**Stem Cells, Pluripotency and Nuclear Reprogramming.**
*R. Jaenisch; Whitehead Institute for Biomedical Research, Cambridge, MA*

One of the key issues raised by nuclear cloning is the question of genomic reprogramming, i.e. the mechanism of resetting the epigenetic modifications that are characteristics of the adult donor nucleus to ones that are appropriate for an embryonic cell. The mechanisms by which embryonic stem (ES) cells self-renew while maintaining the ability to differentiate into virtually all adult cell types are not well understood. Major progress has been achieved to understand the molecular circuitry of pluripotency and self-renewal. This information provides crucial insights into mechanisms by which pluripotent cells may be stimulated to differentiate into different cell types or by which somatic cells might be reprogrammed back to the pluripotent state by exposure of the somatic nucleus to the egg cytoplasm. The recent demonstration of in vitro reprogramming using transduction of 4 transcription factors by Yamanaka and colleagues represents a major advance in the field. Major questions regarding the mechanism of in vitro reprogramming need to be understood and will be one focus of the talk. Also, our progress in using iPS cells for therapy and for the study of complex human will be summarized.
Minisymposium 1: Cancer Cells (2 – 7)

2 Imaging the Metastatic Process.
E. Sahai, S. Giampieri; Tumour Cell Biology Laboratory, Cancer Research UK London Research Institute, London, United Kingdom

Cancer cells can invade surrounding tissue either as single cells or in collective units. We use intravital imaging to demonstrate a reversible transition to a motile state as breast cancer cells spread. Imaging primary tumours reveals heterogeneity in cell morphology and motility. Two distinct modes of motility are observed: collective and single-celled. By monitoring the localisation of Smad2 and the activity of a TGFβ-dependent reporter gene during breast cancer cell dissemination we demonstrate that TGFβ signalling is transiently and locally activated in motile single cells. TGFβ1 switches cells from cohesive to single cell motility through a transcriptional programme involving Smad4, EGFR, Nedd9, and numerous regulators of actomyosin contraction: M-RIP, FARP and RhoC. In contrast, different regulators of the actomyosin cytoskeleton are used during collective invasion. Blockade of TGFβ signalling prevents cells moving singly in vivo but does not inhibit cells moving collectively. Cells restricted to collective invasion are capable of lymphatic invasion but not blood-borne metastasis. Constitutive TGFβ signalling promotes single cell motility and intravasation but reduces subsequent growth in the lungs. Thus, transient TGFβ signalling is optimal for blood-borne metastasis.

3 Regulation of Cellular Self-Renewal by the Arf Tumor Suppressor.
A. Gromley, M. L. Churchman, C. J. Sherr; Department of Tumor Cell Biology, St. Jude Children’s Research Hospital/HHMI, Memphis, TN

The p19Arf and p16Ink4a tumor suppressor proteins (encoded by alternative reading frames of the Cdkn2a (Ink4a-Arf) locus) respectively regulate p53 and Rb-dependent gene expression programs triggered by aberrant oncogenic signals. When expressed at elevated levels, p19Arf and p16Ink4a induce cell cycle arrest, senescence, and/or apoptosis to eliminate the expansion of incipient tumor cells. However, the fact that the Ink4a-Arf locus is conserved in species of mammals and birds that do not develop cancer begs the question of whether these “tumor suppressors” play broader physiologic roles in governing cellular self-renewal. Emerging findings now suggest that the Ink4a-Arf locus regulates the homeostatic equilibrium between self-renewing tissue stem cells and their amplifying progeny in several different biological settings. For example, recent use of lineage tracing strategies in mice has documented transient expression of Arf in proliferating progenitor cells during specific stages of male germ cell development, formation of stratified epithelia, and during postnatal regression of the hyaloid vasculature system in the vitreous of the eye. As a general rule, the Ink4a-Arf locus is epigenetically silenced in stem cells but becomes poised to respond to proliferative stress signals as cells undergo lineage commitment and further differentiation. Disruption of Ink4a-Arf gene silencing and the ensuing activation of the locus limit cellular self-renewal and contribute to aging phenomena; conversely, deletion of the locus strongly predisposes to aberrant cellular proliferation and tumor formation. This fundamental role of the Ink4a-Arf locus in gating cellular self-renewal appears to explain both its evolutionary conservation and broad impact on processes governing both aging and cancer.

4 The Role of miR-128 in Glioma Tumor Initiation and Maintenance.
T. Papagiannakopoulos1, A. Weaver2, R. Gill1, I. Hernandez1, E. Huillard3, D. H. Rowitch2, F. M. White2, K. S. Kosik1; 1Neuroscience Research Institute, UC Santa Barbara, Santa Barbara, CA, 2The David H. Koch Institute for Integrative Cancer Research, MIT, Cambridge, MA, 3Pediatrics and Neurological Surgery and the Institute for Regeneration Medicine, UC San Francisco, San Francisco, CA
MicroRNAs (miRNAs) are a class of small non-coding RNAs (20-25nt) that bind to the 3' untranslated region of target mRNAs through an imperfect match to repress their translation and stability. miRNAs regulate diverse cellular functions in various biological processes. Several studies have confirmed that miRNAs regulate cancer cell proliferation and apoptosis. Furthermore, these non-coding RNAs can control cellular identity and mediate differentiation. Aberrant expression of miRNA genes can lead to human diseases, including cancer. Gliomas are highly aggressive brain tumors that are thought to arise from malignant Neural Stem Cells (NSCs) that have lost their differentiation potential. To investigate the function of miRNAs in gliomagenesis, we chose an established glioma mouse model. This model utilizes tumor-initiating NSCs (tiNSCs) that contain known glioma lesions. To determine whether miRNAs are involved in the transformed state of these tiNSCs, we profiled 187 mouse miRNAs and identified numerous repressed miRNAs. Among these miRNAs, miR-128 was down-regulated. This miRNA has been previously implicated in CNS development and is down-regulated in human glioma tumors. Thus, with a combination of molecular, cellular and in vivo methods we proceeded to characterize the role of miR-128 in NSC-induced gliomagenesis and glioma tumor maintenance. In culture, miR-128 overexpression led to repression of tiNSC growth and differentiation into a neuronal lineage. MiR-128 represses growth by directly targeting a network of key glioma oncogenes involved in Receptor Tyrosine Kinase (RTK) mitogenic signaling. With the use of quantitative tyrosine phospho-proteomics we are able to determine the extent of miR-128 regulation on tyrosine signaling in tiNSCs. We are currently testing the potential of miR-128 to repress tiNSC gliomagenesis and tumor maintenance in vivo. Using a novel peptide-based therapeutic approach we are attempting to suppress tumor growth by overexpressing miR-128 in glioma tumors by systemic delivery. Overall, using a multifaceted approach we are able to characterize the tumor suppressive role of miR-128 in gliomas.

**p21WAF1 Dependent Emi1 Down-regulation After DNA Damage Maintains G2 Arrest.**  
J. Lee1,2, J. A. Kim1,2, V. Barbier2, A. Fotedar2, R. Fotedar1,2,3; 1Institut de Biologie Structure Jean Pierre Ebel, Grenoble, France, 2Sidney Kimmel Cancer Center, San Diego, CA, 3Burnham Institute for Medical Research, La Jolla, CA

Cell cycle checkpoints safeguard genome integrity. p21WAF1, an inhibitor of cyclin dependent kinases (CDKs) has an important role in checkpoint response to DNA damage. It has been previously shown that following DNA damage, p21<sup>+/+</sup> cells stably arrest in G2 whereas p21<sup>−/−</sup> cells ultimately progress into mitosis. We have analyzed the role of p21WAF1 in G2-M phase checkpoint control and in prevention of polyploidy after DNA damage. The role of Anaphase promoting complex (APC), whose activity is not high in G2 phase, has not been extensively studied in the DNA damage checkpoint in mammalian cells. APC, a multi-protein complex with E3-ubiquitin ligase activity, regulates progression through mitosis to G1 and its substrates include cyclins (A2 and B1). We report that APC activation in G2 leads to stable arrest in irradiated p21<sup>+/+</sup> cells. We find that p21 down-regulates Emi1, an APC inhibitor whose destruction controls progression through mitosis to G1, in cells arrested in G2 by DNA damage. This down-regulation contributes to APC activation and results in the degradation of key mitotic proteins including cyclins A2 and B1 in p21<sup>+/+</sup> cells that prevents the G2 arrested cells from entering mitosis. Inactivation of APC in can overcome the G2 arrest in irradiated p21<sup>−/−</sup> cells. Short interference RNA mediated Emi1 down-regulation prevents irradiated p21<sup>−/−</sup> cells from entering mitosis whereas concomitant inactivation of APC counteracts this effect. Our results demonstrate that Emi1 down-regulation and APC activation leads to stable p21 dependent G2 arrest after DNA damage. Our work is the first demonstration that Emi1 regulation plays a role in the G2 DNA damage checkpoint. Further, our work identifies a new p21 dependent mechanism to maintain G2 arrest after DNA damage.

6  
**Effects of p120 Ablation on Normal Mammary Gland Development and PyMT-Induced Mammary Tumor Progression.**  
S. Kurley1, M. A. Davis1, B. Bierie1, W. J. Muller2, A. B. Reynolds1; 1Cancer Biology, Vanderbilt University, Nashville, TN, 2Biochemistry and Medicine, McGill University, Montreal, QC, Canada
p120-catenin (p120) modulates epithelial cell-cell adhesion by controlling the stability of E-cadherin, an important suppressor of tumor progression and metastasis. Areas of p120 loss are observed in most carcinoma types, including ~10% of ductal breast carcinomas, but the significance of this observation is unclear. Here, we have used tissue specific p120 knockout mice to examine the in vivo effects of p120 ablation in normal and transformed mammary epithelium. Surprisingly, p120 appears to be essential for mammary gland development. Cre expression by the MMTV promoter in our model is initiated concurrently with pubertal mammary gland development. Under this condition, p120 null cells were clearly evident in developing ducts at 4 weeks, but were undetectable at time points thereafter. Ductal outgrowth was initially delayed as p120 null cells were eliminated and replaced by p120 positive cells that subsequently behaved normally. Furthermore, at early time points, p120 knockout mice presented stunted growth of mammary terminal end buds that was overcome at subsequent time points. Exactly why p120 is required is not yet clear, but p120 null cells were also deficient in E-cadherin, as well as β-catenin, which could account for the observed changes to tissue morphology, apparently compromised cell-cell adhesion, and drastic alterations in mammary gland development. To examine p120 loss in the context of tumor progression, we crossed our p120 knockout mice into the MMTV-Polyoma Middle T (PyMT) mouse model of breast cancer described previously by Dr. W. Muller. In the context of PyMT, p120 ablated cells survived and participated in tumor formation. Interestingly, p120 null tumor regions were exclusively pseudopapillary, whereas both solid and pseudopapillary tumors were observed when p120 was present. p120 negativity was also associated with macrophage infiltration, an increased presence of myofibroblasts, and almost complete absence of E-cadherin and junctional β-catenin. Tumor latency and volume in p120 knockout mice were unchanged, however lung metastases were significantly increased. Experiments are underway in both systems to clarify underlying mechanisms.

7 Pseudopodial-Enriched Atypical Kinase One (PEAK1) is a Novel Protein that Regulates ErbB2-Induced Cellular Mitogenesis and Migration.

J. A. Kelber1,2, Y. Wang1,2, H. Tran Cao3, W. Wang1,2, S. Kaushal2, R. Hoffman3, M. Bouvet2,3, R. Klemke1,2; 1Pathology, University of California San Diego, La Jolla, CA, 2Moores Cancer Center, University of California San Diego, La Jolla, CA, 3Department of Surgery, University of California San Diego, La Jolla, CA

Cell migration is an integral process during development, immune function, and cancer metastasis. Using quantitative phosphoproteomics to analyze migratory regions within the cell known as pseudopodia, we recently identified a new phosphoprotein we’ve termed pseudopodial-enriched atypical kinase one (PEAK1). We have found that PEAK1 is necessary for the mitogenic and migratory effects of the epidermal growth factor (EGF) receptor, ErbB2, in cancer cells. Additionally, PEAK1 undergoes Src-dependent tyrosine phosphorylation in response to EGF ligands and extracellular-matrix (ECM) proteins; potentiates fibronectin-induced Paxillin, ERK and CAS phosphorylation; binds to ErbB2, Raf, CAS and Crk and co-localizes with the actin and focal adhesion cytoskeleton. Based upon our functional and biochemical analysis of PEAK1, we predicted that PEAK1 may mediate ErbB2-induced tumorigenesis by coupling ErbB2 activation to the oncogenic Ras/Raf/ERK and Src/CAS/Crk signaling cascades. In this regard, we show that PEAK1 binds to ErbB2. Using PEAK1 truncation mutants that bind ErbB2 and CAS or ErbB2, CAS and Crk, we further demonstrate that PEAK1 mediates ErbB2-induced cell migration/invasion via the Src/CAS/Crk pathway. Finally, we show that PEAK1 is promotes oncogenic growth in vitro and in vivo and is upregulated in metastatic cancer cells. Collectively, these studies provide a mechanistic understanding of how PEAK1, an important regulator of cancer progression, couples to the cytoskeletal signaling machinery in order to mediate cancer cell migration/invasion. With this new understanding of the mechanism of PEAK1 function, unique small molecule reagents may be developed to target specific PEAK1-mediated functions of ErbB2 during cancer progression.
**Minisymposium 2: Cell-Cell Interactions (8 – 13)**

**Drosophila Lar, a Receptor Tyrosine Phosphatase, Regulates Cell Adhesion between Germline Stem Cells and the Niche.**

S. Srinivasan¹, A. Mahowald², M. Fuller¹; ¹Developmental Biology, Stanford University, Stanford, CA, ²Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

Adult stem cells function to replenish the pool of highly differentiated but short-lived cells in tissues. Adult stem cells can self-renew to maintain their numbers and differentiate to give rise to tissue cells. Many adult stem cells reside in a niche, which provides signals to critically balance the choice between self-renewal and differentiation. Stem cell-niche cell adhesion is important to regulate stem cell fate by keeping stem cells close enough to receive short-range signals. Stem cells can attach to and orient towards the niche to achieve asymmetric stem cell divisions. We hypothesize that one outcome of the niche signal important for stem cell maintenance might be to increase the cell adhesion between stem cells and the niche. We examined the role of cell adhesion in specifying stem cell fate using the *Drosophila* male germline as a model system. 

**leukocyte antigen receptor** (*lar*) was identified as being upregulated in an expression analysis of early germ cells. *lar* is required in male germ cells for maintenance of germline stem cells (GSCs); male germ cells mutant for *lar* are lost to differentiation. Wild-type male GSCs anchor to the niche through adherens junctions. Ultrastructural analyses reveal that the adherens junctions between GSCs and the niche are weak in *lar* mutants suggesting a role for Lar in maintaining GSCs by promoting niche-stem cell adhesion. Lar is expressed by GSCs and localizes to the niche-GSC interface consistent with its role in regulating adhesion between the niche and GSCs. Germ cells expressing Lar may recognize the niche via the heparosulfate proteoglycan Dally-like (Dlp), a known ligand of Lar, which is expressed by the niche cells. Lar also interacts with Enabled (Ena), a member of the Ena/VASP family of proteins that regulate F-actin elongation. Ena is expressed in GSCs and localizes to the hub-GSC interface. This polarized localization of Ena is lost in *lar* mutants. Our current model based on these data is that Lar through its interaction with Dlp ensures the activation and/or correct localization of Ena to the hub-GSC interface to promote hub-GSC adhesion by localized regulation of cortical F-actin assembly.

