) and IIB (MIIB) were studied by staining with phalloidin, western blotting and immunocytochemistry, respectively. Traction force microscopy (TFM) assays were employed to study tension exerted on the substrate. Results: Cells exposed to HG showed reduced migration velocity (about 40-60%) and larger lamellipodia on 2D assays. In 3D substrates, HG cells showed extensive branching projections at the front. TFM experiments showed lower tension exerted by HG cells on the adhesions to the substrate. HG did not affect the total amount of MRLC, MIIA and MIIB proteins. MIIB distribution, however, was changed. In cells cultured under low glucose MIIB was mostly present in the cell body and rear, whereas in HG cells it was spread throughout the cell, including the lamellipodia. MIIA distribution, on the other hand, was not changed. Conclusion: fibroblasts under high glucose show impaired contractility, which leads to a reduced tension on the substrate through cellular adhesions. This impairment may be involved in the deficient migration of fibroblasts in diabetic patients. Support: FAPESP, CAPES.

P2195**Board Number: B822****Free β -subunit of human chorionic gonadotropin stimulates choriocarcinoma cell invasion independent of LH/hCG receptor.**C. Lee¹, P.C. Chiu¹, L. Hautala², W.S. Yeung¹, K.M. Koli³, U. Stenman², H. Koistinen²;¹Department of Obstetrics and Gynecology, The University of Hong Kong, Queen Mary Hospital, Hong Kong, Hong Kong, ²Department of Clinical Chemistry, University of Helsinki, Helsinki, Finland, ³Research Programs Unit, Translational Cancer Biology, University of Helsinki, Helsinki, Finland

Human chorionic gonadotropin (hCG) is a heterodimer consisting of an α - and a β -subunit (hCG α and hCG β) that are non-covalently linked. Intact hCG, but not free subunits, bind to the LH/hCG receptor in the corpus luteum stimulating its progesterone production, which is essential for successful pregnancy. hCG has been found to stimulate trophoblast invasion in an autocrine fashion. In pregnancy, trophoblast invasion is a tightly controlled process, disturbances in which may lead to pregnancy complications. In addition to placenta, several cancers have been shown to express hCG and hCG β . Most trophoblastic tumors of placental and germ cell origin produce hCG, while many non-trophoblastic tumors, including bladder, renal and gastrointestinal cancers, often produce hCG β . The stimulatory activity on trophoblast invasion has been ascribed especially to a so-called hyperglycosylated form of hCG (hCG-h) expressed in early pregnancy. hCG-h is also a major form of hCG produced by choriocarcinoma and testicular cancers, although tumor-derived hCG-h is often glycosylated differently than that produced by the placenta. We compared different forms of hCG in their stimulatory activities on the invasion of JEG-3 choriocarcinoma cells. Various forms of hCG and hCG β were purified from urine of a patient with nonseminomatous testicular cancer, one with invasive molar disease, and a pregnant women. Both hCG and hCG β , and their hyperglycosylated forms stimulated the invasion of JEG-3 cells to a similar extent. Down-regulation of the LH/hCG receptor by RNA-interference did not significantly reduce the effect of hCG β and hCG on cell invasion. Increased invasion was associated with increased activity of MMP-2, MMP-9 and uPA in conditioned culture medium from JEG-3 cells. Unlike suggested by some previous studies, highly purified hCG or hCG β , or their hyperglycosylated forms, did not activate TGF β -receptor or induce phosphorylation of ERK1/2. Our findings suggest that hCG and hCG β stimulate the invasion of choriocarcinoma cells by an unknown mechanism, that is independent of the classical LH/hCG-receptor. These results may explain the association of increased serum hCG and hCG β with adverse prognosis both in trophoblastic and non-trophoblastic tumors.

P2196**Board Number: B823****The role of an R-Ras/ARF6 signaling module in adhesion-induced epithelial spreading and migration.**J.C. Salem¹, L.C. Santy²;¹Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA, ²Department of Biochemistry, Microbiology and Biochemistry, Pennsylvania State University, University Park, PA

Overexpression of ARF-GEF cytohesin-2/ARNO causes immobile epithelial cells to become highly migratory and scatter away from neighboring cells. Through robust activation of ARF6 and assembly of a multi-protein complex, cytohesin-2/ARNO behaves as both an ARF-GEF and a scaffold to promote activation of small GTPase Rac. R-Ras is a small GTPase that specializes in enhancing cell spreading and promoting integrin activation. It was recently shown that small GTPase R-Ras signals upstream of cytohesin-2/ARNO to promote adhesion-induced migration. Given that both R-Ras and cytohesin-2/ARNO function in a similar pathway, we wondered if ARF-activation via cytohesin-2/ARNO could direct R-Ras traffic, and if so, through which intracellular compartment. Therefore, transfected HeLa cells were plated on fibronectin, and imaged using fixed and live immunofluorescence. We demonstrate that overexpressed R-Ras traffics through a tubular EHD1 recycling endosome compartment. Destroying the GEF activity of cytohesin-2/ARNO (E156K) traps R-Ras in EHD1 recycling endosomes. In contrast, phorbol 12-myristate 13-acetate (PMA), a cytohesin-2/ARNO stimulator, promotes dissolution of EHD1 tubular endosomes containing R-Ras. Both R-Ras and ARNO each promote cell spreading, as constitutively active (38V) R-Ras can only partially rescue cell spreading in cells co-expressing E156K ARNO. Finally, we provide evidence suggesting α 5-integrin is also trapped in an EHD1 compartment upon E156K-ARNO expression. Given that cytohesin-2/ARNO is required for β 1-integrin recycling and migration on fibronectin, we propose that R-Ras effects on integrin activation, ruffling, and spreading are highly governed by cytohesin-2/ARNO-induced ARF6 activation.

P2197**Board Number: B824****A novel mechanism of cell locomotion regulation by LOSK/SLK kinase.**A.I. Fokin¹, T.S. Klementyeva², E.S. Nadezhdina^{1,2}, A.V. Burakov¹;¹A.N.Belozersky Institute for Physico-Chemical Biology, Lomonosov Moscow State University, Moscow, Russia, ²Institute of Protein Research of Russian Academy of Sciences, Moscow, Russia

Cell locomotion is a complex process which requires both actin and microtubule cytoskeleton involvement. Actomyosin component of the cytoskeleton generates force for movement. Microtubules are assumed to induce cell polarization and maintain direct movement. SLK is a serine/threonine-protein kinase associated with microtubules and centrosome, originally described as LOSK (Long Ste20-Like). Inhibition of its activity results in disorganization of microtubule system and reduction of Golgi polarization in moving cells (Burakov et al., 2008, Zhapparova et al., 2013). Hence they demonstrate

decreased ability to directional movement.

It is known that LOSK phosphorylates a series of cytoskeletal proteins such as RhoA (Guilluy et al., 2008) and p150Glued subunit of dynactin (Zhapparova et al., 2013) which are essential for cell locomotion. To test the role of RhoA and p150Glued phosphorylation by LOSK we performed transfection of Vero fibroblast-like cells with dominant negative LOSK[K63R-ΔT], dominant negative and constitutively active RhoA, phospho-mimic and non-phosphorylatable mutants of RhoA and p150Glued at LOSK phosphorylation site. Moreover we co-transfected cells with RhoA and p150Glued constructions described above against LOSK inhibition by LOSK[K63R-ΔT]. Also we used inhibitor of downstream RhoA effector ROCK kinase. Standard wound scratching assay and ImageJ plugin Manual tracking were applied to specify parameters of cell movement. Besides we examined in details the structure of microtubule system and polarization of Golgi in these cells. We estimated that the regulation of cell motility and the microtubule ordering by LOSK occurs independently in two different signaling pathways. It is turned out that cell motility impaired by LOSK inhibition could be restored, using phospho-mimic (inactivated) RhoA as well as ROCK inhibitor; also it partially rescued Golgi polarization despite the fact that the microtubules remains disordered. On the other hand, the p150Glued construct which could not effectively rescue cell motility, successfully restores the microtubule system and Golgi polarization. Thus, it was first shown in this study that LOSK-dependent microtubule disordering does not affect the cell motility and regulation of cell migration is accomplished through another LOSK-dependent signaling pathway. This work is financially supported by the Russian Foundation for Basic Research (grants 12-04-33178 mol-a-ved and 14-04-01729a).

Analysis of Diatom Motility in Multi-species Assemblages.

S.A. Cohn¹, D. Halpin¹, A. Ismail¹, W. Macke¹, S. Olszewski¹, A. Wolske¹;

¹Biological Sciences, DePaul Univ, Chicago, IL

Diatoms are unicellular algae, present in almost all freshwater and marine aquatic environments, known for their characteristic hardened silica cell walls. Diatoms live within complex multi-species algal communities, and provide a large percentage of earth's primary production and oxygen formation. Investigating the environmental effects on cell behavior, such as the light-regulated gliding motility of pennate diatoms that is crucial for their ecological success, is therefore critically important to understanding their overall ecological sustainability. Previous studies in our lab suggested that the presence of multiple diatom species alters the cells' adhesive ability relative to cells from unialgal cultures (*Diatom Res.* **18** :225). In order to determine if the presence of other species also affects cell motility, we analyzed the motile responses of three diatom species (*Craticula cuspidata*, *Pinnularia viridis*, and *Stauroneis phoenicenteron*) to high intensity irradiations of blue (470nm), or red (650nm) light at their leading or trailing ends, in the presence or absence of one of the other diatom species. Our analysis of the response times of light-stimulated direction changes in these cells suggests that under some conditions there are significant inter-species effects on diatom motility, which may relate to their

niche partitioning. For example, while *Craticula* cells show little change in their response times in the presence of other species, *Stauroneis* cells show a strong repression in response times for blue light exposures of their leading ends in the presence of *Craticula* cells (36 ± 3 sec for *Stauroneis* alone; 88 ± 9 sec for *Stauroneis* in the presence of *Craticula*). *Stauroneis* cells show similar repression to red light exposures of the leading end (96 ± 10 sec for *Stauroneis* alone; 148 ± 13 sec for *Stauroneis* in the presence of *Craticula*). In contrast, *Pinnularia* cells show decreased response times for red-light leading end exposures in the presence of *Craticula* (163 ± 20 sec for *Pinnularia* alone; 92 ± 21 sec for *Pinnularia* in the presence of *Craticula*). We have also analyzed the effect of multiple sequential trailing end cell irradiations to determine the degree to which these exposures repress subsequent direction changes at the leading end. With blue irradiations of the trailing end, *Craticula* and *Stauroneis* show a strong dose-dependent effect that indicates the repression lasts 30-90 sec, while *Pinnularia* shows a longer lasting repression that remains for more than 2 min. Red irradiations of the trailing end of *Stauroneis* cells show an effect that lasts 90-120 sec. This work was supported by grants through the DePaul College of Science and Health, the DePaul University Research Council, and equipment purchased previously through NSF Grant IBN-9982897.

Syndecan-4 regulates Eph receptor-mediated fibroblast clustering during wound repair.

R. Brooks¹, J.A. Roper¹, C.D. Nobes^{1,2}, M.D. Bass¹;

¹Department of Biochemistry, University of Bristol, Bristol, United Kingdom, ²Department of Physiology and Pharmacology, University of Bristol, Bristol, United Kingdom

Fibroblast migration into a wound bed is essential for wound contraction and healing. Migration relies on cell-matrix and cell-cell contacts, both of which are regulated by transmembrane receptors that are differentially regulated during wound healing. The expression of the fibronectin receptor syndecan-4 is increased upon wounding, which in fibroblasts promotes migration through activation of small GTPases and the recycling of integrin $\alpha 5\beta 1$. Members of the Eph family of receptor tyrosine kinases, which regulate cell-cell contacts, are also differentially regulated in fibroblasts upon wounding. However, little is known about the relationship between these receptors and how this might regulate the balance between cell-cell and cell-matrix contacts.

We demonstrate an inverse relationship between syndecan-4 and EphA2, which mediates cell-cell repulsion. EphA2 expression is elevated in syndecan-4 knockout mouse embryonic fibroblasts through a Src family kinase-dependent mechanism. Elevated EphA2 expression increases sensitivity to the EphA2 ligand ephrin-A1 and increases the rate and frequency of cell-cell repulsion when compared to wild type. Importantly, our findings are translated *in vivo*; EphA2 expression is increased in syndecan-4 knockout mouse wounds compared to wild type. This may contribute to the healing defect previously observed in syndecan-4-null mice¹.

Na⁺/Ca²⁺ exchanger 1 regulates Ca²⁺ dependent ERK signaling and migration.

S. Balasubramaniam^{1,2}, A. Gopalakrishnapillai², R.L. Duncan¹, S. Barwe^{1,2};

¹Biological Sciences, University of Delaware, Newark, DE, ²Biomedical research, Nemours, Wilmington, DE

The sodium pump, Na⁺/K⁺-ATPase, contains a catalytic α -subunit (Na,K- α) and a regulatory β -subunit (Na,K- β). These proteins regulate ion homeostasis, in addition to maintaining epithelial polarity and structural integrity. The activity of Na⁺/K⁺-ATPase is closely coupled with another transporter, Na⁺/Ca²⁺ exchanger 1 (NCX1). The efflux of 3 Na⁺ by Na,K-ATPase provides the gradient for NCX1, which enables the influx of 3 Na⁺ and efflux of 1 Ca²⁺. Earlier studies from our lab have shown that mice with heart-specific ablation (KO) of Na,K- β were insensitive to ouabain-induced cardiac contractility with reduced NCX1 expression, and no change in other Ca²⁺ handling proteins (Barwe et al., *J. Mol Cell Cardiol*, 2009). In addition we show that Na,K- β co-localizes with NCX1 and confirm their association by immunoprecipitation. These data support the hypothesis that Na,K- β acts as a chaperone in regulating the membrane expression and localization of not only Na,K- α , but also NCX1. Other studies have shown a similar role for sodium transporters such as Na,K,2Cl transporter (Carmosino et al., *J. Hypertension*, 2014). To understand the cause and consequences of this reduced NCX1 expression, we utilized Madin Darby Canine Kidney (MDCK) cells with Na,K- β knockdown (β -KD). β -KD cells express reduced levels of NCX1, accompanied by a 2-fold increase in free intracellular calcium concentration, consistent with the fact that NCX1 is the major calcium extrusion mechanism in MDCK cells. A corresponding increase in the rate of migration was observed using wound healing assay. Replenishment of Na,K- β in β -KD (β -KD/WT-R) cells restored NCX1 protein at the cell surface, reduced the intracellular calcium levels and migration rate similar to that in parental MDCK cells. The Ca²⁺ chelator BAPTA suppressed migration in β -KD cells, indicating that the increased migration was calcium-dependent, thus implying a role for NCX1 in the regulation of migration. MDCK cells treated with NCX1 inhibitor, KB-R7943, showed an increase in cell migration similar to β -KD cells, confirming the role of NCX1 activity in regulating cell migration. To delineate the signaling pathways in the regulation of cell migration by NCX1, we used specific inhibitors of PI3-kinase, Akt and MEK1/2, since β -KD cells display PI3-kinase dependent ERK1/2 and Akt activation (Barwe et al., *J Cell Sci*, 2012). Our data revealed that migration induced by reduction of NCX1 in β -KD cells or NCX1 inhibition is dependent on PI3-kinase and ERK1/2 (direct downstream target of MEK1/2), but is Akt-independent.

P2201**Board Number: B828****Activation of Rac by Asef2 Promotes Myosin II-Dependent Contractility to Inhibit Cell Migration in both 2D and 3D Environments.**L. Jean¹, D. Majumdar¹, M. Shi¹, L. Yang², Y. Gao², J. Broussard¹, L. Hinkle¹, B. Brewer², D. Li^{2,3}, D. Webb^{1,3,4};¹Department of Biological Sciences, Vanderbilt University, Nashville, TN, ²Department of Mechanical Engineering, Vanderbilt University, Nashville, TN, ³Vanderbilt Institute for Integrative Biosystems Research and Education, Vanderbilt University, Nashville, TN, ⁴Department of Cancer Biology, Vanderbilt University, Nashville, TN

Non-muscle myosin II (MyoII) contractility is important to the regulation of many cellular processes, including migration. The small GTPase Rho has been shown to regulate MyoII contractility, but the role of other GTPases, such as Rac, in modulating contractility is not well understood. In this study, we show that activation of Rac by the guanine nucleotide exchange factor (GEF) Asef2 increases MyoII contractility to impair cell migration on two-dimensional (2D) type I collagen. Knockdown of endogenous Rac using short hairpin RNAs (shRNAs) or treatment of cells with the Rac-specific inhibitor NSC23766 results in a significant decrease in the amount of active MyoII, as determined by serine 19 (S19) phosphorylation, and negates the Asef2-promoted increase in contractility. Furthermore, treatment of cells with blebbistatin, which inhibits MyoII activity, abolishes the Asef2-mediated effect on migration. Because adhesion growth and maturation have been linked to actomyosin contractility, we also examined the effect of Asef2 on adhesions. Interestingly, Asef2 increases active β 1 integrin levels in adhesions and induces large, mature adhesions that assemble and disassemble (turnover) more slowly compared with controls. In addition, the Asef2-promoted increase in the level of active β 1 integrin in adhesions was diminished by treatment with the Rac inhibitor NSC23766. Because three-dimensional (3D) matrices more closely mimic the physiologic environment of cells, we investigated the role of Asef2 in regulating migration and MyoII activity in 3D environments. For these studies, we developed microfluidic devices that afford a controlled, reproducible platform for generating 3D matrices. Using these devices, we show that Asef2 inhibits cell migration in 3D type I collagen matrices, and treatment of cells with blebbistatin abolishes the Asef2-mediated decrease in migration. Moreover, Asef2 enhances MyoII activity as shown by increased S19 phosphorylation, and treatment with NSC23766 abolishes the Asef2-promoted increase in active MyoII. Collectively, these results indicate that Rac activation, promoted by Asef2, is critical for modulating MyoII activity and cell migration in both 2D and 3D environments.

P2202**Board Number: B829****Glycodelin abolishes PMA-induced migration of MCF-7 breast cancer cells.**L. Hautala¹, R. Koistinen¹, H. Koistinen¹;¹Department of Clinical Chemistry, University of Helsinki, Helsinki, Finland

Glycodelin is a secreted glycoprotein mainly expressed in well-differentiated epithelial cells in reproductive tissues. Previously, glycodelin has been shown to induce cell differentiation in endometrial and breast cancer cells. We have transfected glycodelin into MCF-7 breast cancer cells to study its effect on cell differentiation. When the cells were grown in Matrigel basement membrane preparation, glycodelin-expressing cells formed glandular structures, while the control cells were less cohesive and had less luminal structures. In addition, glycodelin-producing cells formed significantly smaller tumors in xenograft mice. The effects of glycodelin are, at least partly, mediated by repressed PKC δ activity, rendering the cells resistant to PKC δ activation by phorbol 12-myristate 13-acetate (PMA). Here we continued these previous studies by addressing the effect of glycodelin on the invasion and migration of MCF-7 breast cancer cells, and studying the affected signaling route in more detail. Activation of signaling proteins was detected with an antibody array of 43 phospho kinases. Cell migration was studied using wound healing test. The cells were grown on chamber slides until they formed a monolayer and then a scratch was made using a pipet tip. After addition of PMA or DMSO control, the migration of the cells was monitored under microscope. For control, PKC δ was down-regulated with RNAi prior to the migration assay. Boyden chamber assay was used to study the invasion through Matrigel. The cells were grown with and without PMA and the amount of invasive cells was quantified. Phospho-kinase array did not reveal any widespread changes in the amount of phosphorylated signaling molecules between the glycodelin-producing and control cells irrespective of the PMA treatment. However, in addition to previously detected decrease in PKC δ levels, increased p27 and Chk-2, and decreased p38 α were observed in glycodelin-producing cells. In wound healing test PMA caused a two-fold increase in the migration of the control cells, but had no effect on the glycodelin-producing cells. When the expression of PKC δ was down-regulated in the control cells using siRNA, the addition of PMA did not increase the migration of the cells. PMA also increased the invasiveness of the cells, but no difference was observed between glycodelin-expressing and control cells. Without PMA treatment both glycodelin-expressing and control cells behaved similarly in wound healing and invasion tests. In conclusion, glycodelin abolished PMA-induced migration in MCF-7 breast cancer cells, while it did not have any effect on the invasion of the cells. Our results suggest that the effect of glycodelin in migration is mediated by reduced activation of PKC δ .

P2203**Board Number: B830****Regulation of cancer cell motility by secreted exosomes.**B. Sung¹, T. Ketova², D. Hoshino¹, A. Zijlstra^{1,2}, A.M. Weaver^{1,2};¹Department of Cancer Biology, Vanderbilt University Medical Center, Nashville, TN, ²Department of Pathology, Microbiology and Immunology, Vanderbilt University Medical Center, Nashville, TN

Directional movement of cells through tissues is critical for embryonic development and cancer metastasis, yet how cells maintain polarity in the face of complex environmental cues is poorly understood. Here, we use intravital live imaging in the chick embryo chorioallantoic membrane (CAM) to demonstrate that secretion of exosomes from late endosomes is required for directionally persistent *in vivo* movement of cancer cells. Knockdown (KD) of three distinct exosome secretion regulators leads to defects in tumor cell migration associated with excessive formation of unstable protrusions and directional switching. Rescue experiments with purified exosomes and matrix coating identify adhesion assembly as a key function of exosomes that promotes cell motility. We propose that autocrine secretion of exosomes is a powerful way to promote directionally persistent cell motility by reinforcing otherwise transient polarization states.

P2204**Board Number: B831****Loss of Dlg5 expression promotes the migration and invasion of prostate cancer cells via Girdin phosphorylation.**L. Tomiyama¹, T. Sezaki¹, M. Matsuo¹, K. Ueda^{1,2}, N. Kioka¹;¹Agriculture, Kyoto University, Kyoto, Japan, ²iCeMS, Kyoto University, Kyoto, Japan

Dlg5 has been reported to participate in cancer progression; however, its role in prostate cancer still remains poorly understood. In this study, we demonstrate that Dlg5 is frequently downregulated in prostate cancer. We show here that Dlg5 is involved in the regulation of cell migration and cancer cell invasion. Knockdown of endogenous Dlg5 markedly increased prostate cancer cell migration and invasion. Our studies, for the first time, demonstrate the interaction between Dlg5 and Girdin, an actin-binding Akt substrate. Importantly, we found that levels of Akt-mediated Girdin phosphorylation (p-Girdin-Ser1416) are increased in Dlg5 -depleted cells. Small interfering RNA directed against Girdin and wortmannin treatment, which was found to reduce Girdin phosphorylation, impaired the effect of Dlg5 depletion on cell migration. Taken together, our findings demonstrate that Dlg5 interacts with and inhibits the activity of Girdin, thereby suppressing the migration of prostate cancer cells.

P2205**Board Number: B832****Novel biosensors for Dbl family RhoGEFs elucidate control of Rac1 by multiple GEFs during breast cancer cell migration.**D.J. Marston¹, M. Vilela², G. Danuser², J. Sondek¹, K.M. Hahn¹;¹Department of Pharmacology, University of North Carolina, Chapel Hill, NC, ²Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX

Dbl-family RhoGEFs are broadly relevant signaling molecules that regulate cytoskeletal dynamics by integrating the effects of growth factors and adhesion molecules. The timing and localization of GEF activity is precisely controlled to generate different Rho family GTPase responses, thereby producing different actin dynamics and specific types of cellular protrusions. We describe a novel design approach, capable of generating biosensors for multiple GEFs, applied here to visualize activation of Vav2, ASEF and Tiam1 in living cells. A pair of fluorescent proteins was inserted in a region of the GEF with no known binding activity, such that relief of GEF autoinhibition altered FRET between the fluorescent pair. High content screening assays were used to optimize donor/acceptor pairs, insertion site, linkers and circular permutants, increasing the dynamic range of the biosensors to produce FRET ratio changes of up to 300%. The Vav2 biosensor reported phosphorylation of Vav2 by Src kinase and reversible Vav2 activation upon EGF stimulation. This biosensor was used to examine activation dynamics during constitutive migration of MDA-MB-231 breast cancer cells, revealing periodic activation of Vav2 during protrusion retraction cycles at the leading edge. Current studies using computational multiplexing are examining the coordination of Vav2 and Tiam1 to regulate Rac-mediated protrusion and cell polarization.

P2206**Board Number: B833****“A Novel Approach for Identifying Cytohesin Variants and their Isoforms in HGF Stimulated Cell Migration using High Resolution Melting Analysis.”.**A. Taylor¹, L.C. Santy¹;¹Department of Biochemistry, Microbiology and Biochemistry, Pennsylvania State University, University Park, PA

Cytohesins are guanine nucleotide exchange factors that play major roles in cell migration, adhesion, and cytoskeleton recycling. The cytohesin family members include: cytohesin1, cytohesin2/ARNO, cytohesin3/Grp1, and cytohesin4. They function by controlling the activation of small GTPases ADP ribosylation factors (ARF1 through 6). These members are closely related and share a similar domain structure. The NH2 terminal domain is comprised of a ~60 residue coil-coil domain that mediates homodimerization scaffolding and localization properties. The central ~200 amino acid catalytic domain is immediately followed by a PH domain. The pleckstrin homology (PH) domain of each of these proteins

is the key determinant of the phosphoinositide binding affinity of these PH domain. Cytohesins undergo alternative splicing of a single three- nucleotide exon, resulting in isoforms containing either a diglycine or triglycine motif in their PH domain. We have previously demonstrated that the number of glycine residues in the PH domain of cytohesin2/ARNO and cytohesin3/Grp1 determines their effects on cell adhesion, spreading and localization. It is important to be able to distinguish between the diglycine or triglycine variants in order to help elucidate their roles in cells. To date, an effective assay to differentiate the diglycine or triglycine splice variants has not been developed. High Resolution Melting (HRM) analysis has recently become an efficient, quick, and robust method for genotyping, mutation scanning, and sequencing matching. HRM has proven to be very efficient in even identifying single nucleotide polymorphisms. This study investigated whether HRM analysis can be used to identify and distinguish between cytohesin2/ARNO and cytohesin3/Grp1 and their respective "2G" and "3G" isoforms in madin darbin canine kidney epithelial cells. Specifically, we employed HRM amplicon melting, HRM "snapback" genotyping (asymmetric and symmetric), and unlabeled probe genotyping analyses. The cytohesin amplicons were cloned and sequenced to assist with the interpretation of HRM data. The cDNA HRM curves correlate well with the DNA plasmid controls, which either contained Cytohesin2/ARNO "2G" or "3G" and Cytohesin3/Grp1 "2G" or "3G". We show that HRM coupled with LC-Green-PCR is a robust, closed-tube, inexpensive analysis for the rapid detection of canine cytohesin2/ARNO and cytohesin3/Grp1 and their respective isoforms. By combining HRM with a simple PCR design, this novel approach is the first assay capable of distinguishing between cytohesin splice variants. Cytohesins are important regulators of proliferation, migration and invasiveness in cancer. This study provides an assay to identify the specific isoforms that are being upregulated, and thus aid in the understanding of cytohesin function in cancer. In addition, identifying cytohesin isoforms as prospective therapy targets for different cancer types and other diseases that affect cell motility could be possible.

Haptotaxis requires a Rac1/WAVE/Arp2/3-based pathway that regulates differential lamellipodial dynamics.

S.J. King¹, S.B. Asokan¹, C. Wu^{1,2}, J.D. Rotty¹, K.T. Chan^{1,3}, I.P. Lebedeva^{1,2}, J.E. Bear¹;

¹UNC Lineberger Comprehensive Cancer Center, Department of Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC, ²Howard Hughes Medical Institute, Chevy Chase, MD, ³Howard Hughes Medical Institute, Chapel Hill, NC

Cells in vivo migrate in response to directional cues such as differing concentrations of extracellular matrix (haptotaxis); however, a mechanistic understanding of how cells sense and respond to these haptotactic cues is lacking. In order to generate the forces required to drive cell migration, actin filaments must be nucleated and organized in a precise manner. One primary mechanism by which new actin filaments are nucleated is the Arp2/3 complex. Using a small molecule inhibitor of the Arp2/3 complex, CK666, and Arp2/3-depleted cells we have previously shown that the Arp2/3 complex is essential for haptotaxis in fibroblasts on a variety of extracellular matrices (Wu, C., S. B. Asokan et al,

Cell, 2012). In order to dissect the mechanism of haptotaxis on fibronectin, an agnostic approach using microfluidic chambers that allow direct imaging of fibroblast haptotaxis on gradients of fibronectin has been utilized. The requirement for the Arp2/3 complex for haptotaxis on fibronectin was confirmed using CK666 on vascular smooth muscle cells, indicating that this result is not cell type specific. It has been proposed that the alignment and maturation of focal adhesions could regulate haptotaxis. However, our experiments suggest that fibronectin based haptotaxis of fibroblasts does not appear to be reliant upon a specific integrin pairing or upon the presence of 'mature' focal adhesions. One important nucleation promoting factor (NPF) for Arp2/3 is the WAVE complex. Our data suggests that the WAVE complex is the primary NPF required for fibronectin based haptotaxis, with N-WASP and WASH being dispensable. Rac1 is required for WAVE activation, lamellipodial formation and is a component of focal complexes. Inhibition or depletion of Rac1 abrogates fibronectin haptotaxis. Additionally, inhibition of other focal complex components, Src or FAK, also blocks fibroblast haptotaxis on fibronectin, implicating focal complexes in the regulation of fibronectin haptotaxis. Kymography has revealed differential protrusion dynamics across haptotaxing cells, which have the potential to provide the force necessary for differential migration. Furthermore, FRAP studies investigating actin dynamics during haptotaxis have revealed that there are differential actin dynamics across a cell on a gradient on fibronectin that is not present in a cell on uniform fibronectin or upon Arp2/3 inhibition. Our current hypothesis is that differential engagement of integrins triggers a Src/Rac/WAVE pathway that leads to Arp2/3 activation. Resulting in differential actin dynamics and protrusion dynamics, ultimately leading to directed migration towards higher concentrations of extracellular matrices.

A simple assay that distinguishes cell migration from proliferation.

H.L. Glenn¹, D.R. Meldrum¹;

¹Center for Biosignatures Discovery Automation, The Biodesign Institute at Arizona State University, Tempe, AZ

Cell motility is a fundamental characteristic of most mammalian cell types and plays a crucial role in normal and pathological processes such as development, wound healing, immune response, and cancer metastasis. Migration is therefore one of the most commonly assayed cellular behaviors. There are a variety of techniques used to evaluate this phenomenon, which range in cost, reliability, and necessary technical expertise. One of the most popular methods is the barrier, or void-filling, assay in which cells are seeded on a surface within a restricted area then allowed to migrate into an adjacent space. This approach is inexpensive, relatively high throughput, can be accomplished with widely available equipment, and does not require advanced expertise or training. The readout is the number of cells that are located in the initially cell-free zone at the end of the migration period. One significant drawback of this approach is that the readout necessarily represents the combined effects of both cell migration and proliferation. We have developed a simple alteration to this approach that employs a commercially available, fluorescent, live-cell stain that is retained through cellular generations. Cell motility is

measured as the ratio of the fluorescent signal in the migration area relative to the seeding and migration areas combined. This method allows the contribution of cell migration to be directly measured without the confounding effects of proliferation. We demonstrate the efficacy of this method with cells that have both high and low proliferation or migration rates. We also show that this method can be used to directly compare migration rates between different cell types.

Arpin-mediated idling and reductions in cell speed are associated with turns.

R. Gorelik¹, A. Gautreau¹;

¹CNRS, Gif-sur-Yvette, France

We recently reported a novel protein, Arpin, which inhibits the Arp2/3 complex, a molecular machine that nucleates actin filaments at the cellular front in the lamellipodium. There, new actin filaments polymerize and exert force to protrude the edge forward. Arp2/3-based positive feedback signaling is the basis for lamellipodial persistence, which drives effective directional migration. Indeed, we observed that Arpin is associated with decreases in two major parameters of cell migration: speed and directional persistence. To understand how Arpin controls these parameters, in this work we re-examined migration trajectories of three different cell types with Arpin perturbations. In all three systems, we found that speed and turn angle are negatively correlated, suggesting a universal linkage between these parameters. Arpin-mediated decreases in instantaneous speed were associated with increases in turn angle. Importantly, in all three systems Arpin induced episodes of idling, defined as moving below a speed threshold. This threshold is a percentage of the average speed, calculated using the first derivative of log mean squared displacements. Observed idling episodes interrupted and effectively shortened duration of the active phase of migration, consistent with a model in which Arpin counteracts a positive-feedback circuit that sustains the lamellipodium over time. Finally, Arpin-associated idling episodes were followed by turns, implicating idling as a means for enacting a turn.

The Role of Cytohesins in Cell Migration After Acute Kidney Injury.

M.M. Reviriego-Mendoza¹, L.C. Santy²;

¹Pennsylvania State Univ, State College, PA, ²Department of Biochemistry , Microbiology and Biochemistry, Pennsylvania State University, University Park, PA

Acute kidney injury (AKI) is a common and potentially fatal complication that affects 5-9% of hospitalized patients, and with a greater incidence (> 10%) in intensive care unit patients every year. The molecular aspects of kidney injury and repair are still uncertain. Studies have shown that hepatocyte growth factor (HGF) promotes recovery of the injured kidney by inducing survival and migration of

tubular epithelial cells to repopulate the bare tubule areas. We have demonstrated *in-vitro* that HGF-stimulated kidney epithelial cell migration requires the activation of Arf6 via the cytohesin family of Arf guanine nucleotide exchange factors (GEFs), and the subsequent activation of Rac1. We hypothesize that this signaling module is required to promote the HGF-stimulated recovery of damaged kidney. We have established an ischemia and reperfusion injury (IRI) mouse model to analyze the effects of modulating this signaling pathway on kidney recovery. We have observed that treatment of injured mice with HGF results in lower creatinine (Cre) and blood urea nitrogen (BUN) when compared to untreated IRI mice, indicative of a faster kidney recovery. In addition, histological analysis of injured kidney tissue samples show that HGF treatment promotes recovery by enhancing kidney tubule repair. We have also treated IRI mice with the cytohesin inhibitor SecinH3. Cre and Bun levels as well as histological analyses show that, unlike HGF, SecinH3 treatment halts injured kidney recovery and delays repair when compared to untreated IRI mice. Analyses to detect active Rac1 and active Arf6 are being carried out to further determine the role of cytohesins and Arf6 in HGF-stimulated kidney recovery. Nevertheless, our results suggest a role of cytohesins in renal ischemia and reperfusion injury repair. We believe that HGF-stimulated cell migration in the injured kidney requires the activation of cytohesin. By testing our hypothesis, we expect to broaden the understanding of cell migration in AKI recovery.

The Role of Active ARF6 in Cytohesin-Induced Rac Activation.

E. Diekema¹, L.C. Santy²;

¹Biochemistry and Molecular Biology, Pennsylvania State Univ, State College, PA, ²Department of Biochemistry, Microbiology and Biochemistry, Pennsylvania State University, University Park, PA

Hepatocyte growth factor (HGF) is a potent signaling molecule that causes epithelial cells to scatter and migrate. Small GTPases play an important role regulating the changes downstream of HGF that lead to the initiation of migration. For example, crosstalk between the small GTPases ARF6 and Rac stimulates epithelial cell migration. The ARF-GEF Cytohesin-2 and the Rac-GEF Dock180 have also been implicated in HGF signaling as treatment with the cytohesin inhibitor SecinH3 or expression of the dominant negative form of Dock180 impairs HGF-stimulated wound healing. We have previously shown that the GEF activity of Cytohesin-2 and its promotion of a complex containing the scaffolding protein GRASP and Dock180 is required for cytohesin-induced Rac activation. However, the role of active ARF6 in this process is unclear. Using live-cell imaging, we found that GRASP and Dock180 co-localize with the recycling endosome markers EHD1 and Rab11 at internal locations. Here, we show that upon stimulation, exogenously expressed GRASP and Dock180 translocate from their internal location to the cell periphery when Cytohesin-2 is also expressed. In addition, we are able to detect a FRET signal in live cells using GRASP and Dock180 as FRET pairs, indicating that we can now use FRET to study the spatial and temporal dynamics of the complex. We hypothesize that activation of ARF6 by Cytohesin-2 regulates trafficking of GRASP and Dock180 from recycling endosomes to the plasma membrane. As either overexpression or up-regulation of HGF has been implicated in both cancer progression and

wound healing, respectively, increased understanding of HGF signaling would be beneficial to lead to the development of novel therapeutics to either fight metastasis or promote injury recovery.

Due to its significance, several in vitro models have been developed to study different aspects of the leukocyte adhesion cascade. However, currently none of these in vitro models can be used for real-time studies of the entire leukocyte adhesion cascade including rolling, adhesion and migration in a single assay. In this study, we have developed and validated a novel bioinspired microfluidic assay (bMFA) and used it to test the hypothesis that blocking of specific steps in the adhesion/migration cascade significantly affects other steps of the cascade. The bMFA consists of an endothelialized microvascular network in communication with a tissue compartment via a 3 μm porous barrier. Human neutrophils in bMFA preferentially adhered to activated human endothelial cells near bifurcations with rolling and adhesion patterns in close agreement with in vivo observations. When the tissue compartment of bMFA was filled with fMLP, 50% of adhering neutrophils migrated into the tissue compartment after 120 min. Treating endothelial cells with monoclonal antibodies to E-selectin or ICAM-1 or treating neutrophils with wortmannin reduced rolling of neutrophils to $\sim 60\%$, adhesion to $\sim 20\%$ and migration to $\sim 18\%$ of their respective control values. Furthermore, antibody blocking of specific steps in the adhesion/migration cascade (e.g. mAb to E-selectin) significantly downregulated other steps of the cascade (e.g. migration). This novel in vitro system provides a realistic human cell based model for basic science studies, identification of new treatment targets, selection of pathways to target validation, and low-cost test bed for rapid screening of candidate agents.

Linking sub-cellular mechanical forces to integrins mobility using Image Correlation Spectroscopy.

R. De Mets^{1,2}, M. Balland³, O. Destaing⁴, A. Delon¹, I. Wang⁵;

¹UMR 5588, Laboratoire Interdisciplinaire de Physique, Grenoble, France, ²Inserm U823, Institute Albert Bonniot, Grenoble, France, ³Materials, Optics and Instrumental Techniques for the Life Sciences (MOTIV), Laboratory of Interdisciplinary Physics (LiPhy), Grenoble, France, ⁴Differentiation and Cell Transformation, Institute Albert Bonniot (IAB) Inserm U823, Grenoble, France, ⁵UJF/UMR 5588, Laboratoire Interdisciplinaire de Physique, Grenoble, France

The ability of cells to sense physical properties of the extracellular matrix (ECM) is essential to regulate their proliferation, migration and differentiation. Cells feel the different properties of ECM and respond to it by exerting forces on their microenvironment. This process is mainly based on the activity of integrin receptors. Integrin activities depend on their ability to bind-unbind cyclically ECM and are then characterized by their diffusion regime at the plasma membrane (Rossier & al, 2012) which might be modulated by active forces.

The present project aims to understand the link between cellular forces and integrin activity in the regulation of mechanotransduction processes. Our work focuses on 2 types of integrins: b_1 that plays a role as force generator and b_3 that rather regulates cellular forces (Roca-Cusachs & al, 2009). The strategy adopted consists in modulating the spatial distribution of cellular forces by using micropatterns of various geometries and coupling forces modulation to temporal Image Correlation Spectroscopy (tICS). Practically, tICS allows us to determine in any point of the cells the mobility and concentration of b_1 and b_3 integrins tagged with GFP. The principle of tICS is based on the temporal autocorrelation of a series of images. From the amplitude and the shape of the autocorrelation functions inside a given ROI, we can extract information about the molecule number, their mean diffusion constant and the immobile molecule fraction. Each chosen ROI corresponds to a particular force arrangement, previously measured using patterned traction cytometry (Tseng & al, 2011).

Based on our set-up, we were able to modulate the spatial distribution of actin generated forces at the single cell level. We then measured the relation between those sub-cellular forces and the local concentration and mobility of those integrins. Interestingly, we found a strong correlation between the amplitude of traction forces and the mobility of b_3 , confirming its role of regulator in cell mechanical activity. Strikingly, we did not find the same behaviour in the case of b_1 integrins. Overall, this work brings new insights in the field of cell mechanics and provides information at the cell level about integrin dynamics and their correlation to cell mechanical activity.

P2214**Board Number: B841****Structured illumination microscopy reveals that focal adhesions are composed of linear subunits.**S. Hu¹, Y. Tee¹, A. Kabla², R. Zaidel-Bar¹, A.D. Bershadsky^{3,4}, P. Hersen^{1,5};¹Mechanobiology Institute, Singapore, Singapore, ²Department of Engineering, University of Cambridge, Cambridge, United Kingdom, ³Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel, ⁴Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ⁵Université Paris Diderot, Laboratoire Matière et Systèmes Complexes, UMR 7057 CNRS, Paris, France

The cells ability to mechanically interact with the extracellular matrix (ECM) is a fundamental feature of adherent eukaryotic cells, and is required for cell migration, proliferation, and differentiation. Adhesion is mediated by protein complexes, called focal adhesions. Recent progress in super resolution microscopy revealed that they have an internal organization, yet such methods do not allow observing the formation and dynamics of focal adhesions' internal structure. Here, we combine structured illumination microscopy (SIM) with total internal reflection fluorescence microscopy (TIRF) to be able to observe focal adhesions at high spatial resolution in live cells. We show that focal adhesion proteins inside focal patches are distributed along elongated subunits, typically 300 nm wide, separated by 300 nm and individually connected to actin cables. These focal adhesions subunits growth speed is in average of 0.3 $\mu\text{m}/\text{min}$. We further show that these structures are intimately linked to actin radial fiber formation. Taken together, our study reveals that, when observed with an appropriate resolution in both space and time, the minimal units of adhesion appear to be elongated, dynamic structures. We anticipate this ultrastructure to be relevant when studying the mechano-biological attributes of focal adhesions and their behavior in response to mechanical stress.

P2215**Board Number: B842****Development of a novel cellular gel substrate system and imaging platform for super-resolution fluorescence microscopy.**V.K. Gupta^{1,2}, M.J. Colville^{3,4}, A. Singh⁵, W.R. Zipfel^{3,5,6}, M.J. Paszek^{2,3,7};¹Sibley School of Mechanical and Aerospace Engineering, Cornell University, Ithaca, NY, ²School of Chemical and Biomolecular Engineering, Cornell University, Ithaca, NY, ³Field of Biophysics, Cornell University, Ithaca, NY, ⁴Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY, ⁵School of Applied and Engineering Physics, Cornell University, Ithaca, NY, ⁶Department of Biomedical Engineering, Cornell University, Ithaca, NY, ⁷Kavli Institute at Cornell for Nanoscale Science, Cornell University, Ithaca, NY

Cells sense the stiffness of their external environment and use this information to influence cell differentiation, tissue development, and pathological states, including cancer. Large protein assemblies

called focal adhesions are primarily responsible for linking the cell to the extracellular matrix (ECM) and converting external mechanical forces into internal biochemical signals. Although recent developments in super-resolution fluorescence microscopy allow one to study the nanoscale architecture of focal adhesions, these studies have only been conducted on glass, due to the challenge of nanometer imaging through standard gel substrates. Our aim was to develop a novel imaging platform and high refractive index gel substrate system of tunable stiffness for super-resolution imaging in both the lateral and vertical dimensions. The gel system that we developed consists of a commercially available silicon elastomer whose stiffness can be systematically varied by altering the ratio of its two components. The fabrication of the gels was optimized to achieve uniform thickness, an even surface, high optical quality and transparency, and minimal background fluorescence, which are critical for super-resolution imaging. The elastic moduli of the gels were measured using Dynamic Mechanical Analysis. By varying the ratio of the two gel parts, we were able to systematically adjust the elastic moduli of our gels from 1.7 kPa to 21 kPa. The gel system was highly compatible with cell culture. We observed that epithelial cells demonstrated similar spreading and growth characteristics on stiff (~21 kPa), fibronectin-conjugated gels compared to glass substrates conjugated similarly.

We next developed a custom imaging platform for Photo-activated localization Microscopy (PALM) imaging of adhesion structures in cells on our gel substrates. Our system employed a custom circular scanning Total Internal Reflection Fluorescence Microscopy (TIRFM) system, in which the focus of the laser beam is scanned around the periphery of the focal plane, to compensate for irregularities of the gel surface and unevenness of the TIRF field. By combining our imaging platform and elastomer system, we achieved high signal-to-noise imaging of individual fluorophores in PALM. As a proof of principle, super-resolution images of paxillin-mEos2 in epithelial cells were acquired on our elastomeric substrates. We now are evaluating quantitatively how substrate stiffness impacts the molecular organization of major focal adhesion proteins including FAK, vinculin, paxillin, and talin. This work will lead to a greater understanding of how adhesion complexes sense and respond to the stiffness of their environment.

Kinesin Motor Kid Plays a Role in Cell Adhesion and Migration by Affecting Focal Adhesion Localization and Dynamics.

L. Xu¹, K. Bartoli², S. Watkins³, W. Saunders¹;

¹Biological Sciences, Univ Pittsburgh, Pittsburgh, PA, ²Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, ³Center for Biologic Imaging, Univ Pittsburgh, Pittsburgh, PA

The kinesin-10 chromokinesin motor family is traditionally considered to play a role mainly during mitosis influencing chromosome alignment. We believe the Kid/KIF22 member of this group has additional functions during interphase of the cell cycle.

We observed that Kid localized to the sites of focal adhesions (FAs) in multiple cell lines and FAs became redistributed when Kid's function was impaired. In wild-type HeLa cells, FAs are mostly distributed near the peripheral edges of the cell. After knockdown of Kid, we found that the number of FAs significantly increased, and they became more scattered throughout the cytoplasm. FAs are integrin-based multiprotein structures that mediate the attachment of cells to the extracellular matrix (ECM). They play essential roles in various cellular processes including cell morphology, migration, proliferation, and differentiation. Hence, we checked if such changes in the number and distribution of FAs have any effect on cell adhesion and/or migration. Indeed, cells after knockdown of Kid showed a much slower rate of spreading compared to control cells when seeded onto fibronectin, which is a component of ECM. Additional results from our wound healing assay suggested that loss of Kid caused an about two-thirds reduction in the rate of cell migration.

Based on these observations, and previous studies showing the role of microtubules in FA stability, we hypothesized that Kid might be involved in regulating assembly and/or disassembly of FAs, thus affecting cell adhesion and migration. Confocal microscopy showed a higher proportion of focal complexes (FCs), which are smaller precursors of FAs, after knockdown of Kid. TIRF microscopy indicated that loss of Kid led to an increased life duration time of FAs. Since the small GTPase Rho is required for the maturation of FCs to FAs, we tested if the regulation of FA dynamics by Kid is Rho-dependent. When wild-type HeLa cells are treated with Rho inhibitor, there were few FAs due to the inhibition of FA maturation. Moreover, there were few FCs as the Rho inhibitor also interrupts actin stress fibers which are required for the assembly of FCs. Interestingly, when we treated cells with Rho inhibitor after knockdown of Kid, there were more FAs and FCs remaining, supporting the idea that Kid functions to destabilize FAs in the absence of Rho activity.

Taken together, these data suggested that Kid plays a role in the localization and dynamics of adhesion structures. This study identified a non-conventional role of Kid during interphase and expanded on our knowledge of how a motor protein might be involved in the focal adhesion network affecting cell adhesion and migration.

Extracellular matrix remodeling during physiological processes is mediated by invasive protrusions called podosomes. Podosomes consist of a polymerizing actin core surrounded by an adhesive ring. In vascular smooth muscle cells (VSMCs), podosomes can be rapidly initiated by PKC activation. We have previously

shown that kinesin KIF1C is important for efficient podosome formation in VSMCs but the mechanism whereby KIF1C performs this function is largely unknown.

Now, our live-cell imaging data show that deposition of KIF1C at distinct sites at the ventral cell membrane correlates with new podosome formation at those sites. In particular, KIF1C accumulates around emerging podosome cores, which are marked by cortactin and TKS5, and acquires a ring-like shape. Our data indicate that KIF1C is delivered and relocated along MTs, but resides at adhesive rings in a MT-independent manner. Because without KIF1C, both the number and size of podosomes are decreased, we hypothesize that this kinesin provides a base for the adhesive ring formation. In addition, KIF1C likely supports relocation of adhesive ring components during movement of existing podosomes to new cellular positions, as seen in relocation of podosomes from the periphery toward the cell center via KIF1C-rich membrane tubes.

These findings indicate that microtubule-dependent KIF1C transport and deposition is critical for podosome positioning in VSMCs. Through this mechanism, our study implicates KIF1C as a regulator in the distribution of podosomes over the ventral cell surface that is thought to be important for a more uniform ECM remodeling by VSMCs rather than site specific degradation typical for cancer cells.

Microtubules Regulate Focal Adhesion Dynamics through MAP4K4.

J. Yue¹, X. Wu¹;

¹The Ben May Department, The University of Chicago, Chicago, IL

Focal adhesions are dynamic organelles that establish a connection between the ECM (extracellular matrix) and cytoskeletal networks and serve as points of traction for cells. The disassembly of focal adhesions allows cell retraction and integrin detachment from the ECM, processes critical for cell movement. A long-standing and intriguing observation is that growth of MT filaments in migratory cells can be guided toward focal adhesions, and targeting of MT growing ends (plus ends) to focal adhesion often precedes focal adhesion turnover. It has been speculated that MTs can serve as tracks to deliver proteins essential for focal adhesion disassembly. However, the molecular nature of the focal adhesion “disassembly factor” remains elusive. By quantitative proteomics, we identified mammalian MAP4K4 (mitogen-activated protein kinase kinase kinase kinase 4) as a focal adhesion regulator that associates with MTs. Conditional knockout (cKO) of MAP4K4 in skin epidermal cells stabilizes focal adhesions and impairs epidermal migration. Exploring underlying mechanisms, we further show that MAP4K4 associates with MT plus end tracking protein, EB2 (end binding 2) and an Arf6-specific guanine nucleotide exchange factor, ARF-GEP100 (ADP-Ribosylation Factor-Guanine Nucleotide Exchange Protein-100 kDa), which is also known as IQSEC1 (IQ motif and SEC7 domain-containing protein 1). Together, our findings provide new insights for this critical cellular process, suggesting that EB2-containing MT plus ends can deliver MAP4K4 toward focal adhesions, where MAP4K4 can in turn activate Arf6 via IQSEC1 and enhance focal adhesion dissolution.