9

**Calcium-Dependent Dynamics of Cadherin Interactions at Synapses and Cell-Cell Junctions.**

E. Schuman¹, S. Kim², J. Mok², C. Tai², E. Mosser²; ¹Division of Biology, "California Institute of Technology/HHMI, Max Planck Institute for Brain Research ", Pasadena, CA, ²Biology, Caltech, Pasadena, CA

Cadherins, a family of homophilic adhesion proteins, play an important role in the calcium-dependent dynamics of structural and synaptic plasticity along with cell-cell contact formation and remodeling. A unique feature of cadherin-cadherin interactions is a strong dependence on extracellular Ca²⁺—which serves to rigidify the molecular structure of cadherins and promote trans-junctional interactions. Fluctuations in extracellular Ca²⁺ could thus, in principle, modify the dynamics of cadherin homophilic interactions across junctions, but this remains unexplored. We have developed a genetically encoded Förster Resonance Energy Transfer (FRET) reporter system that permits the direct visualization and quantification of spatiotemporal dynamics of N-cadherin interactions across intercellular junctions in live cells. We found that upon rapid chelation of extracellular Ca²⁺ N-cadherin exhibited a sudden, but partial, loss of homophilic interactions. A cadherin mutant that lacks adhesive activity (W2A) exhibited a more substantial loss of homophilic interactions, suggesting two types of cadherin interactions—one that is rapidly modulated by changes in extracellular Ca²⁺ and another with relatively stable adhesive activity that is Ca²⁺-independent. These data indicate a previously unrecognized sensitivity of cadherin molecules to fluctuations in extracellular Ca²⁺. To transfer our FRET reporter system into neurons, N-cadherin constructs are expressed using viral gene delivery such that a FRET donor
(cerulean-cadherin) is expressed in presynaptic neurons while a FRET acceptor (venus-cadherin) is expressed in postsynaptic neurons. FRET will then be used to detect cadherin interactions between pre- and postsynaptic cells under various conditions. In particular, we will examine the effects of synaptic activity and varying extracellular calcium concentrations on cadherin-cadherin dynamics. These experiments will test our hypothesis that cadherins act as extracellular calcium detection system to coordinate synaptic plasticity across the synapse.

10 Imaging Trans-Synaptic Protein-Protein Interactions to Study the Molecular Mechanisms of Synapse Development.
A. Thyagarajan, A. Y. Ting; Chemistry, Massachusetts Institute of Technology, Cambridge, MA

Methods to image the size and dynamic properties of inter-cellular protein-protein interactions (PPIs) will facilitate studies of cell-cell interactions in development and in disease. Here we introduce a method for fluorescent labeling of inter-cellular PPIs via proximity biotinylation between a protein fusion to biotin ligase (BirA), and a protein fusion to BirA’s 15-amino acid “acceptor peptide” (AP) substrate. When the two proteins interact BirA covalently ligates a biotin onto the acceptor peptide. Biotinylated protein complexes are visualized by staining with fluorophore-conjugated monovalent streptavidin. We applied this methodology to image the trans-synaptic neurexin-neuroligin adhesion complex at single neuronal synapses in hippocampal neurons. We demonstrate that this trans-synaptic adhesion complex grows both during developmental maturation of synapses and in response to acute chemical stimulation. Complex growth occurs via a combination of new neurexin-neuroligin interaction formation, and arrest of both neurexin and neuroligin internalization. Strikingly, both processes require NMDA receptor activity. Using proximity biotinylation in conjunction with pHluorin-GluR1 time-lapse imaging, we discovered that neurexin-neuroligin complex growth is required for activity-dependent AMPA receptor recruitment to the postsynaptic membrane. Together, our results suggest an important role for the neurexin-neuroligin interaction in synapse maturation and stabilization.

11 Mechanosensitive Cadherin Complex with Links to the Keratin Cytoskeleton Regulates Cell Polarity and Directed Protrusions Driving Collective Cell Migration.
G. Weber, M. A. Bjerke, D. W. DeSimone; Department of Cell Biology, University of Virginia, Charlottesville, VA

The mesendoderm of the Xenopus gastrula is a motile population of cells comprising a multilayered cell sheet that moves directionally upon a fibronectin (FN) matrix assembled by the blastocoel roof. The leading edge protrusions of each cell within the sheet are in contact with FN while the rear or “retracting” edge of each cell rests upon the leading edge of the cell behind it. The fidelity of this morphogenetic process requires cell-cell contact; directed monopolar protrusive activity characteristic of this collective behavior is lost upon dissociation to single cells. Moreover, the intact sheet advances under tension and release of substrate adhesion with a mAb directed against integrin α5β1 causes the rapid retraction of the sheet. We hypothesize that anisotropic tension transmitted through C-cadherin (C-cad) adhesions is an intrinsic property of this tissue required for the coordination of directed cell motility. To approach this problem we developed a magnetic bead pull assay and asked whether mechanical force applied through cadherins could re-establish cell polarity and directed protrusive activity in single dissociated mesendoderm cells on FN. Mechanical force applied to attached C-cadFc coated beads but not FN or poly-l-lysine coated beads induced multipolar cells to become monopolar protrusive and to migrate away from the direction of magnetic bead pull. Co-immunoprecipitation and colocalization analyses in live explants established that a subset of C-cad molecules in these cells was associated with the keratin intermediate filament network through the catenin family member plakoglobin. Dissociated mesendoderm cells obtained from cytokeratin or plakoglobin antisense morpholino-injected embryos were unresponsive to C-cad bead pull. Intact mesendoderm from morphant embryos had defects in cell polarity and cytoskeletal organization. We have identified a cadherin mechanosensory complex that specifies cell polarity in a true collective cell migration
event. Linkage of classical cadherins to the keratin filament network is critical for mechanosensitive signaling to direct cell polarity and movement in this tissue. This work was supported by USPHS grants HD26402 and GM83542.

12 Alpha-Catenin Regulation of Actin Dynamics and Cell-Cell Adhesion.
A. V. Kwiatkowski1,2, J. M. Benjamin2,1, S. Pokutta3,1, W. I. Weis3,1, W. Nelson2,1; 1Dept. of Molecular and Cellular Physiology, Stanford University, Stanford, CA, 2Dept. of Biology, Stanford University, Stanford, CA, 3Dept. of Structural Biology, Stanford University, Stanford, CA

The development of multicellular organisms requires the orchestrated movement and adhesion of cells that are driven by the regulated assembly and organization of actin networks. Cadherins are key regulators of cell-cell adhesion and are associated with the actin cytoskeleton primarily through α-catenin, which binds the cadherin/β-catenin complex and F-actin. In vitro studies indicated that the oligomeric state of α-E-catenin, the epithelial form of α-catenin, modulates its binding affinities: the monomer forms a ternary complex with β-catenin and E-cadherin, whereas the homodimer preferentially binds to actin filaments and inhibits Arp2/3-mediated actin polymerization. To investigate how α-catenin regulates actin dynamics underlying cell-cell adhesion and cell motility, the cytosolic pool of α-E-catenin was sequestered to mitochondria or the plasma membrane without affecting α-E-catenin levels or the strength of cadherin-mediated cell-cell adhesion. Mitochondrial sequestration of α-E-catenin increased cell migration, lamellipodial dynamics, cortical actin filament polymerization and branched-actin organization. In contrast, recruitment of α-E-catenin to the plasma membrane decreased membrane dynamics, cortical actin polymerization and branched-actin structures. Thus, α-E-catenin functions in cell-cell contact dependent and independent modes to regulate actin dynamics during epithelial cell-cell adhesion and cell migration. In contrast to α-E-catenin, the highly related neuronal form α-N-catenin is predominantly monomeric at concentrations (≈10 μM) that promote α-E-catenin homodimerization. Functional complementation tests conducted in MDCK cells, in which endogenous α-E-catenin expression was silenced using RNAi knockdown, revealed that expression of α-N-catenin rescues cadherin-mediated cell-cell contact formation and cell-cell adhesion defects. Thus, homodimerization does not appear to be required for α-catenin function in cell-cell adhesion. Together, these experiments define new functions for α-catenin and offer further insight into the role of α-catenin in cadherin-mediated adhesion.

13 An Essential Role for p120-Catenin in Vascular Patterning and Endothelial Proliferation.
R. G. Oas1, K. Xiao2, S. Summers1, K. B. Wittich1, C. M. Chiasson1, W. Martin2, H. E. Grossniklaus2, P. A. Vincent7, A. B. Reynolds2, A. P. Kowalczyk1,6; 1Cell Biology, Emory University, Atlanta, GA, 2Transgenic Mouse Core Facility, Emory University, Atlanta, GA, 3Department of Ophthalmology, Emory University, Atlanta, GA, 4The Center for Cardiovascular Sciences, Albany Medical College, Albany, NY, 5Department of Cancer Biology, Vanderbilt University, Nashville, TN, 6Department of Dermatology, Emory University, Atlanta, GA

The armadillo family protein p120-catenin binds to the cytoplasmic domain of classical cadherins and stabilizes them at the cell membrane by preventing their endocytosis. To examine the role of p120 in mouse vascular development, a conditional Cre/loxP gene deletion strategy was used to ablate p120 expression, using the endothelial-specific Tie2 promoter to drive Cre recombinase expression. Mice lacking endothelial p120 died embryonically beginning at E11.5. Major blood vessels appeared normal at E9.5. However, both embryonic and yolk sac vasculature of mutant animals were disorganized and displayed decreased microvascular density by E11.5. Importantly, both VE-cadherin and N-cadherin levels were significantly reduced in vessels lacking p120. This decrease in cadherin expression was accompanied by a reduction in the recruitment of pericytes to developing brain blood vessels and the occurrence of hemorrhages. Primary cultures of p120-null endothelial cells displayed a loss of VE-cadherin expression and revealed proliferation defects that could be rescued by exogenous expression of VE-cadherin. Furthermore, the expression of VE-cadherin, as well as the proliferation defect, could be rescued by the re-
expression of both wild-type p120 and Rho-uncoupled mutant p120. This result suggests that the observed proliferation defect is cadherin-dependent and supports our earlier observation that the internalization of VE-cadherin is Rho-independent. These findings reveal a central and indispensable role for p120 in mammalian vascular development and demonstrate that p120 is required for the regulation of endothelial cadherin levels during vascular development, as well as for microvascular patterning, vessel integrity, and endothelial cell proliferation.

Minisymposium 3: Cell Polarity (14 – 19)

14
Cell Polarity in the C. elegans Embryo.
J. Ahringer; Wellcome Trust/Cancer Research UK Gurdon Institute, University of Cambridge, Cambridge, United Kingdom

Cell polarity is critical for many of the functions of animal cells, such as migration, directional secretion, axis formation, and asymmetric cell division. In addition, loss of cell polarity is a contributing factor in cancer. Many of the known molecules involved in generating and transducing cell polarity are conserved across animals, however, the mechanisms by which these function are not well understood and additional cell polarity genes remain to be discovered. The one-celled C. elegans embryo is one of the best-established systems for investigating cell polarity. It allows study of the all of the essential features of cell polarity common in polarized cells: the polarity cue and its reception by the cytoskeleton, the polarisation events that occur in response to the polarity cue, and the transduction of information to downstream polarisation events such as asymmetric spindle positioning. Our long-term goal is to provide an understanding of cell polarity, from delivery of the cue to the observed asymmetries. I will discuss our recent results on cell polarity establishment and transduction in the C. elegans embryo. In addition, I will present our progress on high-throughput RNAi screening for suppressors of a large number cell polarity and asymmetric spindle positioning mutants, with the goal of expanding and making novel connections within the cell polarity network. The experimental amenability of C. elegans will allow new testable models to be interrogated with specific experiments.

15
Microtubules and PAR-2 Break Symmetry to Initiate Polarization of the C. elegans Zygote.
S. A. Zonies, F. Motegi, G. Seydoux; Johns Hopkins University School of Medicine, Baltimore, MD

Microtubules have been implicated in the induction of polarity in several cell types but how they interact with the PAR group of polarity regulators is not well understood. Here we report that microtubules bind the polarity regulator PAR-2, and that this interaction is sufficient to break symmetry and initiate polarization of the C. elegans zygote. Polarization of the C. elegans zygote begins when an asymmetric actomyosin wave sweeps the anterior PAR complex (PKC-3/PAR-3/PAR-6) towards one end of the zygote. While in transit, the PAR proteins amplify the wave (PAR-actomyosin feed-back loop) (Munro et al, 2004). The wave initiates near the sperm-donated centrosome, but the cues that trigger the wave are not known. Using conditions that slow down the wave, we have uncovered a role for microtubules and PAR-2 in this process. PAR-2 is a RING finger domain protein that is excluded from the cortex by direct phosphorylation by PKC-3. We have found that PAR-2 binds microtubules in vitro and in vivo (KDapp<0.2 microM). Microtubule-binding protects PAR-2 from phosphorylation by PKC-3 and allows PAR-2 to localize to the cortex in a small region nearest the sperm centrosome. Once on the cortex, PAR-2 is sufficient to trigger the actomyosin wave. Our genetic analyses suggest that PAR-2 does this by interfering with the PAR-actomyosin feed-back loop. The anterior PAR complex stimulates myosin accumulation on the cortex and PAR-2 antagonizes this activity locally, creating an asymmetric actomyosin contraction. The contraction depletes PKC-3, which in turns allows more PAR-2 to accumulate on the cortex. Our findings provide a simple model for how microtubules can break symmetry by helping PAR-2 overcome cortical exclusion by PKC-3.
Cell polarity is critical for differentiation. A dramatic example of polarization can be found in syncytial cysts of developing *Drosophila melanogaster* spermatids, in which haploid nuclei are found at one end and sperm tail growth occurs at the other. Remarkably little is known about how spermatid polarity is established. Here we identify the membrane lipid phosphatidylinositol 4,5-bisphosphate (PIP2) as a critical regulator of spermatid cyst polarity. Severe reduction of plasma membrane PIP2 in developing male germ cells results in unpolarized spermatid cysts, whereas moderate reduction results in formation of bipolar cysts, with nuclei localizing to both ends during elongation. Cell polarity markers that localize to the growing end in wild-type cysts relocalize to the middle of the cysts when PIP2 levels are reduced. Defects in polarity are evident from the earliest stages of elongation, indicating that PIP2 is required for establishment of polarity. The PIP2 biosynthetic enzyme Skittles (Sktl) and PIP2 colocalize at the growing end of the spermatid cysts with the exocyst complex, which drives targeted membrane addition and cell polarization in a variety of systems. Flies mutant for two exocyst components phenocopy PIP2-depleted flies by showing unpolarized spermatid cysts. Strikingly, the exocyst becomes completely delocalized when PIP2 levels are reduced. Overexpression of Sktl restores exocyst localization and spermatid cyst polarity. Our data are consistent with a mechanism in which localized synthesis of PIP2 recruits the exocyst to promote targeted membrane delivery and polarization of the elongating cysts.

Early embryos of many animals polarize radially when contacts differentiate the outer (contact-free) and inner (contacted) surface of each cell. In *C. elegans*, contacts polarize the embryo radially by spatially regulating Rho GTPase signaling, which induces an inner-outter cortical asymmetry in PAR polarity proteins. In a screen for additional regulators of radial polarity, we identified the *tat-5* gene. *tat-5*, which encodes an aminophospholipid translocase predicted to move phosphatidylserine from the outer leaflet of the membrane bilayer to the inner leaflet, is required for the formation of inner-outter PAR asymmetry. TAT-5 localizes to the plasma membrane and endomembranes of early embryonic cells, and is also needed for proper organization of the plasma membrane at contact sites following cytokinesis as well as for endocytosis of midbodies. These findings suggest a link between membrane organization/composition and the generation of cell polarity in response to cell-cell contact.

Formation of epithelial lumens requires the spatiotemporal co-ordination of apico-basal polarization in cells contributing to the lumen. We here demonstrate that a Rab11a-directed
network co-ordinates apical membrane delivery and single lumen formation in three-dimensional MDCK cyst cultures. Rab11a functions in lumen formation in part by recruiting the Rab GEF Rabin8, co-opting Rab8a to function in apical trafficking. Rab11a also controls Cdc42 and Par3 apical targeting, the latter of which depends on coupling of Rab11a to the exocyst. The exocyst and Par3/aPKC complex assembles at a transient apical fusion patch, allowing surface delivery of apical membrane from Rab11 vesicles. Loss of function of these components disrupts formation of the luminal surface. We thus describe a membrane transport module regulating lumen morphogenesis of multicellular epithelial structures. Moreover, we reveal a novel interplay of the machineries of vesicular transport and apical polarity.

19
Reversal of Neuronal Polarity After Axon Removal: Converting a Dendrite into a Regenerating Axon by Rebuilding the Microtubule Cytoskeleton.
M. C. Stone, M. M. Nguyen, J. Tao, M. M. Rolls; Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA

Axon regeneration is crucial for recovery after trauma to the nervous system. In order for neurons to recover from complete axon removal they must re-specify a dendrite into an axon- a complete reversal of polarity. We find that mature dendrites can reverse polarity and become regenerating axons, and that this involves complete remodeling of the microtubules throughout the neuron. Dendritic microtubules not only reverse polarity, changing from minus ends distal to the cell body (minus-end-out) to plus-end-out, but the number of dynamic microtubules is also dramatically and unexpectedly increased. Both JNK signaling and new microtubule nucleation are required to initiate the response. To assay neuronal responses to axon removal, we use an in vivo Drosophila system and sever axons or dendrites with a UV laser in whole animals. Axon, but not dendrite, injury induces two types of global microtubule rearrangements: 1. 10-fold upregulation of the number of growing microtubules and 2. polarity reversal such that one dendrite takes on the axonal microtubule rearrangement. After microtubule reversal, the process initiates tip growth, and takes on morphological and molecular characteristics of an axon. Growing microtubule number and microtubule polarity were determined by monitoring the number and direction of movement of EB1-GFP comets in dendritic arborization neurons. Reduction of JNK signaling or msp (XMAP215)-stimulated microtubule dynamics blocked repolarization of a dendrite to a growing axon. Using RNAi, we show that downstream of JNK, nucleation of new microtubules is required to initiate the global microtubule rearrangements that lead to re-specification of a mature dendrite to a regenerating axon. Based on our data we conclude that, in vivo, axon injury initiates a specific response that is different from dendrite injury. This response includes a dramatic upregulation of microtubule dynamics, which leads to a complete remodeling of the microtubule cytoskeleton.

Minisymposium 4: Chromatin Organization and Dynamics (20 – 25)

20
Dosage Compensation in Drosophila.
A. Akhtar, J. M. Vaquerizas; Gene Expression Unit, European Molecular Biology Laboratory Heidelberg, Heidelberg, Germany

In Drosophila, dosage compensation of the single male X chromosome involves upregulation of expression of X linked genes in Drosophila. Dosage compensation complex (DCC) or the male specific lethal (ML) complex is intimately involved in this regulation. The MSL complex members decorate the male X chromosome by binding on hundreds of sites along the X chromosome. Recent genome wide analysis has brought new light into X chromosomal regulation. It is becoming increasingly clear that although the X chromosome achieves male specific regulation via the MSL complex members, a number of general factors also impinge on this regulation. Our progress will be presented.
21

O-GlcNAc is Part of the Histone Code.
K. Sakabe, Z. Wang, G. W. Hart; Biological Chemistry, Johns Hopkins University, School of Medicine, Baltimore, MD

The modification of Ser and Thr residues of nucleocytoplasmic proteins by N-acetylglucosamine (O-GlcNAc) is a dynamic post-translational modification. This post-translational modification is absolutely required for life in plants and mammals. More than one thousand GlcNAcylated proteins have been identified ranging from components of the transcriptional machinery including RNA polymerase II, signaling molecules such as kinases and adaptor proteins, ribosomal proteins, and cytoskeletal proteins. Modification with O-GlcNAc is known to regulate protein functions such as protein-protein interactions, activity, and degradation, indicative of its vital role in signal transduction pathways. Here, we report that histones, the basic component around which DNA is wound, are GlcNAcylated. GlcNAc moieties on histones were detected either immunologically or by in vitro labeling with galactosyl transferase. Additionally, histones are substrates for O-GlcNAc Transferase (OGT) in vitro. Previous studies have shown that Coactivator Associated Arginine Methyltransferase 1 (CARM1) targets OGT to specific substrates. Pre-incubating histones with CARM1 increased GlcNAcylation of histones and this increase was not dependent on CARM1 activity. Additionally, knocking-down CARM1 levels in cells using siRNA, reduces the GlcNAcylation of histones, supporting that CARM1 serves to target OGT to histones in vivo. We also identified several O-GlcNAc sites on histones using a chemo-enzymatic approach that tags O-GlcNAc with biotin, enabling facile enrichment of GlcNAcylated peptides. Coupling this technique with Beta-Elimination and Michael Addition of DTT (BEMAD) and LC-MS/MS, we were able to identify several sites on histone H2A, H2B, and H4. The sites identified on H2B and H4 are known phosphorylation sites, while H2A is a novel site found within the core. These findings add O-GlcNAc to the repertoire of post-translational modifications comprising the histone code. Supported by NIH grants DK61671 and CA42486. Dr. Hart receives a share of royalty received by the university on sales of the CTD110.6 antibody. Terms of this arrangement are managed by JHU.

Double Strand DNA Breaks Recruit Centromere Protein A.
S. G. Zeitlin1,7, N. M. Baker4,3, B. R. Chapados6, E. Soutoglou5, J. Y. Wang2, M. W. Berns3, D. W. Cleveland7,1; 1Cellular and Molecular Medicine, UCSD, La Jolla, CA, 2Moores-UCSD Cancer Center, UCSD, San Diego, CA, 3Bioengineering, UCSD, San Diego, CA, 4Electrical Engineering, UCSD, San Diego, CA, 5IGBMC, Strasbourg, France, 6The Scripps Research Institute, La Jolla, CA, 7Ludwig Institute for Cancer Research, La Jolla, CA

The histone H3 variant Centromere Protein A (CENP-A) is required to specify centromere location through a loading mechanism independent of DNA sequence. Using multiphoton laser damage and DNA cleavage at unique sites by I-SceI endonuclease, we demonstrate that CENP-A is rapidly recruited to double-strand breaks, along with CENP-N, CENP-T, and CENP-U. The centromere-targeting domain (CATD) of CENP-A is both necessary and sufficient for recruitment to double-strand breaks. CENP-A accumulation at DNA breaks is enhanced by active non-homologous end-joining but does not require DNA-PKcs or Ligase IV, and is independent of H2AX. Thus, induction of a double-strand break is sufficient to recruit CENP-A in human and mouse cells. Finally, since cell survival after radiation-induced DNA damage correlates with CENP-A expression level, we propose that CENP-A may have a function in DNA repair.

The MRG15 Chromodomain Protein Physically Interacts with Condensins to Modulate Global Chromosome Architecture and Local Gene Expression.
G. Bosco, H. F. Smith, T. A. Hartl, M. Roberts; Molecular & Cellular Bio, University of Arizona, Tucson, AZ
The dynamic structure and 3-dimensional organization of chromosomes play critical roles in the regulation of gene expression. However, the factors that control global changes in chromosome architecture, and how these factors might impinge on local chromatin structures are not well understood. We have previously shown that Drosophila condensins function to antagonize global homologous chromosome alignment and homolog pairing. Condensins also inhibit the transfer of transcriptional states from one allele to another, such as in the case of transvection at the Ubx and yellow genes. Here we show that the Cap-H2 condensin protein physically interacts with the MRG15 chromodomain protein. Condensins require the MRG15 chromodomain protein in order to effect this chromosome anti-pairing activity. By using 3-D fluorescent in situ hybridizations we find that MRG15 mutants enhance condensin mutant homolog and chromatin pairing phenotypes. MRG15 mutants also enhance transvection at the Ubx gene demonstrating that interchromosomal interactions regulating enhancer-promoter interactions in interphase nuclei are sensitive to MRG15 and condensin activities. Furthermore, we show that the Set2 histone methyltransferase responsible for methylating histone H3 Lysine-36 is also required to recruit MRG15 and condensins to chromatin, and mutations in Set2 or RNAi knock-down of Set2 in Drosophila tissues enhance condensin mutant chromosome structure phenotypes. We propose a model whereby condensins physically interact with MRG15 to regulate global chromosome structure, and Set2 methylation of H3 Lysine 36 marks specific genomic regions to which the MRG15/condensin complex is tethered. This is the first demonstration of any specific chromatin binding factors that are necessary for recruitment and activation of condensin activity. This model also explains how global chromosome maintenance machines, such as condensins, can also function at local and specific gene sequences to modulate gene expression.

RNA:DNA Hybrids Control Pericentric Heterochromatin Formation and Chromosome Segregation through the SUV39H2 and SETDB1 Histone Methyltransferases.
L. Strickland, A. F. Straight; Biochemistry, Stanford University, Stanford, CA

Epigenetic regulation of chromatin through histone and DNA modification influences nuclear organization and gene expression but how these modifications are targeted to specific chromosomal sites is poorly understood. We have investigated the role of chromosome associated RNA in the organization and post-translational modification of mitotic chromatin. We isolated mitotic chromosomes from cultured human cells, digested the chromatin with RNases of varying specificity and characterized changes in post-translational histone modifications after RNase digestion. Digestion of RNA:DNA hybrids with RNase H caused the re-distribution of pericentric histone H3 tri-methyl lysine-9 (3me-H3K9) to sites throughout chromosome arms and the release of an H3 histone methyltransferase (HMTase) activity from chromosomes. To identify this activity, we used RNAi to knockdown each of the known human HMTases and screened for the loss of H3-specific HMTase activity after digestion with RNase H. Depletion of SUV39H2 and SETDB1 resulted in loss of the HMTase activity released from chromatin by RNase H digestion, suggesting that association of SUV39H2 and SETDB1 with centromeres is dependent upon an RNA:DNA hybrid. We further found that SUV39H2 and SETDB1 interact with each other and form a complex with HP1 and alpha-satellite RNA. Depletion of SUV39H2 or SETDB1 resulted in chromosome cohesion defects and segregation errors during mitosis. SUV39H2/SETDB1 depletion did not result in activation of the mitotic checkpoint, though RNAi-transfected cells were capable of activating the checkpoint in response to nocodazole or taxol. BubR1 but not MAD2 was recruited to metaphase kinetochores in RNAi-transfected cells. One possibility is that loss of cohesion after SUV39H2/SETDB1 depletion prevented the establishment of tension across bioriented kinetochores, leading to BubR1 recruitment. However, if kinetochores were able to establish microtubule attachments to the mitotic spindle, MAD2 recruitment and full activation of the mitotic checkpoint would not be expected, consistent with our observations.

25
Cis and Trans Determinants of Large-Scale Chromatin Structure.
A. Belmont\textsuperscript{1}, Y. Hu\textsuperscript{1}, W. Wu\textsuperscript{1}, M. Plutz\textsuperscript{1}, Q. Bian\textsuperscript{1}, I. Kireev\textsuperscript{1,2}; \textsuperscript{1}Department of Cell and Developmental Biology, University of Illinois at Urbana-Champaign, Urbana, IL, \textsuperscript{2}Electron Microscopy, Moscow State University, Moscow, Russia

How chromatin folds into mitotic and interphase chromosomes remains unknown. Over a number of years we have used engineered chromosome regions tagged with lac operator repeats as a means of visualizing the structure of specific chromosome regions while also facilitating a reductionist experimental approach to this problem. We have progressed from gene amplified chromosome regions, to regions created by multi-copy integration of plasmids, and now to engineered chromosome regions formed by multi-copy BAC repeats carrying 100-200 kb of defined genomic loci. Recent results with the multi-copy BAC constructs suggest that transcription at levels approaching within several fold the level of the corresponding endogenous gene locus occurs on a condensed template which, however, undergoes a global, long-range several fold decondensation with transcriptional induction. Moreover, sequences contained within specific BACs are sufficient to target these sequences to specific nuclear compartments. We have begun to apply these engineered chromosome regions to determine cis and trans determinants of large-scale chromatin structure. Using a Drosophila S2 cell line containing multiple copies of a MT BAC transgene we have used an RNAi screen of over 200 genes related to chromatin structure and transcription to determine the contribution of their gene products on the large-scale chromatin structure of the MT transgene array before and after gene induction. We identify a large number of genes whose knockdown results in increased condensation or increased decondensation before and/or after gene induction. To investigate cis determinants of large-scale chromatin structure, we have begun by dissecting what sequences on a Hsp70 BAC transgene are required to confer nuclear speckle association after heat shock. We show that targeting to nuclear speckles of the Hsp70 BAC transgene is conferred by specific, several kb sequences contained within the Hsp70 BAC. We conclude that engineered chromosome regions can be used to enable specialized screens to investigate specific questions related to large-scale chromatin structure and nuclear organization.

Minisymposium 5: Clocks (26 – 31)

26

The Essence of Time: Biological Clock Nanomachines, DNA Topology, and Fitness.
C. Johnson; Department of Biological Sciences, Vanderbilt University, Nashville, TN

Cyanobacteria have become a major model system for analyzing clock phenomena. The temporal program in this organism enhances fitness in rhythmic environments and is truly global—essentially all genes are regulated by the circadian system. The topology of the chromosome also oscillates and possibly regulates the rhythm of gene expression. The underlying circadian mechanism appears to consist of both a post-translational oscillator (PTO) and a transcriptional/translational feedback loop (TTFL). The PTO can be reconstituted in vitro with three purified proteins (KaiA, KaiB, and KaiC) and ATP. These three proteins rhythmically form a complex that acts as a nanoclock. The three core oscillator proteins have been crystallized and structurally determined, the only full-length circadian proteins to be so characterized. The timing of cell division is gated by a circadian checkpoint, but the circadian pacemaker is not influenced by the status of the cell division cycle. This imperturbability may be due to the presence of the PTO that persists under conditions in which metabolism is repressed. Recent biochemical, biophysical, and structural discoveries bring the cyanobacterial circadian system to the brink of explaining heretofore unexplainable biochemical characteristics of a circadian oscillator: the long time constant, precision, and temperature compensation.

27

A Cyanobacterial Model for How Cells Tell Time.
S. S. Golden; Molecular Biology, University of California- San Diego, La Jolla, CA
Cyanobacteria, like diverse eukaryotes, possess circadian clocks that allow cells to coordinate physiological processes with the predictable daily patterns of environmental fluctuations on Earth. An autonomous oscillator comprised of three distinctive proteins, KaiA, KaiB, and KaiC, underpins the circadian clock of the cyanobacterial model organism *Synechococcus elongatus* PCC 7942. Our work applies genetic, genomic, biochemical, and structural approaches, integrated with cell biology, to achieve a comprehensive understanding of how the *S. elongatus* cell harnesses this oscillator to control cellular activities. The emerging picture is one of a clock that is set daily by sampling the cellular redox environment as a proxy for light and which uses protein-protein interactions and subcellular localization to coordinate gene expression, cell division, and chromosome dynamics. A functional genomics project has produced inactivation alleles of nearly all *S. elongatus* loci. Gene expression assays of the 700 mutants tested so far suggest that about 10% of loci affect circadian period or phasing.

28
**Role of a Jumonji-Domain Containing Protein in Circadian Clock.**
*S. Panda; The Salk Institute for Biological Studies, La Jolla, CA*

Circadian rhythm in behavior and physiology in mammals is generated by a cell autonomous transcription-translation feedback loop. Two bHLH domain containing transcription factors, BMAL1 and CLOCK, heterodimerize and bind to cis-acting E-box element present in the promoter regions of *Period (Per)* 1, 2, and *Cryptochrome (Cry)* 1, and 2 genes and drive their transcription. The PER and CRY proteins in turn repress CLOCK/BMAL1 activity and generate ~24 h rhythms in mRNA and protein levels of PER and CRY gene products. The roles of chromatin modification and chromatin modifying proteins in this transcriptional rhythm are not clearly understood. We have found that a jumonji domain containing protein functions as a co-activator of CLOCK/Bmal mediated transcription. This jumonji protein physically interacts with Clock/Bmal1 in vivo and is recruited to the promoter of Per genes. siRNA knockdown or genetic ablation of this jumonji protein results in significant alteration in chromatin modification in Per promoter leading to reduced amplitude and shortened period length of Per transcription. The results highlight the roles of an emerging class of chromatin modifying proteins in circadian function.

29
**Cellular Basis of Rhythmic Behaviors.**
*A. Sehgal, K. Xu, J. DiAngelo; Department of Neuroscience, University of Pennsylvania School of Medicine/HHMI, Philadelphia, PA*

Circadian rhythms are 24 hour cycles of behavior and physiology found in virtually all organisms. While the best known example of such a rhythm is the sleep:wake cycle, these rhythms pervade most aspects of physiology and are found in clocks located in many peripheral tissues in addition to the brain. Using the fruit fly, *Drosophila melanogaster*, as a model, we showed recently that metabolic functions are controlled by clocks in neurons as well as in the fly fat body (equivalent of the liver and adipose tissue). These two tissues have opposing effects on the storage of nutrient reserves and thereby on food consumption and the response to starvation. A circadian rhythm of feeding is also likely controlled by metabolic and neuronal clocks. To determine how the fat body regulates feeding and metabolism, we profiled gene expression in this tissue at different times of day through microarray analysis. We found cyclic expression of genes that function in several different pathways- lipid metabolism, immune response, detoxification etc. While the cycling of some genes is controlled by the fat body clock, others cycle under the control of clocks elsewhere. Interestingly, metabolic cues can regulate the phase of circadian gene expression in the fat body. Current research is directed towards determining whether synchrony of clocks in different tissues is important for fitness. Key words- Circadian rhythms, genetics, clocks, *Drosophila*, metabolism, feeding

30
**AMP Kinase Regulates the Circadian Clock by Cryptochrome Phosphorylation and Degradation.**
K. Lamia, U. Sachdeva, L. DiTacchio, S. Panda, R. Shaw, C. Thompson, R. Evans; Gene Expression Laboratory, The Salk Institute for Biological Studies, La Jolla, CA; Molecular and Cellular Biology Laboratory, The Salk Institute for Biological Studies, La Jolla, CA; Regulatory Biology Laboratory, The Salk Institute for Biological Studies, La Jolla, CA; Abramson Family Cancer Research Institute and Department of Cancer Biology, University of Pennsylvania School of Medicine, Philadelphia, PA; Howard Hughes Medical Institute, The Salk Institute for Biological Studies, La Jolla, CA; Howard Hughes Medical Institute, University of Pennsylvania School of Medicine, Philadelphia, PA

Circadian clocks coordinate behavioral and physiological processes with daily light-dark cycles by driving rhythmic transcription of thousands of genes in mammalian tissues. While the master clock in the suprachiasmatic nucleus is set by light, pacemakers in peripheral organs are reset by food availability. In either case, the setting mechanism remains mysterious. Light-dependent clock resetting in plants and insects depends on blue light-driven destabilization of cryptochromes. In mammalian clocks, cryptochrome degradation is mediated by the F-box protein FBXL3 in a light-independent manner. We demonstrate that the nutrient-responsive AMP-activated protein kinase (AMPK) phosphorylates the clock component CRY1 and destabilizes it by increasing its interaction with FBXL3. AMPK activity and nuclear localization are rhythmic, and inversely correlated with CRY1 protein abundance. Stimulation of AMPK destabilizes cryptochromes and alters circadian rhythms. Genetic inactivation of AMPK blocks these effects and disrupts peripheral clocks. Thus, AMPK-dependent phosphorylation enables light-resistant cryptochromes to act as chemical energy sensors and likely contributes to metabolic entrainment of mammalian circadian clocks.