P2219**Board Number: B846****Phosphorylation of Serine 106 Regulates Asef2 GEF Activity and Asef2-Mediated Cell Migration and Adhesion Turnover.**B. Erdogan¹, J. Evans¹, K. Hines^{2,3,4}, J. Forsythe^{2,3,4}, M. Shi¹, S. Hill⁵, K. Rose^{5,6}, J. McLean^{2,3,4}, D. Webb^{1,4,7};¹Department of Biological Sciences, Vanderbilt University, Nashville, TN, ²Department of Chemistry, Vanderbilt University, Nashville, TN, ³Vanderbilt Institute for Chemical Biology, Vanderbilt University, Nashville, TN, ⁴Vanderbilt Institute for Integrative Biosystems Research and Education, Vanderbilt University, Nashville, TN, ⁵Mass Spectrometry Research Center, Vanderbilt University, Nashville, TN, ⁶Department of Biochemistry, Vanderbilt University, Nashville, TN, ⁷Department of Cancer Biology, Vanderbilt University, Nashville, TN

Asef2 is a recently identified guanine nucleotide exchange factor (GEF) that regulates cell migration and adhesion turnover via activation of Rho family GTPases, including Rac. Asef2 is activated by binding of the tumor suppressor adenomatous polyposis coli (APC) to its N-terminal region; however, much less is known about other modes of Asef2 regulation, such as post-translational modifications. In this study, we identified six phosphorylation sites in Asef2 using liquid chromatography coupled with high-resolution mass spectrometry (LC-MS) and tandem mass spectrometry (MS/MS). One of these phosphorylation sites, serine 106 (S106), is located within the APC binding region, suggesting a potential role in Asef2 regulation. To probe the effects of S106 phosphorylation on Asef2 activity, Asef2 mutants were generated in which S106 was changed to either alanine (S106A) or aspartic acid (S106D), which represent non-phosphorylatable and phosphomimetic analogues, respectively. GFP-tagged Asef2 S106 mutants were transfected into HT1080 cells and activation of Rac was assessed using a pulldown assay. S106A mutation greatly reduced Rac activation by Asef2, while the phosphomimetic mutation (S106D) led to an increase in active Rac levels. Next, we tested the effects of S106 mutation on cell migration using live-cell time-lapse microscopy. Wild-type GFP-Asef2 promoted migration of HT1080 cells on fibronectin, as we have previously shown. Expression of GFP-Asef2-S106A abrogated Asef2-promoted migration, whereas GFP-Asef2-S106D expression promoted migration similarly to GFP-Asef2. Because our previous study showed that Asef2 promotes cell migration by increasing adhesion assembly and disassembly (adhesion turnover), we next determined if S106 phosphorylation affects cell migration by modulating adhesion turnover. Cells expressing wild-type GFP-Asef2 showed an approximately 50% decrease in the $t_{1/2}$ values for adhesion assembly and disassembly compared to control cells expressing GFP, indicating that adhesions turn over more rapidly in Asef2-expressing cells. Conversely, expression of GFP-Asef2-S106A led to an increase in the $t_{1/2}$ values for adhesion assembly and disassembly compared to GFP-Asef2 expression, indicating that S106A expression negates the Asef2-mediated effect on adhesion turnover. Moreover, expression of GFP-Asef2-S106D caused more rapid adhesion turnover comparable to that observed with GFP-Asef2 expression. These results demonstrate that Asef2 S106 phosphorylation promotes faster adhesion turnover, which is critical for efficient cell migration. Taken together, we have identified a new regulatory mechanism for Asef2, S106 phosphorylation, which is crucial for Asef2-mediated Rac activation, cell migration, and adhesion turnover.

P2220**Board Number: B847****Septins enhance the mesenchymal-like motility of renal epithelia by promoting stress fiber connectivity and focal adhesion maturation.**L. Dolat¹, J.L. Hunyara¹, J.R. Bowen¹, E.P. Karasmanis¹, V. Galkin², E.T. Spiliotis¹;¹Biology, Drexel University, Philadelphia, PA, ²Physiological Sciences, Eastern Virginia Medical School, Norfolk, VA

Epithelial-mesenchymal transition (EMT) underlies renal fibrosis and the metastasis of renal cell carcinomas (RCCs). EMT is characterized by disruption of cell-cell adhesions, cell scattering and the enhancement of cell motility with a front-rear polarity. While the disruption of cell-cell adhesion during EMT is extensively studied, little is known about the molecules and mechanisms that enhance the mesenchymal-like motility of epithelial cells. Septins are filamentous G proteins that are over-expressed in metastatic RCCs, but their functions in the mesenchymal-like motility of epithelial cells is unknown. Using the Madin-Darby canine kidney (MDCK) model of partial EMT that allows the study of epithelial motility in 2D and 3D matrices after stimulation with hepatocyte growth factor (HGF), we discovered a novel network of septin filaments that underlies the organization of the transverse arc and radial (dorsal) stress fibers in the leading lamella of migrating epithelia. We show that this lamellar network of septin filaments is required for the maturation of nascent focal adhesions as septin depletion results in smaller and more transient and peripheral focal adhesions with increased levels of phosphorylated paxillin-Y118. In addition, septin-depleted cells consisted of a disorganized transverse arc and shorter and fewer radial stress fibers. These phenotypes were independently rescued by alpha-actinin and the actin-binding motor-dead myosin II N93K, but not by alpha-actinin-deltaABD, which cannot bind or bundle actin, or the constitutively active myosin regulatory light chain RLC-DD. These data suggested that septins function as actin-binding and cross-linking proteins. Using low speed sedimentation assays and negative stain EM, we show that pre-assembled actin filaments are bundled by septin 9 (SEPT9), whose expression is increased after induction of renal epithelial motility with the hepatocyte growth factor. We show that SEPT9 over-expression enhances renal cell migration in 2D and 3D matrices, while SEPT9 knock-down decreases the velocity and alters the mesenchymal-like shape of epithelial cells migrating in 3D matrices. Taken together, these results suggest that septins promote epithelial motility by reinforcing the connectivity of lamellar stress fibers and thereby, stabilizing nascent focal adhesions in the leading edge of motile epithelia.

P2221**Board Number: B848****Evidence of multiple roles for Diaphanous-Related Formins (DRFs) in Invasion.**E.W. Miller¹, S.D. Blystone¹;¹Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

In cancer cells, the actin cytoskeleton performs multiple functions in invasion and metastasis, partially through F-actin dense, matrix-degradation structures known as invadopodia. Assembly of monomeric actin into filaments is regulated by several different proteins, including a relatively new group of proteins known as formins. A subfamily of this group of proteins, the diaphanous-related formins (DRFs), share a common domain architecture and interact directly with Rho-family GTPases. Using quantitative real-time reverse transcriptase PCR (qRT-PCR), we determined expression levels for all ten DRFs in the highly-invasive breast cancer cell line MDA-MB-231. We then questioned whether depletion of endogenous DRF expression would result in impaired MDA-MB-231 cell invasion. Using DRF-targeting siRNA, we silenced expression of endogenous Dia1, Dia2, and FMNL1 by 75.2%, 65.0%, and 83.5% respectively. Cells treated with DRF-targeting siRNA were then subjected to an *in vitro* Matrigel invasion assay. Interestingly, knockdown of Dia1 and FMNL1 significantly inhibited invasion while knockdown of Dia2 exhibited only moderate inhibition. This led us to speculate that DRFs may have different roles in the invasion process. Using a combination of two DRF-targeting siRNA oligonucleotides, we simultaneously knocked down three combinations of DRFs, all of which had a significant, but neither all additive nor all compensative, effect on the invasive capacity of MDA-MB-231 cells. In order to determine DRF function within the cell, we used immunofluorescence-based microscopy to understand sites of activity. Interestingly, we found both endogenous FMNL1 and Dia2 to be dispersed throughout the cytoplasm with some localization to the perinuclear region of the cell. We then proceeded to investigate one of these DRFs, FMNL1, more closely. Since knockdown of FMNL1 resulted in a significant inhibition of 3D invasion, we questioned whether knockdown would have the same effect on 2D migration. Cells were treated with DRF-targeting siRNA and subjected to a scratch-wound assay. While cells treated with control siRNA closed the wound within 18 hours, cells treated with FMNL1-targeting siRNA required >24 hours to complete wound closure. FMNL1 is of particular interest as three alternative splice isoforms of this protein have been identified, all of which we detected in MDA-MB-231 cells using PCR. Future examination of all ten DRFs, especially FMNL1, and subsequent meta-analysis will allow us to determine whether there are unique events specific to individual formins which may be targeted by novel therapeutics to treat metastasis.

P2222**Board Number: B849****A plastic relationship between vinculin-transmitted tension and adhesion area defines adhesion complex size and lifetime.**U. Berge¹, P. Hernandez Varas², J.G. Lock¹, S. Strömblad²;¹Dept. of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden, ²Department of Biosciences and Nutrition, Karolinska Institute, Stockholm, Sweden

Cell-matrix adhesions mediate critical mechanical force transduction, but the interplay between force and adhesion regulation remains unclear. Here, live cell imaging enabled the mapping of time-dependent cross-correlations between mechanical tension and adhesion area, revealing a high degree of plasticity in this relationship. Interestingly, while an expected positive cross-correlation dominated in mid-sized adhesions, small and large adhesions displayed negative cross-correlation. Furthermore, while large changes in adhesion area followed tension alterations, small increases in area preceded tension dynamics. Modelling based on this mapping of the tension-adhesion area relationship confirmed its biological validity, and indicated that the tension-adhesion area relationship can explain adhesion size and lifetime limits, keeping adhesions focal and transient. We also identified a subpopulation of adhesions that remain stable in size and tension, whose disassembly may instead be microtubule-mediated. In conclusion, we define a plastic relationship between tension and adhesion area that controls cell-matrix adhesion focality.

Integrins and Cell-ECM Interactions 2**P2404****Board Number: B851****Nitric oxide plays a role in transmitting biochemical signal from the extracellular matrix for mammary epithelial morphogenesis.**S. Furuta¹, M.J. Bissell¹;¹Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA

Nitric oxide (NO) is a short-lived, gaseous signaling molecule produced in response to biochemical or mechanical stress in diverse tissues and organisms. Despite its evolutionary conservation and ubiquitous expression, the bioactivities of NO have been primarily studied in specialized tissues, including mammalian neurons, muscles, endothelial or immune cells, where NO triggers cell membrane hyperpolarization and relaxation or exerts cytotoxic action. In the past decade, however, different functions of NO in other tissues and organisms have been gradually unraveled, including embryogenesis and morphogenesis of *Xenopus*, pond snail and *Drosophila*. Nevertheless, whether NO is involved in the establishment of a mammalian tissue is yet to be determined. We found that non-malignant mammary epithelial cells (MECs) produced NO in response to the extracellular matrix (ECM) proteins laminin-5 and -1 and that NO production was essential for their ability to form growth-arrested polarized acini (the functional unit of mammary gland) in three-dimensional (3D) laminin-rich (1r) ECM cultures. While this mechanism was abrogated in breast cancer cells that failed to form acini in 3D cultures, induced NO production by the use of an NO donor allowed them to restore the formation of normal-like polarized

colonies. We further found that such an essential role of NO in mammary acinar formation was attributed to its ability to trigger cell membrane hyperpolarization and hence enhance tight junctions through co-localization of E-cadherin and cortical actin. These observations, for the first time, uncover that NO is produced by MECs in response to a biochemical stimulus of the ECM and plays a critical role in mammary acinar morphogenesis, whereas the lack of NO production is relevant to the malignant phenotype of breast cancer cells.

Dynamic and hierarchical reorganization of integrin-associated molecular complexes in nascent adhesions.

A. Bachir¹, J. Zareno¹, K. Moissoglu², E. Plow³, E. Gratton⁴, A.R. Horwitz⁵;

¹Department of Cell Biology, Univ of Virginia, Charlottesville, VA, ²Center for Cancer Research, National Cancer Institute, NIH, Bethesda, MD, ³Department of Molecular Cardiology, Lerner Research Institute, Cleveland Clinic, Cleveland, OH, ⁴Laboratory of Fluorescence Dynamics, University California-Irvine, Irvine, CA, ⁵Cell Biology, University of Virginia, Charlottesville, VA

An intricate network of putative molecular interactions comprises cell-matrix adhesions. Most of these interactions are inferred from co-immunoprecipitation, often using over expressed components. However, few have been demonstrated or characterized functionally in living cells, due to challenges in capturing highly regulated and transient associations that may form and evolve in adhesions. Our study uses high-resolution and image-based fluorescence fluctuation microscopy to map the formation and stoichiometry of integrin-associated molecular complexes in the nascent adhesions that populate the leading edge of migrating cells. We focus on putative integrin activating (kindlin and talin) and actin-linking (talin, vinculin and α -actinin) molecules and show that all molecules are present in nascent adhesions as soon as they are visible; however, they form integrin containing complexes hierarchically, at different times and with variable stoichiometry within the adhesion itself. These observations suggest a working model for nascent adhesion assembly, whereby transient complexes containing ~ 3 α -actinin and integrin molecules help nucleate nascent adhesions. Subsequently, integrin complexes form that contain kindlin in a 1:1 ratio, but not talin. Talin localizes to adhesions independently of the integrin-kindlin complex, and associates with vinculin in molecular complexes. However, once the nascent adhesion has formed, myosin II activity promotes talin association with the integrin-kindlin complex in a 2:1 stoichiometry, suggesting that each talin molecule cross-links two integrin-kindlin complexes. Finally, as adhesions mature into larger structures, talin increases to a 1:1 ratio with integrin and kindlin; whereas the ratio of vinculin to the other molecules continues to increase. In summary, using novel fluorescence fluctuation microscopy, we show that hierarchical adhesion assembly and reorganization accompanies adhesion formation.

P2224**Board Number: B852****Cytoskeletal integrity and dynamics regulate force mediated cell detachment.**A. Fuhrmann¹, A.J. Engler¹;¹Bioengineering, University of California, San Diego, La Jolla, CA

Integrin mediated cell adhesion is regulated by extracellular factors including divalent cations, which vary with niche. Since adhesion is ubiquitous to all adherent cells and involved in many processes, e.g. migration, quantitative information about adhesion strength is fundamental for understanding cell-ECM interactions. While it is commonly assumed that adhesion assays measure integrin-ECM bond strength, reports now show that cell material remains behind after exposure to acute shear and subsequent detachment. Here we show that many focal adhesion (FA) proteins but not actin remain behind after shear induced detachment of HT1080 fibrosarcoma cells suggesting that the cytoskeleton-FA connection disconnects during detachment more so than integrins when bound to planar substrates in the presence of divalent cations. Cytoskeletal stabilization with Phalloidin oleate (PO) did indeed increase attachment strength by 8-fold while crosslinking integrins to the substrate with DTSSP only caused a 50% increase. However, drug treatments can significantly affect cell function well before shear application. Conversely reducing the temperature only during shear application also increased attachment strength 8-fold. Even at lower temperatures, e.g. 8°C, cells leave FA proteins behind that co-localize with actin suggesting that the maximal integrin-ECM bond strength was not exceeded. The importance of temperature in stabilizing adherent cells' cytoskeleton is not well appreciated in adhesion assays with many of them operating at not further specified 'room temperature', and so we determined the dependence of attachment strength on temperature. We found that the rate of attachment strength change is most significant around room temperature (16°C – 28°C), highlighting the importance of carefully monitoring measurement temperature. Finally by observing this fracturing behavior in mouse and human fibroblasts as well as determining that it is ligand-independent, we demonstrate the ubiquity of this cytoskeleton-FA mode of detachment despite small variation in the strength of the response. Together these data demonstrate that the cytoskeleton and its dynamic coupling to focal adhesions are critically important for cell adhesion in niche with divalent cations.

P2225**Board Number: B853****Nanoscale architecture of tension generation within focal adhesions.**A.H. Mekhdjian¹, M. Morimatsu¹, A.C. Chang¹, S. Tan¹, A.R. Dunn¹;¹Chemical Engineering, Stanford University, Stanford, CA

Living cells are exquisitely responsive to mechanical cues from their surroundings. A primary means by which cells sense and transmit mechanical force is through integrins, a class of heterodimeric, transmembrane proteins that physically link the cell cytoskeleton to the extracellular matrix (ECM). The cytoplasmic domains of integrins recruit numerous proteins that collectively comprise focal adhesions

(FAs), micron-sized assemblies responsible for mechanosensing and traction force generation. However, the underlying mechanisms responsible for the spatial and temporal organization of force generation within FAs remain poorly understood. We used Förster resonance energy transfer (FRET)-based molecular tension sensors (MTSs) to directly visualize mechanical forces exerted by individual integrins. Simultaneous super-resolution imaging of MTSs and GFP-tagged cellular proteins results in maps of the force-producing structures within FAs with better than 100 nm spatial resolution, allowing us to correlate local force generation with the presence of specific integrin heterodimers and cytoskeletal proteins. We find that $\alpha\beta3$ integrin localizes to high force regions, whereas $\alpha5\beta1$ integrin localization is more diffuse. The canonical FA proteins paxillin, vinculin, talin, and α -actinin colocalize with force production to varying degrees. Surprisingly, paxillin, which is not generally considered to play a direct role in force transmission, shows a higher degree of spatial correlation with force than vinculin, talin, or α -actinin, proteins with hypothesized roles in mechanotransduction. In addition, simultaneous time-lapse imaging of either GFP-paxillin or GFP- α -actinin with MTS-measured local traction forces reveals that paxillin and tension are closely related in both space and time in assembling and disassembling adhesions, while α -actinin exhibits a more complex relationship with tension. The high degree of spatial correlation of both paxillin and $\alpha\beta3$ integrin with mechanical tension suggests that these proteins may work in concert to regulate both FA dynamics and intracellular, mechanically induced signal transduction.

Focal adhesion kinase links lamellipodial actin and nascent adhesions to the ECM through the Arp2/3 complex to regulate leading edge dynamics.

V. Swaminathan¹, C. Waterman²;

¹Cell Biology and Physiology Center, NHLBI/NIH, Bethesda, MD, ²National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD

Efficient cell migration requires proper dynamic interaction between the extracellular matrix (ECM) and the cytoskeletal network through the focal adhesion (FA) system. While FA molecules like vinculin are known to couple stress fibers through mature adhesions to the ECM, what couples dendritic actin at the leading edge through nascent adhesions (NA) to the ECM is unknown. Focal adhesion kinase (FAK) is a non-receptor tyrosine kinase that localizes to nascent and mature adhesions and plays key roles as a scaffold and a signaling molecule. FAK is thought to regulate the disassembly of mature FA, although recent evidence points to FAK playing a critical role in early adhesion events. FAK has been shown to recruit the integrin-actin linker talin to NA and also interacts with the Arp2/3 complex that nucleates the actin network in lamellipodia. Based on these results, we hypothesized a novel role for FAK in linking lamellipodial actin dynamics and NA via its interaction with Arp2/3. Using fibroblast cells derived from a FAK knockout (KO) mouse combined with high resolution DIC and TIRF microscopy, we found that FAK KO cells showed faster lamellipodial protrusion and retraction velocities as well as increased frequency in these cycles. Fluorescent speckle microscopy of actin revealed increased actin retrograde flow and

weaker engagement of the NA to the ECM marked by their sliding in the lamellipodia and a wider lamellipodia compared to controls. These defects were rescued by expression of FAK. These results implicate FAK in stabilizing NA, attenuating actin polymerization and retrograde flow at the leading edge, and delineating a lamella-lamellipodia border. To test whether FAK's role at the leading edge was dependent on its interaction with the Arp2/3 complex, we expressed a FAK mutant defective in Arp2/3 binding in FAK knockout cells. The FAK mutant was effectively recruited to NA and FA and resulted in attenuation of leading edge protrusion and actin flow velocities compared to FAK KO, indicating that FAK reduces actin polymerization and retrograde flow independent of its interaction with Arp2/3. However, compared to knockout cells expressing full length FAK, lamellipodial retraction was faster, suggesting an adhesion engagement defect. Indeed, compared to control, in cells with the FAK-Arp2/3 interaction disrupted, NAs often failed to engage to the ECM, had shorter lifetimes, and showed sliding behavior at the same rate as actin retrograde flow, similar to what was observed in the FAK KO cells. Together, these results implicate the specific interaction of the Arp2/3 complex and FAK in stabilizing the NA-ECM linkage at the leading edge of a cell which is required to attenuate edge retraction and result in overall net advance of the leading edge.

Semaphorin3A Shifts the Biphasic Relationship Between Cell Motility and Substratum Concentration Through Increased Focal Adhesion Formation.

A. Miller¹, S. Gehler²;

¹Augustana College, Bloomington, IL, ²Biology, Augustana College, Rock Island, IL

Cell migration plays an essential role in normal and pathological processes such as embryonic development, wound healing, and tumor metastasis. Interactions between integrin-mediated adhesions and the extracellular matrix (ECM) are important regulators of cell migration. Studies have shown that cells exhibit a biphasic relationship between cell migration speed and substratum concentration, suggesting cells experience an optimal level of cell-substratum adhesiveness to facilitate maximal cell migration (DiMilla et, al. 1993). Although these observations are well documented, mechanisms by which extracellular ligands regulate cell migration speed in response to changes in substratum concentration are not clearly understood. Semaphorin3A (Sema3A) has been found to increase integrin receptor expression in breast cancer cells (Staton et, al. 2011) as well as inhibit breast cancer cell motility (Pan et, al. 2009). Because maximal cell motility occurs when there is a balance between substratum concentration and integrin expression, we propose Sema3A alters cell adhesion dynamics to influence breast tumor cell motility on different concentrations of various ECM molecules. First, using a range of concentrations for both collagen type I and fibronectin, MDA-MB-231 cells exhibited maximal migration at intermediate concentrations. However, cells treated with Sema3A exhibited maximal cell migration at lower concentrations of both collagen and fibronectin, while Sema3A inhibited migration at intermediate and high concentrations. Second, integrin-mediated adhesion to different concentrations of either collagen or fibronectin was assessed using a spreading assay. Treatment with Sema3A resulted

in maximal cell area at lower concentrations of both collagen and fibronectin, but reduced cell area at intermediate and high concentrations of both substrata. Third, *Sema3A* increased focal adhesion formation at all concentrations of both collagen and fibronectin. These results suggest *Sema3A* shifts the optimal level of cell-substratum adhesiveness to lower concentrations of collagen and fibronectin to yield maximal cell migration. Furthermore, the data indicate *Sema3A* alters cell adhesion dynamics at intermediate and high concentrations of collagen and fibronectin, resulting in reduced cell migration speed.

PAK6 interacts with β -integrin tails and regulates integrin-mediated cell adhesion.

E.M. Morse¹, B. Ha², J. Gao², J.R. Olberding¹, K.M. Draheim², T.J. Boggon², D.A. Calderwood^{1,2};

¹Department of Cell Biology, Yale University, New Haven, CT, ²Pharmacology, Yale University, New Haven, CT

PAK6 is a member of the p21-activated kinase (PAK) family, a group of six serine/threonine kinases known for their roles in modulating cell growth, survival, adhesion and motility. PAK6 was first identified as a protein that interacts with androgen receptor, and its expression has been correlated to the progression of prostate cancer. However, until recently, little more was known about the cellular roles of PAK6. Here we demonstrate that PAK6 makes a unique contribution to cell growth given that knockdown of PAK6 inhibits cell growth and this growth defect cannot be rescued by its most closely related kinases, PAK4 and PAK5, while it is rescued by re-expression of PAK6. Further, we find that PAK6 regulates cell-matrix adhesion, as knockdown of PAK6 results in increased focal adhesion size and cell spreading. We also find that PAK6 is able to directly interact with the cytoplasmic tails of β -integrins, a family of transmembrane cell adhesion receptors that link the extracellular matrix to the actin cytoskeleton. Taken together, these data support a regulatory role for PAK6 in both cell growth and cell-matrix adhesion, two basic cellular processes crucial to cancer progression.

Super-resolution microscopy reveals a role for the tetraspanin CD82 in regulating integrin molecular clustering.

C.M. Termini¹, M.L. Cotter¹, K.D. Marjon¹, K.A. Lidke², J.M. Gillette¹;

¹Department of Pathology, University of New Mexico Health Sciences Center, Albuquerque, NM,

²Department of Physics and Astronomy, University of New Mexico, Albuquerque, NM

Hematopoietic stem and progenitor cell (HSPC) adhesion to the surrounding microenvironment is critical for maintaining HSPC proliferation, differentiation, and survival. However, our present understanding of

the mechanisms that regulate this adhesive interaction remains incomplete. Previously, our lab identified the tetraspanin, CD82, as a critical regulator of HSPC adhesion and homing to the bone marrow microenvironment. More specifically, we found that CD34+ cells treated with monoclonal CD82 blocking antibodies display reduced homing and engraftment in vivo. Tetraspanins, like CD82, are membrane scaffold proteins that promote the organization of membrane proteins, such as integrins, which contribute to cellular adhesion and migration. Therefore, we hypothesize that CD82 regulates HSPC adhesion by modulating integrin organization and density at the nanoscale. In order to test this hypothesis, we generated stable KG1a cells that overexpress wild-type CD82 (CD82OE). We found that the CD82OE cells display increased adhesion to fibronectin when compared to control cells. Pre-treating CD82OE cells with LDV, an $\alpha4\beta1$ specific blocking peptide, inhibited the CD82-mediated increase in adhesion, suggesting the involvement of the $\alpha4\beta1$ integrin in HSPC adhesion. In order to determine how molecular clustering contributes to HSPC adhesion, we used the super-resolution microscopy technique, dSTORM. We quantified CD82 clustering by pair-autocorrelation analysis and determined that there is an increase in CD82 cluster size in CD82OE cells when compared to the control cells. The palmitoylation of tetraspanins has been shown to regulate lateral membrane protein packing, which is critical for cell adhesion and migration. In order to test the role of CD82 palmitoylation in modulating membrane complex organization and cell adhesion, we also generated KG1a cells that overexpress a mutant form of CD82 that cannot be palmitoylated (Palm-CD82OE). As predicted, we found that the Palm-CD82OE cells display reduced cell adhesion and significantly smaller CD82 clusters than CD82OE cells. Additionally, we used the DBSCAN clustering algorithm to quantify the $\alpha4$ cluster area from our super-resolution data, finding that CD82OE cells display decreased $\alpha4$ cluster area when compared to control and Palm-CD82OE cells. Interestingly, we found an increase in the number of $\alpha4$ molecular locations per $0.01 \mu\text{m}^2$ in CD82OE cells when compared to control and Palm-CD82OE cells. Taken together, these data suggest that CD82 regulates $\alpha4$ molecular density and palmitoylation of CD82 is critical for its regulation of tightly packed $\alpha4$ clusters within the plasma membrane. Additionally, we will discuss how CD82 expression and mutation control $\beta1$ integrin activation and signaling.

Discoidin Domain Receptor 1 Impacts Myosin-Dependent Collagen Remodelling.

N.M. Coelho¹, P.D. Arora¹, C.A. McCulloch¹;

¹Matrix Dynamics Group, University of Toronto, Toronto, ON

The discoidin domain receptor 1 (DDR1), a tyrosine kinase receptor that is activated by type I collagen, is associated with MMP1-dependent remodelling of collagen. Our objective was to examine the contribution of DDR1 to collagen remodelling by phagocytosis, pericellular proteolysis and traction. Using mouse fibroblasts, human breast cancer cells (MCF7) and cells that do not express $\beta1$ integrin (GD25 cells), we analysed the conditioned medium and cell lysates of cells cultured on biotinylated type I collagen. With this approach we tracked the fate of exogenous collagen in different collagen remodelling processes. DDR1 expression levels were positively associated with increased collagen

phagocytosis as detected by collagen-coated bead internalization and by immunodetection using streptavidin. With the use of FITC-labeled fibrillar collagen we found that DDR1 expression was associated with higher levels of collagen compaction and fiber reorganization. In cells expressing higher levels of DDR1, there was increased pericellular collagen clearance as detected with FITC-collagen and with collagen ¾ neoepitope antibodies. Inhibition of DDR1 tyrosine kinase activity with nilotinib blocked collagen compaction, fiber alignment and phagocytosis in DDR1 expressing cells but not in DDR1 knockdown cells. Blebbistatin, an inhibitor of non-muscle myosin, did not affect the association of DDR1 and non-muscle myosin IIA in cells plated on collagen but blebbistatin strongly inhibited collagen compaction, alignment and phagocytosis. Collectively these data indicate that DDR1 associates with non-muscle myosin II to mediate collagen remodelling by mechanical reorganization and phagocytosis.

A strategy for tissue self-organization that is robust to cellular heterogeneity and plasticity.

A. Cerchiarì¹, J. Garbe², N. Jee³, M. Todhunter^{3,4}, T. Desai⁵, M.A. LaBarge², M. Thomson⁶, Z.J. Gartner^{3,6};
¹Bioengineering, UC Berkeley - UCSF, San Francisco, CA, ²Lawrence Berkeley National Laboratory, Berkeley, CA, ³Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, ⁴Tetrad Graduate Program, University of California, San Francisco, San Francisco, CA, ⁵Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA, ⁶Center for Systems and Synthetic Biology, University of California, San Francisco, San Francisco, CA

A combination of cell-intrinsic and extrinsic cues dictates how cell-cell and cell-ECM adhesions orchestrate the self-organization of cells into tissues. The balance between these interactions is central to the outcome of morphogenesis, tissue homeostasis, wound healing, disease progression, and the reconstructions of human tissues in vitro. Characteristics such as differential expression of cadherins and regulation of cortical tension are important cell-intrinsic parameters that influence this process. However, how extrinsic parameters, such as the physicochemical properties of the ECM, modify and relate to intrinsic interactions in the context of tissue self-organization is poorly understood. To clarify how cell-intrinsic and extrinsic cues combine to define tissue architecture in complex epithelia, we FACS-sorted human mammary epithelial cells derived from breast reduction mammoplasties into their luminal (LEP) and myoepithelial (MEP) lineages, quantified the differential mRNA and protein expression of key cell-cell and cell-ECM adhesion molecules via qPCR and flow cytometry, quantified their adhesion to each other as well as to the ECM via contact-angle measurements, translated these measurements into works of adhesion, and computationally modeled the self-organization process as a function of variable cell intrinsic and extrinsic parameters using a Metropolis-Hasting algorithm. The mathematical model predicted that MEP-ECM interactions are the dominant factor directing tissue self-organization, and that final tissue architecture is robust to perturbations to other parameters contributing to self-organization. The model also predicted that specific alterations to the balance of parameters directing self-organization could drive catastrophic breakdown of tissue architecture. To test the predictions of our model, we reconstituted compositionally and geometrically defined aggregates of luminal and basal cells

fully embedded in different ECMs using 3D cell-patterning technologies we have previously developed. This allowed us to test the consequences of specific perturbations generated with siRNA knockdowns of proteins affecting the primary cell-cell and cell-ECM interactions. We found that talin1 knockdown decreased the work of adhesion between MEPs and the ECM and promoted tissue inversion. In contrast, perturbations such as p120 knockdown in MEPs and/or LEPs decreased work of cell-cell adhesion but had no consequences on cell positioning through self-organization. Contrary to studies of early metazoan development, our results suggest that a single interaction between the basal cells and the ECM overrules cell-cell interactions and directs the self-organization of dynamic and heterogeneous epithelial tissues such as the human mammary gland.

¹Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, ²Sol Sherry Thrombosis Research Center, Temple University School of Medicine, Philadelphia, PA, ³Cancer Biology Program, Fox Chase Cancer Center, Philadelphia, PA, ⁴Pharmacology, Temple University School of Medicine, Philadelphia, PA, ⁵Cardeza Foundation for Hematologic Research, Thomas Jefferson University, Philadelphia, PA

Many Ras family small GTPases are expressed in human platelets, including Rac, RhoA, Rap, and H-/N-/R-Ras1. However, the signaling and cellular functions of most Ras family GTPases in platelets remain poorly understood. Like R-Ras1, TC21/R-Ras2 reverses suppression of integrin activation by oncogenic H-Ras; hence, TC21 may be important for integrin activation. However, a role for TC21 in platelets has not been explored. In this study, we demonstrate that TC21 is expressed in human and murine platelets and is activated in human platelets in response to agonists for the glycoprotein VI (GPVI)/FcR[gamma] ITAM-containing collagen receptor (collagen-related peptide (CRP) and convulxin). TC21 activation by GPVI required Src family kinase activity. Platelet aggregation, integrin [alpha]IIb[beta]3 activation, and [alpha]- and dense-granule secretion were significantly inhibited in TC21-deficient platelets in response to GPVI stimulation with CRP *ex vivo*. In contrast, aggregation and secretion in TC21-deficient platelets were normal in response to stimulation with 2-MeSADP (P2Y receptor agonist), AYPGKF (PAR4 receptor agonist) and fucoidan (CLEC-2 receptor agonist), indicating that the function of TC21 in platelets is GPVI/FcR[gamma]-ITAM-specific. CRP-induced phosphorylation of Syk, PLC[gamma]2, Akt, and ERK were substantially inhibited in TC21-deficient murine platelets. Stimulation with CRP, but not with other agonists, induced enrichment of TC21 at the plasma membrane in human platelets, and TC21 was required for GPVI-induced activation of Rap1b, indicating Ras small GTPase crosstalk. Using a thrombosis model with FeCl₃-induced injury to the carotid artery, we observed a delay in initial thrombus formation in TC21-deficient mice compared to WT controls; furthermore, thrombi in TC21-deficient mice were

unstable, leading to prolonged time to thrombotic occlusion. Tail clip bleeding times showed similar effects in these mice. Thus, TC21 plays an essential role in GPVI/FcR[gamma]-mediated platelet activation and is important for thrombus stability *in vivo* via control of Rap1b and integrins.

Defining Phosphatidylinositol Phosphate 5-Kinase Igamma Function in Cell Migration and Anoikis Evasion.

N. Thapa¹, R.A. Anderson¹;

¹Molecular Pharmacology, University of Wisconsin-Madison, Madison, WI

Type I phosphatidylinositol-4 phosphate 5-kinases (classified into PIPKIalpha, PIPKIbeta and PIPKIgamma) generate phosphatidylinositol 4,5-bisphosphate (PIP2), a lipid signaling molecule that regulate diverse cellular functions, including cell cycle progression, cell survival, endosomal trafficking and cell migration. PIPKIgamma is overexpressed in triple-negative breast cancer tissues and inversely correlates with breast cancer patient survival. In order to define the PIPKIgamma function in tumor progression, we interrogated the PIPKIgamma function in the context of epithelial cells transitioning into the mesenchymal cells, as EMT provides an important platform for understanding how normal cells acquire different traits crucial for tumor progression. Mammary epithelial cells transitioning into mesenchymal cells by TGFbeta1 treatment or by culturing in extracellular matrix proteins displayed significantly increased expression of PIPKIgamma and its focal adhesion targeting variant, PIPKIgamma2. In these cells and other breast cancer cells, PIPKIgamma/PIPKIgamma2 were required for activation of phosphoinositide signaling in response to activation of cells with growth factors and extracellular matrix proteins. During epithelial mesenchymal transition, PIPKIgamma2 lose its association with epithelial protein (E-cadherin) and gain increased association with different pro-migratory molecules, such as talin, moesin, N-cadherin, Src and IQGAP1. Consistently, the loss of PIPKIgamma2 and its associating partners dramatically impaired cell migration. Furthermore, PIPKIgamma2 and talin interaction and their collaborative function were required for providing the signaling inputs from the extracellular matrix proteins and growth factors to maintain the migratory and mesenchymal phenotypes of epithelial cells transformed into mesenchymal cells.

Anoikis evasion and the ability to grow in anchorage-independent condition define one of the key properties of metastasizing tumor cells. PIPKIgamma and PIPKIgamma2 shows increased expression in anoikis resistant cancer cells during suspension culture and is crucial for sustaining phosphoinositide signaling. The loss of PIPKIgamma and PIPKIgamma2 dramatically impaired the ability of different tumor cells to grow in anchorage-independent condition. These indicate the diverse pro-tumorigenic function of PIPKIgamma and PIPKIgamma2 in cancer.

P2234**Board Number: B862****Phorbol ester alters cell migration of lung adenocarcinoma on laminin-511.**K. Ikari¹, S. Fujii², F. Katagiri², K. Hozumi², M. Nomizu², Y. Kikkawa²;¹School of Pharmacy, Tokyo Univ Pharm/Life Sci, Tokyo, Japan, ²School of Pharmacy, Tokyo Univ Pharm/Life Sci, Hachioji, Japan

Progression of tumor cells results from a multi-step process of carcinogenesis that involves not only sequential genetic alterations but also frequent chemical exposures. Epithelial cells of several organs such as skin and lung are subject to frequent carcinogens and pathogens. Tumor-initiated cells seem to be also transitioned to malignant tumors by exposure to tumor-promoting agents. Although precancerous cells of epithelium stably anchor to basement membrane, malignant tumors pass through it to achieve metastasis. Of basement membrane components, laminin-511 ($\alpha 5$, $\beta 1$, $\gamma 1$; LM-511) has been found to be a major isoform in many adult basement membranes. Several studies have also shown that LM-511 promotes not only cell adhesion but also tumor cell migration. Thus, LM-511 can be viewed as a double-edged molecule in normal and tumor cells. This is because tumor cells that arise from chemical exposures could alter cell adhesion to LM-511. In this study we examined the effects of potent tumor-promoting agent on lung adenocarcinoma adhering to LM-511. 12-O-tetradecanoylphorbol-13-acetate (TPA) is a phorbol ester that links to the modulation of protein kinase C in epithelial cells. The cells readily attached to LM-511 and Fibronectin (Fn) and spread on the substrata. After adhering to the substrata, the cells were treated with TPA. TPA-treated cells exhibited cuboidal shape on LM-511. On the other hand, the morphology of the cells on FN was flatter or spindle. Flow cytometric analysis showed that the treatment of TPA on A549 cells did not influence the expression of laminin receptors such as integrins and lutheran. Cell attachment assay showed the attachment of TPA-treated A549 cells to LM-511 was weaker than that of control cells, suggesting that the treatment of TPA modulated the binding of laminin receptors. We also examined the cell migration of TPA-treated A549 cells on LM-511. Cell migration was monitored using time-lapse video microscopy. The treatment of TPA promoted cell migration on LM-511 but not FN. We conclude that tumor cell migration on LM-511 requires that the treatment of TPA modulates cell-attachment through the laminin receptors. We suggest that tumor promotion is involved in a transition from static to migratory cell behaviors.

P2235**Board Number: B863****An anti-human Lutheran phage antibody isolated from hepatocellular carcinoma phage library inhibits cell migration on laminin-511.**Y. Kikkawa¹, Y. Enomoto², K. Ikari³, F. Katagiri¹, K. Hozumi¹, M. Nomizu¹, Y. Ito²;¹School of Pharmacy, Tokyo Univ Pharm/Life Sci, Hachioji, Japan, ²Graduate School of Science and Engineering, Kagoshima University, Kagoshima, Japan, ³School of Pharmacy, Tokyo Univ Pharm/Life Sci, Tokyo, Japan

The Lutheran glycoprotein (Lu), also known as basal cell adhesion molecule (B-CAM) is an Ig superfamily (IgSF) transmembrane receptor for laminin $\alpha 5$, a subunit of laminin-511 that is a major component of basement membranes in various tissues. So far the molecule has been studied primarily in the contexts of blood group antigens and sickle cell disease. B-CAM, a splice variant of Lu, has the same N-terminal extracellular domain as Lu, but it lacks the C-terminal 40 amino acids of the cytoplasmic tail which carries an SH3 binding motif and potential phosphorylation sites that could be involved in intracellular signaling pathways. B-CAM was also identified as an up-regulated antigen in carcinoma, suggesting its involvement in tumor progression. Our previous study showed that although Lu/B-CAM is not present in normal hepatocytes, the expression of Lu/B-CAM is significantly increased in hepatocellular carcinoma cells (HCCs). In this study we isolated thirteen phage antibodies against human Lu/B-CAM from phage library of peripheral blood of HCC patients, suggesting that HCC patients produced autoantibody against endogenous Lu/B-CAM. The RNA of peripheral blood cells was provided from Dr. Hui Kam Man, Natl Cancer Center, Singapore. To characterize the phage antibodies, we determined the epitopes of phage antibodies on Lu. The extracellular domain of Lu contains five IgSF domains, D1-D2-D3-D4-D5. The epitope of A7 phage antibody was localized in D5 domain. The other phage antibodies recognized to D2 domain that is recognized with function blocking mouse monoclonal antibody. Not only C7 phage antibody recognizing to D2 domain inhibited the binding of Lu to ligand, it also prevented tumor migration on laminin-511 (LM-511). However the C7 scFv purified from the periplasm fraction of bacteria could not exhibit the inhibitory effects, indicating that scFv form was not enough to inhibit spatially the binding of Lu to LM-511. Furthermore we identified the amino acid residues to form the epitope recognized by C7 phage antibody. The chimeric mutant study using human and mouse Lu showed that it was formed with amino acid sequences from Ala²³⁸ through His²⁵⁷. The mutagenesis study showed that Arg²⁴⁷ is necessary for forming the epitope. C7 phage antibody and its epitope may be useful for developing drugs to prevent HCC progression.

P2236**Board Number: B864****Integrin-integrin Crosstalk Suppresses Fibroblasts Adhesion via PI3K signaling.**K. Hozumi¹, C. Fujimori², F. Katagiri¹, Y. Kikkawa¹, M. Nomizu¹;¹School of Pharmacy, Tokyo Univ Pharm/Life Sci, Hachioji, Japan, ²Tokyo Univ Pharmacy/Life Scis, Hachioji, Japan

Various cell surface receptors such as growth factor receptors, GPI anchored receptors, syndecans, and different subtypes of integrin are synergistically related to integrin mediating cell attachment. Several studies has been reported about the crosstalks between different subtypes of integrin and revealed that combination specific integrin-integrin crosstalk is critical on the various biological functions. Here, we focused on various crosstalks of two different subtypes of integrins using the unique integrin binding peptides conjugated polysaccharide (chitosan or alginate) matrix. Six different integrin binding peptides, FIB1 (integrin $\alpha v \beta 3$), EF1zz (integrin $\alpha 2 \beta 1$), 531 (integrin $\alpha 3 \beta 1$), CS1D (integrin $\alpha 4 \beta 1$), and A2G10 (integrin $\alpha 6 \beta 1$), were mixed and conjugated on the polysaccharide matrix with five different mixture ratios (9:1, 4:1, 1:1, 1:4, 1:9). Human dermal fibroblast (HDF) attachment activities to the 20 different peptide-chitosan matrices were different depending on the peptides and mixture ratios. Ten different pair of mixed peptides-chitosan matrices did not show any special variation by mixture of peptides, and the mixture of FIB1/A2G10, FIB1/CS1D, and EF1zz/CS1D relatively promoted HDF attachment by mixing of two peptides. Interestingly, although EF1zz:531=1:4 showed significant decreasing of cell attachment, but other mixture ratios between EF1zz and 531 did not indicated any differences on both chitosan and alginate matrices, respectively. When we focused on the signal transduction of the EF1zz/531 at 1:4 mixtures, Y397 phosphorylation of FAK was relatively decreased, however Y514 phosphorylation of Src was not. Next we observed the effect of various activator and inhibitor on HDF adhesion to the EF1zz/531-alginate matrices. Integrin activation by TPA or function antibody TS2/16 and PI3K inhibitor of Wortmannin rescue the suppression of HDF attachment at EF1zz:531=1:4, whereas PKC inhibitor of Go 6976 did not affect on that suppression. Further, PKA inhibitors accelerate the suppression of HDF attachment, these suggesting that this suppression was mediated by PI3K signaling through the activation of integrin. From these results, specific integrin-integrin crosstalk promotes or suppresses the cell attachment, and mixed peptide-polysaccharide matrix is useful tool to understand the integrin functions.

P2237**Board Number: B865****Hypoxia enhances differentiation into invasive extravillous trophoblast following BMP4 treatment of human embryonic stem cells.**A.K. Wakeland¹, M. Moretto Zita², F. Soncin², Y. Li², M. Horii², M. Parast²;¹Biomedical Sciences, University of California San Diego, San Diego, CA, ²Pathology, University of California San Diego, San Diego, CA

Trophectoderm lineage specification and the bulk of placental growth occur under low oxygen tension. Cytotrophoblast (CTB) are epithelial stem cells in the placenta, which differentiate further into two lineages: hCG-secreting villous syncytiotrophoblast (STB), or invasive extravillous trophoblast (EVT). Proper differentiation into these two lineages is important for appropriate placental function and fetal growth *in utero*. We have recently shown that human trophoblast lineage specification and terminal differentiation can be modeled *in vitro* using human embryonic stem cells (hESC). Following treatment with bone morphogenetic protein 4 (BMP4), hESC first differentiate into proliferative CTB, and subsequently into STB and EVT. Differentiation into EVT is characterized by changes in integrin expression as well as expression of matrix metalloproteinases (MMPs), confirming the importance of extracellular matrix (ECM) remodeling in this process. We tested the effects of different ECM and oxygen tension, first on differentiation of primary CTB isolated from first trimester placental tissues. We found that decreasing oxygen levels resulted in impaired differentiation into villous STB based on hCG secretion. Conversely, we found that low oxygen tension directed trophoblast differentiation into invasive EVT lineage, based on increased surface expression of HLAG and integrin alpha-1, as well as secretion of MMP2, which are specific to invasive EVT. EVT differentiation was most optimal when cells were plated on fibronectin, and least optimal on laminin. Similar results were obtained when hESC-derived CTB were induced to terminally differentiate, with cells optimally differentiating into EVT when plated on fibronectin and cultured under low oxygen (2%). In addition, hypoxia appeared to accelerate trophoblast lineage specification, with a 20% increase in percentage of EGFR+ CTB after only 2 days of BMP4 treatment under hypoxia. These results show the importance of both ECM and oxygen tension in EVT differentiation, but more importantly, confirm the utility of BMP4-treated hESCs as a model that correctly recapitulates primary EVT differentiation. This is particularly critical as hESC can thus provide a ready alternative to first trimester CTB for the study of EVT differentiation, a process that is highly important to pregnancy success. We are currently testing the role of an intact hypoxia-inducible factor (HIF) complex in both establishment and terminal differentiation of the trophoblast lineage, and hypothesize, based on mouse models of placentation, that it plays a pivotal role in this process, but particularly in differentiation of invasive EVT.

P2238**Board Number: B866****The integrin beta3 tail controls switching between Rac-driven collective migration and Rho-stimulated cell scattering.**A. Jimenez Orgaz*¹, E. Anthony*², H. Truong¹, I. van den Bout¹, I. Kuikman¹, P. Secades¹, A. Sonnenberg*¹, C. Margadant*²;¹Department of Cell Biology, Netherlands Cancer Institute, Amsterdam, Netherlands, ²Department of Molecular Cell Biology, Sanquin Research, Amsterdam, Netherlands

Expression of the fibronectin-binding integrin alpha5beta1 in epithelial cells induces cell scattering, RhoA activity, random single-cell migration, and a switch to a fibroblast-like phenotype. In contrast, the alternative fibronectin-binding integrin alphavbeta3 supports Rac activation, and stimulates collective, directional migration with intact cell-cell contacts. We tested the importance of cytoplasmic domains in the beta3-subunit on cell behaviour. Disruption of the talin-binding NPxY and/or the kindlin-binding NITY motif reduced initial cell adhesion and cell spreading, which was recapitulated by depletion of talin-1 or kindlin-2, respectively. Downstream of cell adhesion, deletion of the NITY motif or Y>A mutation induced an 'alpha5beta1'-like phenotype, consisting of cell scattering, Rho activity, and random, single-cell migration. These effects are independent of kindlin-2 or Src, but entirely dependent on Rac, and are recapitulated by either the expression of dominant-negative Rac mutants, or constitutively-active Rho. Similarly, the phenotype of cells that express beta3-NITY>A mutants is reversed by overexpression of constitutively-active Rac, or by the inhibition of Rho. Thus, the NITY motif of beta3 controls the balance between Rac-driven collective migration and Rho-stimulated cell scattering, in a kindlin- and Src-independent manner.

Bioengineering of Cell–Matrix Interactions**P2239****Board Number: B867****Minimal matrix model with scar-like fractal heterogeneity reveals a mechano-sensitive repressor in stem cell plasticity.**P.P. Dingal¹, A. Bradshaw¹, S. Cho¹, J. Swift², M. Raab³, A. Buxboim⁴, D.E. Discher^{1,5};¹Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA, ²University of Pennsylvania, Philadelphia, PA, ³UMR 144, Institut Curie, Paris, France, ⁴Hebrew University of Jerusalem, Jerusalem, Israel, ⁵Molecular and Cell Biophysics Lab, University of Pennsylvania, Philadelphia, PA

Scarring in higher animals has an adverse and sustained effect on tissue, but the diversity of cell types in a scar complicates understanding of the factors affecting cell phenotype. Here, co-polymerization of collagen-I with polyacrylamide was used to produce a minimal matrix model of a scar in which fractal fiber bundles segregated heterogeneously to the subsurface of an inert hydrogel. Matrix stiffens locally

– as in scars – while allowing separate control over adhesive ligand density. Mesenchymal stem cells (MSCs) that are now being used in various tissue repair contexts respond to the model matrices with phenotypes often seen in scars: they polarize (more so than on rigid plastic) and slowly increase expression of ‘scar marker’ smooth muscle actin (SMA). MSCs also traffic to injured sites *in vivo*, and here they polarize and ‘durotax’ towards scar-like regions of matrices where a subset of stiffness-sensitive proteins respond within hours. Over days, a repressor of SMA transcription, NKX2.5, translocates from nucleus to cytoplasm in response to matrix rigidity, suggesting a mechanism for SMA de-repression. Expression of nuclear-localized mutants of NKX2.5 indeed overrides matrix-rigidity sensing with inhibition of cell spreading and SMA. MSCs cultured for weeks or longer on rigid substrate reinforce a ‘mechanical memory’ by down-regulating NKX2.5, thereby stabilizing an SMA-high, scar-like phenotype.

Board Number: B868

The Interplay of Duro- and Hapto-taxis in Regulating Stem Cell State.

J.H. Wen¹, O. Choi², A.J. Engler¹;

¹Bioengineering, University of California, San Diego, La Jolla, CA, ²Biomedical Engineering, National Yang Ming University, Taipei, Taiwan

Anchorage dependent cells can sense and respond to extracellular matrix (ECM) properties, e.g. stiffness and ligand density, but gradients of these cues are often found *in vivo* via normal tissue variation or pathological conditions, such as the post-infarct myocardial scar which is several fold stiffer as well as compositionally different from healthy tissue. Scar tissue and fibrotic tissue are often characterized by the presence of excess matrix proteins such as collagen and fibronectin due to increased deposition and decreased degradation, forming gradients adjacent to healthy tissue. We have previously shown that cell migration can be regulated by substrate stiffness *in vitro*, but stiffness-directed migration, i.e. durotaxis, may be additionally accompanied *in vivo* by haptotaxis, i.e. migration up a ligand concentration gradient. To better understand how corresponding and opposing gradients regulate cell migratory behaviors, tunable gradients of stiffness and collagen concentration in a polyacrylamide hydrogel system were constructed using density gradient multilayer polymerization, a technique that utilizes phase separation between liquids of varying density to create layers of distinct composition. Stiffness gradients were obtained by varying the monomer to crosslinker ratio, or by applying a UV photomask in order to activate a photoinitiator gradient. Ligand gradients were obtained by varying the concentration of acrylic acid, thus sequentially varying the density of EDC/NHS linker, in each hydrogel layer; this creates a polyacrylamide substrate with a surface density gradient of covalently bound collagen. Stiffness and ligand gradients were overlaid to investigate the effect of corresponding and opposing haptotactic and durotactic gradients on fibroblast and mesenchymal stem cell (MSC) migratory behavior. Fibroblasts tended to haptotax towards regions of increased collagen concentration and durotax towards stiffer regions of the substrate. While MSCs also underwent durotaxis, surprisingly they

did not haptotax. These data suggest that fibroblasts residing in a tissue with such gradients may be more responsive than MSCs, which must home to the tissue from marrow to aide in its repair.

Malignant melanoma cells dynamically construct a tumor biofilm that promotes survival in response to drug treatment and hypoxia.