31
Src-Family Tyrosine Kinase Phosphorylation Directs the Degradation of the Clock Protein Timeless via Ubiquitylation and c-Cbl Interaction.
L. O'Reilly, T. E. Smithgall; Department of Microbiology and Molecular Genetics, University of Pittsburgh School of Medicine, Pittsburgh, PA

The circadian clock, an endogenous internal timekeeping system, imposes a 24 hour cycle regulating the essential functions of metabolism and behavior. The molecular basis of the clock involves an autoregulatory loop composed of cycling gene products that control their own synthesis. Drosophila have the ability to reset their circadian clock by light-dependent degradation of the central clock protein, Timeless. Timeless is proteosomally degraded via association with Cryptochrome, which recruits the E3 ubiquitin ligase Jetlag, thus relieving inhibition of transcription and resetting the circadian clock. Timeless degradation is preceded by tyrosine phosphorylation, although the identity of the kinase responsible for this key event triggering the degradation pathway has remained elusive. In mammals, the circadian clock is more complex. Although mammalian Timeless associates with the circadian protein Period and exhibits 24-hour oscillation, Timeless has not yet been definitively placed in the mammalian circadian clock. However mammalian Timeless appears to have essential functions in cell cycle control and embryonic development. Here we report a novel interaction of mammalian Timeless with members of the Src-family of non-receptor protein-tyrosine kinases. Timeless interacts with the SH3 domains of the Src-family members Hck, Fyn, c-Yes and c-Src. Co-expression with each of these kinases in 293T cells led to tyrosine phosphorylation of Timeless. Phosphorylation, particularly with c-Src, enhanced Timeless ubiquitylation. In contrast, treatment of 293T cells with Src-family kinase inhibitors blocked Timeless degradation. As protein-tyrosine phosphorylation is known to recruit the E3 ubiquitin ligase c-Cbl, we also investigated whether c-Src-mediated phosphorylation would recruit c-Cbl to Timeless as part of the proteosomal degradation pathway. Co-expression of Timeless, c-Src and c-Cbl did indeed enhance Timeless degradation, which was blocked with the proteosomal inhibitor ubiquitin aldehyde. Our data demonstrate that SFK-mediated tyrosine phosphorylation directs the proteosomal degradation of Timeless in a light-independent manner, which may be important for Timeless turnover related to non-circadian functions.
Minisymposium 6: Intracellular Trafficking (32 – 37)

32
A Novel Sec24 Mutant Links Cargo Capture to the GTP Cycle of the COPII Coat.
L. Kung-Tran1, R. Buchanan1, E. Futai2, R. Schekman2, E. Miller1; 1Biological Sciences, Columbia University, New York, NY, 2Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Vesicle budding from the endoplasmic reticulum is initiated by the G-protein Sar1p, which is converted from a soluble GDP-bound form to a membrane-associated GTP-bound form. Sar1p:GTP recruits the cargo adaptor complex, Sec23p/Sec24p, which in turn recruits the outer coat complex, Sec13p/Sec31p. Following vesicle release, the coat must be shed to permit vesicle fusion. Coat disassembly is an intrinsic property of the COPII coat, in that the GTP cycle on Sar1p is regulated by components of both the inner (Sec23p) and outer (Sec31p) layers of the coat. The GTPase activity of the full COPII coat creates a paradox whereby rapid coat disassembly in the presence of GTP may preclude the creation of a coat complex of sufficient stability to recruit cargo proteins and deform the membrane. In studying the cargo-binding capacity of the Sec24p subunit, we have discovered a novel mutation that confers a severe secretion block and renders cells temperature-sensitive when present as the sole copy of Sec24p. This mutant protein, Sec24p-A11, is perfectly capable of budding vesicles in vitro in the presence of GMP-PNP, but is dramatically impaired in its ability to support vesicle formation in the presence of GTP. This phenotype is reminiscent of vesicle formation in the absence of Sec16p, which similarly cannot support GTP-dependent budding. Cells expressing sec24-A11 are synthetic lethal with sed4Δ and sec16-2 mutants, and the Sec24p-Sec16p interaction detected by yeast 2-hybrid analysis is perturbed by the A11 mutation. We propose that association of Sec24p with Sec16p retards the GTPase activity of the Sar1p/Sec23p/Sec31p complex such that when this interaction is perturbed (by A11 mutation or removal of Sec16p from membranes), GTP hydrolysis occurs prematurely and productive vesicle budding is reduced. Indeed, in vitro GTPase assays demonstrate that a fragment of Sec16p has GAP inhibitory activity that is abrogated by the A11 mutation. We propose that Sec24p represents a critical regulatory factor that couples cargo selection (via the known cargo-binding sites) to GTP hydrolysis (via Sec16p interaction at the A11 site).

33
Transporting Cholesterol out of the Lysosome: A Pocket-to-Pocket Handoff from NPC2 to NPC1.
R. E. Infante1, H. Kwon2, M. L. Wang1, L. Abi-Mosleh1, J. Deisenhofer2, M. S. Brown1, J. L. Goldstein1; 1Molecular Genetics, University of Texas Southwestern Medical Center, Dallas, TX, 2Biochemistry, University of Texas Southwestern Medical Center, Dallas, TX

Mammalian cells acquire cholesterol (chol) by receptor-mediated endocytosis of LDL. Once within lysosomes, LDL’s cholesterol esters are hydrolyzed by acid lipase. The released chol is transported across the lysosomal membrane to the ER and plasma membrane where it performs regulatory and structural functions. Exit of chol from lysosomes requires two proteins: NPC1, a 1278-amino acid (aa) polytopic membrane protein; and NPC2, a 131-aa soluble protein. Mutations in the genes encoding either of these proteins produce an excessive accumulation of chol in lysosomes, leading to a fatal neurodegenerative disease called Niemann-Pick C. Purified NPC2 and the soluble 240-aa N-terminal domain (NTD) of NPC1 both bind chol with high affinity, yet their binding kinetics differ: NPC2 binds chol rapidly, whereas NPC1(NTD) binds slowly. NPC2 accelerates binding of chol to NPC1(NTD) by >100 fold. X-ray crystallography of NPC1(NTD), together with alanine scan mutagenesis, reveal two distinct subdomains: one for chol binding (buried pocket) and the other for chol transfer (exposed helices). NPC1(NTD) binds chol with its 3β-hydroxyl buried and isooctyl side chain exposed. This orientation is opposite to the binding of chol within the NPC2 pocket. Entry of chol into the binding pocket of NPC1(NTD) is hindered by a narrow constriction point, requiring its opening by reorientation of helices within the
transfer subdomain. Point mutations in this subdomain prevent pocket-to-pocket chol transfer from NPC2 to NPC1(NTD). When NPC1-deficient fibroblasts were transfected with cDNAs encoding full-length NPC1 with point mutations in either the binding or transfer subdomain, chol exit from lysosomes was not restored. We propose the following model: after lysosomal hydrolysis of LDL’s cholesteryl esters, chol binds NPC2 (isooctyl side chain buried; 3β-hydroxyl exposed), opening the constriction point in NPC1(NTD) and permitting chol transfer to NPC1(NTD) (3β-hydroxyl buried; isooctyl side chain exposed). This transfer reverses chol’s orientation, allowing insertion of its isooctyl side chain into lysosomal membranes - possibly through the interaction of the NTD of NPC1 with its own membrane domain.

34 Building the Primary Cilium Membrane: Regulation of GEF Trafficking and Activity and a Rab11-Rab8 Cascade.

C. J. Westlake1, K. J. Wright1, M. Nachury2, L. M. Baye3, J. Rahajeng5, K. E. Ervin1, J. S. Beck4, L. Phu5, D. S. Kirkpatrick3, S. Caplan5, D. C. Slusarski3, V. Sheffield6, R. H. Scheller1, P. K. Jackson1; 1Genentech, South San Francisco, CA, 2Department of Molecular and Cellular Physiology, Stanford University, Stanford, CA, 3Department of Biology, University of Iowa, Iowa City, IA, 4Department of Pediatrics and Howard Hughes Medical Institute, University of Iowa, Iowa City, IA, 5Department of Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE

Aberrant primary cilia function/formation have been linked to human genetic diseases, including Bardet-Biedl syndrome (BBS). A core complex of BBS genes, the BBSome, has been proposed to function in vesicle trafficking during cilium formation, by binding to Rabin8, a Rab8 guanine nucleotide exchange factor (GEF), and which in turn activates Rab8 to promote ciliogenesis. We study here how membrane trafficking events regulate Rab8-dependent ciliary membrane biogenesis. Using a stably expressed GFP-Rab8 fusion, we find Rab8 rapidly relocating to the basal body in RPE cells following initiation of ciliation induced by serum withdrawal. Rab8 assembles into a pericentriolar preciliary vesicle, which extends and elongates during cilia growth for ~100 minutes, and is then lost from mature cilia. Remarkably, Rab8-dependent preciliary/ciliary membrane formation is preceded by microtubule-dependent vesicular transport of Rabin8 to the centrosome, observable within 10 minutes of serum depletion. Using purification/mass spectrometry and a yeast two-hybrid screen with a library of GTP-locked Rabs, we discover that Rabin8 preciliary trafficking is controlled by association with Rab11-GTP and the TRAPP II complex, endosome recycling compartment (ERC) regulators. Rab11 and the TRAPP II complex bind to distinctive domains on Rabin8. We also demonstrate that another ERC regulator EHD1, a membrane bending protein, is required for ciliation. Interestingly, EHD1 localizes distinctively to the proximal region of the ciliary membrane, and MEFs from EHD1 knockout mice have shorter and fewer cilia. Investigation into BBSome involvement in ciliary trafficking showed that BBS1 modulates Rab8 activation by binding to the Rabin8 GEF domain. BBS1 depletion stimulates Rab8 activation resulting in the formation of Rab8 membrane tubules and also increases the length of mature cilia. A Rab11-Rab8 cascade model is proposed, wherein Rabin8 is trafficked by Rab11-positive vesicles to the centrosome, leading to BBS-regulated activation of Rab8, which targets preciliary vesicles and EHD1 to generate the polarized ciliary membrane.

35 Interplay Between Epsins and Sla2 Is Essential for Endocytosis in Yeast.

M. Skruzny, T. Brach, R. Ciuffa, M. Wachsmuth, M. Kaksonen; Cell Biology and Biophysics, EMBL, Heidelberg, Germany

Clasthrin-mediated endocytosis is driven by a complex and highly dynamic molecular machinery. The ENTH/ANTH domain proteins epsins and Sla2 (homolog of mammalian HIP1/HIP1R) are essential for actin-dependent formation of endocytic vesicles. We used live-cell fluorescence microscopy and genetics to elucidate the endocytic roles of epsins Ent1/2 and Sla2 in Saccharomyces cerevisiae. We first used FRAP (fluorescence recovery after photobleaching) to
systematically assess the exchange rates of endocytic proteins at endocytic sites when endocytosis was arrested by latrunculin A (latA). The recovery half-times varied from ~3 s to >2 min. The most stable proteins were the Pan1 complex (Pan1/Sla1/End3) and ENTH/ANTH proteins Ent1/2, Sla2 and Yap1801/2. Notably, all these stable factors are associated with the endocytic coat. To confirm our results with a different method of endocytic arrest, we repeated the FRAP analysis in sla2 null cells, where the actin polymerization at endocytic sites is uncoupled from membrane invagination. While the turnover of most proteins did not change in comparison to the latA experiment, the turnover rates of epsins increased dramatically, suggesting that Sla2 stabilizes epsins at the endocytic site. In addition, Ent1 colocalized with endocytic actin structures revealing an unexpected interaction of epsin with the actin cytoskeleton. We then analyzed cells where both redundant epsins were depleted. The epsin depletion resulted in an endocytic phenotype identical to sla2 deletion. Expression of epsin fragments in epsin depleted cells showed that both the ENTH domain and the C-terminal part of the protein localized to endocytic sites, but only the ENTH domain was able to rescue the endocytic function. Notably, the localization of the ENTH domain, but not the C-terminal part, was lost in the absence of Sla2 protein. These results strongly suggest that Sla2 is required for stable association of epsin ENTH domains with the endocytic membrane. The Sla2-dependent stabilization of epsin ENTH domain in the endocytic coat, together with the direct link of Ent1 and Sla2 to the actin cytoskeleton, could be fundamental for transmitting force from the actin meshwork to bend the membrane.

A Novel, Evolutionarily Conserved Rab5 Effector Controls Rab GTPase Conversion on the Surface on Phagosomes.

J. M. Kinchen, K. S. Ravichandran; Center for Cell Clearance, Dept. of Microbiology, University of Virginia, Charlottesville, VA

Engulfment of apoptotic cells occurs throughout life in multi-cellular organisms as part of normal development, homeostasis, and wound healing. Impaired clearance of apoptotic cells due to defects in recognition, internalization or corpse degradation results in autoimmune diseases (such as lupus and chronic polyarthritis) linked to exposure of auto-antigens. Understanding how defects in corpse removal translate into diseased states critically depends on identifying players that orchestrate different steps of engulfment. Here, through a combination of genetic, biochemical and cell biological studies in worm, yeast and mammalian cells, we identify SAND−1 (and its orthologue MON1) as a critical evolutionarily conserved player during phagosome maturation. In sand−1 deficient worms, apoptotic cells are properly internalized, but phagosomes containing apoptotic cells are arrested at the RAB−5(+), PtdIns3P(+) stage, prior to RAB−7 recruitment. Similarly, mammalian MON1a and MON1b are jointly required for acidification of apoptotic cell containing phagosomes. Mechanistically, we define the requirement for SAND−1 (MON1) in at least three steps of phagosome maturation. First, MON1 specifically interacts with Rab5(GTP), identifying MON1 as a novel Rab5 effector. Second, we find that MON1, in complex with another protein CCZ1, can interact with Rab7; thus, by associating with active Rab5(GTP), CCZ1 and Rab7, MON1 provides a protein:protein interaction bridge from active Rab5(GTP) to Rab7, suggesting a mechanism for Rab7 recruitment. Lastly, we show biochemically and in cells that MON1:CCZ1 facilitates nucleotide release from Rab7. Taken together, we identify SAND−1 (MON1) as a distinct type of Rab5 effector and suggest a novel molecular mechanism for the conversion of Rab5 to Rab7 on the surface of the phagosome.

Regulation of Golgi Division and Mitotic Progression by Golgi Matrix Proteins.

J. Wei, J. Seemann; Department of Cell Biology, University of Texas Southwestern Medical Center at Dallas, Dallas, TX

The mammalian Golgi apparatus is comprised of a series of stacked cisternae that are interconnected into a ribbon-like network in the pericentriolar region. Two protein families of the Golgi matrix, GRASPs and Golgins, play essential roles in maintaining the integrity of the Golgi ribbon as well as tethering the vesicles during intra-Golgi transport. In mitosis the Golgi complex
is disassembled and partitioned into the nascent daughter cells where a functional Golgi reassembles. Upon mitotic entry, matrix proteins are phosphorylated by mitotic kinases, which facilitates the rapid disassembly of the Golgi. Moreover, these proteins also regulate spindle assembly and mitotic progression. The disassembled mitotic Golgi membranes accumulate around the spindle poles, implying a role for the spindle in Golgi partitioning. By inducing asymmetrical cell division where the spindle is segregated into only one of the daughter cells, we show that the inheritance of the higher-ordered Golgi ribbon depends on the mitotic spindle. Taken together, we present the mutual influence between the Golgi apparatus and the spindle machinery during mitosis.