K. Tanner¹, A. Afasizheva¹;

¹NCI/NIH, Bethesda, MD

Cutaneous melanoma cells secrete and assemble a myriad of extracellular matrix (ECM) molecules into dense fibrillar and globular networks. This process is dynamic, mimicking biofilm formation by bacteria in response to nutrient deficiencies, antibiotic treatment and oxidative stress. We hypothesize that the melanoma 'tumor biofilm' is similarly adaptive and protective in response to external insults, including pharmaceutical intervention and hypoxic stress. Using quantitative proteomics, we identified the components and determined the temporal evolution of the tumor biofilm. Isogenic melanoma lines were cultured in 3D to recapitulate tumor morphology and interrogated for the establishment of a de novo tumor microenvironment as a function of dimension, oxygen tension and drug treatment. We recreated an established tumor and drug regimen using a modified 3D soft agarose assay to evaluate anchorage independent proliferation. Modulation of the observed tumor biofilm in culture was monitored using confocal microscopy, protein expression analysis and immunofluorescence, and its physiological impact on primary tumor establishment was examined in a mouse subcutaneous injection model. Fibronectin was found to be one of the key architectural components, regulating drug efficacy for a broad spectrum of drug therapies. Stable cell lines engineered to secrete minimal levels of fibronectin became sensitive to cisplatin, BRAF, and ERK inhibition as clonally derived 3D tumor aggregates, emphasizing the importance of 3D architecture in tumor proliferation. Reduced levels of tumor-generated fibronectin also impeded successful tumor formation in mice. We reason that this architectural complexity provides the degree of plasticity and flexibility that allows for better colonial adaptability and survival in response to external perturbations, such as hypoxic stress and drug treatments

P2242**Board Number: B870****Cell-bioactive glass scaffold interactions: The role of substrate nano-structure.**T.J. Kowal¹, T. Chokshi¹, H. Jain², M.M. Falk¹;¹Biological Sciences, Lehigh University, Bethlehem, PA, ²Material Science and Engineering, Lehigh University, Bethlehem, PA

It is not well understood how cells of the human body can interact with biologically active scaffolds used to guide tissue regeneration, especially on the nano-scale level. In order to design the ideal material for the regeneration of different tissues, we must first acquire a comprehensive understanding of the fundamental mechanisms that allow cells to not only attach to these bioscaffold materials, but to also take cues from them as to what tissue should be regenerated.

Here we present evidence of the ability of MC3T3-E1 pre-osteoblasts to detect differences in nano-structure on two different substrates. The first substrate, a bioactive glass with a simple composition of 30 mol%CaO – 70 mol%SiO₂ contains both nano- and macro-pores. The only variable between samples of this type of substrate is the nano-pore size (3.7 nm vs. 17.7 nm), which is measured using BET (nitrogen adsorption analysis), while total surface area is kept constant. The second substrate, a bioactive glass with a more complex composition of 24.4 mol%Na₂O–26.9 mol%CaO–2.6 mol%P₂O₅–46.1 mol%SiO₂ called 45S5 Bioglass[®] (Hench et al., 2006; J Mater Sci: Mater Med), varies in the nano-structure due to phase separation, resulting in either a spinodal interconnected morphology or a droplet nucleation morphology as determined by SEM analysis (Golovchak et al., 2014; Acta Biomaterialia). Cellular response to either substrate was measured through quantification of initial adhesion to the surfaces using immunofluorescence analyses. On the glass samples varying in nano-pore size, we observed that cells preferred the smaller nano-pores (Wang et al., 2013; Tissue Engineering, PartA). Additionally, a clear preference was observed using the glass that differed in nano-structure in that more adherence was observed on the spinodal interconnected morphology than the droplet nucleation morphology. In the case of both substrates, cells showed a significant preference to one of the nano-structures, indicating that remarkably cells are able to sense morphological details of the substrates that are app. 1000 times smaller than the cells themselves. Research performed in our laboratories aims to uncover the underlying principles that allow cells to respond to such nano-scaled substrate details, allowing to engineer superior tissue regenerative materials.

P2243**Board Number: B871****Cellular response to substrate curvature is cell-type dependent.**A. Yip¹, K. Chiam^{1,2};¹Bioinformatics Institute, A*STAR, Singapore, Singapore, ²Mechanobiology Institute, National University of Singapore, Singapore, Singapore

Experiments have shown that cells experience and respond to a variety of mechanical forces in physiological conditions, such as those caused by neighbouring cells as well as those due to geometrical constraints of the extracellular matrix. For example, it has been shown that cells can sense and respond to the rigidity of the extracellular matrix, topographical features of the extracellular matrix, and imposed shear stresses. However, little is known about the effects of substrate curvature on cell behavior. In this study, we fabricated substrates of a range of rigidities with cylindrical grooves of varying radii of curvature. We then characterized the morphology of both mesenchymal NIH 3T3 fibroblasts and A549 human lung adenocarcinoma epithelial cells on these substrates. The radius of curvature of the cylindrical grooves were varied from dimensions comparable to a single cell diameter (20 μm) to dimensions of approximately ten cell diameters wide (250 μm). We found that as the radius of curvature decreased, mesenchymal cells became increasingly elongated with a larger proportion of the cells orienting along the long axis of the cylindrical grooves. In contrast, epithelial cells do not show any variation in cell elongation or orientation when the radius of curvature is changed. We then investigated the role of cadherins in the epithelial monolayers in contributing to this effect by the addition of EDTA. Finally, we developed a quantitative model to explain these results. In summary, our results suggested that mesenchymal and epithelial cells respond differently to substrate curvature, and could provide new insights into the process of epithelial to mesenchymal transition.

P2244**Board Number: B872****Low adhesive scaffold collagen, inducing spheroid formation, promotes the osteogenic differentiation.**S. Kunii¹, E. Yamamoto¹, Y. Horiuchi², H. Ito¹, K. Morimoto¹;¹Biology-Oriented Science and Technology, Kindai University, Kinokawa, Japan, ²Kindai University Faculty of Medicine, Kindai University, Osakasayama, Japan

[Background] Collagen has biocompatibility and biodegradability with tissue or organs, therefore, collagen is the most promising material for tissue engineering. In particular, the binding of collagen to specific cells is considered an essential function to develop scaffolds. However, in some cases the binding inhibits the cell motility. We succeeded in developing low adhesive scaffold type I collagen (LASCOL) by enzyme treatment (patent pending). In this study, we report that LASCOL markedly facilitates osteogenic differentiation of rat marrow mesenchymal stem cells (rMSCs). Furthermore, we investigated the effects of bone wound healing by implanting LASCOL in a defect of rat tibia. [Methods] We obtained

LASCol by the enzyme treatment of pig type I collagen. The culture dish was coated with LASCol or pepsin-treated collagen (PepCol). Subsequently, rMSCs were cultured on each coated-dish with osteogenic basal medium. We observed the morphology of rMSCs by using a phase-contrast microscope. To evaluate osteogenic differentiation, we quantified the mineralization by SEM-EDX. Furthermore, we transplanted each collagen material into the defect of rat tibiae (ϕ 2.5 mm critical-sized defect). After 15 days, bone regeneration efficiency of each implant treatment was evaluated by histological observation of tibia horizontal section with HE stain. Osteocalcin in each serum was measured by ELISA kit. [Results] Rat MSCs formed spheroid bodies by culturing on the LASCol coated dish. We observed that spheroids adhered to LASCol scaffold. Each cell of spheroid highly expressed alkaline phosphatase activity. The mineralization of rMSCs was significantly promoted by culturing on LASCol. Only spheroid cultured on LASCol showed the activity of mineralization by staining with Alizarin red S reagent. Similarly, the P and Ca contents markedly increased. Interestingly, the results *in vivo* demonstrated that LASCol graft induces bone regeneration of rat tibia and is more bioabsorbable material than PepCol. Osteocalcin in serum of LASCol implant rats (194 ng/mL) was two-fold higher than that of PepCol (105 ng/mL). [Funding] This work was supported by Adaptable and Seamless Technology Transfer Program through target-driven R&D, Japan Science and Technology Agency (AS2414037P to K.M.).

Quantitative Investigation of Differences in Differentiation of Reactive and Non-reactive Astrocytes in Response to Nanophysical Cues.

V. Tiryaki¹, V.M. Ayres¹, I. Ahmed², D.I. Shreiber²;

¹Michigan State University, East Lansing, MI, ²Rutgers, The State University of New Jersey, Piscataway, NJ

Recent studies of cell responses to elasticity, surface roughness, surface polarity and nano-patterning suggest that controlling aspects of the nanophysical environment holds potential for inducing preferential differentiation of reactive astrocytes into non-inhibitory pathways. In the present studies [1,2], these cues were presented by an implantable electrospun polyamide nanofibrillar scaffold that has demonstrated promising wound healing properties including *in vivo* mitigation of astrocytic scarring. Only external cues were used to trigger cell responses. Four physical properties of the nanofibrillar polyamide versus poly-L-lysine (PLL) glass, PLL Aclar and Aclar culture surfaces were considered potentially directive: nanoscopic elasticity, work of adhesion, surface roughness, and macroscopic surface polarity. These were quantified using AFM and contact angle measurements. Differentiation of untreated versus reactive-like (dBcAMP-treated) astrocytes was investigated using AFM, super-resolution microscopy and confocal laser scanning microscopy z-series, with 50-cell minimum protein quantification for major neuro-reactivity markers: glial fibrillary acidic protein (GFAP), Beta tubulin and neuro-inhibitory chondroitin sulfate proteoglycans (CSPGs) and also Rho GTPase cytoskeletal upstream regulators Cdc42 (filopodia), Rac1 (lamellipodia), and RhoA (stress fiber/stellation).

The physical property differences of the culture environments triggered statistically significant (ANOVA with pairwise comparisons by Tukey's test, P

Label-free quantitative analysis of cancer cell dynamics in topologically and mechanically defined 3D matrices.

J. Sapudom¹, S. Rubner¹, S. Martin¹, T. Pompe¹;

¹Biophysical Chemistry, Universität Leipzig, Institute of Biochemistry, Leipzig, Germany

Interactions between cells and their extracellular microenvironment influence multiple aspects of cellular functions and fate decision in physiological and pathological processes. Cancer cells have a highly distinctive ability to adapt and communicate to their microenvironments. The properties of extracellular microenvironments, namely topology, mechanics as well as composition, regulate the development and progression of cancer. Moreover, migration and invasion of cancer cells through extracellular microenvironments are crucial steps for metastasis. A deep understanding on underlying mechanisms is still hampered by the complexity of the mechanical regulation of cell behavior as well as the heterogeneity of relevant cell populations. Understanding how extracellular matrix properties, regulate cell behavior at single cell level would provide potential strategies in approaches to fight cancer.

In this work, we reveal cellular characteristics of melanoma cells, including migration pattern, proliferation and differentiation features, under exogenous influence of ECM topology and mechanics. In order to mimic three-dimensional (3D) *in vivo* like microenvironments, we reconstruct 3D collagen matrices with well-defined pore size, fibril diameter and stiffness. The topological and mechanical parameters are varied by adjusting polymerization conditions and were quantified by image analysis tools and force spectroscopy, respectively. The impact of biophysical parameters of 3D matrices on single cell behavior was analyzed using automated quantitative label-free 3D single cell tracking. First cell experiments reveal distinct migration characteristics of different melanoma cell types in correlation with 3D matrix properties. The matrix-specific migration characteristics of melanoma cells allowed a mechanistic understanding of invasive migratory behavior and prediction of cell fate. Furthermore, we observed that fibril orientation of collagen matrices contribute in guiding migration of melanoma cells in a size-dependent manner.

Summarizing, our work emphasizes the complex relationship between structural-mechanical properties of the extracellular matrix and invasive migratory behavior of cancer cells and provides new approaches for studying heterogeneous populations of primary cells in a biomimetic 3D microenvironment.

P2247**Board Number: B875****Oral administration of Nano-sized avian eggshell membrane is digested, absorbed, distributed to various organs, and contribute to support good health.**E. Ohto-Fujita¹, M. Shimizu¹, N. Nogawa², H. Eguchi², K. Ijiri², Y. Hasebe³, Y. Atomi¹;¹Div. of Material Health Sci., Dept. of Technol., Tokyo University of Agriculture and Technology, Tokyo, Japan, ²Radioisotope Center, The University of Tokyo, Tokyo, Japan, ³Almado Inc., Tokyo, Japan

Eggshell membrane (ESM) is a double-layered insoluble sheet locates between eggshell and egg white and works as a scaffold for biomineralization to fabricate egg shell (Rose and Hincke, 2009). ESM mainly consists of various extracellular matrix (ECM) materials necessary for maintaining homeostasis against stimuli from environment during embryogenesis and development until chick birth. The membrane is formed in the isthmus of the hen's oviduct before shell mineralization and egg laying. Recently ESM containing cosmetics and supplements are on the market worldwide based on the evidence from traditional folk medicine in Asian countries. Until last year we have reported that topical application of alkaline-solubilized avian eggshell membrane (ASESM) improved gene expression pattern to younger skin after 10 days, like increases of gene trio like type III collagen, decorin, and MMP2 on the skin of hairless mice, and increased elasticity of human skin after 3 months. In the present study digestion, absorption and disposition after single oral administration of tritium-labeled ESM were examined using C57BL/6J mice was examined. Tritium derived from peroral labeled ESM showed peak in blood after 6 hour and later disposed into various tissues including liver. Similar to topical effect to improve dermis ECM condition non-labeled nano-powdered ESM peroral administration showed to improve liver ECM environment, such as significant decreased gene expression of type I and III collagen, which increases with liver fibrosis, compared with control. Chicken ESM may work as materials digested during embryogenesis to contribute the development as well as filter, shelter and as a scaffold for biomineralization. ESM has an ability to keep ECM environment of various differentiated tissue to be young through unsolved mechanism.

P2248**Board Number: B876****Avian eggshell membrane as an effective ingredient for health supplement preventing liver fibrosis by suppressed collagen gene expression.**M. Shimizu¹, E. Ito¹, A. Atomi¹, E. Ohto-Fujita¹, Y. Hasebe², Y. Atomi¹;¹Div. of Material Health Sci., Dept. of Technol., Tokyo University of Agriculture and Technology, Tokyo, Japan, ²Almado Inc., Tokyo, Japan

Avian eggshell membrane (ESM) has long been utilized as a Chinese medicine for recoveries from burns, injuries, and wound. Even nowadays, Japanese Sumo wrestlers use it for wound healing. Extra-fine powdered ESM is on market and used as a supplement that improve various health problems. ESM has a

fibrous network mainly comprised of extracellular matrix (ECM) proteins such as type I, V, and X collagens. We have found that water-soluble alkaline-digested form of ESM can stimulate type III collagen, decorin, and MMP2 expression in human dermal fibroblast cells (Ohto-Fujita et al, 2011). As a part of understanding the whole-body health benefit of ESM, here we report the molecular basis of ESM supplement on liver. Either 6 weeks old male Hairless mouse (Hos HR-1) or Wister rat were used after one-week acclimation. Mice were fed ad libitum and additionally let them take either low or high-dose nano-sized powdered ESM supplement daily for 7 days. Rats were fed ad libitum and ESM was administered by gastrointestinal intubation for 14 days. Total RNA from liver was prepared and quantitative real time PCR analysis was performed. Results showed that down-regulated collagen expression (both type I and III collagen for mouse significantly and type I collagen for rat) and up-regulated HSP70 (mouse at high dose). These results were comparable to the report on gene expression in rat liver (Jia, et al., 2013). Since 45% of deaths in the United States can be attributed to fibrotic disorders (Nature Rev Immunol, 2004), suppressed expression of type I collagen is useful evidence for health. Previous and current data shows ESM is an ECM conditioner and mediate tissue rejuvenation with unsolved mechanism.

Anisotropic effects of three-dimensional confined geometries on cell growth and cell-derived extracellular matrix.

J.V. Serbo¹, S.C. Kuo², S. Lewis³, M. Lehmann⁴, D.H. Gracias⁵, L.H. Romer⁶;

¹Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, MD, ²Biomedical Engineering, Cell Biology, Johns Hopkins Univ Sch Med, Baltimore, MD, ³Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, ⁴Chemical and Biomolecular Engineering, Johns Hopkins University School of Medicine, Baltimore, MD, ⁵Chemical and Biomolecular Engineering, Chemistry, Johns Hopkins University, Baltimore, MD, ⁶Biomedical Engineering, Anesthesiology and Critical Care Medicine, Cell Biology, Pediatrics, the Center for Cell Dynamic, Johns Hopkins Univ Sch Med, Baltimore, MD

Extracellular matrix is a complex, 3D mesh of proteins, proteoglycans, and bound growth factors that provides mechanical and biochemical environmental cues for cellular growth. Previous work in our lab showed that matrix produced and assembled by human fetal lung fibroblasts (WI38) provided a morphogenic stimulus to endothelial cells, inducing both matrix remodeling and tubulogenesis. Microvascular development in a natural complex scaffold material is an attractive platform for regenerative therapies.

The current study tests the hypothesis that confined 3D geometries induce early anisotropy in WI38 growth, actin organization, and matrix deposition. Using microfabrication and photolithography, we created arrays of PDMS wells that included three rectangular shapes with increasing aspect ratios (1:2, 1:4, and 1:8), and corresponding paired squares with the same depth, total surface area, and total volume. Microcontact printing of bovine serum albumin (BSA) was used to block fibroblast adhesion to

the top surface of the PDMS block. The orientation of W138 stress fibers and fibronectin fibrils were examined 1 and 2 days after seeding using laser scanning microscopy and a custom routine that was developed for quantitative autocorrelation analysis (MATLAB (MathWorks)). Anisotropic actin filament organization and fibronectin fibril deposition were observed in the rectangular shapes. In these shapes, cells showed increasing alignment with the long axis as the aspect ratio of the rectangles increased. Actin filaments of cells cultivated in rectangular wells with aspect ratios of 1:4 and 1:8 exhibited anisotropy scores that were significantly higher than those grown in the corresponding squares or in lower aspect ratio rectangular wells. Similar trends were seen with fibronectin. These data suggest that shape-specific effects of 3D confinement on fibroblasts influence actin stress fiber alignment and matrix deposition.

Latrunculin A (0.05uM) decreased cytoskeletal and matrix anisotropy at all but the highest (1:8) aspect ratio. Cells treated with nocodazole (0.02uM) did not exhibit alignment of the microfilament or microtubule cytoskeletons or of cell-assembled matrix with anisotropic spatial confinement. In contrast, treatment with Y27632 (4uM) did not inhibit the development of cytoskeletal or matrix anisotropy. These data implicate both actin and microtubule polymerization, but not ROCK-dependent acto-myosin interactions, in anisotropic responses of cellular growth and matrix assembly to spatial confinement. Next phases of this project include definition of the effects of 3D, confined geometries on blood vessel growth and orientation in natural matrix.

Defective development of Natural Killer cells during aging.

S. Nair¹, M. Fang², L.J. Sigal¹;

¹Immune Cell Development and Host Defense Program, Fox Chase Cancer Center, Philadelphia, PA, ²CAS Key laboratory of Pathogenic Microbiology and Immunology, Chinese Academy of Sciences, Beijing, China

Natural Killer (NK) cells are important in combating both infections and cancer. Using Ectromelia virus (ECTV), the agent of mousepox, as a model of viral infection, our group has shown that mice increasingly succumb to infection as they age since they lack fully mature NK cells that are vital for protection. We have previously shown that under homeostatic conditions, aged B6 mice have a deficit in the maturation of NK cells in the blood, spleen, lymph nodes and bone marrow and that this results in impaired migration of NK cells to the draining lymph node and susceptibility to mousepox. Using an adoptive transfer model, we demonstrate that the age of the host and not the donor bone marrow cells affects the recovery of mature NK cells in the bone marrow suggesting that the radio resistant mesenchymal/stromal cells in aged cannot support the full maturation of NK cells whereas the hematopoietic precursor cells of aged are capable of generating mature NK cells. Aged mice also display

reduced proliferation of NK cells, multiple signs of immaturity and altered expression of activating and inhibitory receptors on NK cells. Gene array and q-PCR analysis of bone marrow stromal cells reveal that the message for Type I collagens, Col1a1 and Col1a2 is dramatically reduced in the stromal subset of bone marrow of aged mice. At the protein level, we found that receptors for Type I collagen, CD49b integrin which is a late stage marker of NK cell differentiation, is also significantly down-regulated on total NK cells and mature NK cell subsets in the bone marrow of aged mice when compared with young mice. Moreover, we show that treatment with complexes of the cytokine IL-15 and IL-15R α induced massive expansion of immature but not of mature NK cells in aged mice. As a result, IL-15/IL-15 α treatment did not restore resistance to mousepox in aged mice. Because many infectious diseases in humans spread systemically via lymph nodes and NK cell-deficient patients have significantly increased incidence of viral infections, it is possible that a defective NK cell maturation and migration also contributes to the increased susceptibility of older people to at least some viruses. Our mouse model provides a unique avenue to investigate NK cell dysfunctions with strong potential to advance our knowledge on causes of increased susceptibility to viral disease that we believe should be translatable to humans.

Functional and Phenotypic Alterations in NK Cells in Amnesic Mild Cognitive Impairment (aMCI) and Mild Alzheimer Patients.

A. Le Page¹, K. Bourgade-Navarro¹, J. Lamoureux², G. Dupuis¹, T. Fulop³;

¹Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, QC, ²Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, QC, ³Faculty of Medicine and Health Sciences, IUGS, Argyll Pavilion, Sherbrooke, QC

Alzheimer's disease (AD) is a progressive irreversible neurological brain disorder characterized by accumulation of β -amyloidogenic peptides, amyloid plaques and neurofibrillar tangles. Inflammation and immune alterations have been linked to AD, suggesting that the peripheral immune system plays a role during the asymptomatic period of AD. NK cells are part of innate immunosurveillance against intracellular pathogens and malignancy, their role in AD remains controversial. We have investigated changes in NK cell phenotypes and functions in amnesic mild cognitive impairment (aMCI) (n = 10) and mild Alzheimer (mAD) patients (n = 11) and, healthy elderly controls (n = 10). Patients selected according to NINCDS-ADRDA criteria were classified using neuropsychological assessment tests. Phenotype analysis revealed differences in expression of CD16 (increased in mAD), NKG2A (decreased in aMCI), TLR2 and TLR9 (both decreased in mAD). Percentage of IL-18 receptor β was lower in aMCI without differences in IL-12 receptors β 1- and β 2 for the three groups. Functional assays revealed that NK cell killing activity and degranulation (CD107 expression) were unchanged in the three groups. In contrast, expression of CD95 receptor was increased in aMCI and mAD. Granzyme B expression and cytokine production (TNF α , IFN γ) were increased in aMCI not in mAD. CCL19- but not CCL21-dependent chemotaxis was decreased in aMCI and mAD, despite the fact that CCR7 expression was increased in

aMCI. Our data suggest that a limited number of alterations that are predominantly observed in peripheral NK cells of mAD patients may affect more severely their capacity to respond to pathological aggression than aMCI subjects in progressive development of AD.

NK-mediated immune surveillance of senescent cells.

A. Sagiv¹, D. Burton¹, Z. Moshayev¹, V. Krizhanovsky¹;

¹Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel

NK-cell-mediated immune surveillance of senescent cells is one component of the coordinated process whereby cellular senescence limits the extent of liver fibrosis and facilitates wound repair. Recent studies also suggest that senescent cell recognition and clearance by immune cells promotes tumor regression in established tumors. Our results demonstrate that senescent cells are preferentially recognized and killed by NK cells. We show that DNA damage-induced senescent fibroblasts specifically upregulate the NKG2D immune ligands MICA, ULBP1, ULBP2 and ULBP5. Furthermore, we demonstrate that this immune ligand upregulation is mediated by ERK signaling and Rb, independent of p53 and NFκB. Importantly, the upregulation of MICA and ULBP2 on the cell surface of senescent cells is pivotal for the NK-mediated recognition, since interference with the receptor-ligands interactions inhibits the NK-mediated clearance both *in vitro* and *in vivo* to limit liver fibrosis and facilitate tissue repair. Lastly, we demonstrate that the granule exocytosis pathway, but not the death receptor pathway, is necessary for the specific killing of senescent fibroblasts and stellate cells by NK cells and participates in the clearance of senescent activated HSCs to limit liver fibrosis. We suggest that this pathway bias is mediated by the upregulation of Dcr2, a decoy receptor for the death ligand TRAIL, by senescent cells. Therefore, NK-cell-mediated recognition of senescent cells via NKG2D ligands and killing through NKG2D signaling and the granule exocytosis pathway contributes to immune surveillance of senescent cells *in vitro* and *in vivo*.

Comparing Nutrient Restrictions and its Gender Specific Effects on Metabolic Output in *Drosophila melanogaster*.

R. Vaders¹, A.A. Nagengast²;

¹Chemistry, Widener University, Chester, PA, ²Biochemistry, Widener University, Chester, PA

Aging is a complex process that has a variety of underlying causes. Reactive oxygen species (ROS) cause oxidative damage to proteins, lipids and carbohydrates, and contribute to aging. Although calorie restriction has been linked to an increased lifespan, previous results showed that *Drosophila melanogaster* raised on a high nutrient diet lived longer than those on a nutrient restricted diet. As

expected, adult males raised on the high nutrient food had higher triglyceride levels but females raised on the high nutrient food had lower triglyceride levels compared to those raised on the nutrient restricted diet. ROS levels were detected by measuring SOD (superoxide dismutase) expression and were found not to vary between the two nutrient conditions in males. However in females, no expression of cytosolic SOD (SOD1) was detected but mitochondrial SOD (SOD2) expression was robust. Both SOD1 and SOD2 enzyme activity require divalent cations and the nutrient restricted food contains higher levels of iron. Studying iron and its direct or indirect effect on other major and trace minerals as the cause of these unfamiliar results opens windows of opportunity to fully understand iron-response elements (IREs) along the 5' UTR. These minerals, which contribute to everyday movement, could be the answer to metabolic mutations that occur under specific nutrient conditions, and contribute to slow aging.

D-galactose decreases mitoNEET (CISD1) levels in HepG2 cells.

S. Paudel¹, L.E. Welker², B.P. Nathan², M.E. Konkle³, M.A. Menze⁴;

¹Biology, Eastern Illinois University, Charleston, IL, ²Eastern Illinois University, Charleston, IL, ³Chemistry, Eastern Illinois University, Charleston, IL, ⁴Biological Sciences, Eastern Illinois University, Charleston, IL

The monosaccharide D-galactose has been used as a tool to study accelerated aging, oxidative stress, and tissue damage in animal models. Supraphysiological levels of D-galactose accelerate aging in rodents by decreasing motor activity and superoxide dismutase activity, and by increasing production of reactive oxygen species (ROS). However, the underlying mechanism of galactose action is still poorly resolved. MitoNEET was discovered as target protein of the drug pioglitazone, a compound widely used to increase peripheral insulin sensitivity. MitoNEET is a small iron-sulfur cluster [2Fe-2S] containing protein localized to mitochondrial membranes. MitoNEET deficiency decreases iron content in the mitochondrial matrix and increases production of ROS in both animal and plant cells. Pioglitazone ameliorates galactose mediated memory deficit in a mouse model of aging. To investigate the role of mitoNEET in galactose-induced aging-related changes, we exposed human hepatocellular carcinoma cells (HepG2) to 10 mM D-galactose and measured endogenous mitoNEET levels by immunoblotting. Galactose treatment for 2 weeks significantly reduced mitoNEET levels in HepG2 cells. This effect was observed both in presence or absence of glucose in the culture medium. D-galactose also decreased levels of mitoNEET-GFP (green fluorescent protein) under the CMV promoter in stably transfected HepG2 cells. Since transcription of the endogenous mitoNEET and mitoNEET--GFP is regulated by different promoters, D-galactose likely increases degradation of mitoNEET. Furthermore, addition of 15 μ M pioglitazone in presence of galactose significantly increased the levels of mitoNEET while concentrations above 30 μ M, significantly reduced mitoNEET levels as compared to galactose treatment alone. This is the first report that links mitoNEET levels to the D-galactose induced model of accelerated aging processes. [This work was funded by an Eastern Illinois University Council on Faculty Research (CFR) grant to M.A.M and a Research and Creativity Award to S.P.]

P2255**Board Number: B884****Mitochondria fusion and fission mutants and their roles in cellular degeneration.**V.M. Khare¹, P. Tran^{1,2};¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA, ²CNRS UMR144, Institut Curie, Paris, France

Mitochondria are highly dynamic organelles that undergo fission and fusion. Defects in their dynamics have been linked to diverse diseases. However, at the single-cell level, it is less clear how defects in fission and fusion modify cellular physiology and influence cell health. To gain new insights into the connection between mitochondria dynamics and cell health, we examined four *S. pombe* genes which are conserved and regulate mitochondria dynamics: *dnm1+* and *fis1+* (fission), and *msp1+* and *ugo1+* (fusion). Wild type fission yeast cells have long mitochondria that align with the cell long-axis. Deletion of either *dnm1* (*dnm1Δ*) or *fis1* (*fis1Δ*) resulted in hyper-fused mitochondria. Conversely, deletion of *msp1* (*msp1Δ*) or *ugo1* (*ugo1Δ*) resulted in fragmented mitochondria. All individual mutants showed reduced cell doubling time compared to wild type, especially *msp1Δ* which had a cell cycle time 3-fold longer than wild type. Interestingly, in a population under good nutrient condition, these mutants exhibited very low cell death not different than wild type. We propose that, at least in one cell cycle, the mitochondria fragmented mutant *msp1Δ* extends the chronological lifespan of the cell. We are currently testing this hypothesis by examining cellular processes such as cell polarity and growth, and cell division.

P2256**Board Number: B885****Involvement of hexosamine biosynthetic metabolites in endoplasmic reticulum stress and aging.**P. Kim¹, A. Estrada², M. Hudson², J. Kirkwood³, J. Prenni³, D. Wang², Y. Wei², M. Pagliassotti²;¹Biological Sciences, Grambling State University, Grambling, LA, ²Food Science and Human Nutrition, Colorado State University, Fort Collins, CO, ³Proteomics and Metabolomics Facility, Colorado State University, Fort Collins, CO

Endoplasmic reticulum (ER) stress and the collapse of proteostasis are recognized as important events in both disease and aging. Glycosylation is one mechanism used by the ER to promote proteostasis. The hexosamine biosynthetic pathway (HBP) provides substrate, in the form of UDP-N-acetylglucosamine, for both N- and O-linked glycosylation. Recent evidence has demonstrated that enhanced HBP activity not only confers resistance to tunicamycin (a drug that inhibits protein glycosylation), but can also promote longevity in *C. elegans*. The aim of this study was to examine the HBP in the aging liver of mice and tunicamycin-induced ER stress in liver cells. Here, we report that HBP end products UDP-N-acetylhexosamines were reduced in the liver of old (27-29 mo) compared to young (4-6 mo) mice. The liver of old mice was characterized by ER stress, activation of the inflammasome, and injury. We also

report that glucosamine, an intermediate metabolite in the HBP, reduced ER stress induced by tunicamycin in H4IIE rat hepatoma cells. Using real time RT-PCR, we found that treatment with 5 µg/ml tunicamycin for 16 hours upregulated splicing of XBP1 and expression of CHOP and GADD34, whereas providing 5 mM glucosamine during the final 10 hours of tunicamycin insult significantly decreased these ER stress markers. These preliminary data suggest that the ability to maintain HBP end products is impaired in aging and that the HBP may be linked to aging-induced ER stress in the liver.

The role of Hsf1 in the maintenance of the endoplasmic reticulum homeostasis during chronological aging in *S. cerevisiae*.

E. Fazio¹, M. Duennwald², P. Lajoie¹;

¹Anatomy and Cell Biology, University of Western Ontario, London, ON, ²Pathology, University of Western Ontario, London, ON

Cellular aging is a ubiquitous process whose molecular mechanisms remain largely unclear. A deeper understanding of cellular aging is important not only in the context of general lifespan, but also to understand the mechanisms behind the toxicity of aging-related diseases, like Alzheimer's and Huntington's disease. The Heat Shock Response (HSR) is a conserved cellular response to various stresses, including exposure to elevated temperatures and the presence of misfolded proteins in the cytosol. In both yeast and humans, the HSR is primarily regulated by the highly conserved heat shock transcription factor, Hsf1. Several genetic studies indicate that the HSR plays a major role in healthy cellular aging, and age-dependent impairment of the heat shock response is well documented in different organisms, including yeast, worms, and flies. Accumulation of misfolded proteins is associated with aging in various model organisms, and to resolve misfolded secretory protein burden, cells have evolved the Unfolded Protein Response (UPR) to help re-establish protein folding homeostasis in the endoplasmic reticulum. The goal of our study is to characterize the interplay between the HSR and UPR during chronological aging in yeast. Chronological aging in yeast is achieved through maintenance of cells in the stationary growth phase, where nutrients have been depleted and cells remain in a quiescent state. We found that chronologically aged yeast cells display increased UPR activation when compared to young cells, suggesting that changes in the ER misfolded protein burden occur during chronological aging. Furthermore, cells with no functional UPR (*ire1Δ*), or that are unable to upregulate the ER chaperone Kar2 (UPREd), have shorter chronological lifespan (the amount of time that stationary phase yeast cells remain viable) than their wild-type counterparts demonstrating that up-regulation of the UPR is essential for healthy chronological aging. Our work also illustrates that constitutive activity of the HSR through overexpression of HSF1 alleviates ER stress and promotes growth in *ire1Δ* cells, and that cells expressing a mutated Hsf1 exhibit decreased chronological lifespan. Ongoing studies aim to determine whether Hsf1 expression in *ire1Δ* and UPREd cells rescues their stunted aging phenotype, and to elucidate the underlying mechanisms. Taken together, our data reveal a role for the HSR in alleviating secretory protein stress and extending chronological lifespan.

P2258**Board Number: B887****Functional Analysis of Vacuolar Membrane Protein Ssg1 Which May Be Involved in the Regulation of Lifespan in *Saccharomyces cerevisiae*.**T. Koyama¹, R. Tsubakiyama¹, K. Kume¹, M. Mizunuma¹;¹Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashi-Hiroshima, Japan

Aging is an unavoidable phenomenon and common to all living organisms. However, the molecular mechanism associated with aging and longevity is little understood. We previously found that a mutation of *SAH1* gene, which encodes S-adenosylhomocysteine (SAH) hydrolase, affected cell growth and chronological lifespan. In fact, the *sah1-1* mutant has a growth defect and a short lifespan. Moreover, we have isolated the long-lived mutant by screening for the suppression of the growth defect of the *sah1-1* mutant. This dominant-mutation was named *SSG1* (Spontaneous Suppressor of Growth-delay of the *sah1-1*). Interestingly, the *SSG1* single mutant was also shown to have a longer lifespan than a wild-type yeast. Therefore, the Ssg1 protein is predicted to be a key factor in longevity. To investigate the function of the Ssg1 protein, we constructed EGFP-Ssg1 and observed its localization by using a fluorescence microscope. We found that the Ssg1 protein was strongly localized in the vacuolar membrane during exponential growth phase and disappeared in stationary phase. Next, to examine whether it was functionally significant for the Ssg1 protein to localize in the vacuolar membrane, we constructed a double mutant between *SSG1* and *vps33* which has a defect in vacuole formation. It was revealed that the Ssg1 protein was spread entire in the cell and the longevity effect of the *SSG1* mutation was canceled by the deletion of *VPS33*, even though the Ssg1 protein was produced at roughly the same level as the *SSG1* single mutant. This suggests the importance of functions in the vacuolar membrane of the Ssg1 protein. Interestingly, we found that the *SSG1* mutation highly accumulated S-adenosylmethionine (SAM) and SAH. Considering these results, it was expected that the *SSG1* mutation promoted SAM and SAH accumulations in the vacuole and we measured the amounts of SAM and SAH both in the cytoplasmic compartment and in the vacuolar compartment. Accordingly, it turned out that SAM and SAH accumulated in the vacuole as a result of the *SSG1* mutation. In conclusion, it is suggested that the Ssg1 protein localized in the vacuolar membrane, and may work as a transporter to carry SAM and/or SAH into the vacuole. We are investigating the role of the Ssg1 in the regulation of longevity in detail.

P2259**Board Number: B888****SCZ genes, which suppress Ca²⁺-sensitivity of *zds1Δ*, are implicated in the regulation of life span in the budding yeast *Saccharomyces cerevisiae*.**I. Yamana¹, R. Tsubakiyama¹, K. Kume¹, M. Mizunuma¹;¹Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashi-Hiroshima, Japan

In any organism, aging is characterized as the gradual decline of multitude of physiological functions which present major risk factors for most diseases and finally leads to death. Much of our understanding of aging derives from studies in model organisms, such as yeasts, worms and mice. However, to date we have not understood of what actually causes aging.

In eukaryotic cells, the calcium ion (Ca²⁺) is involved in the regulation of various cellular functions as a signal molecule. The *zds1Δ* strain of *Saccharomyces cerevisiae* shows sensitivity to Ca²⁺ and the Ca²⁺-induced phenotypes which are G2 cell cycle arrest, and polarized bud growth, due to the activation of cellular Ca²⁺-signaling pathways mediated by calcineurin (CN) and the Mpk1 MAP kinase pathway. To uncover the growth control regulated by the the Ca²⁺-signaling pathways in more detail, we screened for suppressor mutants of the Ca²⁺-sensitive phenotypes of *zds1Δ* cells (*scz* mutants). We have clarified into 14 complementation groups and *SCZ14* was found to be allelic to *SIR3*, which is involved in the regulation of gene expression and lifespan. Therefore, it is expected that other mutants would also regulate lifespan. So we have conducted a lifespan analysis using all identified *scz* mutants.

In budding yeast, two different paradigms of aging have been developed: replicative lifespan (RLS) and chronological lifespan (CLS). Previously, we measured the RLS (the number of daughter cells produced by a mother cell) of all *scz* single mutants. All mutants turned out to have a reduction of their RLS, suggesting that SCZ genes are implicated in the regulation of aging. In particular, the increase in CN activity by the *zds1* deletion reduced RLS. Further, increasing the extracellular Ca²⁺ level causes a shortened RLS in WT. Therefore, it was suggested that Ca²⁺ homeostasis influences RLS.

To investigate whether the SCZ genes affect CLS, we measured the CLS (the length of time that a mother cell can survive in a non-dividing, quiescence-like state) of *scz1~14* single and *zds1Δ scz1~14* double mutants. In contrast to RLS, some mutants extended CLS. One of the long-lived *scz* mutants was the *cnb1Δ* strain, which encodes the regulatory subunit of CN. It has been reported that CN-deficient animals have an extended lifespan through the induction of autophagy in *C. elegans*. We examined whether autophagy is affected by the deletion of CN. However, *cnb1Δ* did not induce autophagy in yeast, indicating that *cnb1Δ* extends lifespan in a different manner. We are currently investigating how the CN affects lifespan.

P2260**Board Number: B889****Nicotinamide reverses senescent cell phenotype: possible differential role of phosphatidylinositol 3-kinase subtype enzymes.**K. Matuoka¹, K. Sasaki¹, K. Nakanishi¹, T. Iida¹, K.Y. Chen²;¹Chiba Institute of Science, Chiba-ken, Japan, ²Rutgers, State University of New Jersey, Piscataway, NJ

Phosphatidylinositol 3-kinase (PI3K) is an enzyme family functioning in energy metabolism and intracellular signaling pathways for cell survival, proliferation and aging. When cells age, they express a set of senescence-specific phenotypes, including enlarged cell shape, decrease in proliferation and saturation density and expression of senescence-associated β -galactosidase (SA-gal). We have observed that nicotinamide (NAM), an NAD⁺ precursor, or PI3K inhibitors can reduce certain aging cell phenotypes. We wonder what could be the causes that lead to this phenomenon. With the recognition of the age-dependent decrease in cellular motility, we wonder whether this decrease may be related to other senescence-specific events. We found that treatment of senescent human fibroblastic cells with NAM (4-10 mM) for 10-20 h led to changes in cell morphology and motility, which were then followed by initiation of cell division and a decrease in SA-gal. Similar effects were also observed with PI3K inhibitors, albeit with different potency: BEZ235 was the most effective one, followed by ZSTK474, LY294002 and then wortmannin. As both NAM and PI3K are known to be involved in energy metabolism, we also examined the effect of sirtuin- and AMP kinase-modulating chemicals, including resveratrol, splitomicin, AICAR and dorsomorphin, on senescence-specific phenotypes. None of these chemicals could fully reproduce the effect of NAM on aging, showing that the action of NAM in reversing the senescent phenotypes may be related to the PI3K system, but not to pathways involving sirtuin or AMP kinase. On the other hand, we also observed that the phosphorylation of Akt, the key signaling molecule downstream of PI3K, was reduced in senescent cells, but tended to be higher after the exposure to NAM. This may imply Akt not playing a direct target of the PI3K inhibitors or NAM. As the PI3K system comprises several classes and subtypes, it is possible that the differential effect of PI3K inhibitors on senescent cells could be related to the different spectrum of their actions on PI3K subtype enzyme species. In this regard we found that class I β mRNA was reduced in senescent cells, whereas the class II α and class II β mRNA levels in senescent cells were higher. We speculate that these different PI3K species may have different roles in regulating age-dependent biological events. They may also have different responses to various known PI3K inhibitors. Current work is aiming at using these inhibitors to elucidate the role of individual PI3K subtypes in aging process.

P2261**Board Number: B890****Cockayne syndrome protein B (CSB) localizes to the nucleolus to regulate rDNA transcription in response to oxidative stress.**E.L. Boetefuer¹, H. Fan²;¹Department of Biology, University of Pennsylvania, Philadelphia, PA, ²Department of Genetics, University of Pennsylvania, Philadelphia, PA

The object of this study is to determine the role of Cockayne syndrome protein B (CSB) in protecting cells against oxidative stress. Cockayne syndrome is a severe, autosomal recessive disorder characterized by sun sensitivity, neurological and developmental defects, and progeroid features. CSB is an ATP-dependent chromatin remodeler and is critical for relieving oxidative stress; however, little is known as to how CSB accomplishes its specific functions in this process. Here, we perform a complementation test, which demonstrates the presence of CSB promotes cell survival upon oxidative stress. Furthermore, chromatin remodeling is required for CSB's protective role. Indirect immunofluorescence was used to examine the cellular localization of CSB, which shows oxidative stress also results in the accumulation of CSB within the nucleolus, the site of rDNA transcription and processing. Mutation analysis indicates this localization requires both the ATPase domain and C-terminus of CSB. RT-qPCR analysis of nascent rDNA transcription indicates CSB functions to suppress rDNA transcription upon oxidative stress. Taken together, we demonstrate a role of CSB in protecting cells during oxidative stress by downregulating nascent rDNA transcription within the nucleolus.

P2262**Board Number: B891****Changes in gene expression profile in human mesenchymal stem cells young and senescent treated with titanium microparticles.**J.C. Tavares¹, D.A. Cornelio², G.O. Brasil³, I.T. Job e Meira², S.R. Batistuzzo de Medeiros²;¹FACISA/UFRN, Santa Cruz, Brazil, ²DBG, UFRN, Natal, Brazil, ³DBG, UFRN, Natl, Brazil

Human mesenchymal stem cells (hMSC) are multipotent cells and have been used in cell therapy. Replicative senescence or acquisition of tumorigenic features can appear after long time cultivation in vitro. Considering the interference of passages and titanium in the gene expression, we decided to evaluate the transcriptome of hMSC isolated from umbilical cord vein. The cells were cultivated until early passages (young cells) and until late passages (senescent cells) without and with exposition to titanium microparticles at 24-hour and 144-hour time point (50 e 100 microparticles/cell, respectively). The cords were obtained from three donors, two with normal karyotype, identified as hMSC/n, and one with an inversion chromosome (46,XY,inv(3)(p13-p25)), called hMSC/inv. Using microarray analysis, we demonstrated a range of differentially expressed genes (DEG) between the young hMSC/inv and young hMSC/n. Interestingly, there were more DEG when they become senescent. There was no DEG between

hMSC/n untreated and treated with titanium for all doses and time tested during the treatment. When highest titanium dose at 24-hour, we verified more DGE between hMSC/inv young and senescent. Only in senescent hMSC/inv treated with titanium at 144-hour there was DEG in a titanium dose-dependent manner. The data clearly show the presence of possible new biomarkers of cellular senescence in both hMSC untreated and treated: DIO2, IGFBP5, MRV1, SCUBE3, KRTAP1-5, HAS3, KRT34, GALNT5, FOXE1, KRT19, PLCB4. We also determine new networks for DEG when comparing senescent and young cells, with the bottlenecks MMP1, THBS1 (senescent hMSC/n) and EGF (senescent hMSC/inv). In senescent hMSC/inv, others functional annotations of segregation of chromosomes, mitotic spindle formation and mitosis and proliferation of tumor lines were the most represented within of functional categories. Genes inserted into functional annotations related to tumors were more pronounced in our analysis, some of them associated to giant cell tumor of bone. The functional categories over-represented in senescent cells without titanium particles were related to cellular development, cell growth and proliferation, cell death, cell signaling and interaction and cell movement. In young cells, the functional category most enriched at 50 particles/cell and at 100 particles/cell dose at 24-hour was cellular development. Specifically, when using 100 particles/cell, other functional categories were represented such as: cell cycle, cellular movement, cell death and survival, cell growth and proliferation and cell morphology. In senescent cells, in this same condition of treatment we identified genes classified as functional category of DNA replication, recombination and repair. Taken together, these data is relevant to improve the knowledge concerning molecular mechanism of the cellular senescence, in presence or absence of titanium particle treatment. Lastly, our data reveal particular genes involved in the initial stages of mesenchymal carcinogenesis. Financial support CNPq

Sirt6 deficiency produces intrinsic osteoblast defects leading to low-turnover (age-related) osteoporosis.

T. Sugatani¹, O. Agapova¹, H. Malluche², K.A. Hruska¹;

¹Washington University School of Medicine, Saint Louis, MO, ²Albert B. Chandler Medical Center, University of Kentucky, Lexington, KY

Several pathological conditions resembling human aging, including osteopenia, have been observed in sirtuin 6 (Sirt6)-deficient mice. However, the mechanism by which Sirt6 controls bone metabolism is unknown. The original report ascribing osteopenia to decreased circulating IGF1 is likely incorrect. Here, we show that loss of Sirt6 function produces a low-turnover osteoporosis caused by impaired bone formation by osteoblasts and bone resorption by osteoclasts. Micro CT analysis of long bones from Sirt6-deficient mice revealed decreased bone volume, trabecular bone mineral density, trabecular number, trabecular thickness, and cortical thickness compared to wild-type mice. Bone histomorphometry revealed impaired bone formation and bone resorption along with decreased osteoblast and osteoclast numbers. Osteoblastogenesis and osteoclastogenesis, which is an osteoblast free system, were impaired in culture. Furthermore, mineralization by Sirt6-null osteoblasts was remarkably suppressed in vitro.

Mechanistically, we discovered that Sirt6 interacts with Sp7, one of the essential transcription factors for osteoblastogenesis, and deacetylates histone H3 lysine 9 (H3K9) at the Dickkopf-1 (Dkk1) promoter in wild-type osteoblasts. In fact, Dkk1 was not detected at protein levels in wild-type osteoblasts with BMP-2 treatment. In contrast, Dkk1 protein expression was detected in Sirt6-null osteoblasts under the same conditions. Given that Dkk1 is a potent Wnt antagonist and negatively regulates osteoblastogenesis and mineralization, up-regulated Dkk1 protein expression might impact osteoblastic development and function in Sirt6-deficient mice. We also found enhanced production of osteoprotegerin (OPG), an inhibitor of osteoclastogenesis, in Sirt6-null osteoblasts with BMP-2 treatment, while OPG production is suppressed by BMP-2 in wild-type cells. Therefore, enhanced OPG expression in osteoblasts may be the cause of impaired osteoclast development and function in Sirt6-deficient mice. In fact, the numbers of osteoclasts were attenuated in co-culture assays using primary Sirt6-null osteoblasts and Sirt6-null bone marrow mononuclear cells compared to the co-culture assay using the both wild-type cells. Since Sirt6-deficient mice reveal characteristic features of age-related osteoporosis in humans, the cellular and molecular mechanisms of Sirt6 in bone turnover are potential therapeutic targets for age-related bone loss.

⁵Neurosciences, CRCHUM, Montreal, QC

Recent studies have demonstrated that human tau can be secreted by neurons and non-neuronal cells, an event linked to the propagation of tau pathology in the brain. In the present study, we confirmed that under physiological conditions, one tau-positive band was detected in the culture medium with an anti-tau antibody recognizing total tau and the Tau-1 antibody directed against unphosphorylated tau. We then examined whether tau secretion was modified upon insults. Tau secretion was increased by starvation [Earle's Balanced Salt Solution (EBSS)], inhibition of lysosomal function (leupeptin) and when both of these conditions were superimposed, this combined treatment having the most important effects on tau secretion. Interestingly, the pattern of tau secretion was distinct from that of control neurons when neurons were treated either with EBSS alone or EBSS + leupeptin. In these conditions, three tau-positive bands were detected in the culture medium. Two of these three bands were immunoreactive to Tau-1 antibody revealing that at least two tau species were released upon these treatments. Collectively, our results indicate that insults such as nutrient deprivation and lysosomal dysfunction observed in neurodegenerative diseases could result in an increase of tau secretion and propagation of tau pathology in the brain.

P2265**Board Number: B894****Earlier onset of mitophagy contributes to the prolonged chronological lifespan of *ras2Δ* yeast strain.**L. Belicova¹, A. Pichova¹;¹Institute of Microbiology, The Academy of Sciences of the Czech Republic, Prague, Czech Republic

Ras/adenylate cyclase (AC)/PKA pathway is one of the major pathways regulating chronological aging in various model organisms. Deletion of *RAS2* gene in yeast *Saccharomyces cerevisiae* attenuates this pathway and results in prolonged chronological lifespan of a *ras2Δ* strain. Mitochondria play an important role in cell aging and their quality control involves autophagic removal of mitochondria – mitophagy. We aimed at investigating whether and how mitochondria and their quality control process – mitophagy – contribute to the prolonged lifespan of the *ras2Δ* strain. Viability, oxygen consumption, reactive oxygen species (ROS) production, and mitochondrial network morphology were assessed in wild-type and *ras2Δ* strain. To evaluate the importance of mitophagy, a key mitophagy gene *ATG11* was deleted in respective strains (thus creating *atg11Δ* and double knock-out *ras2Δ atg11Δ*). The results showed that the extended lifespan of the *ras2Δ* strain is most probably enhanced by earlier removal of damaged mitochondria by mitophagy and by reducing their respiratory metabolism. In our study, a disruption of mitophagy resulted in higher ROS production and loss of viability in the *ras2Δ* strain. Inability to perform mitophagy did not influence the wild-type strain in any of the studied parameters. The strain *atg11Δ* therefore compensates the *ATG11* deletion by alternative processes. Our results point to a possible interconnection between mitophagy and Ras/AC/PKA signaling pathway. Understanding the interplay of mitophagy and Ras pathway might help to elucidate how cells ensure the mitochondria quality control in the aging process.

Autophagy**P2266****Board Number: B895****TRIM family proteins regulate selective autophagy and act as a new class of autophagic receptors.**M. Mandell¹, T. Kimura¹, V. Deretic¹;¹Molecular Genetics and Microbiology, University of New Mexico, Albuquerque, NM

Tripartite-motif containing proteins (TRIMs) constitute a large family with effects on cell cycle control, innate immunity, inflammation, and antiviral defense. We screened the TRIM family for roles in autophagy and found that more than half of TRIMs modulated autophagy. For most TRIMs tested to date (TRIM5α, TRIM6, TRIM17, TRIM22, and TRIM49), this is accomplished by TRIMs serving as

platforms for the assembly of autophagy initiation factors ULK1 and Beclin 1 in their activated states, although TRIMs such as TRIM55 also employ additional and/or alternative mechanisms to promote autophagy induction. We next considered whether TRIMs played additional roles as selective autophagy receptors, this being of interest due to a present dearth of the known selective autophagy receptors in mammalian cells. All TRIMs tested interacted with mammalian Atg8s (mAtg8s), a class of proteins functionally associated with autophagosome membranes. To find a putative autophagic cargo for a TRIM, we used TRIM5 α , as it has a well-known physiologically relevant target: retroviral capsid. We found that knock-down of autophagy factors in rhesus cells increased retroviral infection with a virus (HIV) known to be restricted by rhesus TRIM5 α but had no effect on a retrovirus (SIV) not recognized by rhesus TRIM5 α . We furthermore found that autophagic degradation of retroviral capsid by TRIM5 α required TRIM5 α 's binding to mAtg8s, thus establishing TRIM5 α as an autophagic receptor. Whereas the target of TRIM5 α is an exogenous protein (retroviral capsid), we have identified several endogenous proteins that interact with and are delivered for autophagic degradation by specific TRIMs. Thus, the function of TRIMs as autophagic receptor—regulators is conserved among the family. Based on our findings and the sheer number of TRIMs (>70 genes in the human genome), we propose that TRIMs direct and conduct selective autophagy of diverse substrates in metazoan cells.