Minisymposium 7: Regulation of Cell Growth (38 – 43)

38

**Growth Control by the mTOR Pathway.**

*D. Sabatini; Whitehead Institute for Biomedical Research/MIT/HHMI, Cambridge, MA*

mTOR is the target of the immunosuppressive drug rapamycin and the central component of a nutrient- and hormone-sensitive signaling pathway that regulates cell growth and proliferation. We now appreciate that this pathway becomes deregulated in many human cancers. We have identified two distinct mTOR-containing protein complexes, one of which regulates growth through S6K and another that regulates cell survival through Akt. These complexes, mTORC1 and mTORC2, define both rapamycin-sensitive and insensitive branches of the mTOR pathway. I will discuss new results from our lab on the regulation of the mTORC1 and mTORC2 pathways. I will provide an overview of mTOR signaling as well as discuss the regulation of mTORC1 by insulin and nutrients and the role of mTORC2 in cancer. We have recently identified new upstream components of the mTORC1 pathway that are involved in amino acid sensing and are starting to understand some of the molecular mechanisms involved in this process. Current evidence suggests that amino acids regulate the mTORC1 pathway by controlling the intracellular localization of mTORC1. Specifically, amino acids promote the movement of mTORC1 to a part of the endomembrane system that also contains its activator Rheb. Amino acids signal through the conserved Rag family of small GTPases that directly interact with the raptor component of mTORC1 in fashion that depends on the GTP-loaded status of the Rags. In addition, I will present evidence that inhibition of mTORC1 by the novel mTOR-interacting protein Deptor is a mechanism for hyperactivating PI3K signaling in multiple myeloma.

39

**hVps34 Activates PLD1 Upstream of mTORC1.**

*M. Yoon1, Y. Yan2, J. M. Backer2, G. Du3, M. A. Frohman4, J. Chen1; 1Cell and Developmental Biology, University of Illinois at Urbana-Champaign, Urbana, IL, 2Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY, 3Integrative Biology and Pharmacology, University of Texas Health Science Center at Houston, Houston, TX, 4Pharmacology and the Center for Developmental Genetics, University Medical Center, State University of New York at Stony Brook, Stony Brook, NY*

The mammalian target of rapamycin (mTOR), in the distinct rapamycin-sensitive protein complex mTORC1, is a critical regulator of cell growth in response to mitogen and amino acids signals. Phospholipase D (PLD) and its product phosphatidic acid (PA) have been established as upstream regulators of mTORC1 mediating mitogenic signals. Another upstream regulator is the class III phosphatidylinositol 3-kinase hVps34, which has been reported to contribute to the regulation of mTORC1 by amino acids. Our recent finding that PLD1 is regulated by amino acids, combined with the fact that PLD1 harbors a PX domain—a potential target of the hVps34 enzymatic product PI3P, prompted us to examine a relationship between hVps34 and PLD1. Here, we find that hVps34 is required for amino acids activation of PLD1, as demonstrated by the effects of RNAi. Exogenous PA rescues amino acids- and insulin-induced mTORC1 activation from the negative effects of hVps34 knockdown, suggesting that PA (and PLD) lies downstream...
of hVps34 in the regulation of mTORC1. Furthermore, overexpression of hVps34 activates PLD1 in a dose dependent manner, and this activation requires the PX domain in PLD1, as a PX-deleted PLD1 mutant does not respond to hVps34. Consistent with the involvement of PI3P, overexpression of a FYVE domain impairs hVps34-induced PLD activation. We also find that Vps34 physically interacts with PLD1, and that this interaction is independent of mitogens or amino acids. Taken together, these observations strongly suggest that PLD1 mediates hVps34 activation of mTORC1 in response to amino acids. Our findings reveal a novel molecular interaction in the amino acid-sensing mTOR signaling pathway and identify a new regulator for PLD1.

Mechanisms Linking Cell Geometry and Mitotic Entry in Fission Yeast.  
J. Moseley\(^1\), A. Mayeux\(^2\), A. Paoletti\(^2\), P. Nurse\(^1\); \(^1\)The Rockefeller University, New York, NY, \(^2\)Institut Curie, Paris, France

Many eukaryotic cell types undergo size-dependent cell cycle transitions controlled by the ubiquitous cyclin-dependent kinase Cdk1. The proteins that regulate Cdk1 activity are well described but their links with mechanisms monitoring cell size, shape, and geometry remain elusive. Here we describe a protein network that controls mitotic entry through Cdk1 and receives signaling inputs related to cell geometry in the fission yeast S. pombe. The core of this network is located in the middle of interphase cells at cortical nodes that contain the Cdk1 inhibitor Wee1 and the Wee1-inhibitory kinases Cdr1/Nim1 and Cdr2. Cdr2 establishes the hierarchical localization of other proteins in the nodes, and receives negative regulatory signals from Pom1, a conserved cell polarity kinase. Pom1 forms a polar gradient extending from the cell ends towards the cell middle and acts as a dose-dependent inhibitor of mitotic entry, working through the Cdr2 network. As cells elongate, Pom1 levels decrease at the cell middle to promote mitotic entry. Because pom1\(^{Δ}\) cells do not enter mitosis as prematurely as wee1 mutant cells, we performed genome-wide screens for additional inputs to the Cdr2-Wee1 network. This identified novel regulators of Cdr2 that display additive genetic defects with pom1\(^{Δ}\) and localize to distinct cortical structures. We propose that combined signals from these structures and the Pom1 polar gradient generate a measurement of cell geometry that controls mitotic entry through Cdr2, Cdr1, and Wee1. Such a system may prevent errors in chromosome segregation, as cell geometry determines the orientation and behavior of the mitotic spindle in a range of cell types including fission yeast.

Control of Organ Size by the Hippo Signaling Pathway.  
D. Pan; Department of Molecular Biology & Genetics, Johns Hopkins University School of Medicine/HHMI, Baltimore, MD

How tissues reach and maintain their characteristic size is a long-standing puzzle in developmental biology. In recent years, we have defined a novel kinase cascade, the Hippo pathway, which plays a critical role in stopping organ growth as cells enter the differentiation phase of organogenesis. In Drosophila, the core of the Hippo kinase cascade comprises the Ste20-like kinase Hippo (Hpo), the NDR family kinase Warts (Wts), and the transcriptional coactivator Yorkie (Yki). Hpo phosphorylates and activates Wts, which in turn, inactivates Yki by phosphorylating the latter and excluding it from the nucleus, where it normally functions as a coactivator for the TEAD/TEF family transcription factor Scalloped (Sd). The Hippo pathway promotes cell death and restricts cell proliferation through the transcriptional regulation of target genes such as the cell cycle regulator cyclin E and the cell death inhibitor diap1. Very recently, we have delineated a mammalian Hippo pathway that links the mammalian homologues of Hpo (MST1/2), Wts (Lats1/2) and Yki (YAP) in an analogous kinase cascade. As in Drosophila, we found that the mammalian Hippo pathway inactivates YAP by excluding it from the nucleus. Using a conditional transgenic mouse model, we showed that YAP induction results in a robust and uniform expansion of liver size to five times normal, followed by rapid progression to hepatocellular carcinoma. These observations implicate the Hippo pathway as a universal size-
control mechanism in flies and mammals, and further revealed a causal link between dysregulation of this size-control pathway and tumorigenesis. We have conducted a cell based RNAi screen to identify additional components of the Hippo pathway in Drosophila. I will present genetic characterization of a novel component of the Hippo pathway.

42
Identifying Targets of the Hippo Tumor Suppressor Pathway that Regulate Growth and Proliferation.
C. M. Pfleger¹, M. Jahanshahi¹, K. Hsiao², A. Jenny³; ¹Oncological Sciences, The Mount Sinai School of Medicine, New York, NY, ²Neuroscience, The Mount Sinai School of Medicine, New York, NY, ³Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY

The hippo tumor suppressor pathway regulates growth, proliferation and apoptosis and is highly conserved from Drosophila to humans. The upstream kinase Hippo phosphorylates other components of the pathway including the downstream kinase Warts. Warts phosphorylates downstream targets such as yorkie (YAP in mammals) and DIAP1, but few other targets have been identified. We performed a genome-wide kinase substrate screen to identify additional downstream targets of the Hippo and Warts kinases. From more than 11,000 gene products screened in small pools, we identified hippo itself as proof of principle. We repeated and identified 36 individual positive hits from roughly 100 positive pools. These in vitro substrates fall into different categories including regulators of endocytosis, mitosis, and protein biosynthesis. We pursued substrates with a putative role in mitotic progression while we continue to identify substrates from the remaining positive pools. Here we report that hps3 (Hippo Pathway Substrate 3) is phosphorylated in vitro and degraded upon hippo over-expression in S2 cells, suggesting its phosphorylation promotes its degradation as seen with DIAP1. Loss of one copy of hps3 in vivo enhances the growth restriction phenotype of hippo over-expression in the eye. Reduction of hps3 using RNAi results in smaller organ size in both the eye and the wing. The reduced eye size is suppressed by mutation in hippo but not by caspase inhibition, suggesting that down-regulation of hps3 mediates the hippo pathway’s role in growth and/or proliferation, but not apoptosis. Our preliminary phenotypic characterization and genetic interaction studies suggest that hps3 regulates organ growth and may inhibit important mitotic exit components. Our model is that (1) hps3 phosphorylation by Warts promotes its instability and that (2) regulation of growth and proliferation by the hippo pathway is in part achieved by down-regulating hps3 to ensure proper organ size control and to upregulate mitotic exit activities. Like yorkie, other targets of the hippo pathway may play an important role in regulating growth and proliferation and could represent novel tumor suppressors and oncogenes.

43
A Novel Mechanism for Cell Size Control by Regulators of the Retinoblastoma Tumor Suppressor Pathway.
J. Umen, B. Olson, C. Lopez, Y. Li; Plant Biology Laboratory, The Salk Institute, La Jolla, CA

Proliferating cells maintain size homeostasis through mechanisms that are thought to involve size checkpoints, but the nature of such checkpoints has been difficult to determine. The unicellular alga Chlamydomonas reinhardtii is a uniquely accessible model for cell size control owing to its multiple fission cell cycle where growth and division are uncoupled. The retinoblastoma (RB) tumor suppressor pathway is a key mediator of Chlamydomonas size checkpoints, but upstream components of the RB pathway that control its activity in response to cell size are unknown. We isolated and characterized two new size checkpoint mutants, cdkg1 (large phenotype) and tny1 (small phenotype), that were both upstream of RB (encoded by MAT3) in a linear genetic pathway. CDKG1 was found to encode a novel algal-specific cyclin dependent kinase (CDK) whose mRNA abundance was cell cycle regulated. CDKG1 over-expression led to a small-cell phenotype indicating that CDKG1 is a rate-limiting size regulator. Interestingly, CDKG1 interacted with Chlamydomonas D-type cyclins in vitro, and recombinant CDKG1-cyclin D complexes could phosphorylate MAT3/RB. Our findings indicate a remarkable evolutionary convergence between
CDKG1 and the independently evolved metazoan kinases CDK4/6 and CDK2 as regulators of the RB pathway. TNY1 was found to be genetically upstream of CDKG1 and encodes a cytoplasmic hnRNP-related RNA binding protein that acts as a cell cycle repressor. Using highly synchronous cultures we determined that TNY1 protein is made once per cell cycle at the time of division, and then remains at a constant absolute level during G1. This pattern of synthesis suggests a model for size checkpoint control where a constant amount of the repressor TNY1 is diluted by an increasing amount of its target RNAs, one of which is likely to be encoded by CDKG1 whose unusually long and uridine-rich 3’ untranslated region is a putative TNY1 target. This titration model involving tightly regulated production of repressors such as TNY1 that are diluted by cell growth to allow synthesis of activators such as CDKG1 may be a widespread principle for coupling cell growth to cell cycle activation or other critical processes.

Bruce Alberts Award (44 – 45)

44

Advancing Science Literacy among Under Represented Minorities.
M. P. Berriozábal; Department of Mathematics, University of Texas at San Antonio, San Antonio, TX

In 1979 Berriozábal received a grant from the U. S. Department of Energy to start the San Antonio Prefreshman Engineering Program (PREP) at the University of Texas at San Antonio. The seven-to-eight summer mathematics-based enrichment program for mostly underrepresented minority middle and high school students focuses on developing their abstract reasoning and problem-solving skills. Ultimately, it prepares and encourages many of the students to pursue college-level work in science, technology, engineering and mathematics (STEM). The program expanded in 1986 to other colleges throughout Texas; it expanded again in 1997 to other states with a continuing focus on minority students, particularly Hispanics. The program has received numerous awards and is considered one of the top K-12 STEM programs in the U.S. To date over 28,000 students are former PREP participants. Results show that 99% of students who attend a PREP summer session graduate from high school; of those, 99% go on to college, 82% graduate from college, and 46% of the college graduates are STEM majors.

A Creative, Rewarding Career Pathway for Scientists: Teaching Pre-College Science.
T. M. Horn; Carnegie Academy for Science Education, Carnegie Institution for Science, Washington, DC

In this century of science and technology, pre-college programs around the country include S&T, but so many students in our urban and rural localities experience science only as "reading the textbook and writing vocabulary." Localities with specialized schools for science that are populated with high achievers and independent schools hire S&T professionals and support laboratory science learning. This was how, in part, Thomas Jefferson High School for Science and Technology (TJ) developed into the school rated #1 nationally by USNews for two years running. But, our country is filled with talented students from urban and rural centers who, though deserving, have been woefully underprepared. DC schools are surrounded by S&T industries, yet the nation's Capital has about the very lowest ranked school system. At TJ, starting in 1985, we developed a series of short courses (like MBL, CSHL) in a rotation with other technologies that introduced 400 9th grade students annually to basics of biotech including microbiology, plant and animal cell culture, enzymology, and molecular biology. Later courses included plant tissue culture, DNA biotech and Senior Research and Mentorship. The program has evolved to include the interests of new faculty. Seniors intern in labs all over the DC Metro area. At McKinley Technology HS and Ballou Senior High School, in NE and SE Washington DC, our group at CASE is assisting in the development of career pathways in biotechnology. The DC school system has outfitted these labs generously. In 20 years, new technologies like thermal cyclers and digital microscopes are becoming available even at the pre-college level, but students still
need to learn the basics of handling themselves and the tools, materials and equipment. Science connects all the subjects and provides interesting context for reading and math, areas where the US is lagging internationally. We scientists know how to DO science. It feels as good when a student "gets it" as when the data from our experiment show a pattern we can interpret. We can't let the kinds of science learning non-opportunities of so many students AND pre-service teachers continue. Would YOU be satisfied if someone told you most days, "This is the book. You are not allowed to read this book. I haven't read the book either, but I will tell you what's in it. You will take tests answering the information I gave you." We well-educated scientists have much to offer to our youth and colleagues who teach youngsters. Teaching is not an alternative career for a scientist; it's a rewarding pathway.

Nicotinic ACh Receptors in the Brain; Structure, Function and Role in Disease.
J. L. Yakel; National Institute of Environmental health Sciences (NIEHS), Research Triangle Park, NC

The human brain contains hundreds of billions of neurons, all interconnected at synapses, the specialized cellular contacts which transmit electrical messages that allow the mind and body to continually sense and respond to the myriad of stimuli in the environment and the other organ systems. Thus, dysfunctions in neuronal signaling, either through disease, injury, or toxic/environmental insult, are a major health hazard. Neurons signal one another at synapses by releasing chemicals neurotransmitters that bind to receptor proteins on the surface of neighboring cells. Neurotransmitter receptors regulate neuronal function by activating ligand-gated ion channels (LGICs; single protein complexes that include both the receptor binding site and the ion channel pore) which rapidly excite or inhibit ongoing electrical activity. In the Ion my group, we study the LGIC superfamily, with a particular emphasis on the nicotinic acetylcholine (ACh) receptor channels (nAChRs). These channels are permeable to cations, and some are also permeable to calcium ions, and this increase in cytoplasmic calcium levels ([Ca^2+]_i) can affect signal transduction cascades, plasticity, and gene transcription. The nAChRs are widely expressed (in neurons and in non-neuronal cells) throughout the brain, both on postsynaptic membranes, where they mediate synaptic transmission by cholinergic neurons, and on presynaptic terminals of non-cholinergic neurons, where they regulate release of other neurotransmitters. The nAChRs are essential for a variety of fundamental brain functions, including cognitive processing, learning and memory formation, and development. Dysfunctions in nAChR function have also been linked to a variety of neurological disorders and diseases, including AD, Parkinson’s disease (PD), epilepsy, and schizophrenia. The goal of my group is to elucidate the role nAChRs play in the pathology of neurological diseases and disorders. Besides understanding the pathology of serious diseases afflicting millions of Americans, this information may also aid in the development and design of therapeutics to treat or mitigate the symptoms of nAChR dysfunction.