REGULATION OF AGO2 FUNCTION AND DEGRADATION DURING GLUTATHIONE DEPLETION.

H. Mancilla¹, J. Slebe¹, G. Meister², I. Concha^{1,3};

¹Bioquímica y Microbiología, Universidad Austral De Chile, Valdivia, Chile, ²Laboratory for RNA Biology, University of Regensburg, Regensburg, Germany, ³i. Bioquímica, Universidad Austral De Chile, Valdivia, Chile

miRNAs interact with Argonaute (Ago) proteins to form RNA-induced silencing complex (RISC) and guide them to specific target sites located in the 3'-UTR of target mRNAs leading to translational repression and deadenylation-induced mRNA degradation. Autophagy is the major intracellular degradation system by which cytoplasmic proteins and organelles are delivered and degraded in the lysosome. Ago2 is directed for degradation as miRNA-free entities by the selective autophagy receptor NDP52. We have previously described that a glutathione (GSH) deficiency triggers autophagy. The aim of this work was to evaluate the degradation of Ago2 during a glutathione depletion condition. Here, we show that HeLa cells treated with BSO, a potent inhibitor of glutathione biosynthesis, decreases the protein level of Ago2. However, when HeLa cells were treated with BSO and chloroquine to inhibit autophagy, accumulation of Ago2 was observed. We found that Ago2 localization and its binding site to the 5'-end of the miRNA are important for its degradation during this condition. Finally GSH depletion and autophagy inhibition affect the interaction of Ago2 with Let7a miRNA. These results suggest that GSH and autophagy machinery are important for the normal gene silencing through miRNAs.

The Small GTPase Rab7 as a Central Regulator of Hepatocellular Lipophagy.

B. Schroeder¹, R. Schulze¹, S. Weller¹, A. Sletten¹, C.A. Casey², M.A. McNiven¹;

¹Mayo Clinic, Rochester, MN, ²VAMC (151), Omaha, NE

Autophagy is a central mechanism by which hepatocytes catabolize lipid droplets (LDs). Currently, the regulatory mechanisms that control this important process are poorly defined. The small GTPase Rab7 has been implicated in the late endocytic pathway and is known to associate with LDs, although its role in LD breakdown has not been tested. In this study, we demonstrate that Rab7 is indispensable for LD breakdown in hepatocytes subjected to nutrient deprivation. Importantly, Rab7 is dramatically activated in cells placed under nutrient stress; this activation is required for the trafficking of both multivesicular bodies (MVBs) and lysosomes to the LD surface during autophagic catabolism. Depletion of Rab7 leads to gross morphological changes of MVBs, lysosomes, and autophagosomes simultaneously reducing the physical interactions between these compartments and therefore attenuating hepatocellular lipophagy. These findings provide additional support for the role of autophagy in hepatocellular LD catabolism while implicating the small GTPase Rab7 as a key regulatory component of this essential process.

Selective VPS34 inhibitor blocks autophagy and uncovers a role for NCOA4 in ferritin degradation and iron homeostasis in vivo.

W.E. Dowdle¹, B. Nyfeler¹, L. Murphy¹;

¹Novartis Institutes for Biomedical Research, Cambridge, MA

Cells rely on autophagy to clear misfolded proteins and damaged organelles to maintain cellular homeostasis. In this study we use a novel VPS34 inhibitor to screen for new autophagy substrates. The inhibitor acutely blocks autophagy, de novo lipidation of LC3 and leads to the stabilization of autophagy substrates. By performing ubiquitin-affinity proteomics on VPS34 inhibited cells we identified new autophagy substrates including NCOA4 which accumulates in ATG7 deficient cells and co-localizes with autolysosomes. NCOA4 directly binds ferritin heavy chain-1 (FTH1) to target the ~450 kDa iron-binding ferritin complex to autolysosomes following starvation or iron depletion. Interestingly, Ncoa4^{-/-} mice display a profound accumulation of iron in splenic macrophages, which are critical for the reutilization of iron from engulfed red blood cells. Taken together this study provides a novel mechanism for selective autophagy of ferritin and reveals a previously unappreciated role for autophagy and NCOA4 in the control of iron homeostasis in vivo.

P2270**Board Number: B899****Ubiquitin-dependent ULK1 negative feedback regulation constraints autophagy activity.**C. Liu^{1,2}, L. Pang^{1,2}, P. Wu¹, M. Lin¹, R. Chen^{1,2,3};¹Institute of Biological Chemistry, Academia Sinica, Taipei, Taiwan, ²Institute of Biochemical Sciences, College of Life Science, National Taiwan University, Taipei, Taiwan, ³Institute of Molecular Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan

Autophagy, a cellular self-eating mechanism, is important for maintaining cell survival and tissue homeostasis in response to various stressed conditions, such as starvation. Although the mechanism of autophagy induction has been well studied, it remains elusive how cells modulate the level of autophagy once it has been induced. KLHL20 is a substrate adaptor of Cullin3-family ubiquitin ligase. Here, we show that ULK1, a serine/threonine kinase critical for autophagy initiation, is a substrate of the Cul3-KLHL20 ubiquitin E3 ligase complex. KLHL20-mediated ubiquitination leads to ULK1 proteasomal degradation. In responses to autophagy induction, the activation and autophosphorylation of ULK1 enhances its affinity to KLHL20, which results in an increased ULK1 ubiquitination and degradation. We further show that this KLHL20-dependent ULK1 regulation controls the amplitude and duration of autophagy to prevent prolonged or overly activated autophagy. This study identifies a novel regulatory mechanism for ULK1 and suggests a role of this regulation in autophagy termination.

P2271**Board Number: B900****A Kinase Independent Role for EGF Receptor in Autophagy Initiation.**X. Tan¹, R.A. Anderson¹;¹Molecular Pharmacology, University of Wisconsin-Madison, Madison, WI

Autophagy is a highly conserved self-eating pathway for homeostasis maintenance in all eukaryotic cells. Misregulation of autophagy is linked to human diseases including cancers. It has been generally established that autophagy prevents tumor initiation in normal cells, but in established tumors autophagy may promote tumor progression by facilitating tumor cell survival in metabolically stressed conditions. The Epidermal Growth Factor Receptor (EGFR) is an oncogenic receptor tyrosine kinase over-expressed and/or over-activated in numerous human cancers. EGFR activation suppresses autophagy in tumor cells, and inhibition of EGFR signaling by tyrosine kinase inhibitors (TKIs) is associated with enhanced autophagy in many cancer cell lines. However, the mechanism by which EGFR inactivation upregulates autophagy is not clear.

We have shown that EGFR inactivation resulting from either serum starvation or EGFR TKI treatment induces EGFR accumulation at late endosomes. The endosomal oncoprotein LPTM4B directly and

selectively interacts with inactive EGFR and is required for the accumulation of EGFR at late endosomes upon serum starvation. Most significantly, both LAPTM4B and EGFR are required for autophagy initiation, and re-expression of either wild type or kinase dead EGFR rescues autophagy in EGFR knockdown cells. LAPTM4B and inactive EGFR interact with the Sec5 exocyst subcomplex that is also required for autophagy. Together, LAPTM4B, inactive EGFR and Sec5 collaborate to control the disassociation of Rubicon (an autophagy inhibitor) from the Beclin 1 complex to initiate autophagosome formation. These findings reveal a kinase independent role for EGFR in autophagy initiation upon serum starvation or EGFR TKI treatment. This could be a mechanism for the prosurvival role of EGFR in established tumors and for the EGFR TKI resistance in clinical therapies.

Detecting the Function of the Small GTP-Binding Protein Arl1 in Autophagy.

S. Yang¹, A.G. Rosenwald¹;

¹Department of Biology, Georgetown University, Washington, DC

Autophagy is a cellular degradation process that sequesters components such as organelles or proteins into a double-membrane structure called the autophagosome, which then fuses with the lysosome or vacuole for the hydrolysis of those components. Autophagy can be triggered in response to a variety of intracellular or environmental stresses such as pathogen invasion, starvation, or unfolded-protein stress. Once induced, autophagy is performed and regulated by several Atg proteins. Factors that control membrane traffic are also essential for each step of autophagy. Here we demonstrate that a small GTP-binding protein named Arl1, which belongs to the Arf/Arl/Sar protein family is involved in starvation-induced autophagy in *Saccharomyces cerevisiae*, but only under high temperature stress. Arl1 normally controls the retrograde trafficking from the endosome to the trans-Golgi and is important for proteins to be targeted to the vacuole. Using an assay which measures the degradation of GFP-Atg8 to free GFP to monitor bulk autophagy under different temperatures, we found that starved cells lacking the ARL1 gene show defects in bulk autophagy at elevated temperature, 37°C but not at 30°C. The same conclusion was reached with assays using fluorescence microscopy to monitor the GFP-Atg8 signal in the cells under different conditions as well as the Pho8Δ60 activity assay to quantify the magnitude of autophagy. Furthermore, experiments with different nucleotide binding alleles of Arl1 demonstrated that the GTP restrictive form of Arl1 (Arl1[Q72L]) can rescue the defect. Finally, we found that loss of Ypt6, another GTP binding protein that is synthetically lethal with Arl1, shows similar defects in autophagy under heat stress. Future work will focus on determining the mechanism for the roles of both Arl1 and Ypt6 in autophagy.

P2273**Board Number: B902****Regulation of Autophagy by ULK3, an Atg1-family kinase.**C.R. Braden¹, T.P. Neufeld¹;¹GCD, University of Minnesota, Minneapolis, MN

Macroautophagy (hereafter autophagy) is a key cellular housekeeping process in which organelles and macromolecules are packaged in a double walled membrane, the autophagosome, and delivered to the lysosome via membrane fusion. Aggregated and long-lived soluble proteins and malfunctioning organelles are all subject to destruction via autophagy, meaning its proper regulation is a requirement for successful maintenance of cellular function. As an aggregate clearance mechanism, autophagy is of interest in aggregate-prone disease states such as Alzheimer's. As a requirement for clearing damaged mitochondria, it is a key element in the study of Parkinson's. As a pro-survival pathway in a variety of stress conditions including starvation, autophagy is scrutinized in the development of cancer treatments, and it is a target of inhibition in chemotherapy.

While many signaling pathways lead to autophagy, most require the involvement of serine-threonine kinase Atg1 (*Drosophila melanogaster*) or its mammalian homologues Unc-51-like kinases 1 & 2 (ULK1 & 2). Under beneficial growth conditions, Atg1 is subject to inhibitory phosphorylation by the Target of Rapamycin (TOR). When inhibition is relieved, such as during amino-acid starvation, Atg1 induces autophagy in a manner dependent on its kinase domain, its binding partner Atg13, and a variety of complex members and downstream targets.

Recently, stimuli that can induce autophagy independent of Atg1/ULK1/2 have been described, and it is unclear how these signals interact with the core autophagy machinery. The ULK family includes an additional member, ULK3, whose potential role in autophagy is poorly characterized, and we hypothesize that ULK3 may represent this missing link. Here we demonstrate that like Atg1, ULK3 is capable of inducing autophagy in the *Drosophila* fat body. Induction of autophagy by Ulk3 overexpression does not require Atg1, but does require the Atg1 binding partner Atg13. Sequence analysis of ULK3 shows a pair of MIT domains, reminiscent of the MIT domain structures identified in Atg1 required for Atg13 interaction. However, unlike Atg1, ULK3 is not required for starvation-induced autophagy. Interestingly, Ulk3 mutation does delay onset of autophagy during treatment with the proteasome inhibitor MG132, a relative of the chemotherapy drug bortezomib. Ulk3 mutant animals are viable, but demonstrate reduced survival rates compared to wild type animals. Taken together, our data suggest ULK3 may act as a junction point between the canonical autophagy signaling cascade and a novel upstream pathway, possibly connected to proteasome malfunction.

P2274**Board Number: B903****The LRRK2 inhibitor GSK2578215A activates autophagy mediated by mitochondrial fission and mitochondrial-derived ROS.**S. Saez-Atienzar^{1,2,3}, L. Bonet-Ponce¹, J. blesa¹, F. Romero¹, J. Jordan³, M. Galindo²;¹Dpt Physiology, Universidad Catolica de Valencia, Valencia, Spain, ²Unidad de Neuropsicofarmacología Traslacional, Complejo Hospitalario Universitario de Albacete, Albacete, Spain, ³Grupo de Neurofarmacología, Universidad de Castilla-La Mancha, Albacete, Spain

Parkinson's disease (PD) constitutes the main motor disorder and the second neurodegenerative disease after Alzheimer's disease. Etiology of PD remains unknown, but both environmental and genetic factors have been implicated. Among the genes associated with PD is the leucine-rich repeat kinase 2 (LRRK2). Mutations in LRRK2 have been described in familial Parkinson's disease and sporadic disease. However, the role of LRRK2 is still unknown and its inhibition is a promising pharmacological target in PD treatment. We used the LRRK2 inhibitor 2 arylmethoxy-5-substituent-N-arylbenzamide (GSK257815A) at a concentration of 1 nM to study the effects of LRRK2 inhibition on the well-established dopaminergic cell line SH-SY5Y. We focused our study on crucial neurodegenerative features such as mitochondrial dynamics, autophagy and cell death. We found out that LRRK2 inhibition, either by pharmacological inhibition (using GSK2578215A and LRRK2-In-1) or molecularly by siRNA to knockdown LRRK2, activates autophagy since it increased the number of autophagosomes after 9 hours of treatment. Using the lysosome inhibitor chloroquine (CQ) and the mRFP-GFP-LC3 plasmid, we denoted that this increment results from both an increase in autophagosomes synthesis and an impairment of its degradation. LRRK2 inhibition also induced mitochondrial fragmentation mediated by Drp-1, in a time-dependent manner, starting at 6 hours after treatment. The use of MDIVI-1, a mitochondrial division inhibitor, avoided autophagy. This data strongly suggest that mitochondrial fragmentation is indeed an early step preceding autophagy. In order to ascertain the role of autophagy, we used autophagy disruptors that revealed the participation of autophagy as a cytoprotective response by removing damaged mitochondria by mitophagy. In order to know the role of mitochondrial-derived ROS, we analyzed 4-hydroxy-2-nonenal (4-HNE). We observe accumulation of 4-HNE after GSK2578215A treatment. The mitochondrial-targeted reactive oxygen species scavenger MitoQ positioned these species as second messengers between mitochondrial morphological alterations and autophagy. In summary, our data show how LRRK2 inhibition activates a cellular response where autophagy results in cytoprotection downstream of a disruption of the mitochondrial dynamics balance via a Drp1-dependent process. Our study suggests that drugs which modulate the functions of Drp-1 or mitochondrial-ROS may represent new opportunities to slow down neurodegeneration linked to Parkinson's disease.

P2275**Board Number: B904****Optineurin is an autophagy receptor for damaged mitochondria in parkin-mediated mitophagy that is disrupted by an ALS-linked mutation.**Y.C. Wong¹, E.L. Holzbaur²;¹Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, ²Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Mitophagy is a cellular quality control pathway in which the E3 ubiquitin ligase parkin targets damaged mitochondria for degradation by autophagosomes. We examined the role of optineurin in mitophagy, as mutations in optineurin are causative for glaucoma and the neurodegenerative disease Amyotrophic lateral sclerosis (ALS), diseases in which mitochondrial dysfunction has been implicated. Using live cell imaging, we demonstrate the parkin-dependent recruitment of optineurin to mitochondria damaged by depolarization or reactive oxygen species (ROS). Parkin's E3 ubiquitin ligase activity is required to ubiquitinate outer mitochondrial membrane proteins, allowing optineurin to stably associate with ubiquitinated mitochondria via its ubiquitin binding domain (UBD); in the absence of parkin, optineurin transiently localizes to damaged mitochondrial tips. Following optineurin recruitment, the omegasome protein DFCP1 (double FYVE-containing protein 1) is transiently recruited to damaged mitochondria to initialize autophagosome formation. Optineurin then recruits autophagosome formation around damaged mitochondria via its LC3 interaction region (LIR) domain. Depletion of endogenous optineurin inhibits LC3 recruitment to mitochondria, leading to increased mtDNA content within cells. This defect in autophagosome formation and mitochondrial degradation is rescued by wildtype optineurin, but not by an ALS-associated UBAN mutant (E478G), or by a LIR mutation in optineurin. Optineurin and the autophagy receptor p62/SQSTM1 are independently recruited to different domains on damaged mitochondria, and p62/SQSTM1 knockdown does not affect either optineurin or LC3-recruitment to damaged mitochondria. Thus, our results demonstrates a critical role for optineurin as an autophagy receptor in parkin-mediated mitophagy. Importantly, as mutations in parkin are linked to Parkinson's disease, our study further indicates that defects in a single pathway lead to neurodegenerative diseases with distinct pathologies.

P2276**Board Number: B905****L84 interferes with autophagic flux and contributes to Parkinsonism.**K. Lee¹, S. Namkoong¹, I. Jang², R. Park¹, J. Park¹;¹Division of Biological science and technology, Yonsei University, Wonju, Korea, ²kbsi, Daejeon, Korea

L84 is an antihypertensive drug that has been used to control the high blood pressure, and one of its adverse effects is that long term treatment of L84 often causes Parkinson's disease in human and animal. However, the precise mechanism of L84 to induce Parkinson's disease is not clear. Here we report that one possible mechanism of L84 to induce Parkinson's disease. L84 treatment induced the

autophagosome formation by inhibiting the autophagic flux, and also accumulates p62, an autophagy adapter molecule.

¹Dpt Physiology, Universidad Catolica de Valencia, Valencia, Spain, ²Unidad de Neuropsicofarmacología Traslacional, Complejo Hospitalario Universitario de Albacete, Albacete, Spain, ³Grupo de Neurofarmacología, Universidad de Castilla-La Mancha, Albacete, Spain

Retinal Pigment Epithelium (RPE) plays a crucial role in the physiology and pathophysiology of the retina due to its location and metabolism. Oxidative damage has been demonstrated as a pathogenic mechanism in several retinal diseases, and reactive oxygen species are certainly important by-products of ethanol (EtOH) metabolism. Under EtOH exposure, autophagy has been shown to exert a protective effect in different cellular and animal models.

Thus we challenged a widely accepted model of human RPE cells (ARPE-19 cells) with 80, 200, 400 and 600 mM EtOH. 24 h after EtOH addition, we found out that EtOH treatment increased GFP-LC3 puncta, starting at 80 mM. LC3-II conversion by western blot was also detected after EtOH treatment, in a concentration dependent-manner. Interestingly, using both the mRFP-GFP-LC3 plasmid and the lysosome inhibitor chloroquine, we observed an increase in autophagy flux, in a concentration-dependent manner. In fact, our data pointed out an implication of the mTOR pathway. Moreover, autophagy activation seemed to be Beclin1 and ATG5-ATG12 dependent, as well. Mitochondrial morphology seemed to be clearly altered under EtOH exposure, leading to an apparent increase in mitochondrial fission. Interestingly, mitochondrial fission appeared to be dynamin-related protein 1 (Drp1) and optic atrophy 1 (OPA1) dependent but Bax independent. Consequently we noticed that mitochondrial autophagy is increased, in a concentration-dependent manner. In fact, we clearly demonstrated that mitochondrial ROS stimulates autophagy. An increase in 2',7'-dichlorofluorescein fluorescence and accumulation of lipid peroxidation products, such as 4-hydroxy-nonenal (4-HNE), among others, were confirmed. The characterization of these structures confirmed their nature as aggresomes. Furthermore, we observed that autophagy efficiently degrades 4-HNE aggresomes. Finally, after autophagy inhibition, we noticed an over 2 fold increase in cell death, only in EtOH-treated cells.

Hence, our data strongly suggest that autophagy plays a cytoprotective role in ARPE-19 cells under EtOH damage, by degrading fragmented mitochondria and 4-HNE aggresomes. Herein, we describe the central implication of autophagy in human RPE cells upon oxidative stress induced by EtOH, with possible implications for other conditions and diseases.

P2278**Board Number: B907****DUAL ROLE OF TFEB IN MICROGLIA.**N. Pastore¹, T. Huynh¹, A. Ballabio²;¹Jan and Dan Duncan Neurological Research Institute, Texas Children Hospital, Houston, TX, ²Telethon Institute of Genetics and Medicine, Naples, Italy

Transcription factor EB (TFEB) belongs to the MITF/TFE subfamily of basic helix–loop–helix leucine-zipper (bHLH-LZ) transcription factors. In mammalian cells, TFEB is known to exert a transcriptional control of autophagy and lysosomal biogenesis. Recently, it has been reported that TFEB is also important for host defense against infections. Lysosomal activity is essential to autophagy, a cellular pathway that delivers cytoplasmic components to lysosomes for degradation and is involved in many diseases. Autophagy has been extensively implicated in immunity. Mutations in autophagy genes increase susceptibility to infections by intracellular pathogens. Microglia plays a crucial role in maintaining brain tissue homeostasis. In pathological conditions, microglia releases pro-inflammatory cytokines and cytotoxic factors, which aggravate the progression of neurodegenerative diseases. In this study we investigated the role of TFEB in microglia in vitro, in BV2 microglial cells, and in vivo, in LysM-Cre; TFEB flox/flox and LysM-Cre; TFEB-3xflag mice that have reduced or enhanced expression of TFEB specifically in macrophages. Real time PCR analysis demonstrated that knockdown of TFEB in microglial cells results in increased levels of pro-inflammatory cytokines (IL1 β , IL6, TNF α) in basal conditions, while the inflammation is reduced after LPS challenge. Brains from LysM-Cre; TFEB flox/flox mice show increased levels of pro-inflammatory cytokines and inflammation, as demonstrated by NF κ B and JNK levels. Serum IL1 β levels are also increased in these mice. LPS-treated LysM-Cre; TFEB flox/flox mice show a decrease in inflammatory response compared to control mice. Overexpression of TFEB either in cells or in mice results in a different inflammatory response depending on the levels of TFEB: low levels overexpression result in increased response to LPS treatment, while high levels overexpression result in reduced inflammation after LPS challenge. Our data suggest that TFEB has a dual role in the microglia depending on cell activation status.

P2279**Board Number: B908****Bax inhibitor 1 Enhances Autophagy in Cyclosporine A Treatment and Reduces Renal Dysfunction.**R.K. Yadav¹, B. Li¹, G. Lee¹, H. Kim², H. Chae^{3,4};¹Department of pharmacology, Chonbuk National University, Jeonju, Korea, Dem People's Rep, ²School of Dentistry, Wonkwang University, Iksan, Iksan, Korea, Dem People's Rep, ³Department of Pharmacology, Chonbuk National University medical school, Jeonju, Korea, ⁴Department of Pharmacology, Chonbuk National University medical school, Jeonju, Korea

Cyclosporine A (CsA), a calcineurin inhibitor, improves allograft survival in solid organ transplantation. Previous evidence indicates that CsA induces autophagy, and that chronic treatment with CsA results in accumulation of autophagosomes and reduced autophagic clearance. Autophagy is a bulk protein degradation system that likely plays an important role in normal proximal tubule function and recovery from acute kidney injury. In the present study, we used human kidney tubular cells to demonstrate that CsA-induced autophagy is highly stimulated in Bax inhibitor-1 (BI-1)-overexpressing cells (BI-1 cells). BI-1 cells exhibit special activity involving highly maintained lysosome activation that promotes autophagosome and lysosome fusion. In BI-1 cells treated with CsA, transcription and nuclear translocation of TFEB is increased. In addition, treatment of BI-1 knockout mice with CsA resulted in decreased autophagosome and lysosome formation. We also found that BI-1 knockout mice were susceptible to CsA-induced kidney injury. Taken together, BI-1 appears to serve as a protective mechanism against CsA-induced nephrotoxicity through autophagy both in vitro and in vivo.

P2280**Board Number: B909****The autophagosome marker LC3 undergoes regulated targeting to the nucleus and nucleolus.**L.J. Kraft^{1,2}, J. Dowler¹, A.K. Kenworthy¹;¹Mol Physiol Biophys, Vanderbilt University Medical Center, Nashville, TN, ²Harvard University, Boston, MA

Autophagy is a lysosomal degradation pathway that is important for the maintenance of cellular homeostasis. Although the formation of autophagosomes occurs in the cytoplasm, it is increasingly evident that several key proteins in the autophagy pathway shuttle in and out of the nucleus. We previously reported that LC3, a protein that participates in autophagosome formation and cargo selection, is enriched in the nucleus in a slowly diffusing form. However, the mechanisms that retain LC3 in the nucleus and control its nuclear dynamics remain poorly understood. To address this, we used a combination of fluorescence microscopy and FRAP to study Venus-LC3 in HeLa cells. We find that mutating residues involved in binding of LC3 to other proteins and RNA moderately decreases its

nucleocytoplasmic ratio, but disrupting LC3 lipid modification does not change its nucleocytoplasmic ratio. This suggests that the majority of LC3 in the nucleus is soluble, and that it is retained in the nucleus by interactions with either proteins or RNA. Consistent with this, soluble nuclear LC3 diffuses more slowly than predicted for a monomer. Perturbing the autophagy pathway with rapamycin or chloroquine has little effect on LC3's nuclear localization, but does change the apparent size of LC3-associated complexes. This implies that soluble nuclear LC3 associates with complexes with functions possibly related to autophagy. Unexpectedly, we also find that nuclear LC3 is enriched within the nucleolus. We show that the triple arginine motif of LC3, a region previously shown to bind to both proteins and RNA, shares similarities with a consensus nucleolar detention sequence. Furthermore, perturbation of LC3's triple arginine motif completely abolishes its localization to the nucleolus. Together, these findings reveal a potential role for both protein-protein and protein-RNA interactions in targeting LC3 to the nucleus and nucleolus.

ATG5 and ATG7 fulfill essential and non-redundant roles in human hematopoietic stem/progenitor cells.

M. Gomez Puerto¹, H. Folkerts², A. Wierenga², K. Schepers¹, J.J. Schurunga², E. Vallenga², P. Coffe¹;
¹Cell biology, University medical center Utrecht, Utrecht, Holland, ²Department of Experimental Hematology, University medical center Groningen, Groningen, Holland

Autophagy is a homeostatic mechanism that is crucial in the degradation of damaged organelles and misfolded proteins. This catabolic process is characterized by the formation of a double membrane vesicle called autophagosome that after engulfing cellular components will fuse with a lysosome for degradation of the cargo. Autophagy can be triggered in response to stress conditions such as starvation, energy limitation, hypoxia and DNA damage. Surprisingly, the role of autophagy in the regulation human hematopoietic stem cell (HSC) function remains unclear. Besides their ability to differentiate into all blood cell lineages, HSCs have the capacity to self renew and remain quiescence for the lifelong maintenance of hematopoiesis. Thus, HSCs require stringent housekeeping mechanisms safeguarding their integrity and protecting them from accumulation of damage. Currently little is known concerning the regulation of autophagy in hematopoietic stem and progenitor cells, or how this may change during myeloid differentiation.

Autophagy was analyzed by Western blotting and FACS. In addition colony forming cell (CFC) assays, long term culture-initiating cell (LTC-IC) assays, apoptosis measurements, cell-cycle analysis and reactive oxygen species (ROS) measurements were performed.

We demonstrated that autophagy is functional in human hematopoietic stem/progenitor cells (HSPCs). Robust accumulation of the autophagy markers LC3-II and p62 were observed in HSPCs treated with bafilomycin-A1 (BafA1) or hydroxychloroquine (HCQ). In addition, CD34⁺CD38⁻ stem cell-enriched cells showed enhanced accumulation of cyto-ID (a marker for autophagic vesicles) compared to CD34⁺CD38⁺ progenitor cells upon BafA1 and HCQ treatment. To study the functional consequences of autophagy,

ATG5 or ATG7 were knockdown in CD34⁺ cells, using lentiviral shRNAs. Downregulation of ATG5 and ATG7 resulted in a marked decrease in progenitor frequencies, which coincided with a strong reduction in expansion of CD34⁺ cells. In addition, a 3-fold reduction in stem cell frequencies was observed. The reduction in HSPCs was not due to impaired differentiation, but was at least in part due to reduced cell cycle progression and an increase in apoptosis. The changes in cell cycle and increased apoptosis coincided with increased expression of p53 and downstream proapoptotic target genes BAX, PUMA and PHLDA3 and cell cycle inhibitor p21. Additionally, ROS levels were increased after ATG5 and ATG7 knockdown. The increased apoptosis in shATG5 and shATG7 transduced cells might be triggered by elevated ROS levels.

Taken together, our data demonstrate that autophagy is an important survival mechanism for human HSCs and their progeny.

Autophagy protects against neurodegeneration in a *Drosophila* model of C9orf72-mediated ALS.

K. Zhang¹, K. Cunningham², J.B. Machamer¹, T.E. Lloyd^{1,2,3};

¹Department of Neurology, Johns Hopkins University, School of medicine, Baltimore, MD, ²Graduate Program in Cellular and Molecular Medicine, Johns Hopkins University, School of medicine, Baltimore, MD, ³The Solomon H. Snyder Department of Neuroscience, Johns Hopkins University, School of medicine, Baltimore, MD

A recently identified GGGGCC hexanucleotide repeat expansion (HRE) mutation in C9orf72 is the most common genetic cause of amyotrophic lateral sclerosis (ALS). In a forward genetic modifier screen of HRE toxicity in *Drosophila*, we discovered that the loss of function of p62 strongly suppresses HRE-induced neurodegeneration. p62 plays a critical role in autophagy, a self-degradation process that prevents the accumulation of toxic misfolded proteins in many neurodegenerative disorders. p62 binds and delivers ubiquitinated proteins to the autophagosome, eventually leading to lysosomal degradation of both p62 and its cargos. Defects in this process cause accumulation of p62 as well as its cargos. Interestingly, we find that flies expressing the HRE display increased p62 protein levels, intracellular p62 protein aggregates in motor neurons, and impaired synaptic transmission at the neuromuscular junction, consistent with the findings reported in C9orf72 ALS patient autopsies. Furthermore, we find that genetic and/or pharmacological activation of the autophagic pathway significantly suppresses neurodegeneration concomitantly with p62 aggregation, strongly suggesting that autophagic clearance of p62-positive aggregates can rescue C9orf72-related neurotoxicity. Hence, we propose that C9orf72 HRE causes cytotoxic protein aggregations containing p62, which can be rescued by increasing autophagy. Our study suggests that activation of autophagy may be a therapeutic strategy for C9orf72-mediated ALS.

P2283**Board Number: B912****BNIP3 Induces Full-length PINK1 Accumulation to Promote Mitophagy.**T. Zhang¹, L. Xue², L. Li¹, C. Tang¹, Z. Wan¹, R. Wang¹, Z. Zeng¹, W. Andy Tao², Z. Zhang³;¹ Central South University, State Key Lab of Medical Genetics, Changsha, China, ²Purdue University, Department of Biochemistry, West Lafayette, IN, ³ Central South University, State Key Laboratory of Medical Genetics, Changsha, China

Mutations in *PINK1* cause early onset familial Parkinson's disease (PD). PINK1 is accumulated on followed by recruiting parkin to the outer membrane of damaged mitochondria to promote mitophagy. Here, we demonstrate that BNIP3, a mitochondrial BH3-only protein, interacts with PINK1 to promote stabilization and accumulation of full length PINK1 on outer membrane of damaged mitochondria, therefore, to facilitate parkin recruitment to mitochondria. The results suggest that BNIP3 plays an essential role in PINK1/parkin-mediated mitophagy and likely contributes to PD pathogenesis.

Keywords: Parkinson's disease, PINK1, BNIP3, mitophagy

Systems and Synthetic Cell Biology**P2284****Board Number: B914****Measuring fast gene dynamics in single cells with timelapse luminescence microscopy.**A. Mazo-Vargas¹, H. Park¹, M. Aydin¹, N. Buchler¹;¹Biology, Duke University, Durham, NC

Timelapse fluorescence microscopy is an important tool for measuring *in vivo* gene dynamics in single cells. However, fluorescent proteins are limited by slow chromophore maturation times and the cellular auto-fluorescence or photo-toxicity that arise from light excitation. An alternative is luciferase, an enzyme that emits photons and is active upon folding. However, the photon flux per luciferase is significantly lower than fluorescent proteins. To date, timelapse luminescence microscopy has been successfully used to track gene dynamics in larger organisms and for slower processes, where more total photons can be collected in one exposure. Here, we tested green, yellow, and red beetle luciferases and optimized substrate conditions for *in vivo* luminescence. By combining timelapse luminescence microscopy with a microfluidic device, we tracked the dynamics of cell cycle genes in single yeast with sub-minute time resolution over many generations. Our protocol is significantly faster and in cells with much smaller volumes than previous work. Fluorescence of an optimized reporter (Venus) lagged luminescence by 20 minutes, which is consistent with its known rate of chromophore maturation in yeast. Our work shows that luciferases are better than fluorescent proteins at faithfully tracking the underlying gene expression.

P2285**Board Number: B915****Two sequential decisions commit human cells to start the cell cycle.**S.D. Cappell¹, S.L. Spencer¹, M. Chung¹, A. Jaimovich¹, T. Meyer¹;¹Department of Chemical and Systems Biology, Stanford University, Stanford, CA

One of the most fundamental decision processes in biology is the commitment of cells to enter the cell cycle and generate two daughter cells. Cell-cycle commitment in mammalian cells is thought to be regulated by a single decision point in G1 called the Restriction Point, after which growth factors are no longer required for the cell cycle to proceed. Using live-cell microscopy of cell-cycle sensors and single-cell analysis, we have identified the moment at which cells cross the Restriction Point and find that more than three hours pass between the Restriction Point and the actual start of DNA replication.

Furthermore, we find that cell stress after the Restriction Point but before the start of DNA replication results in cell-cycle exit and a return to a pre-Restriction Point state, providing evidence for another later decision to commit to the cell cycle. We present evidence for a second bistable switch regulating S-phase entry. The trigger for this second switch is the CDK2/Cyclin E-mediated partial inactivation of APCCdh1, an E3-ligase that controls the degradation of proteins necessary for S-phase progression. We show that the switch is driven by a double negative feedback between the regulatory protein Emi1 and APCCdh1. Markedly, Emi1 functions as both an inhibitor and a substrate of the APC, which generates a bistable and irreversible switch regulating S-phase entry. Thus, cells commit to the cell cycle by making two sequential decisions. They first monitor mitogen signals to decide whether to cross the Restriction Point, and then monitor stress signals to decide whether to irreversibly inactivate APCCdh1, start DNA replication, and fully commit to the cell cycle.

P2286**Board Number: B916****Multiplexed transcriptional analysis of p53 targets in single cells.**J.R. Porter¹, B.E. Fisher¹, E. Batchelor¹;¹Laboratory of Pathology, NCI/NIH, Bethesda, MD

The transcription factor p53 is activated in response to a wide range of biological stresses. To cope with different stresses, p53 regulates the expression of over a hundred different target genes in a stress-specific manner. Understanding how stresses are relayed by p53 into distinct regulation of such a large number of genes is a major challenge. The problem is confounded by the fact that common transcriptomic methods often rely on measurements of populations of cells, which can obscure information regarding single-cell heterogeneity and the coregulation of specific targets. To address these concerns, we used a microfluidic platform to analyze the expression of nearly one hundred well-characterized p53 target genes simultaneously in individual cells. We focused on p53's dynamic response to DNA double strand breaks, which we had previously characterized as an undamped pulsatile

dynamical response. We identified distinct classes of downstream target dynamics, including oscillatory and delayed target gene expression. We also characterized target genes based on expression noise as a measure of single-cell heterogeneity. From our co-expression measurements, we identified gene regulatory sub-networks operating downstream of p53. Our findings provide new mechanistic insights into how p53 coordinates stress-specific responses in individual cells, and may provide novel therapeutic strategies for altering cell fates.

Constant Growth Rate Can Be Supported by Decreasing Energy Flux and Increasing Aerobic Glycolysis.

N. Slavov^{1,2}, A. van Oudenaarden³;

¹Massachusetts Institute of Technology, Cambridge, MA, ²Systems Biology, Harvard University, Cambridge, MA, ³Hubrecht Institute, Utrecht, Netherlands

Fermenting glucose in the presence of enough oxygen to support respiration, known as aerobic glycolysis, is believed to maximize growth rate. We observed increasing aerobic glycolysis during exponential growth, suggesting additional physiological roles for aerobic glycolysis. We investigated such roles in yeast batch cultures by quantifying O₂ consumption, CO₂ production, amino acids, mRNAs, proteins, posttranslational modifications, and stress sensitivity in the course of nine doublings at constant rate. During this course, the cells support a constant biomass-production rate with decreasing rates of respiration and ATP production but also decrease their stress resistance. As the respiration rate decreases, so do the levels of enzymes catalyzing rate-determining reactions of the tricarboxylic-acid cycle (providing NADH for respiration) and of mitochondrial folate-mediated NADPH production (required for oxidative defense). The findings demonstrate that exponential growth can represent not a single metabolic/physiological state but a continuum of changing states and that aerobic glycolysis can reduce the energy demands associated with respiratory metabolism and stress survival.

Variable stoichiometry among core ribosomal proteins.

N. Slavov^{1,2}, A. van Oudenaarden³;

¹Massachusetts Institute of Technology, Cambridge, MA, ²Systems Biology, Harvard University, Cambridge, MA, ³Hubrecht Institute, Utrecht, Netherlands

Understanding the regulation and structure of the eukaryotic ribosome is essential to understanding protein synthesis and its deregulation in disease. While ribosomes are believed to have a fixed

stoichiometry among their core ribosomal proteins (RPs), some experiments suggest a more variable composition. Reconciling these views requires direct and precise quantification of RPs. We used mass-spectrometry to directly quantify RPs across monosomes and polysomes of budding yeast and mouse embryonic stem cells (ESC). Our data show that the stoichiometry among core RPs in wild-type yeast cells and ESC depends both on the growth conditions and on the number of ribosomes bound per mRNA. Furthermore, we find that the fitness of cells with a deleted RP-gene is inversely proportional to the enrichment of the corresponding RP in ribosomes bound to multiple mRNAs. Together, these findings support the existence of ribosomes with distinct protein composition and physiological function.

How do bacterial growth rates relate to evolutionary fitness landscapes for energy-efficiency?.

A. Maitra¹, K.A. Dill¹;

¹Laufer Center for Physical and Quant. Biology, Stony Brook University, Stony Brook, NY

We are interested in energy flows in bacteria, and how energy gets trafficked between producing ribosomal and nonribosomal proteins under different growth conditions. We describe an analytical model that leverages extensive data on experimental growth laws to infer the underlying fitness landscape in *E. coli*. This model gives insight into some of the complex nonlinear relationships between energy utilization and ribosomal and non-ribosomal production as a function of cell growth conditions. We draw inferences about what evolution has optimized in *E. coli*. Is *E. coli* optimized for growth speed or for energy efficiency? Experimental data shows that at its replication speed limit, *E. coli* produces 4 mass equivalents of non-ribosomal proteins for every mass equivalent of ribosomes. The model shows that this ratio is expected if the bacterial fitness function is the energy efficiency of fast-growing cells. We conclude that a principal evolutionary driving force for bacteria is the energy efficiency of the fastest growing cells.

Engineering a modular synthetic cyclic AMP generator.

M. Ritt¹, S. Sivaramakrishnan¹;

¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

Adenylyl cyclases (ACs) are key amplifiers of GPCR signaling. Mammalian cells express nine distinct AC isoforms, all of which convert ATP to the second messenger cyclic AMP (cAMP). While much is known

about the structure of ACs and the signaling pathways they control, the differential function of AC isoforms and their spatio-temporal regulation remains poorly understood. Here we describe the detailed characterization of a genetically encoded synthetic adenylyl cyclase (SYNAC) that can be generalized to any AC isoform and targeted independent of the native AC. SYNAC activity can be monitored orthogonally using FRET, and is controlled by forskolin and G α s in a manner similar to native AC. We also describe a modular extension of SYNAC that can be used to modify its activity independent of endogenous G proteins.

The optimal cell based lineage for cardiac-regeneration still remains a mystery. Here we have developed a novel cell based assay to screen novel synthetic compounds for cardiovascular safety and regenerative profiles for clinical development. The human cardiomyocytes were isolated from adult ventricular and atrial appendages, characterized, and electrically profiled for functional physiological cardiac evaluations. The electrophysiology of adult human cardiomyocyte consists of 4X4 array of platinum microelectrodes and electronic measurement system based on a 1mV rms noise level amplifier and 16 channel 16bit data acquisition card. This High throughput ElectroPhysiological Assay (HEPA) cardiac chip technology was developed by Biopico Systems Inc., for characterization of the human cardiomyocytes electrophysiology functional index for cardiovascular safety and regenerative profiles. Prior to utilizing the human cardiomyocytes they were tested positive with Real time PCR, IHC and Western Blot Analysis for the following biomarkers: ckit, Actinin, ANP, Connexin 43, Desmin, KDR, Nkx2.5, GATA-binding protein 4 (GATA4) and SERCA2. The in-vitro assay procedure was established to determine cardiovascular safety and regenerative index of newly identified led molecules. In this study we tested CEP1430, a novel anti-tumor agent targeting pancreatic stem cells for cardiovascular safety; our lead molecule had no adverse cardiovascular liability. In-vivo daily administration of CEP1430 for 20 days had no cardiovascular adverse effect. From this study we were able to conclude that we have identified a lead compound for targeting pancreatic cancer stem cells that has no adverse cardiovascular effect when monitored for 20 days with once daily administration of the compound by intraperitoneal injections. This in-vitro cell based cardiac assay enabled us to determine the cardiac safety value help us determine the molecule to be a potential candidate for clinical development.

P2292**Board Number: B922****Biosynthesis of Silver Nanoparticles using *Biden frondosa* and its Tyrosinase Activity.**Q. Abbas¹, S. Seo¹;¹Department of Biology, College of Natural Sciences, Kongju National University, Kongju, Korea

Herbal Nanoparticles gain lot of attention because of their novel drug delivery system. In this study the silver nanoparticles (AgNPs) were synthesized by using aqueous extract of *Biden frondosa*. The appearance of brown color indicates the formation of *Biden frondosa*-AgNPs. The Formation and stability of AgNPs were determined by UV–Vis spectroscopy; Fourier Transform Infrared (FTIR) data confirm the presence of various aromatic and –OH moieties. The formation of herbal AgNPs further assured by energy dispersive X-ray spectroscopy (EDX) and Scanning electron microscopy (SEM) size ranging 30-50nm. The mushroom tyrosinase inhibitory activity of synthesized AgNPs was evaluated and it was found that they exhibited potent tyrosinase inhibitory activity compared to control. The IC50 value of AgNPs was found to be 9 and that of kojic acid is 15µg/mL. AgNPs of *Biden frondosa* may be considered as potential candidate for the production of medical and cosmetic products.

P2293**Board Number: B923****Bacterial Cell Adhesion to Switchable Polymer Brushes.**T. Babar¹, A. Sidorenko¹, M. Bruist²;¹Department of Chemistry and Biochemistry, University of the Sciences, Philadelphia, PA, ²Chemistry Biochemistry, University of the Sciences, Philadelphia, PA

Polymer brushes have the potential to be used for medical supplies and as new materials for industry that require a reduction or elimination of bacterial growth. We propose that the modification of solid surfaces with switchable polymer brushes allows adherence of bacteria to a hydrophobic surface or the controlled detachment of the bacteria from a hydrophilic polymer surfaces. Based on the research by Cunliffe, *et. al* (1991), we analyzed the physical adhesion properties of *Escherichia coli* and *Salmonella typhimurium*¹ when applied to switchable hybrid molecular brush (HMB) systems. HMB's are composed of a chitosan backbone with added polystyrene (PS) and polyacrylamide (PAAm) side chains. Upon optimization of production of the brushes, with respect to the polymer thickness and wettability, the bacterial response to each surface polymer was characterized using Atomic Force Microscopy (AFM). Through AFM, the initial stage of bacterial adherence, in which the bacteria recognize the surface using responding extracellular extensions, topographical images were acquired. The images show the cellular appendages, fimbria, extended from the cell's surface while adhered to polystyrene. There is an absence of fimbria when cells are on polyacrylamide. Further experiments will be conducted to observe the surface characteristics of cells when they are allowed to grow on the brushes for longer periods of times; along with comparisons of cell adherence and surface characteristics on modified HMB's.

Reconstitution of regulated FtsZ localization by Min protein gradients in vitro.

K. Zieske¹, P. Schwille²;

¹Max Planck Institute of Biochemistry, Munich, Germany, ²Max Planck Institute for Biochemistry, Martinsried, Germany

The controlled placement of the division apparatus plays a key role for cell development. During cell division in *Escherichia coli* the oscillatory self-assembly of the MinCDE proteins directs the assembly of the division machinery. To investigate the minimal requirements for division site localization in a controlled environment we engineered a biomimetic system by reconstituting the cell division protein FtsZ and the Min protein system in membrane clad soft-polymer compartments. This bottom-up system allows studying complex organizational principles, such as the self-assembly of Min protein concentration gradients and controlled localization of FtsZ to the middle of a cell-like. Furthermore the role of geometric boundary conditions and minimal biochemical requirements for division site localization can be addressed.

Actomyosin network dynamics in epithelial morphogenesis.

K.L. Ong¹, S. DiNardo²;

¹Cell Molecular Biology Graduate Program, University of Pennsylvania, Philadelphia, PA, ²Department of Cell Developmental Biology, University of Pennsylvania, Philadelphia, PA

The lowest energy state of a simple epithelium is a hexagonal packing composed of 3-cell junctions. To generate cell geometries away from equilibrium, two types of molecular machines are required: (1) force-generating networks to remodel or stabilize cell-cell contacts and (2) polarity determinants to control the pattern of cell shape changes. Coordination of cell shape changes in a group of cells is required for proper tissue morphology and function. Dysregulated tissue morphogenesis underlies pathologies such as developmental defects and cancer.

As a model of epithelial morphogenesis, we study a dramatic alignment in the *Drosophila* embryonic epidermis that produces columns of aligned, rectangular cells. These columns give rise to lines of hooks required for larval mobility, thus the geometry of this epithelium is key to its function. Past work in our

lab has suggested that actomyosin-mediated junction remodeling events that convert 3-cell junctions to 4-cell junctions produce this rectilinear arrangement. Recently, we have characterized the cell shape changes in this epithelium at higher temporal resolution. We find that the straightening of Dorsal-Ventral (DV) interfaces between cell columns does not always temporally coordinate with junction remodeling events. By live imaging of fluorescently tagged myosin light chain, we observe two separate pools of myosin with different behaviors. First, actomyosin cables stably co-localize with the adherens junctions of straightening DV interfaces throughout alignment. Second, an apical pool of myosin located medially in aligning cells undergoes rapid cycles of contraction and disassembly. Based on these findings, we hypothesize that two distinct actomyosin networks, regulated in sequence or parallel, exert different forces on the cells in this tissue to mediate alignment: (1) actomyosin cables generate tension across all DV contacts to straighten interfaces between columns and (2) medial-apical myosin elevates force on select contacts to induce junction remodeling events. In the future, we hope to determine the polarity mechanisms that temporally regulate these two pools of actomyosin, quantitate the contractile dynamics of the medial-apical actomyosin population with respect to junction remodeling, and dissect the contribution of these distinct actomyosin pools to collective cell shape changes.

Paradoxical sleep deprivation and its consequences on the morphophysiology of ventral prostate.

R.A. Fochi¹, J.Q. Antoniassi², R.M. Goes³, S.R. Taboga⁴;

¹Department of Biology, São Paulo State University, IBILCE/UNESP, São José Do Rio Preto, Brazil,

²Department of Structural and Functional Biology, State University of Campinas, IB/UNICAMP, Campinas, Brazil, ³Biology, São Paulo State University, IBILCE/UNESP, São José Do Rio Preto, Brazil,

⁴Biology, São Paulo State University, IBILCE/UNESP, S J do Rio Preto, Brazil

This study aimed to evaluate possible morphological and functional changes in the ventral prostate of the adults (90 days) Mongolian gerbil (*Meriones unguiculatus*) after the paradoxical sleep deprivation (also known as rapid eye movement phase – R.E.M.). The REM sleep deprivation was induced over a period of four consecutive days using the modified multiplatform method. Through this technique, the animals of treated group (PSD) remained in cages containing 18 fixed platforms, allowing their movement and access to food and water ad libitum, filled with water up to 1 cm below the surface of the platforms. When animals of the PSD group enter in the REM sleep, they lose muscle tone and fall in the water, disrupting the sleep cycle. The animals of control group (NC) remained in polypropylene cages filled with shaving woods during the whole experiment, receiving water and food ad libitum. The serum dosage for testosterone and corticosterone was performed by ELISA. Prostatic fragments were analyzed by morphometry and stereological techniques, as well as immunohistochemistry for proliferating cell nuclear antigen (PCNA) and TUNEL for apoptosis evaluation. In the prostate of PSD animals occurred an evident regression of the glandular epithelium besides some foci of hyperplasia, while the muscular stroma also becomes thinner and disorganized when compared to NC. These

morphological changes occurred without testosterone serum levels fluctuations, but an important increase in corticosterone serum levels was noted (5.37 ng / mL to 19.99 ng / ml). The animals subjected to sleep deprivation also showed a significant reduction in body weight (62.50 g to 52.75 g), however, the ventral prostate weight remained unchanged. Furthermore, there was also a decrease of PCNA-positive cells in the epithelial and stromal compartments, which was accompanied by an increase in apoptosis, particularly in the stromal region. Based on these results, it can be concluded that sleep disruption triggers important hormonal oscillations that negatively reflect in the morphophysiology of prostate gland and this condition could be considered a promoter factor of prostatic lesions.

Scarb2a gene expression is required for Notochord Development in Zebrafish.

A. Diaz Tellez¹;

¹IFC, UNAM, DF, Mexico

Scarb2 is a glycoprotein, with two transmembrane sites, several sites for N-glycosylation and a C-terminal di-leucine motif . In humans, mutations in Scarb2 were described as causing of Action Myclonus Renal Failure Syndrome (AMRF), which is diagnosed as a progressive myoclonus epilepsy. Zebrafish has three homologous genes for *scarb2* (*scarb2a*, *scarb2b* and *scarbc*). *Scarb2a* insertional-mutant was obtained in a large-scale forward genetic screening, this mutant is characterized by the presence of vesicular bodies in the brain at 1 dpf and hypopigmentation at 2 dpf both phenotypes are restored by itself at 3 dpf . Furthermore, since 1 dpf *scarb2a* mutant show a particular defect in the notochord formation, in which notochord vacuoles never reach their normal size. Whole mount in situ hybridization revealed that *scarb2a* is expressed in the brain and in the notochord at early stages. Interestingly, as development progress, *scarb2a* expression is dynamically displaced in an anterioposterior direction. We also notice, by immunostaining, that laminin is not arranged properly at the notochord basal membrane. Through electronic microscopy, we identified that specific basal membrane defects are specifically localized at the intermedial zone, however internal and external layers seems unaffected.

Dachsous, Fat and actin modulators contribute to planar cell polarity in the Drosophila ventral epidermis.

G.E. Osborn¹, D. Ly¹, K. Lawlor¹, S. DiNardo¹;

¹Department of Cell Developmental Biology, University of Pennsylvania , Philadelphia, PA

Morphogenesis is orchestrated by the cooperation of many cells: for proper execution, cells must respond to directional information and transmit these cues to neighboring cells. To accomplish this,

epithelial cells tend to establish polarity within the plane of the epithelium, in addition to apicobasal polarity. Such planar cell polarization (PCP) allows cells to define their position within a field, thereby allowing cells to coordinately produce asymmetric responses essential for tissue function. The molecules that control planar cell polarity have been identified and well studied; polarizing systems such as the conserved Frizzled (Fz) and the Dachshous/Fat (Ds/Fat) systems allow cellular neighbors to establish and maintain polarity. Less understood is how these systems integrate with downstream effectors to choreograph asymmetric responses. Here we study the *Drosophila* ventral epidermis, an epithelium in which cells produce a stereotyped template for the production of denticles, critical for larval motility. This template is comprised of actin-based protrusions (ABPs), which are asymmetrically polarized within these cells. The Ds/Fat system is essential for the proper localization of ABPs; the current model is that Ds signals through the Fat receptor to impose polarity. We are performing functional domain analysis of Fat, in order to determine critical motifs of this molecule and to predict downstream effectors of the Ds/Fat system. In addition, through live imaging and genetic techniques, we have begun analysis of candidate cytoskeletal molecules (actin modulators, myosin II) to identify the machinery that engages in the construction and placement ABPs at the posterior edge of these cells. By working from receptor to cytoskeleton, we hope to understand how molecular polarity determinants integrate with structural effectors to functionally polarize tissue, a process critical in both development and disease.

Claudin localization to tight junctions is required for neural tube morphogenesis.

A. Baumholtz¹, A. Simard¹, A. Ryan²;

¹Human Genetics, McGill University, Montreal, QC, ²Pediatrics and Human Genetics, McGill University, Montreal, QC

Neurulation is a critical developmental process that converts the flat neural plate into a closed neural tube. Throughout this process the neural plate epithelium undergoes extensive remodeling including cell intercalation and apical constriction. These events require the maintenance of cell interactions within the neural epithelium through intercellular junctions. The most apical of these junctions are tight junctions (TJs), where members of the claudin family regulate apical-basal cell polarity and cell adhesion, and link the TJ to the actin cytoskeleton. We hypothesize that claudins are required for coordinating the morphogenetic events that drive neural tube closure. To test our hypothesis, we used the C-terminal domain of *Clostridium perfringens* enterotoxin (cCPE) to remove Claudin-4 and -8, and Claudin-3 and -4 from TJs of the neural and non-neural ectoderm of chick embryos respectively. Disrupting the localization of these claudins to tight junctions led to folate-resistant NTDs in 100% of embryos. In situ hybridization analysis of gene expression in the ectoderm and along anterior-posterior boundaries of the neural tube suggested that NTDs were not due to defects in ectoderm differentiation or patterning. cCPE-treated embryos displayed defects consistent with a disruption of convergent extension: a shortened anterior-posterior axis, a reduced length-to-width ratio, misshapen somites, and a broadened notochord. Transmission electron microscopy analysis of cCPE-treated embryos showed that midline

cells failed to undergo apical constriction. Furthermore, we showed reduced apical accumulation of RhoA and pMLC, an activated form of myosin II that is phosphorylated by Rho kinase (ROCK), in cCPE-treated embryos. These data indicate that claudins function upstream of RhoA/ROCK signalling to regulate actin-myosin contraction and thus, cell intercalation and apical constriction. This is the first time that claudins have been shown to directly regulate neural tube closure.

Slug/Snail2 expression during the development of squamous metaplasia in airways of patients with chronic obstructive pulmonary disease (COPD).

C. Ben Brahim¹, C. Courageux¹, N. Ferhani¹, J. Brard¹, M. Pretolani¹, M. Aubier¹, P.A. Leroy¹;

¹INSERM UMR1152, Université Paris Diderot, Faculté de Médecine Bichat, Paris, France

Chronic obstructive pulmonary disease (COPD), a major cause of morbidity and mortality worldwide, is clinically characterized by a slow and progressive airflow obstruction and decline in lung function, resulting from a remodeling of the airways that includes several epithelium abnormalities. Inhaled agents, mainly cigarette smoke, are the main cause of COPD. The airway epithelium, first in line during exposure to inhaled environmental factors, is often injured and need to be repaired. The normal bronchial epithelium is pseudostratified, consisting of ciliated, goblet and basal cells. The latter are stem/progenitor cells that can self-renew and/or differentiate into ciliated and goblet cells in a well controlled balance to reconstitute a functional epithelium. Chronic toxic injury can repetitively perturb this balance and lead to epithelium abnormalities such as mucous cell hyperplasia or squamous metaplasia (SM). SM is frequent in the bronchial epithelium of smokers but its extent is increased in smokers with COPD compared to smokers without COPD. In COPD there is also a loss of normal pseudo stratified epithelium with transition into a fully squamous epithelium (Wilson et al, ATS2013). The objective of our work is to understand the molecular mechanisms underlying the abnormal airway epithelial repair that are specific to COPD. Slug was found to be one of the most expressed genes in mouse bronchial basal cells when compared to non-basal cells (Rock et al, 2009). We hypothesized that Slug is a key regulator of basal cell renewal and differentiation and could be involved in the development of SM. We found, by immunohistochemical labeling of bronchial biopsies, that Slug is expressed in the nuclei of cells in zones of SM in both control and COPD patients; however, lower levels are observed in biopsies from COPD. To follow the expression of Slug during the regeneration of a bronchial epithelium, we used primary human bronchial epithelial cells (HBECS) cultured in air-liquid interface (ALI). This culture system allows regeneration of a normal epithelium at high concentration of ATRA, while in conditions depleted in ATRA, SM is induced as shown by involucrin increase and cytokeratin 18 decrease of expression. Using this model, we found that stable SM is associated with a decrease of Slug protein expression. When cells are treated with TGF β , a factor previously reported to induce SM, we observed a decrease of Slug associated with SM in COPD and this correlates with a decrease in pAKT. In summary, our work shows that the more stable and mature SM found in COPD correlates with a decrease of Slug expression and that Slug may be involved in the reversibility of SM.

P2301**Board Number: B932****Male offspring of diabetic rats exhibit increased activity of MMP-2 associated to higher content of TGF- β , androgen receptor and cell proliferation in the ventral prostate.**A.A. Damasceno¹, C.P. Carvalho¹, F.A. Araujo¹, F.V. Botelho¹, R.M. Goes², D.L. Ribeiro¹;¹Histology, Institute of Biomedical Sciences/ Federal University of Uberlândia- UFU, Uberlândia, Brazil,²Biology, São Paulo State University, IBILCE/UNESP, São José Do Rio Preto, Brazil

This study presents a comprehensive view of histological and functional status in the prostate of adult rat offspring of mothers subjected to gestational diabetes. Diabetes was induced in pregnant female Wistar rats by alloxan (i.p. 100 mg/kg b.w.). The ventral prostate of male adult offspring of diabetic (DP) or normal mothers (CP) was evaluated for collagen fibres, cell death (TUNEL), immunohistochemistry (fibroblasts, smooth muscle cells, cell proliferation), western blotting (PCNA, metalloproteinases, androgen receptor-AR), TGF β -1 (ELISA), catalase and total antioxidant activity. The prostates of DP animals showed lower weight compared to the CP group and these animals also exhibited hyperglycaemia and hypotestosteronaemia. Cell proliferation and AR were higher in the diabetic offspring. The DP group also showed a reduction in α -actin, which may interfere with the reproductive function of the prostate. They also had enhanced activity of MMP-2, although the absolute content of this MMP was lower in this group. This finding was associated with an increase in TGF β -1 and a decrease in collagen distribution. The prostates of DP rats also exhibited reductions in catalase and total antioxidant activity. These data indicate that rats developing in a diabetic intrauterine environment have glycemic and hormonal changes that impact on the structure and physiology of prostate in adulthood. They exhibit increased AR expression, which may be responsible for the elevated cell proliferation. There was also stromal remodelling characterized by enhanced activity of MMP-2 and collagen degradation, even with increased TGF β -1 activation. These changes associated with increased oxidative stress may interfere with tissue architecture and glandular homeostasis, favouring the development of proliferative disorders in the prostate.

P2302**Board Number: B933****Analysis of the different functional domains relevant for chicken Scratch2 function.**T.Y. Nakamura Kanno¹, M. Soares Fogo¹, F. Monteleone Vieceli¹, C. Yan¹;¹Department of Cell and Developmental Biology, Universidade de São Paulo, São Paulo, Brazil

cScratch2 (cScrt2) is an evolutionarily conserved transcription factor that belongs to the Snail/Slug superfamily. This superfamily is involved in different developmental processes including neural differentiation, cell division, cell survival and left–right identity. As a norm, members of this family act through transcriptional repression. The repressor activity of these transcription factors depends both on the amino-terminal SNAG and carboxi-terminal Zinc-Finger domains. cScrt2 is expressed in the chick embryonic neural tube. Specifically, it is found in early postmitotic neural progenitors. Consistent with its cellular function, MYC-cScrt2 localizes to the nucleus of chick embryonic neural progenitors and HEK293T cells. An *in silico* search for subcellular localization regulatory sites revealed that residues tyrosine77 (Y77) and serine78 (S78) are possible targets for tyrosine or serine/threonine kinases. The sequence containing these residues is completely conserved between the homologues of cScrt2 in chicken, human and mice. Overexpression of cScrt2Y77F, cScrt2Y77E, cScrt2S78A and cScrt2S78D in HEK293T and chicken embryos remain in the nucleus as observed by immunofluorescence and Western Blot. The truncated protein with only the C-terminal domain is also restricted to the nucleus. Thus, it is possible that the nuclear localization of cScrt2 is mainly controlled by the Zinc-Finger domain. We thus investigated if phosphorylation of Y77 and S78 is relevant for repressor activity. All of the different Y77 and S78 point mutants decreased repressor ability as seen by luciferase assays. Given that we observe alterations in cScrt2 repressor activity independently of the charge value of the residue that substituted the endogenous Y77 or S78. We propose that all of the above mutations alter protein conformation and, as a consequence, the ability to recruit the nuclear partners involved in the cScrt2mediated transcriptional regulation. In other words, our results suggest that Y77 and S78 are relevant for the correct conformation of interaction domains involved in recruiting nuclear repressor machinery partners while the subcellular localization of cScrt2 could be controlled by the DNA-binding Zinc-Finger domain.

P2303**Board Number: B934****8-Nitro-guanosine 3',5'-cyclic monophosphate mediates elongation of the growth plate cartilage in mice.**M. Hoshino^{1,2}, Y. Miyamoto¹, K. Yoshimura¹, D. Suzuki¹, T. Akaike³, K. Mishima⁴, K. Baba², R. Kamijo¹;¹Department of Biochemistry, Showa University School of Dentistry, Tokyo, Japan, ²Department of Prosthodontics, Showa University School of Dentistry, Tokyo, Japan, ³Department of Environmental Health Sciences and Molecular Toxicology, Tohoku University Graduate School of Medicine, Miyagi, United States, ⁴Division of Pathology, Department of Oral Diagnostic Sciences, Showa University School of Dentistry, Tokyo, Japan

The majority of our bones develop through endochondral ossification, except for the collarbones and flat bones such as the skull bones and the jawbones that are formed through membranous ossification. Endochondral bone formation is regulated by growth and differentiation of chondrocytes in growth plates. It is known that nitric oxide (NO) plays important roles in controlled elongation of growth plates and hypertrophic differentiation of chondrocytes. It is also reported that C-type natriuretic peptide (CNP) stimulates proliferation and hypertrophic differentiation of chondrocytes through elevation of intracellular level of guanosine 3',5'-monophosphate (cGMP). Recently, 8-nitro-cGMP was identified in various types of cells including macrophages, glia cells, and cardiomyocytes as a novel signaling molecule. Therefore, we hypothesized that 8-nitro-cGMP may function as a mediator of proliferation and/or differentiation of chondrocytes in the growth plates. In this study, we investigated the formation and function of 8-nitro-cGMP in the growth plate cartilage in mice. Tibias excised from mice on embryonic day 16 were cultured for 4 days in the presence of CNP and either an NO synthase inhibitor, L-NAME, or its control D-NAME, the optical isomer of L-NAME. Tibias grew $1087 \pm 188.2 \mu\text{m}$ in the direction of the long axis in 4-day culture with CNP and D-NAME, whereas they grew only $766.2 \pm 181.0 \mu\text{m}$ in the culture with CNP and L-NAME. Histochemical analyses revealed that L-NAME caused suppressed elongation of the growth plate cartilage induced by CNP, indicating NO was involved in the proliferation of chondrocytes in the growth plates. Formation of 8-nitro-cGMP was detected immunohistochemically in the growth plates after cultivation with CNP, while that was inhibited by L-NAME. In addition, chemically synthesized 8-nitro-cGMP induced the *ex-vivo* growth of tibias in a concentration-dependent manner. Hence we examined the effect of chemically synthesized 8-nitro-cGMP on the proliferation and differentiation of mouse primary chondrocytes *in vitro*. 8-Nitro-cGMP induced the proliferation of chondrocytes in a concentration-dependent manner, while it did not have little effect on the expression of marker genes of hypertrophic differentiation. Collectively, it is suggested that 8-nitro-cGMP is a novel signaling molecule that facilitates proliferation of chondrocytes and elongation of growth plate cartilage.

P2304**Board Number: B935****The Role of Twist1 in endothelial cell sprouting in the lung.**T. Mammoto¹, A. Mammoto²;¹Vascular Biology Program, Boston Children's Hospital/Harvard Medical School, Boston, MA, ²Boston Children's Hosp/Harvard Med Sch, Boston, MA

Recent significant advances in stem cell research and bioengineering techniques made a great progress in utilizing biomaterials to regenerate or repair damages in simple tissues in the orthopedic and periodontal fields. However, attempts to bioengineer the structures and functions of more complex three-dimensional organs such as lungs have not been very successful. Angiogenesis –the formation of new blood capillaries- plays an important role in organ development, homeostasis, and regeneration and deregulated angiogenesis contributes to various disease states. Newly formed vasculatures not only deliver oxygen, nutrients and various cell components, but also provide instructive signals to surrounding cells in tissues. Thus, in order to engineer functional organs such as lungs, we need to understand the mechanisms that govern angiogenesis. The transcription factor, Twist1, controls mouse embryonic development and the epithelial-mesenchymal transition that occurs in lung fibrosis and lung cancer, diseases in which angiogenesis is deregulated. Here we demonstrate that Twist1 controls the expression of angiogenic factor receptor, Tie2 and endothelial cell sprouting in lung human microvascular endothelial (L-HMVE) cells. Furthermore, we recently developed a unique method to implant fibrin gel on the mouse lung, which enables the precise analysis of the biological process of host lung-derived angiogenesis and interaction between the newly formed blood vessels and other cellular (e.g., alveolar cells, immune cells) and non-cellular components in mice. When the fibrin gel supplemented with angiogenic factors vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) (0, 10 and 100 ng/ml each) is implanted on the surface of living mouse lung, host-derived CD31-positive vascular networks are constructed inside the gels 7 days after implantation in a VEGF/bFGF dose-dependent way. Importantly, angiogenesis is inhibited in fibrin gels implanted on lungs of Tie2-specific Twist1 conditional knockout mice. These results suggest that Twist1 controls angiogenesis in vitro and in the mouse lung in vivo and that Twist1 may be one of the key molecules to control lung organ morphogenesis.

P2305**Board Number: B936****Prenatal exposure to estrogen disrupts development of male and female prostate in Mongolian gerbil.**B.C. Zani¹, J.S. Maldarine², J.A. Vieira², M.M. Jesus³, F.A. Santos⁴, M.F. Biancardi⁴, B.D. Sanches³, S.R. Taboga⁵;¹Biology, UNESP, São José Do Rio Preto, Brazil, ²Biology, UNESP, S J do Rio Preto, Brazil, ³Biology, UNICAMP, Campinas, Brazil, ⁴Biological Sciences, Federal University of Goiás, Goiania, Brazil, ⁵Biology, São Paulo State University, IBILCE/UNESP, S J do Rio Preto, Brazil

Prenatal estrogenization disrupts development of prostate gland in male rodents, causing alterations in the gland growth, as well, deep changes in urethral structure. Despite much is known about the effects in male prostate, there is little research on intrauterine estrogenization in the female prostate and the differences between genders. The aim of this study was to evaluate the effects of prenatal estrogenization on the ventral prostate of Mongolian gerbils (*Meriones unguiculatus*), this species is relevant for this type of research, since the presence of functional prostate in female is almost ubiquitous. Developing prostate complexes were collected from animals at 20, 22, 24 days of postnatal life exposed to high dosages of estrogen (500 mg/kg BW/day) during perinatal life, fixed and processed for paraffin embedding and cut in series. The slides were stained with HE and immunohistochemistry essays, as well three-dimensional reconstructions were performed. Results suggest gender differences: females were more susceptible to developmental disruptions, as a decrease in the number of prostatic ducts and a increase in their thickness. Acknowledgements: FAPESP, CNPq and CAPES for financial support and scholarships.

P2306**Board Number: B937****Evaluation of Intrauterine oestrogenic exposure on female prostate development in Mongolian Gerbil.**B.D. Sanches¹, J.S. Maldarine², M.F. Biancardi³, B.C. Zani⁴, F.A. A CLEM approach to studying the membrane repair process in zebrafish myofibers in vivo. Effect of high pressure freezing on fluorescence emission by fluorescent proteins.

C. Antony¹, V. Middel², T. Beil³, U. Straehle⁴;

¹IGBMC, CNRS, Strasbourg, France, ²ITG, Karlsruhe Institute of Technology, Karlsruhe, Germany, ³ITG, KIT, Karlsruhe, Germany, ⁴ITG, KIT, Karlsruhe, Germany

In order to study the process of membrane repair in myofibers in zebrafish embryos after sarcolemma injury, we designed a workflow to track the fluorescent positive myofibers (labelled with proteins of interest involved in the repair process) by LM so as to be able to eventually find them in the EM scope for high resolution investigation. For this purpose which involves the vitrification of 3-days-old embryos by HPFreezing (with a HPF device, Compact O2, Wohlwend, CH) we first tested that the fluorescence signal was preserved right after HPFreezing of our samples. We discovered that some fluorescent proteins stand the effect of the high pressure (2100 bar) and the freezing to liquid nitrogen temperature, as seen with samples visualized under liquid nitrogen with a macroscope (UV illumination), while some others do not and, as a consequence, lose their ability to emit fluorescence. Later on, after freeze substitution (FS) and plastic embedding in HM20 Lowicryl resin, the fluorescence was preserved within 250-300 nm thick sections in cases where the fluorescence was intact after the HPFreezing step, while it was extinguished in case where it was no longer detected after the vitrification step. This shows that fluorescent proteins (FPs) display a differential sensitivity to the vitrification process, probably depending on the molecular structure of FPs and/or their environment. We currently investigate which FPs are optimally suitable for CLEM studies.

P2308**Board Number: B939****Cell Rearrangement and Rosette Formation During Epithelial Morphogenesis of the *Xenopus laevis* Neural Plate.**D.S. Vijayraghavan¹, L.A. Davidson^{1,2};¹Bioengineering, University of Pittsburgh, Pittsburgh, PA, ²Developmental Biology, and Computational and Systems Biology, University of Pittsburgh, Pittsburgh, PA

During neurulation cells within the planar neural plate must coordinate their behaviors in order to deform into an elongate tubular structure. Neural tube formation is comprised of several steps including cell shape patterning of the early neural plate, neural fold formation at the lateral edge of the plate, bending at and fold convergence towards the dorsal midline, and finally fold fusion. Much of the focus of neural tube mechanics have been on the bending of the neural plate and formation of hinge points both at the midline and mediolaterally at the folds. Researchers have identified coordinated apical constriction of epithelial cells are crucial to these bending processes. However, even before bending occurs, the neural plate, as well as the whole embryo, undergoes a large convergence mediolaterally and extension in the anterior posterior direction. Convergence and extension (CE) of the neuroepithelium is thought to be driven in part by cell rearrangements through planar polarized actomyosin contractility. We have undertaken a stage-by-stage analysis of cell shape changes and local geometric patterning within the dorsal apical surface of fixed *Xenopus laevis* embryos. Cells within neural plate undergo directed cell rearrangement and form large multi-cellular rosettes where 5 or more cells share a single vertex. Directed formation and resolution of rosettes have been implicated as a driver of convergence and extension in *Drosophila* germ band epithelial morphogenesis and has been observed in later stage chick neural tube formation. Preliminary analysis of live imaging confocal data of labeled actin in the neural plate demonstrates cells frequently change neighbor both through rosette formation and more general T1 transitions. Rosettes resolution typically occurs within 1 hour after formation. High magnification time-lapses reveal a dense and highly contractile actin cortex within the neural epithelium. These observations support the notion that actively rearranging cells coincide with convergence and extension. However, it remains to be seen whether rearrangements provide the motive force driving CE or whether rearrangements merely serve to dissipate stresses acting within the epithelium.

P2309**Board Number: B940** **α integrin cytoplasmic tails can rescue the loss of Rho-family GTPase signaling in the *C. elegans* somatic gonad.**C. Meighan¹, V. Kelly¹, E. Krahe¹, A. Gaeta¹;¹Christopher Newport Univ, Newport News, VA

Integrin signaling impacts a diverse set of cell behaviors through multiple, distinct pathways. The Rho family of GTPases are integrin signaling partners that regulate cell polarity, actin dynamics, and cell migration. Though the connection between integrins and the Rho family has been studied extensively, there is still much that is unknown about the complex interplay between these protein families. To further resolve this issue, we used the nematode *C. elegans* as a simple model for integrin and Rho family function. *C. elegans* has two α integrins, *ina-1* and *pat-2*, that pair with β integrin *pat-3*. Our previous work developed chimeric α integrins which link the extracellular domain of α integrin *ina-1* to the cytoplasmic tail of α integrin *pat-2* and the extracellular domain of *pat-2* to the cytoplasmic tail of *ina-1*. These constructs showed the α integrin cytoplasmic tails have tissue specific functions during development. Here, we present evidence showing the cytoplasmic tails of α integrins *ina-1* and *pat-2* have a cell type dependent ability to bypass signaling from members of the Rho family of GTPases.

P2310**Board Number: B941****Role of shootin1 during embryonic development in zebrafish.**A. Urasaki¹, T. Matsui¹, K. Kawakami², Y. Bessho¹, N. Inagaki³;¹Bioscience, Nara Institute of Science and Technology, Nara, Japan, ²National Institute of Genetics, Mishima, Japan, ³Grad. Sch. Bio. Sci., Nara Institute of Science and Technology, Ikoma, Japan

Axon outgrowth is essential for the formation of neuronal networks. Shootin1 was identified as a protein involved in the polarization of primary cultured hippocampal neurons. Shootin1 functions as a linker “clutch” molecule that couples treadmilling F-actin and the adhesive substrate at the growth cones to promote axon outgrowth. However, little is known about the *in vivo* functions of *shootin1*. Here we identified three shootin family members (*shootin1*, *shootin2* and *shootin3*) in the zebrafish genome and analyzed the functions of *shootin1* in zebrafish. Zebrafish is widely used to study vertebrate development. Their external fertilization, rapid development and optical clarity make them well-suited for studying important cellular processes during embryonic development such as cell proliferation, migration and rearrangement. To see whether *shootin1* is expressed in zebrafish embryos, we performed whole-mount *in situ* hybridization. *shootin1* was expressed in the ventral forebrain and eyes. Next, to understand whether *shootin1* is required for forebrain and eye formation, we performed knockdown experiments. The *shootin1* knockdown embryos exhibited defects in the forebrain and eyes. Our data suggest that *shootin1* is involved in the forebrain and eye formation. Furthermore, *shootin1* was also expressed in the posterior lateral line primordia, thereby suggesting that *shootin1* may be

involved in collective cell migration of these cells. To confirm these possibilities, we are currently generating the *shootin1* mutant by using the CRISPR system in zebrafish.

RNA-binding proteins regulate dendrite morphogenesis in *C. elegans*.

S. Antonacci¹, D. Forand², E.C. Olesnicky², D.J. Killian¹;

¹Molecular Biology, Colorado College, Colorado Springs, CO, ²Biology, University of Colorado Colorado Springs, Colorado Springs, CO

Neurons are polarized cells with complex morphology that enables processing and transmission of information to and from the neural network and surrounding environment. The growth and maintenance of neuronal processes such as dendrites are key to establishing sensory fields and the synaptic connections that control cognition, behavior, and adaptive responses to the environment. A growing body of evidence highlights mRNA transport and local translational control as key processes in generating dendritic branches, maintaining cell structure, and promoting synaptic plasticity. Therefore it is important to investigate the role of RNA-binding proteins (RBPs), which are involved in mRNA processing, transport, localization, stability, and translational control, in the regulation of dendrite form and function.

To determine the extent to which RNA-binding proteins influence dendrite morphology, Olesnicky et al. (2014) conducted a genetic screen of all RBP-encoding genes in the *Drosophila* genome and found 63 RBPs required for normal dendrite morphology in dendritic arborization (*da*) sensory neurons. An *in silico* analysis showed a high sequence-similarity among diverse species for the RBPs that affect *da* dendrite structure in *Drosophila*, including 54 homologous genes in *C. elegans*. This suggests that conserved RBPs may regulate dendrite morphology in diverse animal species. To test this hypothesis we screened these 54 RBP-encoding genes in *C. elegans* for dendrite defects using the multidendritic PVD sensory neuron as a model.

Using a combination of mutant alleles and RNA interference, our screen identified 12 conserved RBP-encoding genes that produce a reduction in the number of dendritic termini upon loss or reduction of gene function. To determine if the reduction of dendritic termini is caused by a failure to form branches, a delay in formation, or a loss of initially established branches, we performed a time-course analysis. Our results suggest that most RBPs are required for dendritic branch formation but two are required for branch maintenance and one influences the timing of branch formation. Reporter transgenes confirm that candidate genes are actively transcribed in the PVD neuron and RBP::GFP fusion proteins were used to determine the subcellular localization of each RBP. Subcellular localization and gene ontology information suggest that nuclear RBPs are involved in mRNA processing such as splicing and that cytoplasmic RBPs are likely involved in mRNA transport and translational regulation. Taken together, our results highlight a fundamental role for RBPs in dendrite morphogenesis, and suggest that these

evolutionarily conserved RBPs participate in molecular mechanisms that contribute to neurite development and maintenance in diverse animal species

Role of BMP signaling in adult tissue homeostasis.

P. Nigam¹, P. Parashar¹, A. Nag¹, A. Bandyopadhyaya¹;

¹Biological Sciences Bioengineering, Indian Institute of Technology, Kanpur, India

Background & Aim: Bone morphogenetic protein (BMP) signaling, in co-ordination with other signaling pathways control key events in organogenesis. Though BMP signaling pathway has primarily been investigated for its role during embryonic development, the identification of *Bmpr1a* and *Smad4* mutations in patients with Juvenile Polyposis Syndrome (JPS), suggests that BMP signaling may be an important regulator of adult tissue homeostasis as well. Here we report our initial observation following depleting Bmp2 and Bmp4 proteins specifically in adult mice which suggests that BMP signaling is required for adult tissue homeostasis.

Methods: We have created a conditional *Bmp2/4* double knockout mouse mutant (genotype - *Bmp2^{fl/fl}; Bmp4^{fl/fl}; ROSA26::CreER-T2*). Eight weeks old control and test mice were administered tamoxifen for seven consecutive days.

Results: Fifteen days after initiating tamoxifen injection we observed signs of mild diarrhea in these mutant mice. Molecular and histological analyses of BMP signaling depleted intestine suggests that BMP loss triggers activation of Wnt signaling in intestinal stem cell niche (crypt) resulting in remarkable increase in cell proliferation. The resultant crypt-villus morphology (ectopic, misplaced & elongated crypts with short villi), following Bmp depletion, resembles conditions similar to JPS. Loss of BMP signaling also resulted in improper nuclear positioning which is suggestive of loss of the baso-apical enterocyte polarity. Bmp ablation also causes detachment of enterocytes from the basal lamina of the villi. In our study, Bmp depletion is also associated with impaired terminal differentiation of cells from secretory lineage. This perturbation of the normal process of tissue homeostasis causes apoptosis of the cells. Interestingly, these mutant mice also exhibited hair fall following Bmp depletion. The molecular changes observed in mutant follicles is reminiscent of the changes observed in the intestine. Taken together, our results suggest that BMP signaling is an important regulator of epithelial tissue homeostasis in adult animals.

Conclusion: We strongly suggests that BMP signaling have a major regulatory role in the homeostasis of an adult epithelial tissue and a better understanding of all of this will help to utilize novel therapeutic strategies to treat conditions like intestinal polyps and cancers.

P2313**Board Number: B944****Discovery of CEP1410, a small molecule inducer that promote proliferation of pancreatic beta cells using novel micro-3D histo-culture assay procedure.**S. Satish¹, C.R. Sharma^{1,2}, J.M. Harris¹, R.R. Rodriguez¹, M.R. Sharma¹, M.B. Navel¹, N. Amezcua¹, J.R. Martinez¹, J. Jani¹, J.P. Sharma¹;¹Stem Cell Biology, Celprogen Inc, Torrance, CA, ²Celprogen Inc., Torrance, CA

Identification of novel small molecule inducers that promote proliferation of pancreatic beta-cell is an important approach to treat diabetes. This unique approach represents a potential regeneration strategy for the treatment of type 1 diabetes. Unfortunately, the lack of availability of suitable human beta cell lines makes such a discovery a challenge. Here, we adapted and successfully developed the human islets micro-3D histo-cultures for high-throughput cell based assays. This micro-3D histo-culture system of culturing human islet for high-throughput screening utilizing a thymidine analog, EdU, to detect beta-cell replication during screening. This culture system allows simultaneous monitoring of Ki67, EdU incorporation and beta cell numbers provides robust assay for beta-cell replication. Importantly, this micro-3D histo-culture system preserved the beta-cell physiological function, as measured by glucose-stimulated insulin secretion. We then performed a pilot screen of 384 compounds, observing some phenotypic effects on cells. This high-throughput human islet cell culture method can be used to assess various aspects of beta-cell biology on a relatively large number of compounds. From this screen we were able to characterize 10 lead compounds CEP1410,1412,1413,1414,1415,1416,1417,1418,1419 and 1420 that were able to increase beta cells mass and responded to glucose –stimulated insulin secretion. CEP1410, our lead compound was tested in-vivo. In diabetic rat model, once a day oral administration of CEP1410 increased the mass of Beta cells. . The gene expression profile of pancreatic Beta-cells revealed high gene expression of Insulin, glucagon, somatostatin, Glut-2 and Isl-1 on Day 20 when study was terminated.

Germ Cells, Gameogenesis, and Fertilization**P2314****Board Number: B945****ISOLATION, CHARACTERIZATION, AND GENE EXPRESSION PROFILE OF RAT EPIDIDYMAL BASAL CELLS.**M. Mandon¹, L. Hermo², D.G. Cyr¹;¹INRS-Institut Armand-Frappier, Laval, QC, ²McGill University, Montreal, QC

Epididymal basal cells are localized to the basal compartment of the epithelium. These cells have thin processes that extend along the base of the epithelium and that can also extend apically and reach the lumen of the epididymis. There is little information on the function and role of epididymal basal cells.

Various studies have suggested that these may be stem cells, be part of the immune system, regulate other epithelial cells via the production of hormones and secondary messengers, and may be regulators of the tight junctions of the blood-epididymis barrier. The objective of this study was to isolate a relatively pure fraction of epididymal basal cells and characterize their function. Immunolocalization studies indicated that integrin- $\alpha 6$ was specifically localized to basal cells in all regions of the rat epididymis. Epididymides from 42 day old rat, an age when there are no sperm in the epididymis, were enzymatically digested and cells isolated. Using a magnetic microbeads and integrin- $\alpha 6$ antibody, basal cells were isolated. Immunofluorescence using a specific marker of basal cells, cytokeratin 5 (KRT5), revealed a 90% enrichment of basal cells. Flow cytometry performed with another marker of basal cells, cyclooxygenase 1 (Cox1), confirmed this result. Electron microscopy of isolated cells also revealed morphological characteristics of basal cells. Total cellular RNA was isolated from the enriched basal cell fraction and subjected to RT-PCR using specific markers of basal cells, principle cells, dendritic cells, and clear cells. Microarray analysis indicated the basal cell fraction contained 1359 differentially expressed genes relative to other epididymal epithelial cells. Among the differentially expressed genes, numerous integrins and proto-oncogenes were expressed in the epididymis. Furthermore, the tight junction protein, claudin1, highly expressed as were connexin 43, 31.1, 30.3 and P-cadherin. Pathways analysis predicted the expression of several intracellular signaling pathways including those implicated in EGFR signaling, integrin signaling, molecular mechanisms of cancer, inflammatory response and canonical WNT signaling. These studies provide novel information on function of the epididymal basal cells and their role in the regulation of the blood-epididymis barrier. Supported by CIHR and FQRNT.

Polyglucosan Molecules Induce Testis Degeneration And Apoptosis In Germ Cells Without Affecting The Integrity And Functionality Of Sertoli Cells.

F. Villarroel-Espíndola¹, I.I. Concha¹, J. Slebe², J.J. Guinovart^{3,4};

¹Bioquímica y Microbiología, Universidad Austral de Chile, Valdivia, Chile, ²Bioquímica y Microbiología, Universidad Austral De Chile, Valdivia, Chile, ³Institute for Research in Biomedicine (IRB Barcelona), Barcelona, Spain, ⁴University of Barcelona, Barcelona, Spain

Glycogen is the main storage form of glucose for most tissues; however, the accumulation of aberrant polyglucosan molecules can lead to degeneration and death in some cell types. Previously, we reported that the accumulation of glycogen in testis of transgenic animals overexpressing a constitutively active form of glycogen synthase (KIN-GS) enhances the apoptosis of premeiotic cells in seminiferous tubules. Similarly, the activation of endogenous glycogen synthase (GS) in a germ cell line (GC-1) stimulates the deposition of glycogen and triggers the activation of caspase 3. Here we sought to further identify the effects of glycogen storage in GC-1 and Sertoli cells (42GPA9 cell line) and the mechanism behind the pro-apoptotic activity induced. By spectrophotometric analysis, we found that glycogen synthesized in both cell lines—by expression of a superactive form of GS or by activation of endogenous GS by PTG (*Protein Targeting to Glycogen*) expression—is poorly branched. In addition, the immunodetection of

cleaved caspase 3/9 suggests that cellular death induced by polyglucosan molecules affects GC-1 but not 42GPA9 cells. The former cells showed changes in intracellular ATP and cytochrome C content after polyglucosan accumulation, thereby suggesting mitochondrial impairment and activation of an intrinsic apoptotic pathway. Furthermore, we analyzed the effects of glycogen deposition during the establishment of an in vitro blood-testis barrier. The results using a non-permeable fluorescent molecule (Evans blue) showed that, in conditions of over-synthesis of glycogen, 42GPA9 cells do not lose their capacity to generate an impermeable barrier. In the same cell line, immunodetection showed that the levels of connexin43 (Cnx43), occludin (Occl), and ZO1 proteins were not affected by glycogen accumulation. Similarly, in the KIN-GS mice, the distribution and intensity of signals for Cnx43, Occl, and ZO1 point to a Sertoli cell-only syndrome in this model, affecting the viability of male germ cells but not the viability or stability of Sertoli cells, as shown by confocal microscopy analysis. These results confirm that the accumulation of polyglucosan molecules has a selective effect—triggered by the intrinsic activation of the apoptotic pathway—in germ cells. UNDERSTANDING THE REGULATION OF CONNEXIN 26 IN THE EPIDIDYMIS.

C. Adam¹, D.G. Cyr¹;

¹INRS-Institut Armand-Frappier, Laval, QC

Connexins (Cxs) are proteins that form gap junctions allowing neighboring cells to communicate by the diffusion of ions and small molecules (<1 kDa). Our laboratory has previously reported that Cx30.3, 31.1 and 32 are expressed in adult rat epididymis, whereas Cx26 is expressed in young animal when the epithelium is undifferentiated; suggesting a role for Cx26 in the differentiation of the epididymal epithelium. The regulation of the *Cx26* gene in the epididymis is unknown. The present objective was to elucidate the mechanisms regulating the *Cx26* gene in the epididymis through the characterization of its promoter. RLM-RACE revealed a single major transcription start site (tss) for *Cx26* at position -3829 relative to the ATG. Computational analysis revealed several AP2 and SP1 binding sites located 5' to the tss. A 1.7kb fragment of the *Cx26* promoter was amplified and cloned into a PGL3 vector containing a luciferase reporter gene. Transfection of the construct in epididymal RCE cells indicated that the promoter fragment could drive the expression of the reporter gene. Several constructs were generated by sequence deletions of the promoter and transfected into RCE cells. The luciferase assays revealed the presence of two binding response elements necessary for the expression of *Cx26*: an AP2/SP1 site and an SP1 site. The implication of those two sites was confirmed by directed mutagenesis. ChIP analysis confirmed that these factors bind to the DNA in vivo. ChIP analysis of DNA from young and pubertal animals indicated that binding of the AP2 and SP1 decreases as a function of age when *Cx26* mRNA levels decrease. DNA methylation studies were undertaken to determine whether or not changes in the methylation of the promoter might explain the decrease in AP2 and SP1 binding. The *Rhox5* promoter was used as a positive control. Results indicated that there were no changes in DNA methylation in the

promoter of young versus pubertal animals. These results indicate that the transactivation of the *Cx26* gene is regulated by AP2 and SP1 sites. The decrease in *Cx26* mRNA levels previously reported is correlated with a decrease in AP2 and SP1 binding to the promoter and this is not the result of changes in DNA methylation. Supported by NSERC.

A Point Mutation in Nonmuscle Myosin II-A Disrupts Mouse Spermatogenesis.

C.B. Lerma Cervantes¹, K. Tokuhira², Y. Zhang¹, M. Conti¹, D.H. Bae³, M. Daniels³, J. Dean², R.S. Adelstein¹;

¹Laboratory of Molecular Cardiology, Genetics and Developmental Biology Center, NHLBI/NIH, Bethesda, MD, ²Laboratory of Cellular and Developmental Biology, NIDDK/NIH, Bethesda, MD, ³Electron Microscopy Core, NHLBI/NIH, Bethesda, MD

Nonmuscle myosin II-A (NM II-A) is a major cytoskeletal protein that is composed of a pair of heavy chains (230 kDa, encoded by the *Myh9* gene in mice) and 2 pairs of light chains (20 kDa and 17kDa). It is ubiquitously expressed in humans and mice, and contributes to cellular processes including cell migration, cell adhesion, and cytokinesis. Humans with mutations in NM II-A have defects in platelets, and develop glomerulosclerosis, cataracts and deafness. We have generated a mouse line with a mutation frequently found in human MYH9 related disease, E1841K. In addition to modeling the above defects, male, but not female, mice homozygous for the mutation are sterile. The male mice demonstrate severe defects in sperm development. Histological analyses of homozygous testis reveal that spermatocytes arrest at the elongated spermatid stage and aberrant spermatids slough off into the lumen. Some seminiferous tubules contain vacuoles, have a large lumen and often lack germ cells, while others appear normal but completely fail to develop a lumen. Electron micrographs uncover an abnormal flattening and extension of the acrosomal vesicle, which appears to lead to the abnormal elongation of spermatids. TUNEL assays of homozygous testis show an increase in apoptotic germ cells when compared to wild type. Caudal epididymis sections have only a few malformed spermatozoa that are rarely motile. Heterozygous mice show similar, albeit less severe, defects and are fertile. Sperm counts obtained from the caudal epididymis confirm a pronounced decrease in mature sperm in homozygous mice, while the heterozygous mice show a modest decrease when compared to wild type. Collectively, these observations suggest a previously unknown, critical role for NM II-A in spermatogenesis and male fertility.

P2318**Board Number: B949****CACN-1, which interacts with the *Caenorhabditis elegans* spliceosome, is an important regulator of germline differentiation.**A.D. Cecchetelli¹, E.J. Cram¹;¹Biology, Northeastern University, Boston, MA

With its easily visible U-shaped gonad arm, *Caenorhabditis elegans* provides an excellent model to study germline stem cell differentiation and development. *C. elegans* produce sperm until the onset of adulthood, when the worm permanently switches to producing oocytes. *cacn-1*, a conserved gene originally identified as a key regulator of cell migration, also plays an important role in this sperm to oocyte switch. Depletion of *cacn-1* leads to a masculinization of the germline and/or abnormal oocytes in addition to sperm. DAPI staining revealed that *cacn-1* loss also causes endomitotically duplicating oocytes (EMO) in a significant number of gonad arms with abnormal oocytes. Previously, the lab has identified CACN-1 interacting proteins using an *in vivo* tandem-affinity purification (TAP) protocol. CACN-1 complexes were isolated and identified by mass spectrometry and characterized using bioinformatics. CACN-1 interactors grouped into a novel network suggesting that CACN-1 interacts with the *C. elegans* spliceosome. All the identified interactors were screened for germline defects using RNA interference (RNAi). Many of these interactors caused severe germline defects when depleted in wild type animals. Phenotypes included abnormal oocytes as well as a masculinization of the germline similar to *cacn-1* deficient animals. DAPI staining revealed that a majority of these proteins also cause the EMO phenotype when depleted. The results of this screen reveal that CACN-1 and interacting proteins are important in proper germline stem cell differentiation and development and that CACN-1 may be involved in pre-mRNA splicing or post-transcriptional regulation to mediate these decisions. Understanding the role of CACN-1 and its interactors in germline differentiation may lead us to a better understanding of the role of post-transcriptional regulation in stem cell differentiation.

P2319**Board Number: B1000****Identifying new players in meiosis using *C. elegans* depleted of the meiotic inhibitory kinase WEE-1.3.**A.K. Allen¹, R. Boateng¹, J. Nesmith², A. Golden²;¹Department of Biology, Howard University, Washington, DC, ²NIDDK/NIH, Bethesda, MD

Meiosis is the specialized cell cycle by which the haploid gametes, oocytes and sperm, are produced. Errors in meiosis can result in serious issues such as infertility, birth defects or tumorigenesis. Meiosis is controlled via dueling regulatory phosphorylation events on the cyclin-dependent kinase (Cdk) component of maturation promoting factor (MPF). The highly conserved Wee1/Myt1 family of kinases places inhibitory phosphorylations on Cdk that are necessary to keep MPF inactive and thus regulate the

progression of meiosis. Despite many years of study, in multiple animal systems, our understanding of meiosis is still incomplete. The studies described here in *Caenorhabditis elegans* are aimed to increase our knowledge regarding players in the meiotic pathway.

In *C. elegans* it was previously shown that depletion of the Myt1 ortholog, WEE-1.3, results in precocious oocyte maturation and infertility (Burrows *et al.*, 2006). We further characterized the precocious oocyte maturation phenotype observed upon WEE-1.3 depletion to better grasp why the oocytes are fertilization-incompetent. We will demonstrate here that WEE-1.3-depleted proximal germlines have begun to transcribe embryonic genes and the precocious oocytes inappropriately express proteins in patterns normally found in embryos. Secondly, we performed an RNA interference (RNAi) suppressor screen of the infertility phenotype exhibited upon WEE-1.3 depletion to identify new players involved in the meiotic pathway. We found 44 genes, that when co-depleted along with WEE-1.3, restore fertility to the animals. Many of these genes previously had no known role in reproduction or meiosis. Finally, we will report on the initial studies being conducted on one specific suppressor, ETR-1. ETR-1 is an RNA-binding protein that was previously characterized as being muscle-specific in the worm (Milne and Hodgkin, 1999). However, homologs in other organisms, including humans, have reproductive roles and mutations in some of the homologs have been linked to fertilization defects. Our data indicates a novel role for ETR-1 in the somatic gonad that ultimately influences oocyte maturation. We are actively investigating the mechanism by which depletion of ETR-1 suppresses WEE-1.3 depletion.

As our studies of ETR-1 are alluding to, many of the genes identified in the RNAi suppression screen have the potential to be unidentified players in both the meiotic and mitotic cell cycles. Thus these studies are providing valuable input into how the cell cycle is appropriately regulated.

A role for dynein light chain in germline stem cell maintenance in *C. elegans*.

X. Wang¹, D. Rasoloson², E. Voronina³;

¹DBS, Univ Montana, Missoula, MT, ²MBG, Johns Hopkins University School of Medicine/HHMI, Baltimore, MD, ³Univ Montana, Missoula, MT

PUF family RNA binding proteins are conserved stem cell regulators in *Drosophila* and planaria (Lin and Spradling, 1997; Salvetti *et al.*, 2005). FBF-1 and FBF-2, two similar PUF family translational repressors, are required for maintenance of germline stem cell in *C. elegans* (Crittenden *et al.*, 2002). Here we report identification of dynein light chain DLC-1 as a specific cofactor of FBF-2, but not FBF-1. In germline stem cells, FBF-2 localizes to perinuclear germ granules or P granules in *C. elegans* (Voronina *et al.*, 2012). This localization is important for FBF-2 binding to target mRNAs and its activity as a translational repressor. By contrast, FBF-1 does not localize to P granules, and its function does not depend on P granule integrity. The goal of this study was to investigate mechanisms of FBF-2 localization to P granules. DLC-1 is an LC8-type light chain, a cargo-binding component of dynein motor complex. Dynein traffics organelles, proteins, and mRNAs toward the minus ends of microtubules. Knock-down of *dlc-1* by

RNAi correlates with loss of FBF-2 perinuclear accumulation even when perinuclear P granules are not affected and also causes a decrease in FBF-2 activity as a translational repressor. By contrast, FBF-1 localization is not affected by *dlc-1* knock-down, and FBF-1 remains able to regulate its targets. In vivo, FBF-2 is found in a complex with DLC-1 by co-immunoprecipitation. In the in vitro pulldown assay, DLC-1 interacts with FBF-2, but not FBF-1, suggesting that specificity of DLC-1 contribution to FBF-2 function is based on selectivity of protein-protein interactions. Interaction between DLC-1 and FBF-2 depends on the regions of sequence divergence between FBF-2 and FBF-1.

We hypothesize that DLC-1 binds FBF-2 and promotes its localization to P granules, which is important for FBF-2-mediated translational regulation and germline stem cell maintenance. Dynein motor complex has been implicated in formation, transport, and dynamics of RNA granules in several cell types. Our findings suggest that LC8-type light chains such as DLC-1 may directly regulate recruitment of specific components to the RNA granules in stem cells.

Board Number: B1002

A novel function for CDK--11 in fertilization and fecundity in *C. elegans*.

C. Williams¹, Y. Liu¹, K.F. O'Connell¹;

¹Laboratory of Biochemistry and Genetics, National Institutes of Health (NIDDK), Bethesda, MD

Functional germ lines produce gametes that are capable of producing viable offspring. When gamete development is disrupted, a reduction in fecundity may occur, with sterility being a potential outcome. The *C. elegans* hermaphrodite produces both oocytes and sperm and is capable of self-fertilization. In the worm, fertility is dependent on the interdependent functioning of the germ line tissue and the surrounding somatic cells (sheath cells). CDK-11 is a conserved kinase with established roles in transcription, centrosome duplication, microtubule nucleation, and apoptosis. *C. elegans* possesses two *cdk-11* genes, (*cdk-11.1* and *cdk-11.2*) and mutation in either produces a significant reduction in brood size. The mutation of *cdk-11.1*, causes gross morphological defects of both the oocytes and sperm in hermaphrodites, whereas *cdk-11.2* mutant hermaphrodites have normal gamete morphology. Transcriptional and translational reporter constructs demonstrate that both *cdk-11* homologs are expressed throughout the entire germ line and also in the sheath cells. However, localization of endogenous CDK-11.2 is found primarily in the meiotic cells of the germ line and in the nuclei of the sheath cells. Although mutant CDK-11.2 is expressed, CDK-11.2 fails to localize normally in the germ line. In addition to gamete defects, CDK-11 mutants also show a reduction in laying rates when compared to wild type worms. In summary, our data suggests that CDK-11 is required for the later stages of gamete production and possibly also plays a role in ovulation.

P2322**Board Number: B1003****A protein complex directs assembly of the vitelline layer of the *C. elegans* eggshell.**D. Partida¹, Z. Wilson¹, H. Lamb¹, S. Olson¹;¹Biology, Pomona College, Claremont, CA

Fertilization triggers rapid remodeling of the zygote surface to create an extracellular barrier that protects the developing embryo and prevents polyspermic fertilization. In nematodes, this barrier is a multi-layered eggshell that assembles in a hierarchical manner. The outermost layer of the eggshell is called the vitelline layer, which is present on the oocyte before fertilization. Immediately following fertilization, the vitelline layer lifts off the oocyte surface and provides a first line of defense. Despite its importance, little is known about the composition of the vitelline layer or how it is remodeled to form the outermost eggshell layer. A previous RNAi screen in the nematode *C. elegans* identified PERM-2 and PERM-4 as proteins required for eggshell formation. PERM-2 and PERM-4 were found to localize to the vitelline layer and were co-dependent for proper localization. PERM-2 and PERM-4 localization also depended on CBD-1, a protein required to stabilize a complex involved in the oocyte-to-embryo transition. The eggshell still forms when PERM-2/4 are depleted, but the shell is more porous as measured by loss of a soluble protein that normally resides in the perivitelline space.

P2323**Board Number: B1004****The small GTPase Arf6 is essential for sea urchin embryogenesis.**P. Ahiakonu¹, J.L. Song¹, K. Landis,¹ M. Dumas¹;¹Biological Sciences, University of Delaware, Newark, DE

Department of Biological Sciences, Newark, DE 19716 Arf6 is a small GTPase that acts as a molecular switch, cycling between the plasma membrane in its active GTP bound form and endosomal compartments in its inactive GDP bound form. While a rich knowledge exists in the cellular functions of Arf6, relatively little is known about its physiological role in development. This study examines the function of Arf6 in early development using the purple sea urchin as a model. We found that perturbation of Arf6 in the form of its knockdown, the constitutively activated GTPase defective Arf6 mutant Arf6 (Q67L), and the dominant active Arf6 mutant Arf6 (T27N), resulted in severe gastrulation defects. We tested perturbation of Arf6 during gastrulation by examining its effect in regulating three main types of cells that undergo critical cell movement during gastrulation: endodermal cells that undergo morphogenesis to form the larval gut, primary mesenchyme cells (PMCs) that undergo migration to give rise to the larval skeleton, and pigment cells that are highly motile to engulf potential pathogens. Arf6 knockdown led to a range of dose-dependent severity of developmental defects including a delay in development, vegetal cell attachment, and exogastrulation. Results indicate that Arf6 perturbed embryos have defective larval gut, aberrant PMC patterning and skeletal structures, and

pigment cell morphological changes. Overall our results demonstrate that Arf6 is essential for proper morphogenic and cell movements of endodermally and mesodermally-derived cell types during early development.

The role of the TORC1 regulator IML1 in meiotic progression and the response to cellular stress.

B. Reveal¹, M. Lilly¹;

¹NICHD, NIH, Bethesda, MD

Under conditions of nutrient stress, yeast cells enter the meiotic cycle and begin sporulation. Target of Rapamycin Complex 1 (TORC1) is a central regulator of growth and metabolism, and its activity needs to be down regulated for yeast to sporulate, linking TORC1 activity to progression into meiosis. In metazoans, it is poorly understood how metabolic inputs influence meiotic progression and gametogenesis. The IML1/GATOR1 protein complex has been shown to down regulate TORC1 activity in times of nutrient stress, and we find that knocking down IML1 expression in the *Drosophila melanogaster* germline delays the oocyte's entry into meiosis suggesting TORC1 needs to be inhibited for meiotic entry during *Drosophila* oogenesis. Conversely, the SEA/GATOR2 complex components Mio and Seh1 are required to oppose the TORC1 inhibitory activity of the GATOR1 components Nprl2 and Nprl3 in the female germline but are not required for the development and/or growth of many somatic cell types. Our data support the model that the central importance of the SEA/GATOR complex in the regulation of TORC1 activity during gametogenesis has been conserved from single celled organisms to multicellular eukaryotes.

Identification of a receptor pair in the gamete membrane adhesion step during cell-cell fusion in *Chlamydomonas*.