Symposium 1: The Human Genetics as Two-Way Information (47 – 49)

47
Mechanosensation in Auditory Sensory Cells: What Did We Learn From Deafness Genes?
C. Petit; ¹Neuroscience, College de France & Institut Pasteur, Paris, Paris Cedex 15, France, ²Inserm UMRS587 - UPMC, Paris 75015, France

Mechanosenses are the most numerous senses but the least understood, mainly because their sensory cells are either very few or scattered throughout tissues. The genetic approach is particularly suitable to resolve this issue. Recent advances in the identification of the genes underlying early onset forms of hearing impairment in humans and the successful application of
multidisciplinary analyses of their mouse models enlightened the way in which the auditory hair bundle develops and functions, and launched the deciphering of the involved molecular mechanisms. The hair bundle, the most sophisticated microvillar structure of the animal kingdom, is a femtoliter cellular compartment of thirty to a few hundred stiff microvilli, improperly called the stereocilia, inter connected by fibrous links and with a shape unique for each auditory sensory cell. It responds with a sharpened frequency selectivity to sound mechanical stimulus, transduces it with an extreme sensitivity and distorts the sound waves that it processes. The remarkable capacities of the hair bundle are associated to extreme vulnerability of this structure. Most of the genes defective in human deafness affect the auditory sensory cells. In most cases, the hair bundle is the primary target of the defect and myosin motors form the prevailing class of the proteins encoded by theses genes. Based on the large group (about 30 genes defects) of hair bundle developmental anomalies observed, a view of the various clues that control the hair bundle shaping is emerging. Currently, the most unexpected results came from the deciphering of the molecular composition of the hair bundle links, the various subsets of lateral links and the tip link, a component of the transduction machinery. The study of Usher syndrome (sensory neural deafness associated to blindness) provided major insights. The proteins encoded by the 9 known genes responsible for Usher type I and II, form molecular complexes that compose two subsets of transient lateral links critical for the hair bundle morphogenesis. Several Usher type I proteins also later make up the core of the mechanoelectrical transduction machinery.

V. Sheffield; University of Iowa/HHMI, Iowa City, IA

The identification of genes, sequence variations, and mechanisms involved in complex human disorders holds great promise for improving health care, but at the same time presents a difficult challenge to the scientific community. To better understand the genetics of complex human disorders, my laboratory has studied Mendelian (monogenic) disorders that share a phenotypic component with common complex disorders. We have used human populations to map dozens of disorders and have used positional cloning methods to identify numerous disease-causing genes. Recent work in our laboratory has focused on the study of Bardet-Biedl syndrome (BBS). BBS has the primary features of obesity, retinal degeneration, polydactyly, hypogonadism, renal anomalies, and mental retardation. Secondary features of BBS include diabetes mellitus, hypertension, and congenital heart defects. Studies by us and others have shown that there are more than 12 genes that independently can cause BBS syndrome. Current efforts are aimed at determining the pathophysiology of specific components of the BBS phenotype, including the function and interactions of the known BBS genes, and defining the components and specific interactions of BBS protein complexes. Animal models have implicated abnormal cilia function in the pathogenesis of BBS. Mice lacking Bbs gene expression have major components of the human phenotype, including obesity and hypertension. Our genetic, cell biological, and animal model work is aimed at understanding and intervention in human disease.

49
Genes that Control the Shape and Size of the Human Cerebral Cortex.
C. Walsh; 1Childrens Hospital Boston, Boston, MA, 2Harvard Medical School, Boston, MA, 3Howard Hughes Medical Institute, Boston, MA

The large human population of the world, and the widespread occurrence of mutations that cause neurological disease, make the study of human genetic disorders of cerebral cortical development a rich source of genes essential for neural development. Improved imaging of the human brain has revolutionized our understanding of brain malformations. Between 5-40% of epilepsy patients show malformations of the cerebrum, which are especially common in children with severe epilepsy. It is increasingly common to find subtle malformations of the cortex in people of normal intelligence. Moreover, other disorders affect synaptic function without causing a gross malformation, producing mental retardation, autism, or other learning disorders. Genetic
studies in our lab and others in the last few years have identified many genes that cause human malformations—LIS1, DCX, FLNA, ARFGEF2, Reelin, POMT1, ASPM, CENPJ, CDK5RAP2, GPR56, etc. However, we are just starting to understand the rich variety of disorders of brain development. Identified genes encode proteins with key roles in proliferation of neuronal precursor cells or migration of neurons, two essential features of the development of our cerebral cortex. Many patients with developmental brain disorders have “de novo” mutations, meaning that the patient is the first in the family to manifest the malformation and the mutation, analogous to cancer, in which a “genetic disease” is not usually inherited in a simple way. The greatest phenotypic and genetic diversity of developmental brain disorders represent rare recessive conditions, for which many genetic causes still remain undiscovered. Continued identification of genes that cause human cortical disorders promises to inform us about how our brain develops and even how it evolved, since a larger and more highly ordered cerebral cortex is a principal feature that distinguishes us from other mammals. Surprisingly, some of the genes essential for human cortical development also appear to have been targets of the evolutionary selection that distinguishes our brain from that of other animals.

Symposium 2 - Under the Hood of the Cell: Dynamic Organelles (50 – 52)

50 How Mitochondria Divide and Fuse.
J. Nunnari; Department of Molecular and Cellular Biology, University of California, Davis, Davis, CA

Mitochondria are essential organelles that perform a myriad of tasks within eukaryotic cells. Unlike their bacterial ancestors, they are not discrete entities; rather, isolated organelles are transient and are in constant communication with each other via fusion. Mitochondrial division antagonizes fusion and together these events fundamentally serve to create a compartment that is connected and thus functional, yet able to be distributed via transport on cytoskeletal networks. In mammals, additional roles for mitochondrial fusion and division proteins have evolved by virtue of their integration with cellular signaling networks. The best characterized is cell death, where these proteins directly modulate mitochondrial dependent apoptosis. Mitochondrial division and fusion are mediated by the action of highly conserved dynamin-related proteins (DRPs) that, through their ability to self-assemble and hydrolyze GTP, control membrane remodeling events. We have developed experimental systems to elucidate how DRPs function to mediate mitochondrial division and fusion as well as to uncover the mechanism of how these events are regulated in cells.

51 Epistatic Mini Array Profiles (EMAPs) Reveal that the Asthma-Associated ORM/ORMDL Family Proteins are Key Mediators of Sphingolipid Homeostasis.
J. Weissman; Department of Cellular and Molecular Pharmacology, University of California, San Francisco/HHMI, San Francisco, CA

Despite the essential role of sphingolipids as both structural components of membranes and critical signaling molecules, we have a limited understanding of how cells sense and regulate their levels. Here we reveal the function of the ORM/ORMDL genes, a conserved gene family that includes ORMDL3, a recently identified potential risk factor for childhood asthma. Starting from an unbiased functional genomic approach based on an analysis of large scale genetic interaction networks, we identify Orm proteins as negative regulators of sphingolipid synthesis that form a conserved complex with serine palmitoyltransferase, the first and rate-limiting enzyme in sphingolipid production. We also define a regulatory pathway in which phosphorylation of Orm proteins relieves their inhibitory activity when sphingolipid production is disrupted. Changes in Orm gene expression or mutation to the Orm phosphorylation sites cause dramatic dysregulation of sphingolipid metabolism. Our work identifies the Orm proteins as critical mediators of...
SUNDAY

sphingolipid homeostasis and implicates misregulation of sphingolipids in the development of childhood asthma.

Autophagosome Biogenesis and Function.
J. Lippincott-Schwartz; National Institute of Child Health and Human Development/NIH, Bethesda, MD

Autophagy is a highly conserved, bulk degradation pathway in eukaryotes that includes turnover of large aggregates and organelles within cells. In this pathway, activation of specific autophagy effectors, including LC3, induces a membrane bilayer to wrap around portions of the cytoplasm to form a double membrane-bounded structure called the autophagosome. The autophagosome then targets to and fuses with the lysosome where the sequestered materials (including protein aggregates or organelles) are degraded by various hydrolytic enzymes and recycled as amino acids for macromolecule synthesis and energy production. Emerging results have revealed the importance of autophagy in various biological and pathological processes, such as cellular remodeling, tumorogenesis and neurodegeneration. However, how this pathway operates and the characteristics of its central organelle (i.e., the autophagosome) are far from understood. We have utilized in cellulo pulse-chase labeling with photoactivatable fluorescent proteins, photobleaching, electron microscopy tomography, and other techniques to investigate whether autophagosomes derive from preformed membrane(s) or by a de novo process, the signals that recruit substrates to autophagosomes, and whether selective types of autophagosomes are used for different cellular functions.

A Journey with Molecular Motors.
R. Vale; Department of Cellular and Molecular Pharmacology and HHMI, University of California, San Francisco, San Francisco, CA

Ever since I was a graduate student, I have been “hooked” on understanding biological motion, a problem that also fascinated Keith Porter. In the mid 1980s, I never thought that one could hope to understand biological motility with any satisfying degree of detail. However, unanticipated tools of single molecule measurements, genomic sequencing, and protein expression have allowed our field to probe and understand how molecular motors work with extraordinary precision. I will provide a brief scientific tour of these past twenty years and then focus on a couple of questions on the dynein motor that occupy our present attention. Interwoven with the science, I will highlight some lessons that I have learned along the way. I have had the good fortune of being guided into this profession by a number of wonderful scientists and mentors, and I hope to emphasize the joy and privilege of being part of the scientific discovery process.

Parasitology (54 – 68)

FRET Peptides Reveal Differential Proteolytic Activation in Intraerythrocytic Stages of the Malaria Parasites Plasmodium berghei and P. yoelii.
L. N. Cruz¹, M. A. Juliano³, L. Juliano³, C. R. Garcia²; ¹Department of Parasitology, Universidade de São Paulo, São Paulo, Brazil, ²Department of Physiology, Universidade de São Paulo, São Paulo, Brazil, ³Department of Biophysics, Universidade Federal de São Paulo, São Paulo, Brazil

Malaria is still a major health problem in developing countries. It is caused by the protist parasite Plasmodium in which proteases are activated during the cell cycle. In this context, Ca²⁺ is an
ubiquitous signaling ion that tightly regulates protease activity through changes in its intracellular concentration. Proteases are crucial to Plasmodium development but the role of Ca^{2+} in their activity is not fully understood. In the present work we are interested in determining the role of Ca^{2+} in protease modulation among different Plasmodium species. Using Fluorescence Resonance Energy Transfer Peptides (FRET) we verified protease activity elicited by Ca^{2+} from the endoplasmic reticulum (ER) after stimulus with thapsigargin (SERCA inhibitor). Classes of affected proteases were investigated with the class-restricted protease inhibitors PMSF (serine proteases), E64 (cysteine proteases) and Pepstatin a (aspartic proteases) after thapsigargin treatment. Intracellular Ca^{2+} chelator (BAPTA/AM) was used to adjust Ca^{2+} concentration. In Plasmodium berghei and P. yoelii, Ca^{2+} released from the ER activated proteolysis of FRET peptides. Effects of protease inhibitors on thapsigargin-induced proteolysis differed between species, Pepstatin a and PMSF increasing proteolysis in P. berghei, but Pepstatin a decreasing it in P. yoelii. E64 reduced proteolysis in P. berghei after thapsigargin, but stimulated it in P. yoelii. The absence of intracellular Ca^{2+} greatly increased peptide hydrolysis in P. yoelii. We concluded that in malaria parasites there are Ca^{2+} modulated species specific proteases and in P. berghei and P. yoelii proteases inhibited by Ca^{2+} are major components of peptide hydrolysis.

Macrophage Plasma Membrane Hyperpolarization Associates with Protection against Apoptosis of Leishmania Infected Macrophages.
L. Clavijo1,2, M. E. Forero 2, N. Matta1, M. M. Camacho1,2; 1Universidad Nacional de Colombia, Bogotá, Colombia, 2Biofisica, Centro Internacional de Fisica, Bogota, Colombia

Leishmania are intracellular parasites that reside within endo-lysosome compartments of macrophages. We have shown that infection with Leishmania amazonensis or Leishmania braziliensis alters the electrical properties of macrophages. Established parasite infection (more than 48 hours post-infection with parasite replication) induces increases in macrophage membrane capacitance, hyperpolarization of the macrophage plasma membrane associated with increases in inward current density. Hyperpolarization has been associated among others with protection against apoptosis in other cell models and there is evidence that Leishmania infection protects macrophages against apoptosis. In this work we study a model of apoptosis in the murine macrophage cell line J774A.1 with cytochrome C as inducer. Apoptosis was assessed by DNA fragmentation and phosphatydilserine externalization. Macrophage electrical properties were recorded using the whole cell configuration of the patch clamp technique in control, pre-apoptotic, apoptotic and Leishmania infected macrophages before and after cytochrome C treatment. We found that apoptosis does not alter macrophage membrane capacitance, therefore the volume changes associated with apoptosis are not accompanied by plasma membrane area reduction. The plasma membrane potential of apoptotic macrophages was 25% more depolarized than control cells. This depolarization was paralleled by an increase of 59.6% in outward current density with no changes in inward currents. Nevertheless, macrophages infected with Leishmania braziliensis were hyperpolarized compared to control and apoptotic macrophages and protected macrophages against apoptosis induced by cytochrome C around 50%.

56/B3
CLC Channels of the Protozoa Leishmania.
Y. Y. Lozano1,2, C. J. Gomez1, M. L. Posada-Buitrago2, M. M. Camacho1,2; 1Universidad Nacional de Colombia, Bogotá, Colombia, 2Biofisica, Centro Internacional de Fisica, Bogota, Colombia

Leishmania spp. alternate during their life cycle in environments with extreme differences in pH. Promastigotes propagate in the alimentary tract of the sandfly vector, which could be alkaline (pH 7.0-9.0) or acidic (pH 5.0-6.0) and amastigotes reside in a highly acidic environment (pH 4.5-5.5) within the host cell, both maintaining an internal pH close to neutral. The expression of chloride channels in these parasites has been shown coupled with proton pump activity. We have shown chloride currents after the injection of Leishmania amazonensis and Leishmania braziliensis mRNA into Xenopus laevis oocytes using voltage clamp. In this study we show for the first time CLC chloride channels of Leishmania, which may be related to the adaptation and survival of the
parasite to the severe environmental conditions found within the host cell. Immunofluorescence images of *L. braziliensis* using an unspecific CLC antibody showed a speckled cytoplasmic pattern consistent with the location of CLC channels in intracellular organelles and in the flagellar pocket. Primers for putative chloride channel genes were designed based on the sequences available for *L. braziliensis* at the GenBank and the GeneDB. Total RNA was extracted from *L. braziliensis* (HOM BR/75M2903) promastigotes with Trizol, cDNA was synthesized with Superscript II and used as template for RT-PCR. The PCR product was purified, cloned into the pGEMT easy vector and sequenced. The sequence showed high homology to the LbrMO1_V2.0210, GeneID: 5412354 from *L. braziliensis* and phylogenetic analysis revealed that it belonged to the eukaryotic branch of intracellular membrane ClCs. Both, the identified putative CLC gene and the immunofluorescence assays confirmed the presence of at least one CLC chloride channel in *L. braziliensis*. Electrophysiological studies of transfected HEK293 cells with a CT-GFP expression vector coding the putative CLC chloride channel using the patch clamp technique showed currents similar to those observed in *X. laevis* oocytes using the voltage clamp technique, being the first description of a CLC chloride channel of *Leishmania* that could be used as a therapeutic target.

Large Phagocytic Loads Explain Altered Cytokine Secretion and Cytoskeleton Distribution in Macrophages Infected with *Leishmania*.