Y. Liu¹, W.J. Snell¹;

¹Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX

Gamete fusion during fertilization is essential to produce a new organism, yet the molecular mechanisms of the gamete membrane fusion reaction are poorly understood. HAP2, a single pass transmembrane protein, is the only broadly conserved protein known to be essential during fertilization in protists, alga, higher plants and several multicellular animals. Previously, we established that 1) the membrane protein FUS1 on plus gametes is essential for membrane adhesion during the membrane fusion reaction between plus and minus *Chlamydomonas* gametes and 2) that HAP2 in minus gametes is essential for membrane merger per se after species-specific membrane adhesion. Here, we report

identification of a membrane adhesion receptor on minus gametes (MAR1) that binds to FUS1. MAR1-FLAG forms a complex with FUS1-HA in mixtures of lysates of MAR1-FLAG minus gametes and FUS1-HA plus gametes. RNA-Seq shows that MAR1 transcripts are specifically expressed in minus gametes and substantially upregulated during gamete activation, consistent with anti-MAR1-FLAG immunoblotting results. MAR1 specifically localizes to the apical membrane patch on minus gametes specialized for membrane fusion. Preliminary knockdown experiments indicate that MAR1 is essential for membrane adhesion. To our surprise, MAR1 also binds to HAP2 in minus gametes, indicating that proteins required for membrane adhesion interact with the protein required for membrane fusion. The discovery of the MAR1-FUS1 receptor pair along with knowledge that HAP2 is essential for membrane fusion now takes Chlamydomonas to the forefront of our understanding of the molecules required for eukaryotic fertilization. This work was supported by NIH GM56778.

Board Number: B1007

The Drosophila SEA/GATOR complex controls meiotic progression and the response to amino acid starvation by modulating TORC1 activity.

Y. Wei¹, M. Lilly²;

¹NIH/NICHD, Rockville, MD, ²NICHD, NIH, Bethesda, MD

In single-celled eukaryotes, the pathways that monitor nutrient availability are central to regulating the meiotic program and spore development. However, how metabolic inputs influence meiotic progression and gametogenesis remains poorly understood in metazoans. Here we define opposing functions for the highly conserved SEA/GATOR complex members Nprl2/Nprl3 and Mio/Seh1 in the regulation of TORC1, a master regulator of metabolism, during Drosophila oogenesis. We demonstrate that Nprl2/Nprl3 inhibit TORC1 activity in response to amino acid starvation and are critical to oocyte survival during times of protein scarcity. Conversely, Mio/Seh1 positively regulate TORC1 and oppose the activity of Nprl2/Nprl3. Independent of nutrient status, in mio and seh1 mutants the constitutive inhibition of TORC1 in the female germline results in the activation of autophagy and a block to oocyte growth and development. In contrast, mio and seh1 have minimal effects on the growth and development of somatic tissues. Thus, in Drosophila the requirement for the TORC1 activating components of the SEA/GATOR complex is tissue specific. Our data support the model that the central importance of the SEA/GATOR complex in the response to amino acid starvation and the regulation of TORC1 activity during gametogenesis have been conserved from single celled to multicellular eukaryotes.

P2327**Board Number: B1008****Orb and Wispy cooperate in the cytoplasmic polyadenylation of gurken (*grk*) mRNA during *Drosophila* oogenesis.**K. Randolph¹, L. Thompson¹, A. Norvell¹;¹Biology, Coll New Jersey, Ewing, NJ

During *Drosophila* oogenesis, the TGF- α like protein Gurken (Grk) is required for establishing both of the major axes of the egg and future embryo. Consequently, Grk protein distribution within the ovary is tightly regulated, both temporally and spatially. It is well established that Grk protein distribution in the oocyte is regulated by a combination of the localization of the *grk* transcript and regulation of *grk* mRNA translation. While it is clear that *grk* translation is both repressed, when the mRNA is not properly localized and activated, once the transcript has reached its destination in the dorsal anterior corner of the oocyte, the molecular mechanism(s) of *grk* mRNA translational control have not yet been fully elucidated. Modulating polyA tail length is one mechanism for regulating translation of other mRNAs and is accomplished through cytoplasmic deadenylation and polyadenylation of transcripts. We have therefore investigated whether translational control of *grk* RNA is achieved through alterations in polyA tail length. Genetic evidence has shown that the cytoplasmic polyadenylation element binding (CPEB) protein Orb is required for appropriate Grk protein accumulation, suggesting that cytoplasmic polyadenylation of *grk* mRNA may have a role in its translational activation. Using a PCR-based polyadenylation assay, we have analyzed *grk* transcript polyadenylation status directly. We have found that *grk* polyA tail length is indeed shorter in transcripts isolated from *orb* mutant females. Additionally, females carrying mutations in *wispy* (*wisp*), a GLD-2 polyA polymerase lay eggs with slight patterning defects that are consistent with suboptimal levels of Grk protein at the D/A corner of the oocyte. *grk* mRNA is also underadenylated in ovaries from *wisp* mutant mothers. Finally, mutations in *wisp* enhance the ventralizing effects of a dominant negative *orb* allele, suggesting that Orb and Wisp function together in the cytoplasmic polyadenylation of *grk* mRNA once it has reached the dorsal anterior corner of the oocyte. Our current efforts are aimed at assessing whether the translational repression of unlocalized *grk* mRNA is also achieved through regulated deadenylation-adenylation. Initial experiments indicate that translationally repressed *grk* transcripts, for example in *spnF* oocytes or associated with the RNA-binding protein Squid (Sqd), are underadenylated. These findings suggest that regulation of Grk protein accumulation is, in part, achieved through polyA tail length alterations.

P2329**Board Number: B1010****Significance of testis specific PP1 γ 2 and its stoichiometric requirement for mammalian male reproduction.**T. Dudiki¹, S. Sen², N. Sinha², D.W. Kline², S. Vijayaraghavan²;¹Biomedical Sciences, Kent State University, Kent, OH, ²Biological Sciences, Kent State University, Kent, OH

Serine/threonine phosphatase family constitutes PP1, PP2A, PP2B and PP2C. PP1 has four isoforms PP1 α , PP1 β , PP1 γ 1 and PP1 γ 2 encoded by three genes. The isoforms PP1 γ 1 and PP1 γ 2 are splice variants of *Ppp1cc* gene, which is comprised of 8 exons. PP1 γ 2 arises due to splicing of intron 7 that is retained in PP1 γ 1. These two isoforms are identical except for the 22 amino acid C-terminus tail of PP1 γ 2 encoded by exon 8. While PP1 γ 1 is ubiquitous in somatic cells including Sertoli cells of testis, it is absent in developing male germ cells and spermatozoa. PP1 γ 2 is expressed at high levels exclusively in developing male germ cells of mammals. Non-mammalian spermatozoa may contain PP1 α or PP1 γ 1. The only phenotype observed in *Ppp1cc* knockout mice is male sterility due to impaired spermiogenesis. Mice with one allele of *Ppp1cc* gene (*Ppp1cc* +/-) however showed only a 28% decrease in PP1 γ 2 protein levels with no effect on sperm function or fertility indicating a dosage compensation or feedback mechanism regulating the levels of PP1 γ 2 in testis. Recent transgenic rescue studies in our laboratory support this hypothesis by showing a threshold level requirement of PP1 γ 2 to restore spermatogenesis and fertility in *Ppp1cc* null mice (PLoS One. 2012; 7(10): e47623). To study the effects of PP1 γ 2 over expression, we generated mice homozygous for the testis specific PP1 γ 2 transgene over wild type (*Ppp1cc* +/+) but observed no phenotype. Molecular analysis revealed additive levels of PP1 γ 2 mRNA without increase in protein levels. This indicates that PP1 γ 2 enzyme levels are tightly regulated and it's over expression could be unfavorable for normal functioning of testis or spermatozoa. However we could successfully express PP1 γ 1 in addition to PP1 γ 2 in developing germ cells by incorporation of testis specific PP1 γ 1 transgene (PP1 γ 1 cDNA lacking intron 7) in *Ppp1cc* +/+ or *Ppp1cc* +/- mice. PP1 γ 1 was also observed in sperm along with PP1 γ 2 but by displacing a portion of PP1 γ 2. The resulting phenotype was reduced male fertility and altered sperm motility characterized by decreased flagellar beat and reduced velocity. The results so far indicate two possible mechanisms regulating the PP1 γ protein levels in male germ cells: 1) expression of PP1 γ 2 by elimination of PP1 γ 1 via splicing and miRNA mediated degradation and 2) a translational regulation mechanism to maintain threshold levels of PP1 γ 2. Evolution of PP1 γ 2 and the mechanisms regulating the PP1 expression in testis appear to be essential for reproductive success of mammals. (Supported by R15HD068971)

P2330**Board Number: B1011****Effects of metabolic status caused by maternal obesity and/or high-fat diet intake on steroidogenic capacity of Leydig cells in adult rats.**M.E. Pinto¹, V. Reame², E.Z. Pytlowanciv³, A. Protzek², A. Rafacho⁴, D.L. Ribeiro⁵, S.R. Taboga⁶, R.M. Goes⁷;¹IBILCE/UNESP, S J Rio Preto, Brazil, ²IBILCE/UNESP, São José Do Rio Preto, Brazil, ³Univ Estadual De Campinas (Unicamp), São José Do Rio Preto - SP, Brazil, ⁴Physiological Sciences, Federal University of Santa Catarina, UFS, Florianópolis, Brazil, ⁵Histology, Institute of Biomedical Sciences/ Federal University of Uberlândia- UFU, Uberlândia, Brazil, ⁶Biology, São Paulo State University, IBILCE/UNESP, S J do Rio Preto, Brazil, ⁷Biology, São Paulo State University, IBILCE/UNESP, São José Do Rio Preto, Brazil

This investigation evaluates the effects of metabolic status caused by maternal obesity (MO) and/or high-fat diet (HFD) intake on steroidogenic capacity of Leydig cells (LC) in adult rats. MO was induced in female rats before pregnancy by HFD (20% lipids) for 15 weeks whereas control females received balanced diet (4% lipids). Male offspring resulting from these matings were divided in groups: Control (balanced diet from gestation to adulthood), O1 (MO during gestation), O2 (MO during gestation/lactation), O3 (HFD from weaning to adulthood), O4 (MO during lactation + HFD from weaning to adulthood) and O5 (MO during gestation/lactation + HFD from weaning to adulthood). Animals were euthanized at 18-week-old and biometric, metabolic and hormonal parameters were determined. Testes were evaluated for ultrastructural analysis, immunohistochemistry and western blotting for 17 β -hydroxysteroid dehydrogenase (17 β -HSD) and aromatase. Body weight, adiposity index and serum leptin levels indicate that all groups were obese, except for O1. Three progressive levels of impaired metabolic status were observed: O1 presented insulin resistance, O2 were insulin resistant and obese, and groups O3, O4 and O5 were insulin resistant, obese and diabetic. These three levels of metabolic damage were proportional to the increase of leptin and insulin, and decreased serum and intratesticular levels of testosterone. Moreover, there was a trend of increase of serum estrogen levels in O2, O3 and O4, and a drastic augment in O5, whereas the intratesticular levels decreased in all these groups. A low expression of 17 β -HSD was detected to all obese groups and a slight reduction of aromatase content was observed in all groups, mainly in O5. Testicular ultrastructural analyses revealed that in O3, O4 and O5 presented accumulation of myelin vesicles in the mitochondrial matrix. These figures were generally related to structural disorganization, increased mitochondrial size and signs of degeneration. In conclusion, MO and/or HFD intake reduces the steroidogenic capacity of LC, either by failures in the differentiation of these cells or due to effects of metabolic disorders arising from obesity, regardless the period of testis development. In addition, MO during gestation and lactation is as detrimental to steroidogenic capacity of LC as the exposure to HFD ingested in other stages of development. Financial Support: FAPESP.

P2331**Board Number: B1012****Maternal dazap2 regulates germ granule formation via inhibition of Dynein in zebrafish primordial germ cells.**M.M. Forbes¹, S. Rothhaemel¹, A. Jenny¹, F.L. Marlow^{2,3};¹Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY, ²Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY, ³Dominick P. Purpura Dept of Neuroscience, Albert Einstein College of Medicine, Bronx, NY

Primordial germ cells (PGCs) are the progenitor cells that give rise to the gametes. In some animals the germline is induced by zygotic factors whereas in others, like zebrafish, PGC specification occurs via the inheritance of maternal determinants known as germ plasm. In these animals, the germ plasm is packaged into ribonucleoprotein (RNP) complexes that are localized and protected in the oocyte and later promote the germ cell fate in the embryo. Within the PGCs germ plasm components localize to perinuclear granular-like structures that are analogous to the germ granules of other species. Although zebrafish PGC germ granules have been studied, the maternal factors regulating their assembly and contribution to germ cell development are not known. Here we identified the scaffold protein Dazap2 as a binding partner of Bucky ball, an essential regulator of oocyte polarity and germ plasm assembly. We show that eGFP-Dazap2 protein colocalizes with the germ plasm in primary oocytes and in the PGCs of embryos. We generated dazap2 maternal-effect mutants (Mdazap2) and identified a specific requirement for MDazap2 in germ granule formation in PGCs. Overexpression of eGFP-dazap2 enlarges germ granules of wild-type and rescues germ granule formation in Mdazap2 PGCs. We show that inhibiting Dynein in Mdazap2 mutants restores germ granule formation, revealing a novel role for dazap2 in regulating germ granule formation by a mechanism that involves Dynein inhibition. Taken together our loss of function and stable transgenic studies indicate that maternal Dazap2 colocalizes with the germ plasm in oocytes, likely via interaction with Buc, where it is sequestered until it is necessary to promote germ granule formation in the embryo.

P2332**Board Number: B1013****Effect of a combination of PTEN and PI3K inhibitors on superovulation in A/J mice.**O. Suzuki¹;¹National Institute of Biomedical Innovation, Ibaraki-shi, Japan

[Aim] Strain and individual differences in superovulation constitute a serious problem in mice. My preliminary study reported in ASCB2013 and AALAS2014 meetings suggested that an inhibitor (dipotassium bisperoxo (picolinato) oxovanadate (V), bpV(pic)) of Phosphatase and Tensin Homolog Deleted from Chromosome 10 (PTEN) on the same day for equine chorionic gonadotropin (eCG) and an

inhibitor (LY294002) of Phosphoinositide 3-kinase (PI3K) on the next day for eCG tended to increase the number of ovulated oocytes at superovulation by eCG and human chorionic gonadotropin (hCG). This study tested whether a combination of both PTEN and PI3K inhibitors promotes superovulation by gonadotropins. [Method] Five i.u. of eCG was intraperitoneally injected to 28-day-old A/J female mice. In “control (C)” group, only vehicle, no inhibitors, was given. In “bpV(pic)-only (B)” groups, 2 mg/kg of bpV(pic) dissolved in Ringer’s solution were given on the same day for eCG. In “LY294002-only (L)” group, 0.1 mg/kg of LY294002 dissolved in Ringer’s solution with 5% DMSO were given on the next day of eCG. In “both (BL)” group, both inhibitors were given on their respective days. Ovulation was induced by 5 i.u. of hCG 48 h after eCG injection. The numbers of oocytes ovulated were counted 16 h after hCG injection. After normality and equal variance were confirmed by Shapiro-Wilk and Levene tests, respectively, pairwise multiple comparisons of average numbers of ovulated oocytes between groups were performed by Tukey tests. [Results] The average numbers of oocytes collected were 7.8 ± 3.0^a , 22.8 ± 3.2^a , 10.2 ± 3.7^{bc} , and 15.0 ± 1.7^{ac} (mean \pm SEM) in groups C, B, L and BL, respectively (n=5 in C, B, and L; n=6 in BL). Values with different superscripts are significantly different ($p < 0.05$). Significantly more oocytes were collected in bpV(pic)-only group (B) than in control (C). More oocytes tended to be collected in LY294002-only group (L) than in control (C), but LY294002 suppressed the beneficial effect of bpV(pic) on superovulation when both bpV(pic) and LY294002 were administered (group BY). [Discussion] This new method using both PTEN inhibitors and gonadotropins is effective for improving superovulation efficiency, although the optimal method to modulate PI3K signaling pathway in the mouse ovary (e.g., use of PI3K inhibitors) should be determined. Maternal protein restriction may cause changes morphophysiology of the male reproductive organs of offspring and other organs during later life. The androgens are essential to ensure normal development of the male reproductive organs in a phase named of fetal masculinization programming window. This study analyzed the effects of maternal protein restriction during pregnancy and lactation period on development of the rat pups testis. Pregnant rats were divided in two experimental groups (n=10/group): Hypoproteic group fed with hypoproteic diet (6% protein) and control group normal diet (17% protein) and the offspring rats were evaluated at 21 days old. The testes were studied through immunohistochemistry analysis to evaluate the expression of Ki-67. Sections of the testis were stained

immunohistochemically using the avidin-biotin-peroxidase complex method. The body and testis weights were determined. The spermatogonia population positive Ki-67 was counted in 20 seminiferous tubules per rat. None alteration in the numbers of positive Ki-67 spermatogonia was observed. On the other hand, there were reductions of body and testis weights in the hypoproteic group. The seminiferous tubules of control group showed spermatogonia, Sertoli cells and primary spermatocytes organized in concentric layers. In the hypoproteic group, the epithelial cells population showed diffuse organization. In the both groups, part of primary spermatocytes been identified in the lumen of seminiferous tubules, indicating cellular migration. We concluded that maternal protein restriction causes alterations in the organization of seminiferous epithelium of pups weaned. ³Biology of Reproduction, UNIVERSIDAD AUTONOMA METROPOLITANA-I, MEXICO DF, Mexico

Perfluorooctane sulfonate (PFOS) is a persistent and bio-accumulative pollutant ubiquitous in wildlife and humans. Studies have shown that PFOS inhibit Gap Junction Communication (GJC) in somatic cells, and as levels of PFCs are found in human follicular fluid, the aim of the present study was to analyze the effects of PFOS on COCs GJC and the in vitro viability and maturation of pig oocytes. Cumulus-oocyte complexes were cultured in maturation medium supplemented with 0 (control), 12.5, 25 and 50 μM PFOS.

Results show that oocyte viability decreased in PFOS-exposed oocytes in a concentration-dependent manner with a lethal concentration (LC50) of 29.8 μM . Oocyte maturation was also inhibited in a concentration dependent manner with a maturation index (MI50) of 9.9 μM .

Gap junction communication was blocked in COCs exposed to 9.9 μM after 4.5 h. Nevertheless, connexin 45 (Cx45), Cx43 and Cx60 expression was not affected.

These findings show a relevant effect of PFOS on the in vitro viability and maturation of pig oocytes, which might be based on the early blockage of GJC in COCs.

Transmitotic persistence of Wnt pathway activity diversifies gene expression in *C. elegans* embryos.

A. Zacharias¹, T. Walton¹, E. Preston¹, J. Murray^{1,2};

¹Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, ²Penn Genome Frontiers Institute, University of Pennsylvania, Philadelphia, PA

Quantitative differences in signaling pathway activity are a powerful potential mechanism for diversifying cell fates during development. However, few examples of this mechanism have been identified *in vivo*, in part due to the challenges of performing quantitative assays. The objective of this study was to evaluate whether *C. elegans* embryos use quantitative differences Wnt pathway activity to regulate gene expression. The Wnt signaling pathway plays a conserved role during animal development, transcriptionally regulating distinct targets in different stages and cell types (i.e. contexts). This dependence of targets on context could reflect not only interactions with differentially expressed transcription factors, but also context-specific differences in the activity of the Wnt pathway itself. We investigated the role of Wnt pathway activity in target expression by using time-lapse microscopy and automated lineage tracing of *Caenorhabditis elegans* embryos to quantify expression of Wnt ligands, target genes, and nuclear localization of transcriptional effectors *in vivo* at single cell resolution throughout development. We measured the Wnt pathway-dependence of candidate targets and identified over a dozen important developmental regulators as new Wnt targets. We found that most targets require the Wnt-effector transcription factor POP-1/TCF for either activation or repression but not both. Contrary to existing models, we observed that Wnt-mediated transcriptional activation is strongest in cells that received a Wnt signal in two or more consecutive divisions. We found that these repeatedly signaled cells have higher nuclear β -catenin concentrations and are more likely to express targets that require POP-1 for transcriptional activation. Taken together, these results suggest that the persistence of Wnt signaling across mitosis can integrate lineage history and allow Wnt to activate distinct targets in different developmental contexts.

P2336**Board Number: B1017****Actomyosin contractility is required for Notch-mediated patterning of sensory organ precursor cells in the *Drosophila notum*.**G.L. Hunter¹, B. Baum², G. Charras³;¹MRC Laboratory for Molecular Cell Biology, University College London, London, United Kingdom,²Laboratory for Molecular Cell Biology, University College London, London, United Kingdom, ³London Centre for Nanotechnology, University College London, London, United Kingdom

The differentiation of sensory organ precursor (SOP) cells in the *Drosophila notum* epithelium is an excellent model system in which to study long-range lateral inhibition via Notch signaling. Previous research showed that robust, tissue-level organization of SOPs requires a population of basal, actin-based protrusions. **Here, we investigate whether forces generated by the cytoskeleton also play a role in the process of long-range lateral inhibition.** (1) We identify a dynamic pool of non-muscle myosin II heavy chain, together with phosphorylated myosin regulatory light chain, which localizes to the basal cytoskeleton of the notum epithelium. (2) Modulation of myosin II activity via the overexpression of phospho-mimetic or phospho-dead myosin regulatory light chain alters basal protrusion dynamics (e.g., retraction and extension rates) and morphology (e.g., branching and lamellopodia) without affecting their length. (3) Decreased myosin II activity, induced through the expression of dominant negative constructs, (a motor-less heavy chain or a phospho-dead regulatory light chain), leads to defects in long-range lateral inhibition, indicated by the decreased spacing of SOP and SOP-like cells in the notum. (4) Moreover, these changes in signaling are not accompanied by striking changes in the localization of Notch or Delta protein. Together these results suggest that actomyosin-based forces play a role in activation of Notch signaling. (5) To investigate how myosin II activity affects the Notch signaling pathway to induce these changes in tissue patterning, we performed live, quantitative analysis of Notch signaling in the notum, using a novel Notch signaling reporter (He and Perrimon, unpublished). Using this tool, we can demonstrate that Notch signaling dynamics in the notum are consistent with previous mathematical models of lateral inhibition, in which cells undergo dynamic changes in their state as they commit to an epithelial or SOP fate. (6) We find that the expression of phospho-dead regulatory light chain results in a shift in the kinetics of the Notch signaling response in notum epithelial cells, and suggests that Notch activation is delayed in the absence of myosin II contractility relative to control. These data suggest that actomyosin contractility plays a key role in the activation of Notch signaling during notum patterning. Thus, protrusions may mediate long range, mechanically-induced Notch signaling in vivo – as previously proposed for Notch-Delta signaling in vitro. This identifies a mechanism by which cells can integrate mechanical forces and cell signaling to drive developmental processes.

P2337**Board Number: B1018****Genome-wide demethylation by 5-aza-2'-deoxycytidine alters the cell fate of stem/progenitor cells.**Z. Hu¹, Y. Zhou²;¹Department of Otolaryngology-HNS, Wayne State Univ, Detroit, MI, ²Wayne State Univ, Detroit, MI

DNA methyltransferase (DNMT) inhibitor 5-aza-2'-deoxycytidine (5-aza-CdR) is able to cause DNA demethylation in the genome and induce the expression of silenced genes. Whether DNA demethylation can affect the gene expression of stem/progenitor cells has not been understood. Mouse utricle epithelia-derived progenitor cells (MUCs), which possess stem cell features as previously described, exhibit a potential DNA methylation status in the genome. In this study, MUCs were treated with 5-aza-CdR to determine whether DNMT inhibitor is able to induce the differentiation of MUCs. With 5-aza-CdR treatment for 72 hr, MUCs expressed epithelial genes including *Cdh1*, *Krt8*, *Krt18*, and *Dsp*. Further, hair cell genes *Myo7a* and *Myo6* increased their expressions in response to 5-aza-CdR treatment. The decrease in the global methylated DNA values after 5-aza-CdR treatment indicated a significant DNA demethylation in the genome of MUCs, which may contribute to remarkably increased expression of epithelial genes and hair cell genes. The progenitor MUCs then turned into an epithelial-like hair cell fate with the expression of both epithelial and hair cell genes. This study suggests that stem cell differentiation can be stimulated by DNA demethylation, which may open avenues for studying stem cell fate induction using epigenetic approaches.

P2338**Board Number: B1019****Shaping the BMP morphogen gradient through the spatiotemporal regulation of metalloprotease activity in the zebrafish embryo.**F. Tuazon¹, M.C. Mullins¹, J. Zinski¹, D. Umulis², Y. Huang²;¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA,²Agricultural and Biological Engineering, Purdue University, West Lafayette, IN

Morphogens are key developmental signaling molecules that specify distinct cell fates in a concentration-dependent manner. The regulation of morphogen signaling across space and time is fundamental to proper tissue patterning, yet how these regulatory mechanisms function *in vivo* remains unknown. Bone Morphogenetic Proteins (BMPs) act as a morphogen to pattern dorsoventral (DV) axial tissues in invertebrates and vertebrates. Since BMPs also pattern the neural tube and developing limbs, understanding the spatiotemporal mechanisms that generate and shape BMP gradients is of great importance.

The shape of the BMP gradient spatially across the DV axis is critical: precise amounts of BMP signaling at discreet DV positions specify distinct cell fates. Since the DV axis is patterned from late blastula

through gastrula stages, the BMP gradient must also be maintained temporally through the cell movement process of gastrulation. Gastrulation generates the three embryonic germ layers, reorganizing a large number of cells in a short period of time and may challenge the mechanisms that shape the BMP gradient. To determine the shape of the BMP gradient, we developed a quantitative immunofluorescence assay of nuclear phosphorylated Smad1/5, a direct intracellular readout of BMP signaling. Using this assay, we discovered that the shape of the BMP gradient significantly changes during gastrulation: the BMP gradient steepens both dramatically and rapidly between mid- and late gastrulation stages.

The spatiotemporal regulation of the shape of the BMP gradient requires extracellular modulators of the BMP ligand. An essential extracellular modulator is Chordin, a BMP antagonist that binds BMPs to inhibit signaling. Chordin is central to generating the initial BMP signaling gradient and continually regulates the BMP gradient during DV patterning. Chordin itself is regulated by two key classes of proteins: (i) the highly homologous metalloproteases Tolloid and Bmp1a, which cleave and inactivate Chordin, and (ii) the metalloprotease inhibitor Sizzled. We discovered that *tolloid* and *sizzled* mutants display distinct alterations in the shape of the BMP signaling gradient at the end of gastrulation, suggesting region-specific roles for Tolloid and Sizzled. Our data indicate that Tolloid maintains the steepness of the late BMP signaling gradient, while Sizzled broadly restricts BMP signaling in lateral regions. These results support a novel requirement for metalloprotease regulation from mid- to late gastrulation stages to steepen the BMP signaling gradient and correctly pattern the posterior tissues of the zebrafish embryo.

Early neuroepithelial progenitors derived from pluripotent stem cells (PSCs) serve as a primary in vitro neural stem cell (NSC) source for generating neural cell type diversity. However, the heterogeneity of neuroepithelial cell cultures and their rapid transition through distinct neural stem and progenitor cell types impedes development of in vitro strategies for understanding lineage transition and neural cell type specification. This is further challenged by the lack of in depth cellular and molecular characterization of progenitor cells, together introducing a major challenge for harnessing their full potential in vitro. To tackle these limitations, here we dissected the transition of neuroepithelial cells through distinct potencies by prospective isolation of primary progenitor cells derived from human ES cells during long-term neural differentiation based on their Notch activation. We demonstrate that Notch activation in neuroectodermal cells is required for the establishment of neuroepithelial cells with

broad developmental potential and strong proliferation capacity. Notch active neuroepithelial cells rapidly progress into early and mid neurogenic cerebral radial glial (RG) cells followed by gliogenic RG in a Notch dependent manner. Transition through these cell types correlates with forebrain specification, cortical lamination and glial transformation at both functional and molecular levels. Furthermore, we found a functional correlation between Notch activation in early RG cells and their ability to form neural rosette structures - the in vitro counterpart of cortical RG cells. Mechanistically, Notch activation in RG cells confers a strong apicobasal cell polarity, which in turn enables their organization into rosette structures demarcating ventricular zone- and subventricular zone-like equivalents. We further demonstrate that rosette organization and Notch activation enable interkinetic nuclear migration and cell division at rosette apical sites, strongly suggesting that these features interplay to ensure the maintenance of neurogenic RG cell pools in vitro. Transcriptional analysis and subsequent shRNA screen validation reveal essential key factors involved in relaying Notch activation through neuroepithelial cell induction, radial glial cell transition and glial transformation. Our observations assign Notch activation and rosette formation as essential components orchestrating NSC ontogeny in vitro, by establishing identity of neuroepithelial cells, maintaining their numbers, and dictating their transition through distinct potencies. Our cellular and molecular observations provide a first insight into human NSC ontogeny and propose a well-controlled platform to dissect the development of normal and pathogenic NSCs and their progeny.

Epithelia patterning and body plan mapping in the *Drosophila* egg chamber: cell fate specific screen.

A.L. Braun¹, B. Chanana¹, I.M. Palacios¹;

¹Department of Zoology, University of Cambridge, Cambridge, United Kingdom

The precise establishment of the fate cells take to make up the different tissues of the body is fundamental to the development of all animals. A clear example of this is the patterning of the female germline of *Drosophila melanogaster*, which ultimately establishes the embryonic body plan of the animal, similar to vertebrates. A group of defined cells in the follicular epithelium encasing the germline, known as posterior follicle cells, are responsible for defining the first axis of the body by signalling their position to the oocyte. Only once this position is indicated to the oocyte can it go on to set the second axis of the body plan. To understand the process, whereby posterior follicle cells induce asymmetry in the oocyte, we designed a cell specific expression-profiling screen comparing the profile of posterior follicle cells to that of the remaining body of follicle cells. From this we identified a number of membrane proteins, transcription factors, G-protein receptors, and many genes that had been previously characterized in the follicular epithelium, as well as a small number having an unknown function in the fly. Three overlapping screens were employed to sift through the candidates from the expression-profiling screen and identify genes that have an essential function in the follicular epithelium: mutant allele, overlapping deficiency, and RNAi Screens. The results from these screens

culminated in the identification of a total of 9 candidate genes that have an interesting phenotype. Two of these, *midline* and *H15*, had recently been shown to be differentially expressed in the follicular epithelium and essential for patterning. The other top two interesting candidate genes, *Galpaf* and that of a previously undescribed transmembrane protein, display tissue architecture defects and oocyte polarizing defects, respectively, when knocked down. To fully characterize the function of these genes, both are currently in our pipeline to create flies with null mutations using the CRISPR/Cas9 system.

Biophysical Properties of the Cellular Microenvironment Influence Hepatocyte Differentiation.

J.C. Tung¹, A.A. Grimm², H. Willenbring³, V.M. Weaver⁴;

¹Department of Surgery and Center for Bioengineering and Tissue Regeneration, University of California, San Francisco, San Francisco, CA, ²Department of Pediatrics and Eli and Edythe Broad Center of Regeneration Medicine and Stem Cell Research, University of California, San Francisco, San Francisco, CA, ³Department of Surgery and Eli and Edythe Broad Center of Regeneration Medicine and Stem Cell Research, University of California, San Francisco, San Francisco, CA, ⁴Center for Tissue Engineering and Regenerative Medicine, University of California, San Francisco, San Francisco, CA

Tissue-engineered liver constructs possess the potential to not only serve as cell-based therapeutics for treating liver disease, but they may also serve as model systems for drug toxicity analysis or the study of disease progression. Unfortunately, the utility of these liver constructs is limited, as current protocols for the differentiation of hepatocytes result in immature hepatocytes that fail to replicate the physiologic function of fully-differentiated adult hepatocytes. Furthermore, current *in vitro* culture methods fail to maintain hepatocyte function over extended periods of time. One possible means for addressing these issues is through manipulation of the biophysical microenvironment, which has been shown to play a significant role in the differentiation and functionality of numerous cell types. While previous studies have varied extracellular matrix coatings and substrate elastic modulus in order to optimize hepatocyte differentiation, little is known about the mechanism by which biophysical properties influence hepatic cell fate decisions. An understanding of this mechanism is key before the biophysical microenvironment can be properly engineered to generate functional liver constructs. In this study, we characterized changes in the biophysical microenvironment during the course of hepatocyte differentiation and began to identify a mechanism by which these properties influence hepatic fate determination. We used a multi-stage protocol for the differentiation of embryonic stem cell-derived hepatocytes during which cells were directed from a definitive endoderm stage, to specified hepatic lineage, to hepatoblast formation, to a final hepatocyte-like maturation state. Flow cytometry analysis demonstrated differentiation stage-specific integrin expression profiles during hepatic differentiation. In turn, these lineage-specific integrin expression profiles drove specific cell adhesion behaviors (cell attachment, cell spreading, actin organization, focal adhesion formation) in response to changes in substrate stiffness and extracellular matrix composition. Furthermore, changes in the biophysical

microenvironment significantly influenced the process of hepatocyte differentiation. These findings demonstrate that biophysical properties, such as substrate elastic modulus and extracellular matrix composition, play a vital role in hepatocyte differentiation. Additional studies are now underway to further identify the mechanism by which biophysical properties influence hepatic differentiation and to harness this insight in order to generate physiologically relevant tissue-engineered liver constructs for cell-based therapeutics, drug toxicity assays, and models of liver disease.

Distinct Actin Nucleation Mechanisms are Required for the Differentiation Programs of EMT and Embryonic Stem Cells.

M.K. Rana¹, B.K. Grillo-Hill¹, C. Choi², D.L. Barber¹;

¹Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA, ²Department of Radiation Oncology, Samsung Medical Center, Seoul, Korea

Marked advancements have been made toward identifying transcriptional events controlling the programs of epithelial to mesenchymal differentiation (EMT) and embryonic stem cell (ESC) differentiation. However, both programs require dramatic remodeling of actin filaments and we know little about how this remodeling is regulated, particularly the role of actin nucleators that generate distinct actin architectures. We found that formins are necessary for EMT but the Arp2/3 complex is necessary for ESC differentiation. The broad spectrum formin inhibitor SMIFH2 but not the Arp2/3 complex inhibitor CK666 blocked EMT of human lung A549 cells and mouse mammary NMuMG cells induced by TGF- β . SMIFH2 blocked the change in cell shape to a mesenchymal morphology, remodeling of actin filaments to actin stress fibers, loss of cell-cell contacts, decreased expression of E-cadherin, increased expression of fibronectin and nuclear translocation of the transcription co-factor MRTF. We also found the surprising result that SMIFH2 inhibited proximal signaling by TGF- β , as indicated by decreased phosphorylation of Smad2 (pSmad2), a TGF- β receptor substrate. We tested shRNA for 9 of the 15 human formin family members and found that silencing expression of only two, FHOD1 and formin-1, inhibited EMT, but through distinct mechanisms. FHOD1 shRNA blocked the assembly of actin stress fibers and increased phosphorylation of myosin light chain that were rescued by expression of wild type FHOD1; however, pSmad2 was not blocked. Formin-1 shRNA blocked loss of cell-cell contacts, internalization of E-cadherin and nuclear translocation of MRTF but not the assembly of actin stress fibers. We are testing whether formin-1 is necessary for increased pSmad2. In contrast to EMT, CK666 but not the inactive analog CK689 or SMIFH2 inhibited mouse ESC differentiation. Using a dual reporter line with self-renewing, undifferentiated cells expressing mCherry and differentiated cells expressing GFP, we used FACS analysis to show that at 72 h of differentiation there were no differences between controls, CK689 or SMIFH2 but with CK666 there were 50% more self-renewing cells and 35% fewer differentiated cells. Differentiated cells had substantially more and larger membrane protrusions and distinct asymmetric clustered actin filaments at protrusions. These changes were completely blocked by CK666 but not SMIFH2. To our knowledge, neither Arp2/3 complex regulation of stem cell

differentiation nor formin-dependent Smad signaling has been reported. We predict that requirements for formin-dependent EMT compared with Arp2/3-dependent ESC differentiation reflect distinct needs of the differentiation program, specifically the need for increased cell contractility with EMT but not ESC differentiation.

Neogenin as a receptor for the early cell fate determination in preimplantation mouse embryos.

J. Lee¹, S. Choi², H. Kim³, W. Xiong⁴, C. Min⁵, S. Lee⁶;

¹Nanyang Technological University, Singapore, Singapore, ²Pharmacology, Sahmyook University, Seoul, Korea, ³Nanobiomedical Sciences and WCU Research Center, Dankook University, Cheonan, Korea,

⁴IMMAS, Georgia Regents University, Augusta, GA, ⁵Biological science, Ajou University, Suwon, Korea,

⁶Animal Sciences, Sahmyook University, Seoul, Korea

The first cell lineage determination in embryos takes place when two cell populations are set apart, each differentiating into the trophectoderm (TE) and the inner cell mass (ICM), respectively.

Positional/polarity cues trigger this differentiation, but it is unclear which receptor transduces extracellular cues into cell fate determination. We provide evidence for neogenin as an authentic receptor in preimplantation mouse embryos. A polarized and transient distribution of neogenin was manifested in early blastomeres. Neogenin up-regulation accelerated embryonic development concomitant with normal ICM development and activation of the ICM-specific genes Oct3/4, Sox2, and Nanog while its depletion by small hair-pin RNAs (shRNAs) caused a developmental arrest accompanied by poorly endowed ICMs and activation of the TE-specific genes Cdx2 and Tead4. Treatment with netrin-1 impaired both embryonic development and ICM formation while RGMc led to opposite consequences, demonstrating that neogenin helps guide blastomeres to the first cell fate determination relaying extracellular cues.

KEY WORDS: Neogenin, preimplantation mouse embryo, cell fate determination, netrin-1, RGMc

Boc promotes neuronal differentiation by interaction with Abl and JNK activation.

V. Tuan Anh¹, J. Kang²;

¹School of medicine, Sungkyunkwan University, Suwon, Korea, ²Sungkyunkwan Univ Sch Med, Suwon, Kyunggi-do, Korea

Neuronal development and differentiation are regulated by multiple coordinated events, such as cell migration, the outgrowth and guidance of axons and dendrites, and the accompanied neuron-specific

gene expression. A multifunctional protein, Boc belongs to the Ig/FNIII subfamily of cell surface receptor. It functions as a Shh coreceptor with the closely related protein, Cdo and another protein Gas1. Triple knockout mice for the Shh coreceptors exhibit phenotypes resembling the Hh signaling deficiency. In addition, Boc promotes myogenic differentiation as a component of multiprotein complexes containing related proteins Cdo and Neogenin, and a cell adhesion molecule N-cadherin. Boc plays a crucial role in the Shh-dependent axon guidance and synapse formation. Here we report that Boc promotes neuronal differentiation through interaction with Abl and JNK whereby activates JNK. Consistently Boc deficient neural stem cells exhibit defective neuronal differentiation and decreased JNK activation. Our data suggest that Boc regulates multiple events of neuronal differentiation including axon outgrowth and guidance.

Investigating the Yeast Zygote Transcriptome.

C. Ni¹, A.M. Tartakoff^{2,3};

¹Departments of Molecular Biology and Microbiology, Cell Biology Program, Case Western Reserve University, CLEVELAND, OH, ²Department of Pathology, Case Western Reserve University, Cleveland, OH, ³Departments of Molecular Biology and Microbiology, Cell Biology Program, Case Western Reserve University, Cleveland, OH

Zygote formation in *S. cerevisiae* provides opportunities to study cell membrane fusion, karyogamy, and organelle rearrangements. We have established a method for efficient zygote formation in physiological conditions, followed by flow cytometry-based purification (Zapanta Rinonos *et al.*, 2012). RNA extracts were then analyzed on microarrays (Affymetrix) to obtain transcriptome data. We studied replicate samples of haploid cells, diploid cells, and purified zygotes, as well as mating factor-stimulated cells. We analyzed each binary comparison of cell types and established a set of gene expression profiles to identify genome-wide transcriptome changes. A pioneering microarray analysis of mating factor-stimulated genes (Roberts *et al.*, 2000) shares 11 genes among the top 50 increased/decreased genes in our data set. A previous study combining ChIP, microarray, and binding motif analysis (cross-species consensus DNA sequences in fungi) identified a group of cell type-specific genes for haploid and diploid cells (Galgoczy *et al.*, 2004). We also identified 80% of these genes as being specific in a/alpha or haploid/diploid comparisons. Three groups of zygote-specific genes were identified by mapping genes that are regulated during this process: (1) spindle pole body, (2) mitochondrial electron transfer chain, and (3) transcriptional regulators. We hypothesize that regulation of these groups of genes is pivotal for cell-cell fusion, zygote formation, and subsequent cell proliferation.

P2346**Board Number: B1027****Investigating mechanisms of spindle orientation by cell-cell signaling.**J.K. Heppert¹, B. Goldstein²;¹Biology, University of North Carolina, Chapel Hill, NC, ²Department of Biology, University of North Carolina, Chapel Hill, NC

Mitotic spindle orientation is a critical process during development and homeostasis, often establishing the positions of cells relative to key developmental or proliferative cues. In some cases, signaling between cells is required for accurate spindle orientation. However, how cell-cell signaling controls mitotic spindle positioning remains unresolved. We are investigating mechanistic links between signaling pathway components and the forces that position the mitotic spindle. Molecules in the Wnt signaling pathway and regulators of the motor protein dynein are necessary to orient the mitotic spindle of a dividing cell in the four-cell stage *C. elegans* embryo. We are establishing a system to examine the roles of these relevant players and determine how their localization may affect their functions during spindle orientation. We used Cas9/CRISPR triggered homologous recombination to insert genes encoding fluorescent proteins at the endogenous loci of genes in the Wnt signaling pathway. Live imaging of *C. elegans* four-cell stage embryos confirmed enrichment of DSH-2/Dishevelled at the cell contact between Wnt signaling and responding cells and further revealed that MOM-5/Frizzled is present at all cell contacts and becomes enriched at the contact between the Wnt signaling and responding cell over time. Disrupting Wnt signaling using *mom-2*/Wnt RNAi in these tagged strains resulted in a lack of local enrichment, suggesting that Wnt signaling is necessary for the localization of MOM-5/Frizzled and DSH-2/Dishevelled at this stage. We are also tagging candidates to test our hypothesis that Wnt signaling controls mitotic spindle orientation by the recruitment or activation of force generators at key cortical sites. We have endogenously tagged DNC-2/p50/dynamitin, a member of the dynactin complex. Using direct cell manipulations, we are testing the ability of a Wnt signaling cell to act as an instructional cue for spindle orientation through the local recruitment of microtubule regulators. Determining how proteins in the Wnt signaling pathway intersect with molecules that generate force to position the mitotic spindle will expand our mechanistic understanding of how cell-cell signaling can control spindle positioning.

P2347**Board Number: B1028****Tunable directed neurogenesis of neural stem cells via optogenetic activation of canonical Wnt signaling.**A. Rosenbloom¹, L. Bugaj², D. Schaffer¹;¹University of California, Berkeley, Berkeley, CA, ²Univ California-San Francisco, San Francisco, CA

Parkinson's and Alzheimer's disease are neurodegenerative diseases that affect 40 million people worldwide. Adult neural stem cells (NSC) have great potential as cell replacement therapies. The adult

NSC microenvironment is likely highly dynamic, with signaling molecules presented at modulating intensities and durations. The canonical Wnt signaling pathway, whose activation involves β -catenin stabilization, is involved in the neurogenic NSC fate; indeed, activation via Wnt3a can lead to robust neurogenesis. To mimic in vivo dynamic signaling, our lab has developed a tunable optogenetic system to modulate β -catenin signaling through the oligomerization of LRP6. We have observed that NSCs undergo neuronal differentiation in a light signal dosage-dependent manner, even in the presence of relatively low level fluctuations or cycling of dark and light pulses. We show the existence of a temporal “buffer” region within which the total number of photons, rather than signal fluctuation, determines the levels of neurogenesis. This type of measurement highlights the novel strengths of our optogenetic system in elucidating a more complete understanding of the molecular mechanisms by which canonical Wnt signaling regulates NSC fate, furthering efforts to harness NSCs for neuroregeneration.

Nrf2 represses neuroectoderm differentiation during early lineage specification of human embryonic stem cells.

J. Jang¹, Y. Wang¹, M.A. Lalli¹, E. Guzman¹, K.S. Kosik¹;

¹Neuroscience Research Institute, Univ California-Santa Barbara, Santa Barbara, CA

Early nervous system development is regulated by sets of lineage-specific transcription factors (e.g. PAX6) that control the expression of many neuronal target genes. However, early events that precede lineage-specific transcription factor expression have not been well studied. Here, we show that Nrf2, a master regulator of antioxidant transcriptional responses, plays a key role in determining early cell fate. First, we profiled whole transcriptome from human embryonic stem cells (hESCs), neuroectoderm (NE) and mesendoderm (ME) cells using RNA-seq. Hierarchical clustering analysis based on the expression of Nrf2 target genes shows similarity between hESCs and ME cells. In contrast, NE cells exhibited low levels of Nrf2 target gene expression. Next, downregulation of Nrf2 activity preceded initiation of PAX6 expression during NE differentiation, suggesting that Nrf2 downregulation might be a prerequisite for NE fate. Consistent with this hypothesis, Nrf2 activation by chemical activators or gene overexpression was sufficient to suppress NE derivation, while further activating ME marker expression. In the opposite experiment, Nrf2 inhibition by shRNA promoted NE differentiation. Collectively, these data suggest that Nrf2 represses NE differentiation and Nrf2 downregulation is an early event that determines NE fate.

P2349**Board Number: B1030****Regulation of MKL1 via actin cytoskeleton dynamics drives adipocyte differentiation.**H. Nobusue^{1,2}, N. Onishi³, T. Shimizu⁴, E. Sugihara³, Y. Oki⁵, Y. Sumikawa⁵, T. Chiyoda³, K. Akashi⁶, K. Kano⁵, H. Saya³;¹Keio Univ Sch Med, Shinjuku-ku, Tokyo, Japan, ²College of Bioresource Sciences, Nihon Univ, Kanagawa, Japan, ³Keio Univ Sch Med, Tokyo, Japan, ⁴Department of Pathophysiology, Hoshi Univ, Tokyo, Japan, ⁵Nihon Univ, Fujisawa, Japan, ⁶Medicine and Biosystemic Science, Kyushu Univ, Fukuoka, Japan

Cellular differentiation is regulated through activation and repression of defined transcription factors. Adipocyte differentiation is regulated by gene expression of a master regulator such as peroxisome proliferator-activated receptor- γ (PPAR γ). A hallmark of differentiation is a pronounced change in cell shape, which is determined by dynamics of the actin cytoskeleton. Adipocyte differentiation is thus associated with a shift in the structures formed by filamentous (F) actin from stress fibers to cortical fibers. The relation between such reorganization of the actin cytoskeleton and the PPAR γ -mediated adipocytic differentiation program has remained unclear, however. Here, we show that regulation of the transcriptional coactivator MKL1 (megakaryoblastic leukemia 1) by actin cytoskeleton dynamics drives adipocyte differentiation mediated by PPAR γ . Exposure of preadipocytes to an adipogenic cocktail results in the rapid disruption of actin stress fibres as a consequence of downregulation of RhoA-ROCK signaling, which regulates the formation of actin stress fibers and focal adhesions, and the consequent increase in monomeric G-actin levels. The resulting increase in the amount of G-actin leads to the interaction of G-actin with MKL1, which prevents nuclear translocation of MKL1 and allows expression of PPAR γ followed by adipogenic differentiation. We further found that depletion of MKL1 can drive adipocyte differentiation in preadipocytes and even in nonadipogenic fibroblasts in the absence of an adipogenic cocktail, and these data revealed that MKL1 functions as a gatekeeper that controls adipocyte differentiation. Moreover, we found that MKL1 and PPAR γ act in a mutually antagonistic manner in the adipocytic differentiation program. Our findings thus provide new mechanistic insight into the relation between the dynamics of cell shape and transcriptional regulation during cellular differentiation.

P2350**Board Number: B1031****A synthetic yeast model for differentiation and division of labor.**M.E. Wahl¹, A.W. Murray^{1,2};¹Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA, ²Harvard FAS Center for Systems Biology, Cambridge, MA

Somatic cells undergo permanent, heritable changes in gene expression that prevent them from replicating the complete organism. Despite the fitness costs entailed by this forfeit of reproductive

capacity, differentiation has evolved independently several dozen times, driving speculation on the compensatory fitness benefits and pre-adaptations necessary for the evolution and maintenance of differentiation. Due to the rarity and long timescale of these processes in nature, hypotheses generated through retrospective inference and modeling have awaited an experimentally-tractable biological model system in which they can be directly tested.

Borrowing the toolkit of synthetic biology, we engineer differentiation in the budding yeast *S. cerevisiae*. We implement inducible and tunable conversion and cell type-specific growth rates, irreversible differentiation through recombinase-mediated gene excision, terminal differentiation by removal of an essential cyclin-dependent kinase gene, and cell type-specific protein expression, including fluorescent markers. By combining this differentiation system with yeast mutations known to prevent cell separation following cytokinesis, we test a hypothesis concerning the order in which multicellularity and differentiation may evolve naturally. We also confirm an analytical result concerning the effect of spatial context on the maintenance of stem cell populations and the steady-state ratio between cell types. The strains developed here may further be used to study other major evolutionary transitions, including the appearance of body plans and life cycles, as well as mutation-selection balance.

Paracrine rescued lobulogenesis in PR null mammary outgrowths by redirected testicular cells.

G.H. Smith¹;

¹BRL, NIH/NCI/CCR, Bethesda, MD

Stem and progenitor cells in most adult tissues reside in specialized, highly regulated microenvironments called stem cell niches. We have previously shown that testicular, neural, bone marrow and cancer cells respond to the signals provided by the mammary niche (stroma, epithelial cells, local and extrinsic factors) and alter their cell fate to that of mammary epithelial progenitor cells. To determine if paracrine signals from progesterone receptor (PR) expressing mammary epithelial cells are required for this redirection, we mixed 100K PR null epithelial cells with 50K testicular cells from adult male mouse seminiferous tubules. The testicular cells were redirected *in vivo* to mammary epithelial cell fate during regeneration of the mammary epithelium and in the process rescued the developmentally deficient PR null cells, signaling them to produce alveolar secretory structures in the chimeric mammary outgrowths at parturition. We identified redirected testicular cells by staining with anti-PR and anti-RANKL antibodies. Positive cells were found both in ducts and in secretory structures. PR null outgrowths were uniformly negative for anti-PR staining. PR and RANKL positive testicular-derived cells were detected in second-generation outgrowths as well. This demonstrates that PR signaling is not required for cellular reprogramming of testicular cells to mammary epithelial cell fate *in vivo*. In addition, the testicular cells, which did not express PR prior to reprogramming, but were capable of providing the necessary paracrine signals required for lobular development of the PR null epithelium. These results demonstrate that once in the mammary niche, reprogrammed cells from other tissues can

not only receive signals from their new environment, but also contribute progeny that provide paracrine signals, which contribute to a “normalized” microenvironment.

Plasmodium falciparum Double C2 Domain Protein, PfDOC2, Binds to Calcium when Associated with Membranes.

S. Jean¹, G. Mayer²;

¹Microbiology and Immunology, Virginia Commonwealth University, Richmond, VA, ²Biology, Manhattan College, Riverdale, NY

The pathogenesis of malaria is strongly correlated with secretion of the micronemes, the apical organelles which contain the adhesins required for invasion of *Plasmodium falciparum* into human erythrocytes. A critical event in *P. falciparum* erythrocyte invasion is the production of calcium transients. After entering the cell, Ca²⁺ binds to soluble Ca²⁺-binding proteins, such as the double C2 domains (DOC2). Recently, deletion of a *P. falciparum* DOC2 protein, PfDOC2, was shown to cause impairment in microneme secretion. However, PfDOC2 remains poorly characterized. Here, we report that PfDOC2 is expressed throughout the erythrocytic cycle and demonstrate that it is associated with membrane fractions and binds to calcium when it is part of these membranous structures. In summary, we show that PfDOC2 is a calcium lipid-binding protein of the protein kinase C type of DOC2 proteins.

Molecular characterization of apical membrane antigene-1 of *Eimeria tenella* isolates from Nigeria.

I.D. Jatau¹, I.A. Lawal¹, J.K. Kwaga¹, A.J. Nok¹, D.P. Blake²;

¹Veterinary Parasitology and Entomology, Ahmadu Bello University, Kaduna, Nigeria, ²Pathology and Pathogene Biology, Royal Veterinary College, Hatfield, United Kingdom

The present study aimed at sequence characterization of apical membrane antigen 1 (AMA-1), a sub-unit vaccine candidate-encoding locus from Nigerian field *Eimeria tenella* isolates for comparison with reference strains from different parts of the world. The full length *E. tenella* AMA-1 (EtAMA-1) coding region was amplified by PCR from cDNA made from *Eimeria* oocyst samples obtained from three different commercial poultry farms in Nigeria. PCR fragments of interest were gel excised and purified using minelute gel purification, cloned using pGEM[®]-T Easy (Promega) vector system kits and transformed into XL1-Blue *Escherichia coli* (Stratagene). Candidate plasmids identified by EcoRI digestion and gel electrophoresis were sequenced (GATC Biotech) using the T7 and SP6 sequences within the T

Easy plasmid and analysed using CLC Main Workbench version 5.7.1 (CLC Bio, Denmark). Ten clones were assembled for each sample for comparison for possible polymorphism among the clones and with isolates from different parts of the world. Principal coordinate analysis results of the AMA-1 cDNA sequences and translated amino acid sequences indicated the occurrence of limited genetic diversity among EtAMA-1 alleles of field *E. tenella* isolates from within and outside the country, with minimal diversity compared to archived laboratory strains. This work therefore, highlighted the need to identify the major EtAMA-1 allelic types circulating in the population for inclusion into a possible multi-allele AMA-1 based anticoccidial vaccine, an approach that is proving to be promising in the development of effective malaria vaccines.

Human antibody responses to surface antigens of *Plasmodium falciparum* gametocyte-infected erythrocytes and their relation with gametocytaemia.

B. Dinko¹, T. Bousema², C. Sutherland²;

¹Dept of Biomedical Sciences, Univ Hlth/Allied Sciences, Ho, Volta Region, Ghana, ²Dept of Immunology and Infection, London School of Hygiene and Tropical Medicine, London, United Kingdom

BACKGROUND: In *Plasmodium falciparum*, only mature gametocytes are found in peripheral circulation and available to uptake by the mosquito vector. Efficient transmission of gametocytes from the human host to mosquitoes contributes to the persistent burden posed by malaria. There is little evidence to suggest that natural immune responses to circulating gametocytes play a role in clearing gametocytes. **METHODS:** Here, magnet-purified and enriched mature gametocytes obtained from a laboratory parasite, 3D7, and a clinical isolate from Kenya, HL1204, were used to test for plasma antibody recognition to the surface of gametocyte-infected erythrocytes (GSA) and to measure longitudinal antibody responses in a cohort of Ghanaian school children using flow cytometry. **RESULTS:** Analysis of plasma antibodies in three sequential weekly samples from 113 asymptomatic *Plasmodium falciparum*-infected individuals showed that a proportion of the children exhibited marked antibody responses that recognized GSA on both 3D7 and HL1204. Some responsive individuals maintained their antibody levels during the study period, irrespective of concurrent gametocyte carriage status. Children with GSA antibodies present at enrolment, were less likely to develop new gametocytaemia at subsequent visits (odds ratio = 0.29, 95% CI 0.06 - 1.05; P = 0.034). **CONCLUSION:** Our data support the hypothesis that conserved antigens exist on the surface of gametocyte-infected erythrocytes in malaria parasites which elicit natural human antibody responses, and that these play a role in reducing gametocyte carriage. The identification of these novel gametocyte surface antigens and their evaluation as potential anti-gametocyte vaccine candidates and/or biomarkers of gametocytes are imminent tasks.

P2355**Board Number: B1037****Three dimensional structure of Maurer's cleft with tiny filaments in Plasmodium falciparum-infected Erythrocytes by "unroofing" method.**E.H. Hayakawa¹, F. Tokumasu², J. Usukura³, H. Matsuoka¹, T. Tsuboi⁴, T.E. Wellems⁵;¹Lab of Medical Zoology and Parasitology, Jichi Med University, Shimotsuke, Japan, ²Department of Lipidomics, The university of Tokyo, Tokyo, MD, ³Structural Biology Center, Nagoya University, Nagoya, Japan, ⁴Cell-Free Science and Technology Research Center, Ehime University, Matsuyama, Japan, ⁵Lab of Malaria and Vector Research, NIAID/NIH, Bethesda, MD

Plasmodium falciparum, human malaria parasites, delivers over 400 proteins to the surface of erythrocytes has no protein transport machinery. Maurer's clefts (MCs) appear in parasitized erythrocyte cytoplasm after invasion and are believed to play a crucial role for protein transportation. Recent data with 3-D reconstruction of thin-layer transmission electron microscopy (TEM) estimated Maurer's cleft structure, but much details are still unknown due to the loss of fine structure information while thin-layer preparation. In this study, we used "unroofing/rip-off" technique and investigated erythrocyte membrane skeleton and MCs from cytoplasm side by TEM. We found oval/global structure connected through fine extensions consistent with estimated MC characteristics. These extensions have 170 – 450 nm in length and

P2356**Board Number: B1038****Cotranscription of Wolbachia surface protein (WSP) with Type IV Secretion System (T4SS) in Wolbachia pipientis wStr.**Y. Li¹;¹Entomology, University of Minnesota, St Paul, MN

Wolbachia is a cytoplasmically transmitted alpha-proteobacterium and is able to induce several reproductive alternations in its arthropod hosts, including cytoplasmic incompatibility (CI), feminization of the males, male killing and parthenogenesis. *Wolbachia* surface protein (WSP) has a transmembrane structure and its participation in host immune response and apoptosis inhibition makes it important for bacterial survival and proliferation within the host. *Wsp* gene is downstream of *virD4* gene that belongs to one of the two Type IV Secretion System (T4SS) operons. T4SS is a membrane spanning apparatus that has 12 components (VirB1-11 and VirD4), most of which are translated from two cotranscribed gene clusters (operon *virB8-11*, *virD4* and operon *virB3-6*). The objective of this study is to analyze the cotranscription of *wsp* and *virD4* genes in *wStr*, a *Wolbachia pipientis* strain that maintains a robust infection in an *Aedes albopictus* mosquito cell line. Total RNA was purified from infected and uninfected control cells. After purified RNAs were verified by polymerase chain reaction (PCR) for absence of genomic DNA contamination, reverse transcriptase (RT)-PCR was used with a pair of primers that

overlaps both *virD4* and *wsp* genes, and the resulting cDNA amplicon was sequenced. Results showed that the cDNA amplicon obtained had the expected size (528bp) after electrophoresed on a 1% agarose gel, and its nucleotide sequence verified the overlap of both *virD4* and *wsp* genes. These results indicate that *wsp* gene is cotranscribed with *virD4* and the upstream T4SS genes. It is widely believed that *Wolbachia* manipulate host reproductive alternations through T4SS-mediated secretion of effector proteins into host reproductive tissues. The fact that *wsp* is cotranscribed with T4SS genes suggests its possible interaction with T4SS and potential role as an effector protein. *Wsp* gene has an extensive genetic divergence in nature, however searching for the precise role it plays in the interaction between *Wolbachia* and host needs future efforts.

Board Number: B1039

Differential proliferation of *Wolbachia* endosymbiont in *Aedes* mosquito cell line.

P. Hosagavi Puttegowda¹;

¹Biological Sciences, Bangalore University, Bangalore, India

The cell lines of *Aedes albopictus* (C636) obtained from NIMHANS, Karnataka, India were maintained in incubators with M&M insect cell culture medium and BSA to establish *Wolbachia* an intracellular proteobacteria. The cell lines were inoculated with *Wolbachia* (A, B and AB super groups) and the strength of the infection was calculated based on the perpetuation of the cells in the in-vitro medium. The comparison between control and infected cell lines suggests a two-fold decrease in infected cells reaching confluence. The inoculum strength differs from the source of *Wolbachia* isolated from different insect hosts. *Wolbachia* extracts with double infections (AB) are highly virulent than single infections. Among single infections, *Wolbachia* B supergroup is more virulent than A supergroup. Further, it was observed that *Wolbachia* derived from *Exorista sorbillans*, *Aedes albopictus*, *Trichogramma japonicum* has greater virulence and cell lines can be infected within few passages. *Wolbachia* isolated from *Talicauda nyseus* did not induce any significant effect on mosquito cell lines. The findings of the current study append the database of potential non-native *Wolbachia* strains that can be introduced in mosquitoes for expression of novel phenotypes. Recent findings reports increased virulence of pathogenic West Nile Virus, when confounded with native *Wolbachia* strains in mosquitoes. Thus screening of alternative *Wolbachia* strains that could be maintained in mosquito cell lines and establishing a 'Wolbachia strain pool' for mosquito trans-infection is of significant importance.

Keywords : *Aedes albopictus*; cell lines; *Wolbachia* infections; virulence

P2358**Board Number: B1040****High molecular weight protein associated to the flagellar attachment zone in *Trypanosoma brucei* cytoskeleton.**M.M. Baqui¹, B.P. Moreira¹;¹Cell and Molecular Biology, University of Sao Paulo, Ribeirao Preto, Brazil

Munira Muhammad Abdel Baqui and Bernardo Pereira Moreira

Department of Cellular and Molecular Biology, Ribeirão Preto Medical School University of São Paulo, Ribeirão Preto, São Paulo, 14049-900, Brazil.

Trypanosoma brucei is a pathogenic unicellular eukaryote that infects humans and other mammals in sub-Saharan Africa. The causative agent of sleeping sickness, *Trypanosoma brucei*, represents an excellent model for cell biology suitable for investigation analysis of basic questions about the cytoskeleton and its evolution in higher eukaryotes. The most prominent organelle, the flagellum harbors most of the cytoskeletal content of the cell and is responsible for cell division, motility, morphogenesis and infectivity. It comprises the axoneme and paraflagellar rod and both are connected to the cell body via the flagellar attachment zone (FAZ). In all genera of the Trypanosomatidae family, we described a novel class of high molecular mass phosphoproteins associated to the cytoskeleton, which, besides their structural function, might play a role in the organization and regulation of cytoskeleton and its constituents. Cytoskeleton of *T. brucei* was obtained after treating parasites with lysis buffer containing TX-100 detergent following its solubilization with 1M NaCl to isolate flagella from the cell body skeleton. SDS-PAGE gradient gel and silver staining revealed the distribution of the high molecular weight protein in all extracts analysed but most concentrated in the flagellar fraction. In order to generate a polyclonal serum, giant protein from the flagellar fraction was cut out from the gel and injected in Balb/C mice. Confocal immunofluorescence microscopy and immunoelectron microscopy revealed the localization at a specific region between the cell body and the flagellum corresponding to the flagellar attachment zone (FAZ). Moreover, this protein did not co-localize with tubulin (axoneme) neither with paraflagellar rod (PFR) suggesting its participation in the FAZ structure. The corresponding giant protein band was excised from the gel and sent to mass spectrometry (MS) analysis. We retrieved a list with putative candidates most of them with no function described so far. Known candidates included calpain-like protein, which has been shown to be essential to remodel parasite shape. The next steps include the expression of tagged proteins and an RNAi assay to reveal what role they might play in the cell.

P2359**Board Number: B1041****Characterization of Inositol Phosphate Pathway in *Trypanosoma brucei*.**C. Cordeiro¹, A. Saiardi², R. Docampo³;

¹Department of Cellular Biology and Center for Tropical and Emerging Global Diseases, University of Georgia, Athens, GA, ²Medical Research Council - Laboratory for Molecular Cell Biology, University College London, London, United Kingdom, ³Center for Tropical and Emerging Global Diseases and Department of Cellular Biology, University of Georgia, Athens, GA

Trypanosoma brucei is a protozoan parasite that infects people and animals. It causes human sleeping sickness, a deadly illness that lead to death if untreated. *T. brucei* is prevalent in sub-Saharan Africa, where it infects thousands of people and poses treat to millions. The lack of vaccines and limited treatment options underlines the need for research on new drug targets. We are studying the inositol phosphates signaling pathway of trypanosomes. Inositol phosphates are polyphosphorylated myo-inositol molecules that play various roles in different cells. Genes coding for kinases that synthesize inositol phosphates are found in all eukaryotes. We identified three kinases that belong to this pathway in *Trypanosoma brucei* genome: Inositol Polyphosphate Multikinase (TbIPMK), Inositol Pentakisphosphate 2-kinase (TbIPPK) and Inositol Hexakisphosphate Kinase (TbIP6K). We used in vitro activity assays to determine substrate specificity and reaction products of the three enzymes. TbIPMK phosphorylates IP3 to synthesize IP5 and PP-IP4. TbIPPK synthesize IP6 using IP5 as substrate. Finally, TbIP6K phosphorylates IP5 and IP6 to form PP-IP4 and IP7, respectively. We also characterized the kinetic parameters of each kinase at different concentrations of ATP and substrate. Complementation of mutant yeasts demonstrated the ability of TbIPMK, TbIPPK and TbIP6K to synthesize inositol phosphates in living cells. Yeast mutants depleted of the IPMK and IP6K homologs have slow growth rate. TbIPMK and TbIP6K complementation in yeast restored normal growth and wild type inositol phosphate levels. We also analyzed *T. brucei* extracts for the presence of inositol phosphates using polyacrylamide gel electrophoresis and high performance liquid chromatography. Interestingly, we could only detect IP, IP2 and IP3 in *T. brucei* procyclic (insect stage) and bloodstream forms (mammalian stage). The highly phosphorylated inositol phosphates were not detected in extracts from cultured parasites, although they express the active enzymes capable of synthesizing them. We are currently investigating functions of the inositol phosphate pathway for *T. brucei* survival upon different stress conditions. Our long-term goal is to understand the functions of this pathway in trypanosomes. The study of inositol phosphates in trypanosomes may lead to better understanding of these molecules in other related organisms and provide new targets for drug discovery.

P2360**Board Number: B1042****Molecular Tools to Probe Signaling Events During Single Cell Regeneration in the Giant Ciliate Stentor.**S. Reiff¹, M.M. Slabodnick¹, P. Sood¹, T. Makushok², G. Ruby¹, J. DeRisi¹, W. Marshall²;¹University of California, San Francisco, San Francisco, CA, ²Biochemistry and Biophysics Dept., University of California, San Francisco, San Francisco, CA

The unicellular ciliates of the genus *Stentor* have the unique ability to fully regenerate after being cut in half, in a way that perfectly preserves cell polarity and structure. There are potentially many parallels between the mechanisms underlying this process and those involved in development and differentiation. Although regeneration in *Stentor* used to be a popular area of study for microscopists, so far the molecular details behind this incredible phenomenon have remained unstudied, in part because of the lack of genetic tools. Recently, however, our laboratory has initiated sequencing of the *Stentor coeruleus* genome, and has developed a system for RNAi knockdown of *Stentor* genes. To gain a better understanding of the regeneration process, with the help of Radiant Genomics we have developed constructs for RNAi knockdown of 1300+ different genes. This large selection of genes consists of a wide variety of protein families. A few of these categories include genes for signaling components such as kinases, GPCRs, calcium channels, and guanylyl cyclases, and proteasomal components. RNAi screening of these individual genes is ongoing, and will ultimately reveal some of the signaling pathways that coordinate the many different precisely timed cellular events required for successful regeneration. Concurrently, a system for tagged transgene expression in *Stentor* is also being developed to facilitate downstream characterization of important proteins identified by this screen. An expression plasmid based on the *Stentor* calmodulin gene has been constructed, containing either a C-terminal GFP or triple HA tag. Experiments are now underway to reveal which electroporation conditions are able to most efficiently deliver plasmid DNA to the nucleus. In the future, a better understanding of the mechanisms behind single cell regeneration will have important implications for basic biology as a whole, and will inform the most fundamental questions in cell biology about how single cells can establish and maintain their polarity, morphology, and size.

P2361**Board Number: B1043****The genetic and physical basis of diatom cell wall patterning.**J.J. Russell^{1,2}, J.A. Theriot^{2,3};¹Department of Biology, Stanford University, Stanford, CA, ²Department of Biochemistry, Stanford University School of Medicine, Stanford, CA, ³Howard Hughes Medical Institute, Stanford University School of Medicine, Stanford, CA

Diatoms are photosynthetic microbes that precipitate silica to form intricately structured glass cell walls, termed frustules. Frustules exhibit species-specific morphologies, including highly reproducible nano- to

micro-scale features. My project aims to develop Crispr-Cas9 genome editing in two sequenced diatoms, *Phaeodactylum tricornutum* and *Thalassiosira pseudonana*, to facilitate a genetic approach to understanding frustule patterning. A genome-wide forward genetic screen for frustule defects aims to identify genes responsible for large- and small-scale frustule morphology. Clonal populations of *P. tricornutum* exhibit three distinct morphotypes, the regulatory genes for which may be identified in mutant populations lacking one or more morphotypes. Mutants with altered nano- to micro-scale features will also be genotyped and characterized. Next, a reverse genetic approach applied to several genes known to encode frustule-localized proteins will test how specific sequence motifs specify morphologic characters. Finally, genes from a diversity of diatoms will be heterologously expressed to determine the potential for engineering chimeric frustules.

Factors that Influence the Life Cycle of a Marine Ciliate Co-Isolated with Eggs of the Sea Urchin *Lytechinus Variegatus*.

C. Priano¹, L. Jayant¹;

¹Science, Borough of Manhattan Community College, New York, NY

This study focused on determining environmental factors that trigger the encystment of a ciliated marine protist that was originally isolated as a contaminant of harvested eggs from the green sea urchin *Lytechinus variegatus*. Upon induced spawning of female urchins, eggs appear to be protist free. Within 24 hours, protists begin to appear and feed on disintegrating eggs. Replicating forms of the protist quickly multiply to high numbers. The vegetative form of the ciliate was recovered and cultures have been maintained at room temperature in media composed of artificially prepared sea water supplemented with a commercial fish food, Marine-S. Experiments were performed in which these protists were grown in culture under conditions of varying temperature and food supply. Cultures were monitored by microscopy at 25 °C and at 4 °C for several days. Results indicated that at room temperature, the vegetative form of the ciliate reproduced exponentially, reaching a density of 10⁵ protists/mL by the fourth day. By the fifth day, however, protist numbers began to decrease rapidly in proportion to an increase in the number of cysts observed. When separate cultures were inoculated with the vegetative protist and placed at 4 °C, only cysts could be seen after 24 hours. The results suggest that this protist becomes encysted in response to environmental stresses of decreased temperature and food depletion. By preliminary analysis, the isolated protist appears to be related to the species *Orchitophrya stellarum*, a parasitic ciliate that resides in the testes of male starfish. Further molecular studies will be done to confirm identification. Whether a similar symbiotic relationship exists between female *L. variegatus* sea urchins and an encysted form of this isolated protist will also be investigated. Possible roles for this organism in marine ecosystem structure will be discussed.

P2363**Board Number: B1045****Identification of two protozoan contaminants of primary cell cultures from the sea star, *Patiria miniata*.**G. Reyes¹, Y. Lee¹, F. Hajredini¹, J. Khan¹, A. Manassero¹, E. Quezada¹, I. Macebuh¹, F. Abreu¹, S. Ahmed¹, A. Tehuitzil¹, H. Alia¹, S. Singh¹, D. Fugar¹, T. Onorato¹;¹Natural Sciences, LaGuardia Community College, Long Island City, NY

During the Spring 2014 semester at LaGuardia Community College, students in the Cell Biology capstone course cultured cells isolated from various tissues of the sea star, *Patiria miniata*. Despite the addition of an antibiotic-antimycotic solution containing penicillin, streptomycin and Fungizone® (amphotericin B), primary cell cultures were contaminated by two unicellular protists. Since microbial contamination is a major obstacle in culturing marine invertebrate cells, we decided to determine the identity of these two protists by using cell biology techniques and metagenomics. Cells were imaged using an EVOS® FLoid® Cell Imaging Station from Life Technologies. The large protist appeared to be a ciliate while the small protist to be a flagellate, as indicated by light microscopy. Staining the DNA of live cells with NucBlue® Live ReadyProbes® reagent revealed the presence of macro- and micronuclei, further confirming that the large protist was a ciliate. No macronuclei were seen in the small protist and its movement was characteristic of an euglenoid. Additionally, lipid membranes of live cells were visualized with the fluorescent stain, DilC12(3) perchlorate. Numerous lipophilic vacuoles were present in the ciliate. Subsequently, metagenomic analyses were performed to identify these protists at the molecular level. Genomic DNA was isolated and sent to Molecular Research LP (Shallowater, TX) for 18S rRNA analysis. The 18S rRNA biodiversity assay revealed that the flagellate belongs to the order *Diplonemida* and the ciliate was identified as *Paranophrys marina*. These metagenomic data confirmed our microscopic observations. Identification and further characterization of these protozoan contaminants will not only help advance the field of marine invertebrate cell culture but may also aid in elucidating the causative agent(s) of the sea star wasting disease. (Funded in part by grant 5T36GM101995-01)

P2364**Board Number: B1046****Release of malaria parasites from red blood cells requires parasite-derived pore-forming proteins.**

S.E. Glushakova¹, C.C. Wirth², M. Scheuermayer³, E. . Leikina¹, G. Humphrey¹, A. Balaban¹, M.M. Kachman¹, G. Pradel², J. Zimmerberg¹;

¹Program in Physical Biology, National Institute of Child Health and Human Development, NIH, Bethesda, MD, ²Institute of Molecular Biotechnology, RWTH Aachen University, Aachen, Germany, ³Research Center for Infectious Diseases, University of Wurzburg, Wurzburg, Germany

Malaria is a disease caused by asexual replication of Apicomplexan parasite *Plasmodium falciparum* inside human erythrocytes. However, parasites must shuttle between humans and mosquitoes to complete its complex life cycle. Human-to-human transmission of infection happens through the bite of infected mosquitoes, where the parasite sexual stage takes place. Both the end of the asexual cycle in human erythrocytes and gamete fertilization in mosquitoes requires egress of parasites from the host erythrocytes. Here we show that erythrocyte membrane perforation precedes egress of sexual and asexual forms of parasites from infected erythrocytes. Using a novel approach and applying fluorescent live cell microscopy we demonstrated that membrane perforation happens a few seconds prior to asexual parasite egress and a few minutes before the emergence of sexual forms from erythrocytes. The pores are large enough for diffusion of hemoglobin and GFP-tagged parasite-derived proteins from the erythrocyte cytoplasm before erythrocyte membrane rupture and parasite egress. Erythrocyte swelling apparently is not needed for successful membrane perforation. Positive-curvature amphiphiles promote parasite egress, and membrane sealants block the process. *Plasmodium falciparum* encodes five perforin-like proteins (PPLP1-5). There is no direct data indicating which is involved in the asexual parasite cycle. Here we show that PPLP2(-) parasites have a normal asexual cycle but are unable to complete the sexual stage of the life cycle. Activated sexual forms remain trapped within erythrocytes whose membranes are impermeable for hemoglobin and fluorescent probes. The physiological consequence of PPLP2 deletion is the inability of malaria parasites to transfer infection from human to mosquito. Thus, the perforation of the erythrocyte membrane is an essential step in parasite egress and parasite life cycle continuation.

P2365**Board Number: B1047****Calcium Dynamics In The Human Malaria Parasite Plasmodium Falciparum Detected By Genetically Encoded Ca²⁺ Indicator.**L. Borges-Pereira¹, B.R. Koresch Leiva Campos², C.R. Garcia³;¹Departament of Parasitology, University of Sao Paulo, Sao Paulo, Brazil, ²Departament of Physiology, University of Sao Paulo, Sao Paulo, Brazil, ³Departament Physiology, University of Sao Paulo, Sao Paulo, Brazil

Calcium (Ca²⁺) is a ubiquitous signaling molecule in all eukaryotic cells, modulating several physiological processes. Changes in Ca²⁺ concentration regulate muscle contraction, neurotransmitter secretion and metabolic pathways. In the life cycle of *Plasmodium falciparum*, the etiological agent of human malaria, Ca²⁺ is involved in motility, cell progression and cell invasion and egress from red blood cells (RBCs). We developed a transgenic line of *P. falciparum* expressing GCaMP3, a genetically encoded calcium indicator (GECI). The ORF encoding the GCaMP3 gene was cloned in the transfection plasmid pDC and used to transfect a synchronized ring culture of *P. falciparum*. The transfected population was submitted to a cell sorting by flow cytometry to select those parasites with increased fluorescence. One clone was selected and the calcium response was tested in the presence of the calcium ionophore ionomycin and the SERCA (sarco / endoplasmic reticulum Ca²⁺ ATPase) inhibitor thapsigargin. Our results demonstrate that PfGCaMP3 parasites are responsive to Ca²⁺ alterations, showing an increased fluorescence when exposed to compounds that cause Ca²⁺ release in the cytoplasm. This novel transgenic parasite will provide new insight on calcium homeostasis, allowing the screening and identification of new classes of compounds with anti-malarial activity capable of interfering with signaling pathways controlling parasite growth and development.

P2366**Board Number: B1048****Lb_0210 has an osmotic effect in Leishmania, essential for differentiation and replication in macrophages.**

A.C. Zapata_Lesmes^{1,2,3}, M.A. García^{4,5,6}, M.A. Viviescas^{3,7}, W. Stühmer⁸, M.L. Posada³, M. Camacho^{3,9};
¹Ciencias Básicas, Universidad de La Salle, Bogotá D.C., Colombia, ²Facultad de Ciencias, Pontificia Universidad Javeriana, Bogotá D.C., Colombia, ³Centro Internacional de Física, Bogotá D.C., Colombia, ⁴Facultad de Medicina, Universidad Nacional de Colombia, Bogotá D.C., Colombia, ⁵Facultad de Medicina, Universidad del Rosario, Bogotá D.C., Colombia, ⁶Centro Internacional de Física, Bogotá D.C., Colombia, ⁷Facultad de Ciencias, Universidad Nacional de Colombia, Bogotá D.C., Colombia, ⁸Molecular Biology of neuronal signals, Max Planck Institute für experimentelle Medizin, Göttingen, Germany, ⁹Biología, Universidad Nacional de Colombia, Bogotá D.C., Colombia

Introduction: Leishmania transits in its life cycle between environments that differ in pH, and osmolarity. Securing transport of nutrients requires H⁺-ATPase pumps that generate an electrochemical gradient to serve this coupled to anion currents. Inhibition of these ion currents alters the capacity of the parasite to control pH and cell volume. In *Leishmania (V) braziliensis*, four sequences are putative CLC chloride channels. The aim of this study was to determine the role of the protein codified by one of them: LBRM010210. Materials and methods: From pGEMT-EasyLb0210 the restriction sites *Bam*HI and *Hind*III were inserted by PCR and the product ligated into p416Met25 before digestion and ligation into pSGEM that was used as a template to synthesize cRNA with the mMESSAGING mMACHINE® kit. To determine voltage and pH dependency *Xenopus laevis* oocytes were injected with 50 ng Lb0210 cRNA. Oocytes were recorded with voltage clamp in the presence of different concentrations of Cl⁻ or pH. Special primers were designed to induce interference by hairpin structures. A conventional PCR was carried out including the restriction sites *Xba*I and *Eco*RI and the fragments then digested and self-ligated before subcloning into pSP72RaneoαGFP. *L. (V.) braziliensis* promastigotes were electroporated with the interfering construct and selected with 60 μg/ml G418 in Schneider's medium plus 20% FBS. The fluorescent parasites were followed in culture, osmotically challenged and used to infect the macrophage-like cell line J774A.1. Parasite growth, shape and movement were determined. Solutions with different osmolarities were used and parasite volume determined by impedance using Beckman Coulter z2®. Infection was followed by light microscopy and percentage of infection, parasite number, parasite transformation and parasitophorous vacuole (PV) volume determined. With analysis of variance statistical differences were accessed and when found the Bonferroni post-hoc test was used (SigmaStat 3.5). Results: Microinjection of Lb0210 cRNA in *X. laevis* oocytes, induced voltage dependent outward rectifying currents of low amplitude. By 72 hours post-injection Lb0210 oocytes had also increased fragility and vitelline membrane detachment indicating volume changes. Transformation of promastigotes with the interfering construct render viable, fluorescent parasites that had greater volume, different swimming pattern, and showed impaired volume regulation compared to wild type, particularly at osmolarities lower than 70 mOsm/L. They were also unable to differentiate into amastigotes or replicate within the PV after 96 h post-infection in J774A1 macrophages. Conclusion: Lb_0210 appears to be important in volume and osmotic regulation and amastigote differentiation.

Complex two-component regulation of bacterial surface adhesion via integrated transcriptional control of *hfiA*, a potent adhesion inhibitor.

A. Fiebig¹, L. Reyes Ruiz², J. Herrou³, S. Crosson³;

¹Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, ²Genetics Genomics and Systems Biology, University of Chicago, Chicago, IL, ³Biochemistry and Molecular Biology, University of Chicago, Chicago, IL

In natural environments, bacteria often adhere to surfaces where they form complex multicellular communities. Surface adherence is determined by the biochemical composition of the cell envelope. *Caulobacter crescentus* secretes a polar adhesion called a holdfast, which enables permanent attachment to surfaces. *Caulobacter* employs a novel regulatory mechanism that integrates cell cycle, nutritional and environmental signals to control development of this adhesive envelope structure. Specifically, we have discovered a 68-residue protein inhibitor of holdfast development (HfiA) that directly targets a conserved glycolipid glycosyltransferase required for holdfast synthesis (HfsJ). Our data suggest that post-translational regulation of cell envelope enzymes by small proteins like HfiA may provide a general means to modulate the surface properties of bacterial cells.

The promoter of *hfiA* is affected by both numerous signaling inputs to ensure appropriate control of surface adhesion. Multiple cell cycle regulators directly control *hfiA* expression and temporally constrain holdfast development to the late stages of G1. HfiA further functions as part of a 'nutritional override' system that decouples holdfast development from the cell cycle in response to nutritional cues. While the mechanism of nutritional sensing is unknown, this control feature can limit surface adhesion in nutritionally sub-optimal environments without affecting cell cycle progression. Moreover, we have shown that the photosensory two-component system, LovK-LovR, regulates *hfiA* expression and holdfast development. However, the response regulator LovR lacks a DNA-binding output domain and thus the mechanism of transcriptional regulation must be indirect.

To better understand how the LovK-LovR environmental sensory system regulates *hfiA* expression, we designed a forward genetic selection to identify mutants in which transcriptional regulation of *hfiA* by LovK-LovR is disrupted. In this screen, the *hfiA* promoter controls the expression of chloramphenicol acetyl transferase (CAT), and growth in the presence of chloramphenicol allows for selection of mutants with increased *hfiA* promoter activity. Selected mutants were further evaluated to confirm faster growth in chloramphenicol, regulation of a second promoter fusion (*PhfiA-lacZ*), and regulation of adhesion. Using whole genome sequencing, we identified mutations in additional two-component signaling genes: a LOV interacting hybrid histidine kinase (LihA), histidine kinase (LihA), and response

regulator (LirA). Our preliminary analyses suggest that direct interactions between LovK, LihA, LikA regulate the *hfiA* promoter via the DNA binding domain of LirA.

Quantitative analysis of E-cadherin-mediated *Listeria monocytogenes* invasion of epithelial cells.

F.E. Ortega¹, M. Rengarajan¹, J.A. Theriot^{1,2};

¹Department of Biochemistry, Stanford University School of Medicine, Stanford, CA, ²Howard Hughes Medical Institute, Stanford University School of Medicine, Stanford, CA

The Gram-positive pathogenic bacterium *L. monocytogenes* invades a wide variety of phagocytic and non-phagocytic host cells. For invasion of epithelial cells, the bacterial surface protein Internalin A (InIA) binds to host cell E-cadherin, which induces local actin polymerization, remodels the host's membrane topology, and culminates in bacterial uptake via clathrin-mediated endocytosis. Experiments with E-cadherin truncation mutants have suggested that the ectodomain is sufficient for *L. monocytogenes* adhesion to the cell surface but interaction of the cytoplasmic domain with beta-catenin is necessary for invasion, and phosphorylation of E-cadherin profoundly regulates its affinity for beta-catenin. We have used epithelial cells expressing non-phosphorylatable and phosphomimetic point mutations in the beta-catenin-binding domain of E-cadherin to determine the quantitative effects of these modifications on bacterial adhesion and invasion. The non-phosphorylatable mutation results in lower surface expression of E-cadherin, but surprisingly neither this nor the phosphomimetic mutation affects the amount of InIA-dependent *L. monocytogenes* adhesion or invasion. Expression of InIA in the non-pathogenic *L. innocua* is sufficient to confer normal levels of both adhesion and invasion and is comparable for wild type, phosphomimetic, and non-phosphorylatable E-cadherin. Furthermore, we find that bacterial expression of Internalin B (InIB), which activates the host cell growth factor receptor c-Met, is not required for normal adhesion or invasion. We conclude that the efficiency of InIA/E-cadherin mediated adhesion and invasion is likely to be a non-linear function of E-cadherin concentration. As our next steps, we propose experiments to: (1) quantitatively analyze how E-cadherin levels regulate *L. monocytogenes* invasion, and (2) study the pathogenesis of listeriosis in a more physiologically relevant context using intestinal organoids.

P2369**Board Number: B1051****Structure of the CTP synthetase filament: a novel cytoskeletal element.**

M. Shepherd¹, R. Barry², E. Lynch³, J.M. Hansen⁴, E.J. Charles⁴, E.P. Baldwin⁵, Z. Gitai², J.M. Kollman^{3,4};
¹Dept. of Biology, McGill University, Montreal, QC, ²Dept. of Molecular Biology, Princeton University, Princeton, NJ, ³Dept. of Biochemistry, University of Washington, Seattle, WA, ⁴Department of Anatomy and Cell Biology, McGill University, Montreal, QC, ⁵Dept. of Molecular and Cellular Biology, University of California Davis, Davis, CA

A growing number of metabolic enzymes have been shown to form filaments in cells, constituting novel cytoskeletal systems. Although the functional significance of enzyme polymerization is unclear in most cases, increasing evidence suggests a link between filament assembly and regulation of enzymatic activity. Here, we report the first high-resolution molecular structure of the filamentous form of a metabolic enzyme, CTP synthetase (CtpS), providing insight into the mechanism and functional consequences of polymerization. CtpS is essential for cell proliferation, and was recently shown to form filaments in both prokaryotes and eukaryotes, suggesting deep evolutionary conservation of CtpS polymerization. We show that filament assembly plays a critical role in inhibiting CtpS enzymatic activity, likely by sterically locking enzyme subunits into an inactive conformation. Structure-guided mutagenesis indicates that linking activity to polymerization promotes cooperative catalytic regulation. This previously uncharacterized regulatory mechanism is important for cell function since a CtpS mutant that is enzymatically active but unable to polymerize disrupts *E. coli* growth and metabolism. We propose that coupling filament assembly to enzyme activity enables ultrasensitive control of activity while storing inactive enzymes in a readily accessible form; this may represent a general mechanism of regulation in other filamentous metabolic enzymes.

P2370**Board Number: B1052****Elucidating the structure and function of the *Vibrio parahaemolyticus* T3SS1 effector VopR.**

N.J. De Nisco¹, D. Salomon¹, P. Li¹, K. Orth¹;

¹Molecular Biology, University of Texas Southwestern Medical Center, Dallas, TX

The gram negative γ -proteobacteria, *Vibrio parahaemolyticus* (*V. para*) is a food-borne pathogen that naturally inhabits marine and estuarine environments. *V. para* is one of the most ecologically versatile of the *Vibrio* species due, in part, to its expanded genome and has been marked as an emerging pathogen and a leading cause of acute seafood-borne gastroenteritis worldwide. As part of its repertoire of virulence factors, the *V. para* genome encodes two type III secretion systems (T3SS). T3SSs are macromolecular machines derived from the bacterial flagellar apparatus that efficiently translocate bacterial effector proteins directly into the cytoplasm of host cells. The first system, T3SS1, which is anciently acquired and found in all *V. para* isolates, orchestrates a regimented host cell infection by

inducing autophagy, cell rounding and finally cell lysis. Several T3SS1 effectors, including *VopR*, remain uncharacterized. VopR is a 325 amino acid protein that has been found to induce HeLa cell rounding and inhibit yeast growth, as well as localize to the host cell membrane through binding P(4,5)IP₂ via a N-terminal phosphoinositol binding domain (BPD). This BPD is conserved in T3SS effector proteins of many mammalian and plant pathogens and is likely very important for effector folding and localization within the host cell. The host cellular activities targeted by VopR are unknown, as the catalytic activity and molecular targets of VopR within host cells remain undefined. Here, we seek to identify the host cell targets and to determine the catalytic function of VopR. In addition, we are employing structural studies to gain a better understanding of both the conserved N-terminal BPD and C-terminal catalytic domain of VopR. Using bioinformatics we have identified the putative C-terminal catalytic domain of VopR. We also discovered that of both the N-terminal BPD and the C-terminal catalytic domain of VopR contribute to toxicity in yeast and HeLa cell rounding, suggesting that VopR acts on its targets specifically at the host cell membrane. A yeast two hybrid against a mouse cDNA library revealed several putative targets of VopR, which we are currently testing in both *in vivo* and *in vitro* studies.

Board Number: B1053

The N-terminal domain of MinE exhibits amyloidogenic property that underlies formation of the MinE ring.

H. Lee¹, I. Chiang¹, Y. Shih¹;

¹Institute of Biological Chemistry, Academia Sinica, Taipei, Taiwan

Pole-to-pole oscillation of the Min proteins regulates the cell division site placement in *Escherichia coli*. MinE of the Min system organizes into a ring-like structure that plays a critical role in triggering the oscillation cycle. Despite of its functional importance, the mechanism underlying the formation of the MinE ring remains unclear. Recently, we reported that MinE self-assembles into fibrillar structures on the supported lipid bilayer. Here, we present evidence that N-terminal domain of MinE possesses the amyloidogenic property via the Thioflavin T fluorescence and Congo red spectroscopic assays, far-UV circular dichroism measurements, and electron microscopy. The amyloidogenic sequence within the N-terminal domain of MinE is confirmed by proteinase K digestion and acid denaturation of the fibrils, followed by HPLC purification and N-terminal sequencing. In addition, the molecular dynamic simulation is used to build a model of the amyloidogenic region of MinE that demonstrates a characteristic cross- β structure of amyloid fibrils. Taken together, the results suggest that the amyloidogenic property of MinE may implicate in the mechanism of MinE-ring formation. Further studies will be performed to address the kinetic property of the ring-like structure in the form of amyloid aggregates during oscillation.

P2372**Board Number: B1054****Elucidating mechanisms of bacterial cell growth through live single-cell imaging and Bayesian model selection.**Z. Barry¹, E.C. Garner², M. Bathe¹;¹MIT, Cambridge, MA, ²Harvard University, Boston, MA

The viability of bacteria relies on the structural integrity of the peptidoglycan cell wall. A detailed understanding of the cell wall synthesis machinery is essential to enabling the discovery of new molecular targets for antibiotics due to the increasing emergence of bacterial resistance to existing compounds. The molecular machinery that synthesizes and maintains the cell wall structure consists of dozens of molecular components with complex and dynamic interactions that can only be properly resolved in the context of intact living cells. Single molecule imaging and computational analysis of the peptidoglycan synthesizing proteins (PGSP) offers the unique opportunity to mechanistically characterize the spatial activity, molecular interactions, and regulation of proteins that drive bacterial growth to elucidate important new antibiotic targets.

Toward this end, we have developed an experimental-computational approach that combines systematic fluorescence labeling and high-resolution imaging with targeted chemical and genetic perturbations. Single-molecule imaging of the proteins that coordinate peptidoglycan (PG) synthesis offers novel single-molecule insight into the process of cell wall synthesis and elongation. For example, it has been shown in rod-like bacteria that the PGSP protein MreB moves in a directed, circumferential manner around the short axis of the cell, possibly driven by the polymerization of new PG.

To capture cell elongation dynamics in real time, fluorescence movies of genetically engineered PGSP fusions in live, single cells are captured, and localizations of the molecules as they move throughout the cell are measured using single-particle tracking. Importantly, automated and objective Bayesian multiple hypothesis testing of competing molecular motion models is performed to elucidate molecular dynamics including binding lifetimes, protein-protein interactions, as well as their modes of motion on the outer cell membrane.

P2374**Board Number: B1056****Alternative Nucleic Acid Structures in the Macronucleus and Micronucleus of the Blepharisma.**A.E. Skiadas¹, D. Carbone¹, C. Gagna^{1,2,3}, I. Isquith⁴, N. Agostino⁴, A. Bradshaw⁴, W. Lambert^{2,3}, A. Khan¹;¹Department of Life Sciences, New York Institute of Technology, Old Westbury, NY, ²Department of Pathology and Laboratory Medicine, Rutgers-New Jersey Medical School, Newark, NJ, ³Department of Dermatology (Medicine), Rutgers-New Jersey Medical School, Newark, NJ, ⁴Department of Biology, Fairleigh Dickinson University, School of Natural Sciences, Teaneck, NJ

Blepharisma is a microphagus, filter feeding, light-sensitive ciliated protozoan, usually found in fresh water. Ciliates are considered the most complex and evolved of the protozoa. Blepharisma contains approximately 40 species with numerous strains and sub-varieties. *B. stoltei* is about 190 micrometers in length and deals with hazardous conditions by forming a cyst. It contains a large macronucleus and several micronuclei which are involved with sophisticated molecular biological processes, such as reproduction and regeneration. Nucleic acids are dynamic molecules that can adopt many different structures, such as right-handed double-stranded (ds-) B-DNA, single-stranded (ss-) DNA, left-handed ds-Z-DNA, triplex DNA and quadruplex DNA. The nuclei of the Blepharisma were immunohistochemically and immunochemically (ELISA) examined for the presence of alternative DNA structures. A variety of anti-ds-B-DNA antibodies, anti-ss-DNA antibodies, anti-Z-DNA antibodies and anti-methylated DNA antibodies were used. Additionally, we used the Feulgen reaction for determination of DNA content. We also examined these organisms for the presence of methylated DNA. Several different fixatives were used to preserve the organism's morphology and genome (i.e., preservation of intact, unaltered DNA), namely, 10% formalin, zinc formalin, Bouin's solution, Zenker's solution, Histochoice, Methacarn, Carnoy's solution, glutaraldehyde, and Davidson's fixative. This was done in order to determine morphology and the distribution/content of nucleic acids in the nuclei of the Blepharisma. Our data show that Blepharisma has all of these different types of DNA. However, the presence of left-handed Z-DNA was better demonstrated using Carnoy's solution. Bouin's fixative did not preserve DNA structure. Antigen retrieval was needed for some of these fixatives. Digestion of nuclear DNA with nicking concentrations of DNase I results in no Z-DNA immunoreactivity. Full nuclease digestion nicking concentrations resulted in no B-DNA immunoreactivity. Certain fixatives resulted in better preservation of morphology and others for certain DNA structures. Our data reveals that Blepharisma contains conventional and alternative nucleic acids. Z-DNA immunoreactivity depends on certain nuclear regions, physiological cycles and fixatives. Less Z-DNA immunoreactivity has been detected in non-cyst conditions. This type of research may shed light on the evolution of DNA structure and function. This research project was supported in part by a NYIT 2011 Institutional Support of Research and Creativity grant.

P2375**Board Number: B1057****Identification and Characterization of Plasmids from Marine Bacteria Isolated from the Sea Urchin *Lytechinus variegatus*.**D.A. Ballard¹, J. Chen², C. Priano¹, L. Jayant¹;¹Science, Borough of Manhattan Community College, New York, NY, ²SUNY at StonyBrook, Brooklyn, NY

Bacterial flora that coexist on the surface and test of the sea urchin *Lytechinus variegatus* were screened for the presence of cryptic plasmids. Several bacterial strains were isolated from the test, spines, mouth and gonads of urchins by gently swabbing these regions with a sterile tip and plating them onto marine agar plates. Strains were also isolated from the water samples in which the urchins arrived. Gram staining of more than sixty isolated bacteria revealed that all were gram negative rods. Isolated bacteria were tested for the presence of plasmids using a Bio Rad Aurum plasmid mini kit. Results indicated that at least two out of the sixty bacterial samples contained plasmid DNA. One of these bacterial isolates was taken from a spine that had been shed from an urchin. A red area at the base of the spine was used for the initial streaking. The second bacterial isolate was obtained from the water sample in which the urchins were shipped. Both plasmids are small, about 2.0 to 3.0 kb in size. 16S rRNA gene sequencing will be performed to further identify and characterize the bacteria that host these plasmids. Restriction mapping and DNA sequence analysis will be used to characterize and identify unique elements of the isolated plasmids. To determine their biological role in these bacteria, further analysis of these plasmids will examine whether they carry resistance to antibiotics or environmental toxins.

P2376**Board Number: B1058****Enzymatic regulation by filament formation: product-stimulated polymerization inhibits the enzymatic activity of CTP Synthetase.**R. Barry¹, A. Bitbol², A. Lorestani¹, E. Charles³, J.M. Hansen³, C. Habrian⁴, H. Li¹, E. Baldwin⁴, N. Wingreen⁵, J. Kollman⁶, Z. Gitai¹;¹Dept. of Molecular Biology, Princeton University, Princeton, NJ, ²Princeton University, Princeton, NJ,³Department of Anatomy and Cell Biology, McGill University, Montreal, QC, ⁴UC-Davis, Davis, CA,⁵Princeton Univ, Princeton, NJ, ⁶Univeristy of Washington, Seattle, WA

Large-scale protein localization screens revealed numerous metabolic enzymes with distinct, non-diffuse localizations. But why do these enzymes assemble into large-scale structures? Here we focus on CTP Synthetase (CtpS), which synthesizes CTP and forms filamentous structures in prokaryotes and eukaryotes. In *C. crescentus*, CtpS polymers help regulate cell shape, but *E. coli* CtpS polymers serve no obvious structural function. Here we demonstrate that CtpS uses a novel polymerization-based mechanism to harness the cooperativity of polymerization to maintain tight control of CtpS activity.

To determine why CtpS polymerizes, we developed a biochemical system to simultaneously monitor CtpS polymerization and enzymatic activity. Increased polymerization correlated with a sharp decrease in enzymatic activity, and polymer assembly was stimulated by the enzyme's product, CTP. Thus, product-induced polymerization functions to inhibit CtpS activity. To understand the mechanism underlying this assembly-mediated form of end-product inhibition, we used electron microscopy to define the structure of CtpS polymers. This structure suggests that polymerization sterically hinders a conformational change necessary for CtpS activity. Structure-guided mutagenesis and mathematical modeling further indicate that coupling activity to polymerization promotes cooperative catalytic regulation. Our hypothesis that polymerization-based regulation facilitates ultrasensitive control of nucleotide biosynthesis is supported by metabolomic analysis of CtpS polymerization disruption in vivo in *E. coli*. This type of regulation may allow cells to respond rapidly to fluctuations in nutrient availability or depletion of key intracellular molecules.

The elucidation of CtpS filament structure and its regulatory role may inform the rationale for localization of other metabolic enzymes. Additionally, the use of similar large-scale assembly-based regulation strategies by ancestral enzymes may explain the evolutionary relationship between metabolic proteins like hexokinases and structural proteins like MreB, such that CtpS could serve as a paradigm for understanding the origins of the first cytoskeletal elements.

Role of cardiolipin in *Rhodobacter sphaeroides* cell morphology.

T. Lin¹, D.B. Weibel¹;

¹Biochemistry, University of Wisconsin-Madison, Madison, WI

Bacteria come in a variety of shapes that are formed by the orchestration of its internal cytoskeleton and external cell wall. Cell shape influences cellular functions and indicates cell health. Although it has been suggested in rod-shaped bacteria that MreB forms filamentous structures along the long axis that serve as an internal scaffold and direct the activity of penicillin-binding protein 2 (PBP2) for cell wall elongation, the morphogenetic factors that guide the formation of these macromolecular structures still remain elusive. In this study, we report that cardiolipin (CL) plays a role in the rod-shaped morphology of *Rhodobacter sphaeroides*. A CL-deficient strain of *R. sphaeroides* shows an alteration in cell shape, from rods to ellipsoids. Complementation of the CL-deficient mutant restores a rod shape. In addition, overproduction of CL in the wild-type strain of *R. sphaeroides* enhances the rod shape and leads to cell elongation. Finally, we found that in *R. sphaeroides*, rod shape formation also requires MreB and PBP2. Future work will be dedicated to understanding the interplay of these three components in *R. sphaeroides* cell elongation machinery.

P2378**Board Number: B1060****Characterization, Comparative Genomics and Genome Mining for Antibiotics and Secondary Metabolite of two Actinomycetales isolates.**R.M. Mariita¹, S. Bhatnagar², K. Newman⁵;¹Biological Sciences, Auburn University, Auburn, AL, ²Microbiology Graduate Group, Univ California-Davis, Davis, CA, ³Plant Biology /Microbiology, University of Zurich, Zurich, Switzerland,⁴Biology/Biological Engineering, California Inst Technology, Pasadena, CA, ⁵California Inst Technol/HHMI, Pasadena, CA

Actinomycetes are ubiquitous Gram (+) bacteria commonly found to have high G+C content and best known for their metabolic by-products and novel enzymes [1]. Isolates CCMMD2014 & MRMD2014 were co-cultured from soil impacted by a rusty fire hydrant in Woods Hole, MA. The *Streptomyces* sp. and *Curtobacterium* sp. isolates were identified by marker genes for 16S rRNA, rpoB, xylose isomerase, tryptophan synthase beta chain and Cytochrome P450 monooxygenase. Both isolates showed lactic acid fermentation and urease activity. The co-isolates were separated by selective culturing with antibiotics. In addition, whole genome sequencing revealed distinct inherent metabolic pathways in each culture that allowed for mutually exclusive selective culture conditions. Assembly was done using HGAP3 with Celera8 assembler using SMRT portal [2,3]. Annotation was done using the RAST server [4], with 7540 and 3969 CDS for *Streptomyces* sp. and *Curtobacterium* sp. respectively being revealed by AMIGene and BASys [5,6]. Subsequently, antiSMASH [7], was used to predict 52 and 26 secondary metabolite biosynthetic clusters that included genes for lantipeptides, terpenes, siderophores, polyketide synthases type I and II, bacteriocin and nonribosomal peptide synthase genes for *Streptomyces* sp. and *Curtobacterium* sp. respectively. The isolates have genes of potentially beneficial traits that could help study, among others, the role of fimbrial adhesins and iron in biofilm formation and investigation on natural products.