A. P. Rojas1,2, G. E. Montoya1,2, N. Chacon1,2, M. M. Camacho1,2; 1Universidad Nacional de Colombia, Bogotá, Colombia, 2Biofisica, Centro Internacional de Fisica, Bogota, Colombia

*Leishmania* spp, are intracellular parasites that reside within phagosomes of macrophages. Parasites decrease macrophage nitric oxide production. We have shown that large phagocytic loads of latex beads also decrease nitric oxide production of activated macrophages. This decrease did not associate with lower mRNA or protein levels of inducible nitric oxide synthase but with altered intracellular distribution of this enzyme. Decrease secretion of interleukin 12 (IL-12) and Tumoral necrosis factor alpha (TNF-a) have also been described in macrophages infected with *Leishmania*. In this study we tested the hypothesis that large loads associate with decrease secretion. We determine mRNA levels by real time PCR, protein levels by western blot, secretion by ELISA and flow cytometry and intracellular distribution of IL-12, TNF-a, actin and tubulin. Activation of macrophages is required for expression of IL-12 and its location is submembranal. *Leishmania* infection does not induce expression of IL-12 but reduces it and alters its intracellular distribution after macrophage activation. There is constitutive production of TNF-a mRNA by control macrophages, that increases with activation but decreases with large loads (*Leishmania* or latex beads). TNF-a distribution is perinuclear in control and activated cells where it is also towards the periphery of the cell and is altered by large loads (*Leishmania* or latex beads). TNF-a secretion is significantly decreased also by large loads (*Leishmania* or latex beads) in activated macrophages. Actin distribution of control macrophages is towards the periphery of the cell and tubulin is cytoplasmic and perinuclear. Activation induces more actin processes and increases perinuclear tubulin location. The levels of actin and tubulin measured by western blot are not altered by large loads (*Leishmania* or latex beads), but their distribution is. Together these results suggest that large phagosomal loads alter distribution of intracellular compartments within the macrophage and compromise secretion.

**CYP5122A1, A Novel Cytochrome P450 Is Essential for Survival of Leishmania Donovani Both In Vitroand In Vivo.**

S. Verma, C. Shaha; Cell Death and Differentiation Research Laboratory, National Institute of Immunology, New Delhi, India

Cytochrome P450s (CYP450) are a versatile superfamily of hemeproteins that are known to be involved in drug metabolism/resistance as well as in carrying out important physiological functions. Although CYP450s are known to be crucial for survival of higher eukaryotes, their functional contribution to the physiology of the kinetoplastid parasites are not known. This study
presents evidence for the crucial role of a novel CYP50, the CYP5122A1 in the survival and infective abilities of Leishmania donovani, the parasite that causes visceral leishmaniasis for which there are distinct endemic pockets throughout the world and the disease is fatal if left untreated. The Leishmania donovani CYP5122A1 (DQ267494), localized to the endoplasmic reticulum of the parasite, shows 87-94% similarity to the orthologues in different members of genus Leishmania while having only 17-19% similarity with human CYP450s. Complete knockouts of CYP5122A1 did not survive while half knockouts (HKOs) with one allele of the gene intact and the other replaced with the neomycin gene survived, although they grew more slowly than the wild-types. These parasites with half the amount of protein as compared to the wild type cells showed higher susceptibility to the anti-leishmanial drug miltefosine. Since miltefosine induced higher expression of CYP5122A1 in wild-type cells, the compromised ability of the HKOs to survive miltefosine exposure together suggested that CYP5122A1 could be related to miltefosine action. The HKOs were also susceptible to oxidative stress, a common agent generated during drug action and also during parasite invasion of the macrophage. Understandably, the HKOs were unable to sustain infection in macrophages as efficiently as the wild-type cells, both in vitro in macrophage cell line J774 and also in vivo in macrophages from hamster infection model. Since CYP450s are also known to be involved in sterol biosynthesis, ergosterol which is the primary sterol in Leishmania membrane was estimated and the HKOs showed the presence of lesser ergosterol (~50%) than the wild-types. Taken together, the data suggest that CYP5122A1 is an essential component for the survival of Leishmania donovani.

Purine Salvage by the Human Pathogen Leishmania mexicana Is Facilitated by a Unique Secretory Nuclease; LmexNUC<sup>s</sup>
Y. Hernandez, M. B. Joshi, D. M. Dwyer; LPD/ Cell Biology Section, National Institute of Allergy and Infectious disease, Bethesda, MD

All Leishmania spp reside and multiply as extracellular promastigotes (Pro) within the midgut of their sandfly vectors and as intracellular amastigotes (Am) within the phago-lysosomal system of human macrophages. These parasites are obligate purine auxotrophs and, in order to survive and multiply, they must salvage such essential molecules from their hosts. Here, we identified and characterized a unique 35kDa secretory nuclease (LmexNUC<sup>s</sup>) which might play a significant role in purine acquisition by <i>L. mexicana</i>. Sequence analysis revealed that LmexNUC<sup>s</sup> possesses a signal peptide and five structural motifs characteristic of the P1/S1 fungal/plant secretory nuclease family. Northern blot and protein analyses confirmed that LmexNUC<sup>s</sup> was transcribed and differentially translated through the parasite’s life cycle (Ax>>Pro). Western blot and enzyme activity analyses verified that LmexNUC<sup>s</sup> was constitutively secreted/released by both <i>L. mex</i> Pro and Am developmental forms. In order to delineate the functional properties of the LmexNUC<sup>s</sup>, the gene was episomally over-expressed in <i>Lmex</i>NUC<sup>s</sup>-HA transfectants. Results of combined anti-HA immunoprecipitation/enzyme activity assays showed that LmexNUC<sup>s</sup> was N-linked glycosylated and that it could readily degrade RNA, ssDNA as well as various synthetic polynucleotide substrates (i.e. poly-A, -I, -U). Further we demonstrated that LmexNUC<sup>s</sup> was irreversibly inactivated by sulphhydral reducing agents e.g. DTT. Cumulatively, our results indicate that LmexNUC<sup>s</sup> must play important roles in facilitating both the growth and development of this important human pathogen.

I. T. Novak<sup>1,2</sup>, F. M. Rodriguez<sup>1</sup>, P. Anton Bejarano<sup>1</sup>; <sup>1</sup>Institute of Cell Biology, Faculty of Medicine, National University of Cordoba, Argentina, Cordoba, Argentina, <sup>2</sup>Natl Univ Cordoba, Fac Med, Cordoba, Argentina

Immune cell factors of the severe chronic chagasic human heart disease were reported; previous work showed occurrence of CD4-T-lymphocyte population, high producers of P.A.S.-positive glycoproteins, with evidences suggesting a role in damages in myocardium and neural structures.
in chagasic heart (Cabral, Lancet 1:1356, 1971; Cabral, Novak, Mem Inst Oswal Cruz, 90 S I:157, 1995, 92, S I, 1997). Interferon Gamma production by such cells of chagasic patients was reported recently (Cabral et al, 2006, Rev Fac Cienc Med Cordoba, 63: 47-52). Occurrence of thick ring nuclei in neutrophils of chagasic patients was reported (Cabral, Br J Haematol, 67: 118, 1987), and the cytological diade: thick ring nuclei in neutrophils and lymphocytes with P.A.S.-positive substance were described in vivo (Cabral et al, Mem Inst Oswal Cruz 83 S I: 95, 1990). Ring-shaped nuclei in human neutrophilic leukocytes in blood of healthy individuals and their wide occurrence in age groups were showed (Cabral et al, Mol Biol Cell. 7 Suppl ASCB, 656a, 1996).

Objective: in the present work we studied cell cultures of total leukocytes to assess such cytological diade. Blood was obtained from 6 patients with positive serological tests for Chagas and 10 healthy controls. Total leukocyte cultures were prepared in TC 199 medium. Samples were undertaken at 0, 5, 8 hours. Likewise for all groups blood fresh smears were prepared and occurrence of ring nuclei neutrophils was assessed. H/E and cytochemical reactions (mieloperoxidase, P.A.S.) were made. With respect to ring nuclei neutrophils, the results showed a significative increase in smears from chagasic patients as compared with controls (p<0.01). Mieloperoxidase showed positive reactivity in ring nuclei neutrophils in all groups and in cultures. The production of lymphocytic P.A.S. positive substances was showed in cultures of all patients. Conclusions: the facts suggest that the above mentioned leukocytic activities in Chagas may be more intense and they occurred in vitro, also.

Condensation-Dependent Sorting of a Single-Type Cargo in Differentiating Giardia: A Minimal Model for Cyst Wall Formation.
C. Konrad, C. Spycher, A. B. Hehl; Institute of Parasitology, University of Zurich, Zurich, Switzerland

The trophozoite stage of the protozoan parasite Giardia lamblia has a basic but effective trafficking system that lacks a Golgi apparatus. for transmission to new hosts, trophozoites differentiate to cysts by secreting a simple extracellular matrix composed of the three members of the cyst wall protein (CWP) family and GalNAc homopolymer chains. CWPs are sorted away from constitutively secreted proteins during ER export and accumulate in organelles called encystation-specific vesicles (ESV). ESVs are the only Golgi cisterna analogs in Giardia and are generated de novo in a COPII-dependent process. This unique system which transports only cyst wall material in differentiating cells corresponds to an inducible and pulsed version of a Golgi according to the cisternal maturation model. Based on this we predicted an as yet unknown sorting step before regulated secretion of ESVs contents. Here, we show that proteolytic processing of CWP2 leads to partitioning of this protein into two fractions with distinct physical states. Using FRAP analysis we demonstrate formation of a condensed core driving cargo partitioning in ESVs and sorting of this material into two different vesicle types by a "sorting by retention" mechanism. In line with genomic evidence for dramatic reduction processes in Giardia during evolution, this constitutes a minimal system for cargo sorting resulting in sequential secretion and polymerization of this material to form a two-layered extracellular matrix. Regulated export of CWPs in differentiating Giardia is the simplest model to investigate basic mechanisms for Golgi neogenesis, protein sorting, as well as ordered assembly of protective biopolymers.

Transcriptomics of the Giardia lamblia Degradome.
B. J. Davids1, D. S. Reiner1,2, M. A. Gilbert1,3, A. G. McArthur4,5, F. D. Gillin1; 1Pathology, University of California, San Diego, San Diego, CA, 2Signal Transduction Group, Burnham Institute for Medical Research, La Jolla, CA, 3Department of Environmental Sciences, The University of Montana Western, Dillon, MT, 4Josephine Bay Paul Center for Comparative Molecular Biology and Evolution, Marine Biological Laboratory, Woods Hole, MA, 5Bioinformatics Consulting Services, Hamilton, ON, Canada

Proteolytic activity is important in the life cycle of parasites and in the interactions with their hosts. While the main class of proteases studied in the protozoan parasite Giardia lamblia has been the
cysteine type, the activity of other protease classes have been implicated in the cell cycle and differentiation. To define the complete set of Giardia proteases (degradome), we queried the Giardia genome database for peptidase homologues and we profiled their transcription expression in the different stages of the Giardia life cycle by serial analysis of gene expression (SAGE). We uncovered 87 candidate peptidase genes that were distributed over 5 catalytic classes: cysteine (43.68%), metallo (21.8%), serine (16.1%), threonine (16.1%), aspartic (1.15%), and unknown type (1.15%). Out of the 87 protease ORFs, 11 did not have SAGE tags and 14 had significant transcriptional variation. Only one protease transcript in the serine catalytic family was upregulated in encystation specifically. This serine protease was most similar to eukaryotic subtilisin-like proprotein convertases (SPC). However, this giardial SPC (gSPC) was annotated as a 'non-peptidase homologue' by MEROPS because a classic catalytic triad was not evident. To analyze gSPC protein expression in encystation, we expressed gSPC under its own promoter in a vector with an AUI epitope tag. Western blot analyses showed that the epitope-tagged gSPC protein was upregulated and processed during encystation with highest expression in cysts. Gelatin zymography showed catalytic activity during encystation. Overall our data show that 1.74% of the annotated Giardia genome is composed of peptidases (1.18%) and their homologues (0.56%), which is in range of any cellular genome. Despite the lack of a conserved catalytic domain, the gSPC homologue is catalytically active supporting the inclusion of 'non-peptidase' homologues in our degradome data set. This study is the most complete quantitative analysis of protease gene expression in Giardia to date. These data give direction for future research of specific protease families and their functions.

63/B10
Protein Tyrosine Phosphorylation in the Human Pathogen Giardia lamblia.
T. Lauwaet, C. Wong, D. S. Reiner, J. Yates, F. D. Gillin; Pathology, University of California at San Diego, San Diego, CA, The Scripps Research Institute, La Jolla, CA, Signal Transduction Group, Burnham Institute for Medical Research, La Jolla, CA

The protozoan parasite Giardia lamblia is a common cause of diarrheal disease worldwide. Infection is initiated by ingestion of dormant cysts. After passage through the stomach, cysts quickly differentiate into motile trophozoites. Trophozoites colonize the small intestinal mucosa and can differentiate into cysts (encystation) that survive outside the human body. Differentiation is tightly regulated and is associated with major morphological changes. Protein phosphorylation and dephosphorylation regulate important biological processes including differentiation. Previous studies have shown that serine/threonine phosphorylation plays and important role in Giardia differentiation. In order to evaluate tyrosine phosphorylation in Giardia, we affinity purified tyrosine phosphorylated proteins from total lysates and immunolocalized and studied their protein expression levels in the life cycle along with the single protein tyrosine phosphatase (PTP). Proteomic analysis identified a number of tyrosine phosphorylated peptides belonging to proteins with a variety of cellular functions. Immunofluorescence analysis demonstrated that in vegetative trophozoites most tyrosine phosphorylated proteins are localized in the nuclei while PTP is present in the basal bodies and posterior-lateral paraflagellar rods. Immunofluorescence and Western blot analysis demonstrate that tyrosine phosphorylation is reduced in encystation and PTP is reduced in cysts. Our results indicate that despite the absence of specific tyrosine kinases in the Giardia genome (Morrisson et al., 2007), a substantial number of Giardia proteins are tyrosine phosphorylated by dual specificity kinases. In contrast to the serine/threonine protein phosphatase 2A (Lauwaet et al., 2007), the localization of PTP did not change during encystation. Future studies are needed to study the role of tyrosine phosphorylation in the Giardia life cycle.

64/B11
Nf-Kappab P65-Dependent Transactivation of miRNA Genes Following Cryptosporidium Parvum Infection Stimulates Epithelial Cell Immune Responses.
R. Zhou, G. Hu, J. Liu, A. Gong, K. M. Drescher, X. Chen; Medical Microbiol & Immunol, Creighton University, Omaha, NE
Cryptosporidium parvum is a protozoan parasite that infects the gastrointestinal epithelium and causes diarrheal disease worldwide. TLR/NF-kappaB-mediated epithelial immune responses are key mediators of the host's defense to C. parvum. MicroRNAs (miRNAs) regulate gene expression at the post-transcriptional level and are involved in regulation of both innate and adaptive immune responses. Here we tested the role of miRNAs in the regulation of TLR/NF-kappaB-associated epithelial anti-C. parvum defense. Using an In Vitro model of human cryptosporidiosis, we analyzed C. parvum-induced miRNA expression in biliary epithelial cells (i.e., cholangiocytes). Our results demonstrated differential alterations in the mature miRNA expression profile in cholangiocytes following C. parvum infection. Database analysis of C. parvum-upregulated miRNAs revealed potential NF-kappaB binding sites in the promoter elements of a subset of miRNA genes. We demonstrated that miR-125b-1, miR-21, miR-30b, and miR-23b-27b-24-1 cluster genes were transactivated through promoter binding of the NF-kappaB p65 subunit following C. parvum infection. In contrast, C. parvum transactivated miR-30c and miR-16 genes in cholangiocytes in a p65-independent manner. Importantly, functional inhibition of selected p65-dependent miRNAs in cholangiocytes increased C. parvum burden. Thus, we have identified a panel of miRNAs regulated through promoter binding of the NF-kappaB p65 subunit in human cholangiocytes in response to C. parvum infection, a process that may be relevant to the regulation of epithelial anti-C. parvum defense.

MicroRNA-98 and Let-7 Modulate Cryptosporidium Parvum-Induced Expression of Suppressor of Cytokine Signaling-4 (SOCS4) in Biliary Epithelial Cells.