Many tumors have low redox potential, with local hypoxia and hypercapnia. The decreased convection-mediated transport of nutrients, gases, and metabolic products during spaceflight may offer a microenvironment for growing cells that mimics many of the metabolic features of tumors. We proposed that molecularly barcoded yeast deletion series can provide a quantitative assessment of the effects of spaceflight on a model organism. In liquid culture yeast have no requirement for substrate adhesion or physical cell-cell interactions and their responses during spaceflight can be quantified and compared to well-established databases of ground-based stressors to allow clear examination of features that are unique to microgravity as well as features that are shared with ground-based perturbations. We screened the complete collection of 4800 non-essential yeast homozygous alleles and a collection of 5900 yeast heterozygous alleles including 1200 alleles encoding essential genes in spaceflight and ground conditions, with and without stimulation by hyperosmolar sodium chloride as a second additive stressor. The genome-wide sensitivity profiles obtained from these treatments were queried for their similarity to a compendium of drugs whose effects on yeast have been studied by chemogenomics. Spaceflight has subtle but significant effects on core cellular processes including growth control via RNA and ribosomal biogenesis, metabolism, modification and decay pathways. Significant roles for DNA repair and replication, response to pH signaling, control of gene expression and mitochondrial function were observed. Our results strongly implicate DNA and RNA damage as the major ground based analogs of spaceflight. Given the unique, and substantial radiation exposure in space, this is consistent with major radiation-mediated effects. The high concordance to the profile induced by diallyl disulfide suggests increased glutathione S-transferase, binding of electrophilic toxins, increased reactive oxygen species and change in redox state. Identification of these vital pathways can guide future experiments by suggesting environmental modifications that can bolster cellular and organismal integrity by avoiding further stress to these pathways, and secondly, by identifying drug

stresses that can exacerbate these pathway requirements in an effort to control pathological cell growth in the case of proliferative diseases. The performance of this platform is significant for spaceflight studies and promises to enable terrestrial experiments in extreme environments that will have direct application to microbial bioprocessing for manufacturing, alternative fuel development and basic research.

Effects of Vitamin E on primary cultures of dystrophin-deficient mdx mice.

A.R. Fogaça¹, A.B. Macedo¹, D.S. Mizobuti¹, T.A. Hermes¹, E. Minatel¹;

¹UNICAMP, Campinas, Brazil

Several studies suggest a role for free radicals in the degeneration of dystrophin-deficient muscle, as observed in Duchenne muscular dystrophy (DMD). In the present study, we investigated the effects of Vitamin E (antioxidant) on primary skeletal muscle cell cultures derived from an animal model of DMD, the mdx mice. Dystrophin-deficient muscle cells were treated with Vitamin E (7.5 μ M) for 24 hours. Untreated dystrophin-deficient muscle cells were used as control. Drug toxicity was assessed using a MTT cell viability assay. Hydrogen peroxide (H₂O₂; a marker of cellular reactive oxygen species production) was measured by using the Amplex red assay kit. 4-hydroxynonenal (4-HNE) analysis was used as a lipid peroxidation marker. The extent of the inflammatory process was assessed by TNF- α and NF- κ B levels by western blotting. Intracellular calcium concentration was indicated by the fluorescent indicator, Fluo-4. The MTT results showed that Vitamin E had no cytotoxic effect on mdx muscle cells. 4-HNE levels and intracellular calcium concentration were not altered by the Vitamin E treatment on dystrophic muscle cells. Vitamin E treatment decreased H₂O₂ production by 4% and TNF- α and NF- κ B levels by 11% and 23% respectively on mdx muscle cells. However, these reductions were not significant ($p \geq 0.05$; Anova). Based on the results, it can be hypothesized that Vitamin E was not potent enough or that the duration of treatment was too short to detect a significant positive effect on dystrophin-deficient muscle cells. Ethical approval: CEUA-IB-UNICAMP #3334-1. Support: FAPESP #2011/02474-4; #2013/17299-9.

P2381**Board Number: B1064****Effects of low-level laser therapy on inflammatory and oxidative stress parameters in dystrophic muscle fibers.**A.B. Macedo¹, D.S. Mizobuti¹, T.A. Hermes¹, L.H. Moraes¹, E. Minatel¹;¹UNICAMP, Campinas, Brazil

Duchenne muscular dystrophy (DMD) is a fatal X-linked disease that affects 1 in 3,500 child births. Reactive oxygen species (ROS) and inflammatory response play a key role in the pathogenesis of DMD. Evidence suggests that low-level laser therapy (LLLT) reduces the release of ROS, decreases the inflammatory process and increases the production of antioxidants. With this perspective in mind, the present study investigates the in vivo and in vitro effects of the LLLT on inflammatory and oxidative stress parameters in dystrophic muscle fibers of mdx, the experimental model of DMD. Primary cultures of mdx skeletal muscle cells were irradiated one time alone with laser and analyzed after 48 hours. While, in the in vivo study, the dystrophic quadriceps muscle was treated with laser three times a week for two weeks. Both studies considered C57BL/10 mice as controls. The LLLT parameter used was 830 nm wavelengths at 5 J/cm² fluence. In the in vitro study, cell viability was assessed by MTT assay; hydrogen peroxide (H₂O₂; a marker of cellular ROS production) was measured by using the Amplex red assay kit and intracellular calcium concentration was indicated by the fluorescent indicator, Fluo-4. In the in vivo study, dihydroethidium (DHE) staining for ROS detection was used. In the in vivo and in vitro studies, the extent of the inflammatory process was assessed by TNF- α level. The laser treatment in dystrophic muscle cells improved the cell viability (15%), significantly decreased H₂O₂ production (25%; $p \leq 0.05$, Anova) and reduced the TNF- α level (by 19%; $p \leq 0.05$, Anova). In the dystrophic quadriceps muscle, LLLT significantly reduced the TNF- α level (8%; $p \leq 0.05$, Anova) and DHE staining (by 50%; $p \leq 0.05$, Anova). These results suggest that the laser decreased inflammatory process and oxidative stress in dystrophic muscle fibers, indicating that LLLT could be a helpful alternative therapy to be associated with other pharmacological treatments. Ethical approval: CEUA-IB-UNICAMP #2974-1. Support: CAPES; FAPESP #2011/02474-4.

P2382**Board Number: B1065****Gamma-sarcoglycan is required for the response of archvillin to mechanical stimulation in skeletal muscle.**J. Spinazzola¹, T.C. Smith², M. Liu³, E.J. Luna², E.R. Barton¹;¹Anatomy Cell Biology, University of Pennsylvania, Philadelphia, PA, ²Cell Developmental Biology, University of Massachusetts Medical School, Worcester, MA, ³Physiology, University of Pennsylvania, Philadelphia, PA

In skeletal muscle, mechanotransduction is mediated in part by the dystrophin-glycoprotein complex (DGC), an assembly of proteins in the sarcolemma that links the cytoskeleton and the extracellular matrix. Mutations of DGC components cause several forms of muscular dystrophies, progressive neuromuscular disorders characterized by severe muscle weakness. Gamma-sarcoglycan (γ -SG) deficiency causes Limb Girdle muscular dystrophy type 2C and is also a secondary consequence of dystrophin mutation in Duchenne muscular dystrophy. While dystrophin deficiency causes contraction-induced mechanical damage that leads to pathology, deficiency in γ -SG alone is sufficient to induce skeletal muscle degeneration and signaling defects, disrupting muscle adaptation to mechanical load. However, mechanisms of γ -SG mediated signaling and the proteins involved are poorly understood.

We investigated γ -SG as a component of the load-sensing machinery of muscle cells, and through yeast two-hybrid screens, identified the muscle-specific protein archvillin (AV) as a γ -SG and dystrophin interacting protein. Archvillin is an attractive candidate because it colocalizes with dystrophin at the sarcolemma, and its isoform, smooth muscle AV, associates with ERK in a stimulus-dependent manner. Archvillin expression and localization were analyzed by IB, qRT-PCR and IHC in hindlimb muscles of wild-type (C57), γ -SG -null (*gsg*^{-/-}), and dystrophin deficient *mdx* mice. Archvillin protein and mRNA expression were significantly upregulated in *gsg*^{-/-} muscle, but were similar to C57 levels in *mdx* muscle. In muscle cross-sections, AV was upregulated at the sarcolemma in *gsg*^{-/-} muscle, but absent in *mdx* muscle. Reintroduction of γ -SG in *gsg*^{-/-} muscle by rAAV injection normalized archvillin levels toward that of C57. Mechanical perturbation of TA muscles with an in situ eccentric contraction protocol revealed that AV associates with P-ERK in a stimulus-dependent manner, but this interaction was lost in *gsg*^{-/-} and *mdx* muscle. Nuclear/cytoplasmic fractionation studies showed that nuclear localization of P-ERK1/2 increased in *gsg*^{-/-} and *mdx* muscle after eccentric contraction.

In this study, we established that AV is a new player in mechanical signal transduction in muscle, and that its localization and actions require the presence of dystrophin and the sarcoglycans, respectively. Mechanical fragility may not be the only deficit contributing to the dystrophic process, and AV may contribute to the aberrant signaling observed in dystrophic muscle. Analyzing potential components of γ -SG-mediated mechanotransduction will be an important step in understanding the pathways leading to dystrophic pathology, and may contribute to the development of therapies for muscular dystrophies.

P2383**Board Number: B1066****Replacement of myosin molecules in thick filament of cultured skeletal muscle.**E. Ichimura¹, Y. Yasukawa¹, K. Ojima², J. Wakamatsu¹, T. Nishimura¹;¹Hokkaido University, Sapporo, Japan, ²Animal Products Res. Div., NARO, ILGS, Tsukuba, Japan

Myosin is one of the major myofibrillar proteins of skeletal muscle. More than 300 myosin molecules assemble into a bipolar thick filament in the sarcomere. We have previously shown that myosin molecules in thick filaments are vigorously exchangeable in cultured myotubes using fluorescence recovery after photobleaching (FRAP) technique. However, it is still unclear how myosin molecules in thick filaments are replaced. In this study, we investigated the replacement of myosin molecules in myotubes, when protein biosynthesis was inhibited. Exogenously expressed eGFP-tagged myosin heavy chain 3 (eGFP-Myh3) were precisely incorporated into the A-band of the sarcomeres. We carried out FRAP experiments in the presence of cycloheximide (CX) to inhibit protein biosynthesis. The fluorescence recovery of eGFP-Myh3 in myotubes treated with CX for an hour was not different from that of control without CX-treatment. However, the fluorescence of eGFP-Myh3 in myotubes treated with CX for ten hours recovered to a less extent compared with the control group. This result suggests that myosin molecules in thick filaments were exchanged largely by myosin molecules which might exist in the cytosol adjacent to myofibrils. To address this, we examined myosin molecules replacement in myotubes treated with streptolysin O (SLO) which makes pores in the cell membrane. The fluorescence recovery of eGFP-Myh3 in myotubes treated with SLO was suppressed compared to the control without SLO-treatment. This might be caused by the decrease in the amount of myosin molecules in the cytosol due to the outflow of myosin molecules that were not incorporated into thick filaments from myotubes. Our data suggest that myosin molecules in the thick filament are actively replaced with myosin molecules that exist in the cytosol of skeletal muscle cells.

P2384**Board Number: B1067****Effects of glucose concentrations on myoblast differentiation, muscle fiber composition and CB1 receptor expression.**D. Zhao¹, A.R. Conley²;¹Lycoming College, Williamsport, PA, ²Biology, Lycoming College, Williamsport, PA

Glucose is most important simple sugar for the human body, and changes in extracellular and intracellular glucose concentrations can have a dramatic effect on a cell's morphology and function. Studying these effects is of high importance due to the increasing presence of type II diabetes in the United States' population. In this study, C2C12 cells, muscle myoblasts, were differentiated at various concentrations of glucose (10mM, 15 mM, and 25mM) in order to determine how glucose levels affected differentiating muscle stem cells. RNA was isolated after one day of differentiation and after

the cells were fully differentiated at day six. RT-qPCR was run to determine how differentiation time and glucose concentration affected gene expression levels. Muscle fiber composition was studied using myosin heavy chain (MHC) primers and the three primers were used to determine the gene expression levels of the cannabinoid 1 receptor (CB1R). Gene expression levels of CB1R and MHCIIx (fast muscle fiber) increased dramatically in the high glucose sample of fully differentiated cells. It can be suggested that altering glucose levels is enough to alter the muscle fiber composition of skeletal muscle cells. Further studies need to be performed to determine if there is a relationship between the increase in CB1R expression and the increase in fast muscle fibers (MHCIIx expression).

IGF-1 gene induced by ingestion of soy peptides inhibits skeletal muscle atrophy.

S. Yamada¹, H. Fujita¹, A. Ozeki¹, H. Matsumoto¹;

¹Jissen Women's University, Hino, Tokyo, Japan

A result of examining the effects of soy peptides intake to muscle atrophy caused by no-load model, it was found that the soy peptides, there is a growth-promoting action of skeletal muscle atrophy and inhibitory effect on skeletal muscle. In this experiment, male ICR mice were used (body weight 42.3 ± 2.7 g average, Japan SLC, Inc.) and 20 animals. In an environment under 24 ± 1 °C room temperature, a 12-hour day-night reversal light-dark cycle, and ad libitum drinking water and food and were housed in individual cages for 7 days. Diet using the MF (Oriental Yeast Co., Ltd.) was used (Fuji Oil Co., Ltd.) soy peptides AM which was prepared in 175 mg / mL and pure drinking water. The molecular weight of the soybean peptide to be used in this experiment was 5000 or less. Pure water intake group (the "Group W"), pure water intake + tail-suspension group (hereinafter referred to as "WTS group"), soy peptides Newt AM high intake group (hereinafter "AM group") soy peptides High Newt AM ingested mouse + I was divided into four groups of five mice tail suspension group ("AMTS group" below). I was using the tail suspension method Emily Morey was devised as a method of inactivity. Seven days after tail suspension, were sacrificed under anesthesia each mouse group W, WTS group, AM group, the AMTS group, were collected each plantaris muscle is a fast muscle and soleus muscle is a slow muscle and weight, electronic balance I was measured by METTLER TOLEDO Co., Ltd.). Myofibrillar protein content was measured according to the Bradford method. After staining with HE Frozen muscle sections were prepared on a cryostat, the area of the cells was measured under a microscope. Furthermore, in order to elucidate the mechanism of the suppression muscle atrophy, a study was conducted by focusing on the behavior of IGF-1. The growth during development of skeletal muscle and skeletal muscle hypertrophy time, IGF-1 is significantly increased, are generally known. The results of these experiments, an increase in IGF-1 concentration was found by AM administration clearly. That the gene expression of the IGF-1 increases by more AM uptake revealed. The increase in IGF-1R was also observed. It is inferred from the above results, a gene of IGF-1 is expressed by AM administration, and IGF-1 is synthesized by the autocrine mechanism, and is suppressed muscle atrophy.

P2386**Board Number: B1069****PEDF and PEDF-derived peptide promotes skeletal muscle regeneration by its mitogenic effect on muscle progenitor cells.**Y. Tsao¹;¹Department of Ophthalmology, Mackay Memorial Hospital, Taipei, Taiwan

Muscle injury triggers an intrinsic regenerative process that includes the proliferation of satellite cells which gives rise to myoblasts before the eventual differentiation into myotubes. In cultured C2C12 myoblast cells, pigment epithelial-derived factor (PEDF) and synthetic PEDF short peptide (PSP; residues Ser93-Leu112) stimulated mitogenesis together with the raise of cyclin D1 expression. PEDF evoked phosphorylation of ERK1/2, Akt and STAT3. Blockade of activity of ERK, Akt or STAT3 by pharmacological inhibitors attenuated PEDF effects on the induction of cell proliferation and cyclin D1 expression. Muscle regeneration promoted by PSP was confirmed by increased myotube formation in a rat model of myonecrosis induced by bupivacaine. BrdU pulse-labeling assay demonstrated that PSP stimulated primary rat satellite cell proliferation in injured soleus muscle and in cell culture and the process is mediated through ERK, Akt and STAT3 signaling. Our results extend the understanding of the biological activity of PEDF on modulating muscle progenitors. Our data suggest that the PEDF peptide benefits muscle repair by mechanism involving its mitogenic effect on muscle progenitors.

P2387**Board Number: B1070****Transforming growth factor type beta 1 (TGF- β 1) induces skeletal muscle atrophy by a mechanism dependent of NADPH oxidase-induced reactive oxygen species.**J. Ábrigo¹, M.G. Morales¹, F. Simon¹, C. Cabello-Verrugio¹;¹Departamento de Ciencias Biológicas, Universidad Andres Bello, Santiago, Chile

TGF- β 1 signaling pathway play an important role in skeletal muscle homeostasis and its expression is linked to normal processes in skeletal muscle such as growth, differentiation, regeneration, and stress response. Recently, TGF- β 1 is linked to skeletal muscle atrophy. Skeletal muscle wasting is characterized by the loss of muscle mass, decline in strength and the increase of myofibrillar proteins degradation, mainly through the ubiquitin-proteasome system (UPS). Two specific muscle E3 ubiquitin-ligases, atrogin-1 and MuRF-1, are upregulated in skeletal muscle atrophy, whose target of degradation are myofibrillar proteins, such as myosin heavy chain (MHC). Recent data shown that TGF- β 1 increase the atrogin-1 expression. However the mechanism involved in TGF- β 1-induced atrophy has not been elucidated. One of the mechanisms induced by TGF- β 1 that could participate in muscle atrophy is the increase of reactive oxygen species oxidative (ROS) levels mediated by NADPH oxidase (NOX). Based on this we decided to evaluate the participation of ROS dependent on NOX in the generation of skeletal

muscle atrophy induced by TGF- β 1. C2C12 myotubes were treated with TGF- β 1. The protein levels of atrogen-1, MuRF-1 and MHC was evaluated by western blot. The diameter of myotubes was determined by indirect immunofluorescence for MHC. The production of ROS induced by TGF- β 1 was evaluated by the fluorescent probe DCF. To evaluate the ROS participation in the atrophy generation induced by TGF- β 1, myotubes was incubated in absence or presence of anti-oxidant N-acetylcystein (NAC), while that apocynin (NOX inhibitor) was used for determinate the participation of NOX. Our results shown that TGF- β 1 regulates the levels of atrogen-1 and MuRF-1 during the differentiation, in a differential fashion, showing an increment of both E3 ubiquitin-ligases at early stages of differentiation (day 2), while MuRF-1 levels are only increased in late stages (day 5). At day 5, TGF- β 1 produce a decrease in the levels of MHC and the myotubes diameter and induce an increase of the ROS levels, mediated by NOX. Finally, we determined that the diminution of ROS prevent the atrophic effect induced by TGF- β 1 in myotubes evaluated by MuRF-1 and MHC levels. The results obtained, provide new evidence about the atrophic effect of TGF- β 1 in skeletal muscle cells, and demonstrated that NOX-induced ROS is a key regulator of the TGF- β 1-dependent atrophy in skeletal muscle cells and represent a new therapeutic target against skeletal muscle atrophy.

The regulation of muscle structure and function by Mio/dChREBP in *Drosophila*.

G.L. Polak¹, A. Pasqualino¹, S. Beck², J. DiAngelo¹;

¹Department of Biology, Hofstra University, Hempstead, NY, ²Biology, Nassau Community College, Garden City, NY

All cells require energy to perform their specialized functions. Muscle is particularly sensitive to the availability of nutrients due to the high-energy requirement for muscle contraction. Therefore the ability of muscle cells to obtain, store and utilize energy is essential for the function of these cells. Mio, the *Drosophila* homolog of carbohydrate response element binding protein (ChREBP), has recently been identified as a nutrient responsive transcription factor important for triglyceride storage in the fly fat body. However, the function of *Mio* in muscle is unknown. In this study, we characterized the role of Mio in controlling muscle function in adult flies. Decreasing *Mio* levels using RNAi specifically in muscle leads to a flight defect and altered myofibril structure in the indirect flight muscles as shown by electron microscopy. *Mio* RNAi flies also have increased glycogen storage in their thoraxes as well as altered glycolytic and glycogenic gene expression, potentially contributing to the impairment in flight muscle function observed in these flies. Together, these data indicate a novel role for Mio to control muscle structure and metabolism and may provide a molecular link between nutrient availability and muscle function.

P2389**Board Number: B1072****Dynamics of secreted proteins from skeletal muscle cells during muscle differentiation.**K. Ojima¹, M. Oe¹, I. Nakajima¹, S. Muroya¹, T. Nishimura²;¹Animal Products Res. Div., NARO, ILGS, Tsukuba, Japan, ²Hokkaido University, Sapporo, Japan

Skeletal muscle cells drastically change their phenotype after differentiation, *i.e.*, proliferating mononucleated cells shift to multinucleated myotubes or myofibers. Growth factors are critical in this muscle differentiation process. Recently, it has been shown that skeletal muscles secrete growth factors, called myokines. However, it is not clear what type of protein is released from skeletal muscle cells during differentiation. To address this, we evaluated the dynamics of secreted proteins using mass spectrometry combined with an iTRAQ[®] labeling method to identify proteins quantitatively and comprehensively. Secreted levels of proteins were compared at four different culture time points, including one proliferating and three differentiating stages. We detected more than 400 proteins in cultured medium from muscle cells and approximately 8% of them were categorized as secreted proteins based on a gene ontology classification. The levels of secreted proteins associated with promoting myotube formation or enhancing vascularization peaked during early muscle differentiation, whereas proteins contributing to repellent activity against nerve cells or suppression of adipogenic differentiation decreased in quantity after muscle differentiation. Our data suggest that muscle cells secrete different types of proteins at different myogenic developmental stages as a tool to communicate with other types of cells that organize skeletal muscle tissues *in vivo*.

P2390**Board Number: B1073****Lipopolysaccharide-induced skeletal muscle atrophy is prevented by Angiotensin (1-7) via Mas receptor.**M.G. Morales¹, H.H. Olguin², E. Brandan², F. Simon¹, C. Cabello-Verrugio¹;¹Departamento de Ciencias Biologicas, Universidad Andres Bello, Santiago, Chile, ²Departamento de Biologia Celular y Molecular, Pontificia Universidad Catolica de Chile, Santiago, Chile

During skeletal muscle atrophy there is a severe loss of muscle mass, a decrease on muscle strength and myosin heavy chain (MHC) levels, an up regulation of muscle-specific ubiquitin 3 ligases atrogin-1 and MuRF-1. Sepsis is a cause of muscle wasting. In a mice model of lipopolysaccharide (LPS)-induced sepsis, skeletal muscle atrophy is observed and characterized by the activation of p38 MAPK pathway. Angiotensin (1-7) [Ang (1-7)], the main peptide of non-classical renin-angiotensin system, exerts its actions through the Mas receptor. We recently demonstrated that: a) Ang (1-7) has anti-atrophic activity in a model of muscle wasting induced by angiotensin II (Ang-II) through a mechanism dependent on AKT;

b) Ang (1-7) decreases the p38 MAPK activation induced by Ang-II in skeletal muscle cells. Therefore, we want to evaluate the effect of Ang (1-7) and Mas receptor on the LPS-induced skeletal muscle atrophy, a model of muscle wasting independent of Ang-II.

For this, C2C12 myotubes and isolated skeletal muscle fibers were incubated with LPS in absence or presence of Ang (1-7) and Mas receptor antagonist (A779). C57BL/10J mice were injected intraperitoneally with LPS and infused through osmotic pumps with Ang (1-7) and A779, and gastrocnemius and tibialis anterior muscles were analyzed. To evaluate muscle atrophy in vivo, we determine the fiber size by H&E staining and the muscle strength by electrophysiological measurements in isolated muscles. For analysis in vitro the myofiber and myotube diameter was determined. In addition, in vitro and in vivo analysis of atrogen-1 and MuRF-1 gene expression was performed by RT-qPCR, and MHC and p38 MAPK (phosphorylated and total) levels were evaluated by western blot. We determined that Ang (1-7), through the Mas receptor, decreases LPS-induced skeletal muscle atrophy, preventing the diminution in fiber diameter and maximal isometric force of the gastrocnemius and tibialis anterior muscle, resulting in a 35% increase in muscle strength compared to mice treated with LPS. Concomitantly, Ang (1-7) inhibits the decreased in MHC levels and abolished the induction of the atrogen-1 and MuRF-1 gene expression. Ang (1-7) decreased the phosphorylation of p38 MAPK induced by LPS in vivo and in vitro, suggesting that the possible mechanism through Ang (1-7) exerts its anti-atrophic effect would involve, at least, the participation of p38 MAPK. The results suggest that Ang (1-7) is a molecule with anti-atrophic properties in a model induced by LPS that is independent on Ang-II, and could be further considered as a new possible therapy to improve muscle mass in a septic condition. Hyperlipidemia inhibits Sca1/VEGFR2 progenitor cell mobilization and angiogenesis in ischemic skeletal muscle in ApoE^{-/-} mice and suppresses SDF/CXCR4 signaling pathway.

J. Nelson¹;

¹Center for Metabolic Disease Research, Temple University, Philadelphia, PA

Rationale: Peripheral artery disease (PAD) has multiple risk factors such as hyperlipidemia. Hyperlipidemia impaired angiogenesis after ischemic injury leading to decreased blood flow recovery. Vascular progenitor cells (VPCs) are currently considered as an important participant in the process of angiogenesis. Objective: To examine the effect of hyperlipidemia on VPCs, elucidate the underlying mechanism in which impaired VPC biological function result in exasperated new vessel formation after ischemia. Methods and Results: Male ApoE^{-/-} mice were fed with standard diet (ApoE group) or 2% high-cholesterol diet (ApoE/HF group) at the age of 8 weeks for 12 weeks. Wild type mice were used as control group (WT group). Hind limb ischemia (HLI) was surgically induced in all animals. Dietary ApoE/HF group revealed elevated total and LDL cholesterol levels and remarkable aortic lesion

compared with WT and ApoE group. Laser Doppler blood flow analysis showed significant decrease in the ischemic/normal limb blood flow ratio in the ApoE/HF group compared with WT and ApoE group (P

Propolis attenuates the capillary regression and anti-angiogenic factor expression in unloading-induced atrophy of skeletal muscle.

H. Fujino¹, H. Kondo², M. Kanazashi¹, M. Tanaka¹, A. Ishihara³;

¹Kobe Univ Grad Sch Hlth Scis, Kobe, Japan, ²Food Science Nutrition, Nagoya Women's Univ, Nagoya, Japan, ³ Human and Environmental Studies, Kyoto Univ Grad Sch, Kyoto, Japan

Aim: The capillary regression in skeletal muscle with a chronic decrease in activity such as unloading is related to a dysfunction of endothelial cells induced by a decrease of oxygen demand and increase of oxidative stress. Propolis is natural polyphenol-rich substance collected by honeybees that may be expected to attenuate capillary regression in atrophied skeletal muscle. The purpose of the present study was to investigate the preventive effects of propolis administration on capillary regression in the skeletal muscle during hindlimb unloading. **Methods:** Twenty-eight adult male Wistar rats were assigned randomly either to a control, control plus propolis administration, hindlimb unloaded or hindlimb unloaded plus propolis administration group for 14 days. The three-dimensional capillary network of soleus muscle was visualized using a confocal laser microscopy, and the capillary volume was measured. In addition, the pro- and anti-angiogenic factors, and oxidative stress maker were determined. **Results:** The capillary volume in atrophied muscle was lower than that in control. Propolis administration attenuated the decrease of capillary volume. In addition, the expression level of thrombospondin-1, as an anti-angiogenic factor, and SOD-1 in propolis administrated muscle were attenuated by propolis administration. **Conclusion:** These data suggest that propolis may be an effective treatment to counter the detrimental effects of a chronic decrease in skeletal muscle use on the capillary. **Keywords** anti-angiogenic factor, antioxidant, capillary, muscle atrophy, oxidative stress.

Osteoactivin, Inducible Heat Shock Protein 70 and Transforming Growth Factor β 1 Expression in Skeletal Muscle of High Repetitive High Force Reaching Rats in Association with Anti-Inflammatory Drugs.

N. Frara¹, S. Abdelmagid², P.W. Fisher¹, S.N. Popoff³, F.F. Safadi⁴, M.F. Barbe³;

¹Anatomy and Cell Biology, Temple University, Philadelphia, PA, ²Northeast Ohio Medical Univers, Rootstown, OH, ³Temple University, Philadelphia, PA, ⁴Northeast Ohio Medical Univ, Rootstown, OH

Osteoactivin (OA) was proposed as a potential repair protein involved in tissue turnover during regeneration and degeneration. Previous studies have shown OA as a negative regulator of

inflammation that attenuates macrophage inflammatory responses by decreasing production of pro-inflammatory cytokines. Although, OA is thought to be involved in tissue injury and repair, its response to overuse has yet to be studied. We have previously developed a rat model of repetitive reaching of overuse/overload that induces injury, inflammatory and fibrotic changes in musculoskeletal tissues. We anticipate that OA will increase in the overloaded tissues. We hypothesize that OA is functioning as a repair molecule in this model and increases in musculoskeletal tissues as microtrauma increases, in order to stimulate tissue turnover and repair. We used our model of overuse/overload in association with anti-inflammatory drugs to evaluate OA's link to inflammation with prolonged overuse. In addition, we examined other proteins involved in tissue repair such as hsp72 and TGF β 1. Young adult female Sprague-Dawley rats trained for approximately 6 weeks (10 min/day, 5 days/week; TR-HF) and then performed a high repetition high force (HRHF) task with 60% maximum pulling force for 6, 12, and 18 weeks (2 hours/day, 3 days/week). Results were compared to age-matched normal control (NC) or food restricted (FRC) rats. At the end of HRHF task week 4, cohorts of HRHF rats were administered either ibuprofen in drinking water daily for 2 weeks, or were treated with an anti-rat TNF- α drug (IP injections) across 2 weeks. Western blot analysis of flexor digitorum muscles of untreated 6-week HRHF rats showed higher expression levels of OA than TR-HF and control rats. ELISA showed a significant increase in hsp72 and TNF- α in muscles of 6-week HRHF rats without anti-inflammatory treatment, compared to TR-HF and control rats. In contrast, 6-week HRHF rats treated with the anti-TNF- α drug in their final 2 weeks showed reduced OA levels to baseline NC levels. Treatment of 6-week HRHF rats with ibuprofen for 2 weeks lead to higher OA levels. However, both anti-TNF- α and ibuprofen treatments decreased the 6-week HRHF muscle hsp72 levels to baseline TR-HF levels and reduced histological signs of muscle fibrosis. Prolonged performance of the HRHF task to 18 weeks without anti-inflammatory treatment showed increased OA and hsp72 in muscles concomitant with increased TGF β 1 and muscle fibrosis. The 18-week HRHF muscles also showed decreased TNF- α expression, indicating a resolution of muscle inflammation by 18 weeks. Thus, performance of highly repetitive tasks was associated with an increase in several anabolic proteins in flexor digitorum musculotendinous tissues, some associated with fibrotic repair, particularly when combined with high force. The reduction of OA after anti-TNF- α treatment indicates that TNF- α , but not cyclooxygenases, plays a role in OA production. The continued increase of OA after the task-induced increase in TNF- α (seen at 6 weeks) had resolved (18 weeks), suggests that other factors also induce OA production.

Changes in Golgi elements are responsible for the disordered microtubule network of DMD muscle fibers.

S. Oddoux¹, W. Liu², K.J. Zaal², E. Ralston²;

¹Aix-Marseille University, Marseille, France, ²NIAMS, NIH, Bethesda, MD

Microtubules have been implicated in the pathology of Duchenne muscular dystrophy (DMD), a severe muscle disease that results from the absence of the protein dystrophin. This protein links the muscle

plasmalemma to cytoskeletal proteins such as actin, intermediate filaments, and tubulin/microtubules. Microtubules of mouse fast muscles form a remarkable orthogonal network near the muscle plasmalemma but in the dystrophin-less mdx mouse, a popular mouse model for DMD, the organization of microtubules is very much disturbed, in agreement with the notion that dystrophin guides microtubules. We have recently demonstrated that the microtubule network in wild-type (WT) mice is formed from dynamic microtubules nucleated from Golgi elements and forming bipolar longitudinal and transverse bundles (Oddoux et al., J.Cell Biol. 2013, 203, 205). We are now investigating dynamics and nucleation of mdx microtubules. We find only small differences in the growth rates measured by tracking EB3-GFP and GFP-tubulin in live mdx fibers, and find no differences in classic parameters of microtubules such as pause frequencies and duration, shrinking rates, and distance covered by growing tips. In contrast, we observe differences in the directionality of microtubule growth (the angle of microtubule growth in relation to the fiber axes), quantitated by a microtubule-targeted software package (Liu & Ralston, 2014, Cytoskeleton, 71, 230). Furthermore, these differences seem to exist practically from the moment growing microtubules emerge from the static Golgi elements, as shown in experiments following microtubule recovery from nocodazole. We have also proceeded to examine the organization of the myofibrillar core of the muscle fibers which also contains microtubules and Golgi elements and may contribute to DMD pathology, especially in fibers with rows of central nuclei characteristic of muscle regeneration. We had so far focused our work mostly on the cortical microtubule layer, in direct contact with dystrophin. Whereas WT fibers show a three-dimensional network of transverse and longitudinal microtubules, mdx fibers show a decrease in transverse and an increase in longitudinal microtubules. In summary, this new work suggests that positioning and orientation of the Golgi elements (first shown to be abnormal in mdx by Percival et al., 2007, Traffic 8,1424), play an essential role in the organization of muscle microtubules and indicate that the absence of dystrophin at the muscle plasmalemma translates into differences in cytoskeletal organization that affect the core as well as the surface of the fibers.

Capillary and metabolic actions of exercise in skeletal muscle of type 2 diabetes.

H. Kondo¹, H. Fujino², F. Nagatomo³, A. Ishihara³;

¹Food Science Nutrition, Nagoya Women's Univ, Nagoya, Japan, ²Rehabilitation Science, Kobe Univ Grad Sch, Kobe, Japan, ³ Human and Environmental Studies, Kyoto Univ Grad Sch, Kyoto, Japan

Purpose: Diabetes affects the peripheral vascular bed. Exercise may play a role of countermeasure in diabetic mitochondrial dysfunction and microangiopathy. Therefore, the purpose of the present experiments was to study the effects of exercise on capillary volume, metabolic activity and expression of the angiogenic growth factors and angiopoietins in the skeletal muscle of diabetes. Methods: Male Goto-Kakizaki (GK) spontaneously diabetic rats and age-matched wild-type Wistar rats were divided into three groups: diabetes (GK), diabetes plus exercise (GK +Ex), and sedentary control. The exercise consisted of endurance training at low-aerobic intensity (plasma lactate <~2mmol/l) and included five 60

min sessions per week for 3 weeks. The three-dimensional capillary network of soleus muscle was visualized using a confocal laser microscopy, and the capillary volume was measured. metabolic activities were determined by succinate dehydrogenase (SDH) and PCG-1 α expression. In addition, the mRNA levels of angiogenic factors were determined by TaqMan probe-based real-time PCR. Results: The level of plasma glucose was higher in diabetic GK rat as compared to control. There was no significant difference in capillary-to-fiber ratio among GK, GK+Ex and control muscles. Although the capillary volume in diabetic muscle was lower than that in control, the exercised muscle capillary was attenuated toward to the level of control. Thus, exercise had effect on capillary volume in diabetic muscle. SDH activity, PCG-1 α expression in exercised muscle were higher than those in sedentary diabetic muscle. The expression levels of angiogenic factors were lower in GK than in control muscle. However, those were attenuated toward to the levels of those in GK+Ex muscle. Conclusion: These results suggest that exercise reduces the microcirculatory complication and improves the mitochondrial activity in skeletal muscle associated with type 2 diabetes.

Investigation of the wound healing process of adult *Danio rerio* wildtype zebrafish.

V. Hoelscher¹, P. deVerteuil², J. Ricketts¹, B. Schoffstall¹;

¹Department of Biology, Barry University, Miami, FL, ²Institute of Ecology and Evolution, University of Oregon, Eugene, OR

Danio rerio (zebrafish) share many physiological and genetic characteristics with humans, making them an attractive model system for scientific research. Zebrafish have been shown to completely regenerate significant portions of heart, fin, and tail tissues without loss of function or formation of permanent scar tissue. However, zebrafish have not yet been established as a model to study regeneration in skeletal muscle and surrounding tissues. Specifically, the healing response following deep tissue burn puncture wounds has not yet been described. We have hypothesized that zebrafish should completely regenerate skeletal muscle and surrounding tissues in response to this type of injury—making them an interesting wound-healing model. Our investigations have initially focused on determining the length of time necessary for zebrafish to fully recover from deep tissue burn puncture wounds. We first standardized methods for introducing a hot puncture wound completely through the myotomal muscle of the zebrafish, one millimeter below the dorsal fin. Healing was tracked by photography of wounded fish daily until healing appeared complete upon gross examination. Our results indicate that deep tissue burn puncture wounds of this type require approximately thirty days to heal, with minimal to no external scarring visible. We have also screened wounds for infection that occurs during the healing process, and have begun to identify the endogenous bacteria that cause these infections. Follow up studies include time point sampling for analysis of the wound healing process at tissue and molecular levels, as well as investigation of biofilm formation and specific identification of bacterial species causing infection during the healing process. Our preliminary results support the use of zebrafish as a model to

investigate cellular and molecular regeneration and healing processes following deep tissue burn puncture wounds. Findings could translate into applications for treatment of burn puncture wounds to skeletal muscle in humans, such as those inflicted during military combat.

Biochemical analysis of SERCA1b, SERCA1 splice variants related in Myotonic Dystrophy Type 1.

Y. Zhao¹, H. Ogawa², S. Yonekura², H. Mitsuhashi³, C. Toyoshima², S. Ishiura¹;

¹Department of Life Sciences, Graduate School of Arts and Sciences, The University of Tokyo, Tokyo, Japan, ²Institute of Molecular and Cellular Biosciences, The University of Tokyo, Tokyo, Japan, ³Life Science Network, The University of Tokyo, Tokyo, Japan

SERCA(sarco/endoplasmic reticulum Ca²⁺-ATPase) is a representative member of P-type ATPase and transports Ca²⁺ from cytosol to lumen. It is crucial for maintaining the intracellular Ca²⁺ homeostasis. SERCA is generally expressed in various types of cell, and its mutations lead to Brody disease and Darier disease as reported. SERCA1 is specifically expressed in fast twitch skeletal muscle. SERCA1 has two isoforms produced by alternative splicing of exon 22, which is included in SERCA1a but not in SERCA1b. Since exon 22 contains a stop codon, SERCA1a is the shorter isoform of 994 amino acids, and SERCA1b consists of 1001 amino acids with the last eight amino acids different. SERCA1b has not been well characterized in contrast to well studied SERCA1a. SERCA1b is expressed only in neonatal stage, suggesting the importance of splicing regulation of SERCA1. In addition, in Myotonic Dystrophy Type 1 (DM1), a genetic disease, multiple genes are aberrantly spliced including that of SERCA1. Furthermore, disturbance of intracellular Ca²⁺ homeostasis has been reported in DM1. Thus, we hypothesized that aberrantly expression of SERCA1b in DM1 patients is an origin of abnormal intracellular Ca²⁺ concentration. To examine this possibility, we first conducted a western blot analysis on skeletal muscle tissue of DM1 model mice, and found that SERCA1b, normally expressed only in new born mice, is aberrantly expressed in adult mice. Next, we tried to dissect functional differences between the two isoforms by overexpressing SERCA1a and SERCA1b in HEK293 cells, and found that both ATPase and Ca²⁺ transport activities of SERCA1b are approximately half those of SERCA1a. The apparent affinity for ATP and that for Ca²⁺ are approximately the same. Thus, aberrantly expression of SERCA1b may be an origin of the intracellular high Ca²⁺ concentration in DM1.

P2398**Board Number: B1081****G-CSF attenuated heart damage in mice exposed to repetitive β -adrenergic stimulation, potentially through the participation of bone marrow mobilized stem cells.**B. NIETO-LIMA^{1,2}, V. GUARNER-LANS², F.A. MASSO-ROJAS², A. PAEZ-ARENAS², G. ZARCO-OLVERA³, A. CANO-MARTINEZ²;¹Posgrado en Ciencias Biologicas, Universidad Nacional Autonoma de Mexico, MEXICO CITY, Mexico,²Department of Physiology, Instituto Nacional de Cardiologia - Ignacio Chavez, MEXICO CITY, Mexico,³Department of Pharmacology, Instituto Nacional de Cardiologia - Ignacio Chavez, MEXICO CITY, Mexico

Fibrosis, a major feature of remodeling in damaged hearts, leads to heart failure and death of organisms. On the other hand, heart damage results in the secretion of cytokines, e.g. granulocyte colony-stimulating factor (G-CSF), capable of mobilizing neutrophils and stem cells from bone marrow. Still, this mobilization is not enough to repair the heart. Exogenous G-CSF improves heart function in animals with acutely induced heart damage; however heart failure results of multiple events of heart damage. We evaluated the effect of G-CSF on the heart of mice exposed to repeated β -adrenergic stimulation (isoproterenol, ISO) to induce heart damage. Four groups were formed and treated with saline solution (control), ISO (5 μ g/kg/d, 7d, s.c), G-CSF (300 μ g/kg/d, 4d, s.c), or ISO (3d)+ISO/G-CSF (4d). Half of the mice were sacrificed 24h after treatments and the others 7d after. Fibrosis was quantified in longitudinal heart criosections using Masson's trichrome stain. Ventricular hypertrophy (VH) was measured to confirm heart damage. Number of stem cells from bone marrow (BM) and peripheral blood (PB) was estimated with the colony forming unit (CFU) assay. Neutrophils were quantified in peripheral blood smears. Isoproterenol (24h) induced the highest percentage of fibrosis, VH and colonies from BM; while neutrophils increased 2.4-fold. At 7d, VH persisted, while fibrosis diminished 8.22% and neutrophils decreased 31.9% compared to ISO (24h). Treatment with ISO+G-CSF lowered fibrosis at 24h (12.3%) and 7d (26.0%) compared to ISO (24h). VH had the same tendency, but it was not different. Colonies from PB were the highest among all groups. Neutrophils increased 3.2-fold (24h) and decreased 26.5% at 7d. An inverse relationship between colonies from BM and PB were found with both treatments at 24h (ISO and ISO+G-CSF). Endogenous β -adrenergic stimulation releases catecholamine, improving peripheral tissue perfusion. However overproduction causes heart damage. Our results show that G-CSF (300 μ g/kg/d) reduces fibrosis, but not VH, suggesting that this cytokine partially attenuated cardiac remodeling induced with repetitive β -adrenergic stimulation. Moreover, fibrosis reduction could be time-dependent. This antiremodeling effect may be related to bone marrow mobilized stem cells; since heart damage significantly increased only colonies derived from BM, meanwhile, with G-CSF the increment was more evident in those from PB. CFU assay and neutrophils also suggest that heart damage promotes mainly the proliferation of stem cell in BM and the release of neutrophils, while the cytokine, at this dose, could be mobilizing stem cells to the circulation. However, further studies are still necessary for a better understanding of the biology of heart damage, G-CSF and stem cells.

Diacylglycerol kinase ϵ -KO mice are susceptible to high fat diet-induced obesity and adipose tissue-specific insulin resistance.

T. Nakano¹, K. Goto^{1,2};

¹Anatomy and Cell Biology, Yamagata University, Yamagata City, Japan, ²Anatomy and Cell Biology, Yamagata University, Yamaga, Japan

Insulin-responsive organs, including adipose tissue, liver and skeletal muscle, play a central role in the metabolism of glucose and lipid. Understanding of its detailed mechanism is important since we know that high fat diet is linked to metabolic diseases such as obesity, fatty liver and type II diabetes. Diacylglycerol (DG) is an intermediate product of various lipids and represents a precursor of triglyceride (TG) synthesis. It also serves as a signaling molecule that activates DG-responsive proteins such as protein kinase C (PKC). In fact, novel PKC (nPKC) is shown to be involved in tissue-specific insulin resistance. PKC ϵ and PKC θ hinder appropriate insulin signaling in liver and fat/skeletal muscle, respectively. Therefore DG-PKC signaling may play a pivotal role in the pathogenesis of metabolic diseases. Diacylglycerol kinase (DGK) participates in lipid metabolism through phosphorylation of DG to phosphatidic acid. In this study, we fed DGK ϵ -knockout (KO), DGK α -KO and wild type (WT) mice with high fat diet (HFD) for 40 days and examined glucose and lipid metabolism. HFD-fed DGK ϵ -KO mice showed increased body weight gain and peri-epididymal white adipose tissue (WAT) mass compared with DGK α -KO and WT mice. Glucose tolerance test demonstrated that DGK ϵ -KO mice are defective in glucose metabolism under HFD-fed conditions. Histological examination of WAT revealed an increased size of adipocytes in DGK ϵ -KO mice compared with that in WT mice. In immunoblot analysis, expression of adipose triglyceride lipase, an enzyme catalyzing lipolysis of TG into DG, was reduced in WAT of HFD-fed DGK ϵ -KO mice. In addition, we observed increased phosphorylation level of PKC δ/θ and dysregulation of insulin signaling in DGK ϵ -deficient WAT. On the other hand, no alteration in phosphorylation level of nPKCs and insulin signaling was found in liver and skeletal muscle. These data show that insulin sensitivity is decreased in a tissue-specific manner in DGK ϵ -KO mice under HFD-feeding conditions. DGK ϵ is shown to localize to endoplasmic reticulum, where TG is synthesized from DG. It may be hypothesized that accumulated DG activates PKC δ/θ , which leads to tissue-specific insulin resistance in WAT. Present study suggests that DGK ϵ plays a crucial role in glucose and lipid metabolism in WAT and its deletion increases susceptibility to HFD-induced obesity. Potential link between DGK ϵ and glucose and lipid metabolism will be fundamental in understanding the prevention and treatment of metabolic diseases.

P2400**Board Number: B1083****The effect of interleukin 1 β on VLDL secretion in steatotic hepatocytes during defatting.**A. Chen-Liaw¹, G. Yarmush², F. Berthiaume²;¹Biochemistry, Cell and Molecular Biology, Univ Scranton, Morris Plains, NJ, ²Biomedical Engineering, Rutgers University, New Brunswick, NJ

Steatotic livers complicate liver transplantation due to their increased susceptibility to primary non-function when exposed to ischemia reperfusion injuries which are inherent in all transplants. To combat this, one option is to perfuse, *ex vivo*, the steatotic livers with a defatting cocktail that reduces lipid droplets accumulated within hepatocytes. The current defatting cocktail functions by upregulating β -oxidation to break down free fatty acids. Additionally, experiments implementing the defatting cocktail have shown minimal levels of secretion of very low density lipoproteins (VLDL) from hepatocytes. Therefore, another synergistic approach involves the reduction of triglycerides (TG) via VLDL secretion from liver cells. This research project investigates the effects of interleukin 1 β (IL-1 β), a proinflammatory cytokine, on VLDL secretion in steatotic hepatocytes during steatosis-reduction treatments. To investigate the role of IL-1 β in VLDL secretion, we cultured a human hepatocyte cell line (HepG2/C3A) in media (Dulbecco's Modified Eagle Medium) supplemented with linoleic acid and oleic acid for two days, thus inducing steatosis. Cells were then switched to media supplemented with IL-1 β , the current defatting cocktail, or the combination of both. The defatting cocktail consisted of: amino acids, forskolin, visfatin, hypericin, scoparone, L-carnitine, GW7647, and GW501516. Intracellular TG content as well as that released in the medium were measured with Nile Red staining and with biochemical TG assays. Hepatocytes treated with IL-1 β alone yielded the smallest reduction in TG content. This may be attributed to increased VLDL secretion. TG reduction was greater in hepatocytes treated with the defatting cocktail and greatest in hepatocytes treated with the defatting cocktail + IL-1 β . These results suggest that although IL-1 β increases VLDL secretion, it may also inhibit β -oxidation pathways activated by the defatting cocktail. Future mechanistic studies will investigate the cellular pathways underlying the activity of IL-1 β . A more profound understanding of its mechanisms may pinpoint future molecular targets for new defatting agents that will increase the efficiency of *ex vivo* defatting therapies for steatotic donor livers.

P2401**Board Number: B1084****Decreased expression of SR proteins alters lipid droplet morphology and triglyceride levels in *Drosophila* larvae.**S. Ng¹, B. Kakrecha², A.A. Nagengast¹;¹Biochemistry, Widener University, Chester, PA, ²Biology, Widener University, Chester, PA

Obesity is a growing epidemic in the United States, and it is influenced by nutrition, lifestyle, and gene regulation. Obesity is characterized by an increased BMI as well as a high lipid profile. Triglycerides are stored in lipid droplets within fat cells. Previous research shows that lipid droplet morphology is altered in response to reduced expression of spliceosomal proteins and SR proteins. SR proteins are serine-arginine rich proteins that enhance splicing of weaker splice sites through exon definition and intron bridging, and they play a vital role in recruiting the spliceosome for alternative splicing. This project focuses on the relationship between lipid storage and the SR protein profile expression. Reduced expression of the SR protein 9G8 has been shown to decrease triglyceride storage in larvae of *Drosophila melanogaster*. Testing of additional SR proteins shows that decreased expression of RSF1, SF2, and hnRNP significantly altered triglyceride levels compared to controls. The SR protein profile is being characterized at different nutrient conditions using a Refeeding Assay and Western Blots with commercially available antibodies including phosphor-specific antibodies. This project will identify key SR proteins in triglyceride storage and potentially obesity, as well as characterize the change in SR protein expression and post-translational modifications as a result of changing nutrient conditions.

P2402**Board Number: B1085****Decreased expression of the SR protein 9G8 and sex determination genes alter lipid droplet morphology and triglyceride levels in *Drosophila* larvae.**J. Iman¹, G. Manilal¹, B. Kakrecha¹, A.A. Nagengast²;¹Biology, Widener University, Chester, PA, ²Biochemistry, Widener University, Chester, PA

The storage of lipids is a tightly conserved process that is important to the survival of all living organisms. The fat body of *Drosophila* responds to different nutrient conditions and controls overall energy metabolism by regulating long-term storage of triglycerides in structures called lipid droplets (LDs), thereby serving a function similar to liver and adipose tissue in mammals. Previous genome-wide RNAi screens in *Drosophila* cells identified mRNA splicing factors as playing a role in LD formation; their decreased expression results in the production of fewer LDs. Using RNAi knockdown experiments under GAL4-UAS control in the fat body of larvae, we have identified several splicing factors that control lipid storage *in vivo*. Interestingly, knockdown of the SR protein 9G8 in the larval fat body is male lethal, decreases triglyceride levels and alters lipid droplet morphology. However, knockdown of sex determination genes alone does not affect triglyceride levels although double mutants of 9G8 and the

sex determination genes had a more drastic LD and triglyceride level phenotype than 9G8 alone. We are currently in the process of identifying the metabolic targets of 9G8 activity that results in decreased triglyceride storage.

Hypolipidemic effects of *Eryngium carlinae* in streptozotocin-induced diabetic rats.

R. Noriega-Cisneros¹, E.R. Esquivel-Gutiérrez¹, R. Salgado-Garciglia¹, M. Clemente-Guerrero¹, A. Saavedra-Molina¹;

¹Instituto de Investigaciones Químico-Biológicas, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mich., Mexico

Patients with diabetes mellitus (DM) are at increased risk of suffering atherosclerotic cardiovascular diseases. Result of hyperglycemia and insulin deficiency has disturbances in lipid metabolism, as reflected high levels of triacylglycerides (TAG) and low-density lipoprotein-cholesterol (LDL-C) and low levels of high-density lipoprotein-cholesterol (HDL-C) in serum. Previously, we reported that the ethanol extract of *Eryngium carlinae* was able to normalize the levels of total cholesterol and TAG in diabetic rats. This study fractionates and analyses the extract composition with the purpose of identifying potential compounds responsible for hypolipidemic effect. Determinations were performed on blood lipid profile and analyzed the activity of HMG-CoA reductase and the LDL receptor levels (LDL-r), comparing our results with a hypolipidemic drug, atorvastatin. The results indicated that the extract of *E. carlinae* decreased triacylglycerides, total cholesterol, non-HDL cholesterol and increased HDL cholesterol levels in the serum to levels equal or even better than atorvastatin. The determinations of the activity of HMG-CoA reductase and LDL-r levels in diabetic rats were not modified by the extract consumption, indicating that the hypolipidemic effect observed was not through the inhibition of the cholesterol biosynthesis as is atorvastatin, but possibly acting at the intestinal absorption level. In this study we reported that one of the identified compounds in the extract is stigmasterol, and it decreases the absorption of dietary cholesterol by competing with it. However, the exact mechanism should be clarified in later works.