G. Hu, J. Liu, R. Zhou, A. Gong, X. Chen; Med Microbiol Immunol, Creighton University, Omaha, NE

Expression of the cytokine-inducible Src homology 2 protein (CIS) and suppressors of cytokine signaling (SOCS) proteins represents an important element of epithelial reactions in response to pathogen infection. Cryptosporidium parvum is a protozoan parasite that infects both intestinal and biliary epithelial cells. MicroRNAs (miRNAs) are small RNA molecules of ~23 nucleotides that negatively regulate protein-coding gene expression via translational suppression or mRNA degradation. Our previous studies demonstrated that C. parvum infection downregulates miR-98 and let-7 to induce CIS expression in human biliary epithelial cells (cholangiocytes)(J Immunol. 2009;183:1617). In this study, we demonstrated that C. parvum infection induced SOCS4 expression in cholangiocytes using an In Vitro model of human biliary cryptosporidiosis. We first identified complementarity of miR-98 and let-7 to the 3'-untranslated region of SOCS4 mRNA. Targeting of SOCS4 3'-untranslated region by miR-98 or let-7 resulted in translational repression, but not mRNA degradation. Functional manipulation of miR-98 caused reciprocal alterations in cellular SOCS4 protein expression. Importantly, transfection of miR-98 precursor abolished C. parvum-stimulated SOCS4 protein expression. In addition, expression of SOCS4 in cholangiocytes caused an inhibitory feedback effect on the phosphorylation of STAT6 induced by C. parvum. Our results indicate that C. parvum infection induces SOCS4 expression in cholangiocytes by downregulation of miRNA-98 and let-7, suggesting an important role of miRNAs in the regulation of epithelial response to C. parvum infection.

Disruption of a Mitochondrial Muts DNA Repair Enzyme Homolog Confers Drug Resistance in the Parasite, Toxoplasma gondii.

E. M. Garrison, M. D. Lavine, G. Arrizabalaga; Microbiology, Molecular Biology, and Biochemistry, University of Idaho, Moscow, ID

MutS homologs (MSHs) are critical components of the eukaryotic mismatch repair machinery. In addition to repairing mismatched DNA, mismatch repair enzymes are known in higher eukaryotes to directly signal cell cycle arrest and apoptosis in response to various DNA damaging agents. Accordingly, mammalian cells lacking certain MSHs are resistant to chemotherapeutic drugs. Interestingly, we have discovered that the disruption of TgMSH-1, an MSH in the pathogenic parasite, Toxoplasma gondii, confers drug resistance. Through a genetic selection for T. gondii...
mutants resistant to the anticoccidial drug monensin, we have isolated a strain that is resistant not only to monensin but also to salinomycin and the alkylating agent, methylnitrosourea. We have shown that this phenotype is due to the disruption of \textit{TgMSH-1} as the multi-drug resistance phenotype is complemented by a wild-type copy of \textit{TgMSH-1} and is recapitulated by a directed disruption of this gene in a wild-type strain. We have also shown that, unlike previously described MSHs involved in signaling, \textit{TgMSH-1} localizes to the parasite mitochondrion. These results provide the first example of a mitochondrial MutS Homolog that is involved in drug sensitivity and implicate the induction of mitochondrial stress as a mode of action of monensin. Interestingly, the parasite-specific electron transport inhibitor, decoquinate prevents monensin-induced death in wild-type parasites, further implicating the parasite mitochondrion as the target for monensin. Preliminary analysis of microarray studies has shown that wild-type parasites exposed to monensin have increased levels of several histone mRNAs, which are known to be up-regulated during S-phase of the cell cycle. We are currently investigating monensin’s potential arresting effect on the parasite cell cycle and the role \textit{TgMSH-1} plays in signaling such an arrest.

**Role of Calreticulin in \textit{Entamoeba histolytica} Phagocytosis.**

A. Vaithilingam, J. Teixeira, C. D. Huston; Department of Medicine, University of Vermont College of Medicine, Burlington, VT

\textit{Entamoeba histolytica} is an enteric amoeba that is an important cause of dysentery in developing countries. Phagocytosis of host cells is characteristic of invasive amoebiasis. Identification of receptors that aid in phagocytosis is important from the standpoint that they may be new vaccine candidates. In this regard, mass spectrometry analysis of phagosomal proteins led to the identification of several proteins including the endoplasmic reticulum lumen chaperone, calreticulin. Based on studies in macrophages, where surface calreticulin binds to the collagenous tail of C1q and collectins present on apoptotic cells and bacteria, we proposed that a similar mechanism may enable amoebic trophozoites to phagocytose host cells during invasion of the intestinal wall. Previous results that support our hypothesis include an increase in phagocytosis by amoebae overexpressing calreticulin and an increase in staining of epitope tagged calreticulin on the surface of amoebic trophozoites following stimulation with human lymphocytes. Using an antibody directed against native calreticulin, the protein was shown to be recruited to the phagocytic cup following stimulation with erythrocytes. In non-permeabilized cells, calreticulin at the phagocytic cup colocalizes with a galactose specific lectin, which is a membrane marker. These results are consistent with directed recruitment of calreticulin from the ER to the amoeba:host cell interface during phagocytosis. Studies are underway to silence calreticulin by RNAi and to confirm the above results using biochemical approaches. Calreticulin being an ER luminal protein, we are also interested in determining the mechanism by which it reaches the phagosomal cup.

**A 330 kD Viral Structural Protein Is a Herpesvirus Microtubule Motor Receptor.**

S. V. Zaichick, G. A. Smith; Microbiology and Immunology, Northwestern University, Chicago, IL

Pseudorabies virus (PRV) is a member of the neuroinvasive group of alpha-herpesviruses, which also includes such important pathogens as herpes simplex virus (HSV) type 1 and 2, as well as varicella-zoster virus (VZV). Microtubule (MT)-based transport of these viruses is not only important for the success of the replication cycle and the establishment of latency, but also for the symptomatic development of herpesvirus infection ranging from sores and shingles to more severe forms, such as herpes keratitis and encephalitis. All these processes involve both dynein and kinesin motors, and finding a virus receptor for these motors is very important for both better understanding the biology of the virus and for development of future therapeutic targets. Here we show that a conserved structural protein, VP1/2, binds both kinesin and dynein motor complexes. Interaction with conventional kinesin depended upon a central region of the the VP1/2 protein. Interestingly, this central region of VP1/2 was not sufficient for the kinesin I interaction, which was also dependent on a carboxy terminal region of VP1/2 that we show recruits the dynactin
complex. Moreover, we show that the C-terminus of VP1/2 co-pellets with polymerized tubulin and decorates MTs in transiently transfected cells. VP1/2 is a capsid binding protein, and we therefore propose that VP1/2 connects the capsid to MTs and MT-associated motors to mediate intracellular and axonal transport of the viral particle.

**Caveolin-1 Is an Efficient Tumor Suppressor In Vivo in the Absence of E-Cadherin.**

L. Lobos-González, L. Aguilar, L. Leyton, A. F. Quest; Molecular and Cellular Biology, Faculty of Medicine, University of Chile, Santiago, Chile

Objective: Caveolin-1 has frequently been attributed a role as a tumor suppressor. Data from this laboratory showed that caveolin-1 in the presence of E-cadherin suppresses β-catenin/Tcf-Lef-dependent transcription of survivin and cyclo-oxygenase 2 (COX2), two genes associated with tumor cell survival. However, whether E-cadherin is required for caveolin-1-mediated tumor suppression In Vivo is unknown. Methodology: B16-F0 cells, a melanoma cell line isolated from C57BL/6 mice that express readily detectable levels of caveolin-1 and metastastic B16F10 cells that express extremely low endogenous caveolin-1 levels were employed in this study. Both cell types lack endogenous E-cadherin. Caveolin-1-expressing derivatives of the B16F10 cell were generated by stable transfection. Alternatively, endogenous caveolin-1 expression in B16F0 cells was reduced using specific short hairpin RNA (shRNA) constructs. Tumor volume was recorded in syngenic C57BL/6 mice injected subcutaneously with 300,000 cells. Results: Animals inoculated with B16-F10 cells develop tumors within 21 days. In B16F10 cells expressing caveolin-1, tumor formation was substantially reduced. Alternatively, the reduced tumor forming ability of B16F0 cells in comparison to B16F10 cells was enhanced in B16F0 (shcav-1) cells, coincident with reduced presence of endogenous caveolin-1. Conclusions: The presence of caveolin-1 in the absence of E-cadherin, in either B16F0 or B16-F10 melanomas, reduced the tumor forming ability of these cells in C57BL/6 mice. Acknowledgements: FONDECYT 1090071, FONDAP15010006 (AFGQ), FONDECYT 1070699 (LL) and CONICYT (LL-G, LA).

**Soluble E-Cadherin Acts as an Anti-Apoptotic Protein Signaling via Epidermal Growth Factor Receptor.**

L. J. Inge, S. A. Rajasekaran, J. Gopal, S. P. Barwe, K. Lu, S. Ryazantsev, A. K. Rajasekaran; 1Nemours Center for Childhood Cancer Research, Nemours/Alfred I. duPont Hospital for Children, Wilmington, DE, 2Pathology and Laboratory Medicine, University of California, Los Angeles, Los Angeles, CA, 3Biological Chemistry, University of California, Los Angeles, Los Angeles, CA

E-cadherin is a calcium-dependent cell-cell adhesion molecule in epithelial cells and alterations in E-cadherin function have been linked to carcinogenesis in a variety of cancers. Recent studies revealed that E-cadherin not only functions in cell-cell adhesion but also interacts and modulates several signal transduction pathways. In addition to its well-known interaction with β-catenin, a component of the Wnt signaling pathway, there is considerable evidence that E-cadherin functionally interacts with epidermal growth factor receptor (EGFR) at the sites of cell-cell contact. The exact role of this association is unclear. Clinical studies identified a soluble form of E-cadherin in sera of patients with different types of carcinoma. Soluble E-cadherin results from cleavage of the E-cadherin extracellular domain by matrix metalloproteinases, releasing it from the cell membrane into the extracellular milieu. Despite the wealth of clinical data available, little is known whether soluble E-cadherin has any patho-physiological significance or contributes to cancer progression. In this study we provide evidence that a clinically relevant dose of a recombinant form of soluble E-cadherin (SECAD) prevents cell death due to serum withdrawal.
and functions as a potent inhibitor of apoptosis. Moreover, at concentrations that had no effect on cell-cell adhesion, SECAD prevented normal development of polarized acini, a process that involves programmed cell death. We further show that SECAD mediates its anti-apoptotic effect through activation of EGFR and its respective downstream pathways. Thus, these findings demonstrate a novel role for SECAD in cell survival and suggest that soluble E-cadherin present in patients' sera might contribute to cancer progression.

Reduced Tumorigenicity of Cervical Cancer Cells through the Regulation of Axl Signaling Pathway.
E. Lee, H. Lee, J. Yi, K. Lee, H. Kang; School of Biological Science and Technology, Chonnam National University, Gwangju, Korea, South

Axl receptor tyrosine kinase is originally known as homeostatic regulators for antigen presentation cells as well as regulator for cell survival, proliferation, and migration, but little is known of the regulatory role in the tumorigenicity of cervical cancer. To elucidate the role of Axl on the human papillomavirus (HPV) E6-mediated tumorigenicity in cervical cancer, HPV type 16 E6-overexpressing HeLa cells (HE6F) and suppressing Caski cells (CE6R) were established. Axl expression was markedly up-regulated in HE6F cells compared to HeLa cells. The overexpressed HPV 16 E6 gene in HE6F cells increased S phase of the cell cycle. Furthermore, apoptosis of HE6F cells were decreased by triggering of Axl signaling pathway. Consistently, stimulation with agonistic anti-Axl increased in the metastasis of Caski cells as well as the cell proliferation in a dose-dependent manner. These findings suggest that Axl plays a critical role in the regulation of HPV 16 E6-mediated tumorigenicity of cervical cancer, and implicate that blockade of Axl signaling in cervical cancer might be an effective way to reduce the progression of cervical cancer.

J. Sharma¹, R. Punzalan¹, C. DiMaggio¹, N. Taw¹, M. Majdoub¹, N. Liles⁵, G. Velazquez⁴, S. Sharma¹, N. Amezcua¹, C. Sharma¹, M. Sharma¹, S. Sharma¹; ¹Stem Cell Biology, Celprogen, San Pedro, CA, ²Molecular Medicine, UCLA, Los Angeles, CA

Malignant tumors are composed of a small subset of distinct cancer cells, termed “cancer stem cells” (typically less than 5 - 15 % of total cancer cells based on cell surface marker expression), which have great proliferative potential, when compared to the more differentiated parental cancer cells. The cancer stem cells (CSC) have the potential of differentiating into their parental cancer phenotypes, which have very limited proliferative potential. Data have been provided to support the existence of cancer stem cells in several different types of cancer, including human blood, brain, prostate, ovarian, melanoma, colon, liver and breast cancers. In this study we have recently reported the identification of a subpopulation of pancreatic cancer stem cells that express the cell surface markers CD133+CD44+CD24+SSEA-1+TRA-1-61+& TRA1-81+ (0.5-2.0% of all human pancreatic parental cancer cells) that function as pancreatic cancer stem cells. The CD133+CD44+CD24+SSEA-1+Oct3/4+TRA-1-61+& TRA1-81+ pancreatic cancer stem cells are highly tumorigenic and possess the stem cell-like properties of self-renewal and the ability to produce differentiated progeny. Pancreatic cancer stem cells also demonstrate upregulation of SSEA3+,SSEA4+ upon differentiation into parental cancer phenotype. As for clinical importance, cancer stem cells have shown resistance to standard therapies and may play a role in treatment failure or disease recurrence. The cell based assay system for pancreatic cancer stem cell enables one to further their drug discovery signaling pathway mechanisms that regulate their growth and survival. This pancreatic stem cell based assay system may provide novel therapeutic approaches into treatment of pancreatic cancer patients, which are resistant to standard chemotherapy and radiation. The pancreatic cancer stem cell based assay system will provide a high through put screening of novel and potential drug candidates for the pancreatic cancer patients.

Several studies support the presence of putative cancer stem cells (CSC) in ovarian cancer (EOC), on the basis of sphere forming capability, presence of a side population (SP) (and expression of the CD133 marker. The chemokine receptor CXCR4, expressed by CSCs of different solid tumors, is frequently present on a subset of ovarian tumor cells, but not yet described as CSC marker in EOC. The present study aims to investigate whether, like CD133, also CXCR4 expressing cells could identify a subpopulation with characteristics of cancer stem/progenitor cells in human primary EOC and ascites. One of the hypotheses on the origin of CSC indicates the corresponding normal stem cells as potential source of the tumor counterpart.

By FACs analysis CD133 and CXCR4 show a variable degree of expression in OSE cells (early passage), ranging from 0.1-20% and from 50-70% of the cells, respectively. By real time PCR, both markers appeared up regulated in early In Vitro passages and then down regulated in later passages. In a wide range of serous ovarian tumors and ascites analyzed, the expression of CD133 and CXCR4 was restricted within a subpopulation of tumor cells. By immunohistochemistry of several EOC samples CD133 had a focal reactivity whereas by FACs analyses of a panel of EOC and ascites CD133 expression ranged between 0.1%-19,1% and 0.3%-34,3%, respectively. Moreover a variable degree of CXCR4 expression was found in primary EOC (from 7% to 70%) and ascites samples (from 3% to 65%). We are now focusing on the sorting separation of CXCR4 and CD133 positive subpopulation of ovarian tumor cells to investigate the possible relationship between the two populations. By serial In Vivo and In Vitro passages of ascitic cells derived from a poorly differentiated EOC positive for CD133 and CXCR4, both expressions were found to be maintained. Sorted CXCR4 or CD133 positive tumor cells were evaluated by Real Time PCR for stem marker (Oct4, Nanog CD133 and Nestin). The obtained results support the idea that ovarian CSC/TIC could arise from OSE stem cells and could be included in the subpopulation of CXCR4+/CD133+ cells.

75/B22
Correlation of Human Papillomavirus (Hpv) in Cervix Cancer, Leiomyoma, and Normal Samples.

Many studies have shown that high-risk human papillomavirus(HPV) is directly associated with development of cervix cancer. There are many types of high-risk HPV which are type 16, 18, 31, 33, 45 and so on. Many organs, such as heart, digestive duct, viscera organs, uterus, have myoma. Among those organs, leiomyomata of the uterus are common. but studies concerning leiomyoma have been less than those of HPV. Leiomyoma is a tumor caused in muscle tissue. So, in order to study about correlation of HPV and leiomyoma, we collected myoma, cervix cancer, and control samples from obstetrics and gynecology of Hospital of Gachon university of medical and science. DNAs were extracted from these samples. We practiced first PCR method using HPV common primer to amplify these DNAs and then we carried out second PCR method using HPV type 16 and 18 primer to amplify DNAs. Then PCR products were analyzed whether HPV type 16 and 18 exist in those samples or not. It is originally well known fact that cervix cancer is associated with HPV. So we will make an experiment in order to confirming that fact and investigating our expectation that HPV is related to myoma.

**Primary Cilia and Aberrant Cell Signaling in Human Ovarian Cancer.**

D. L. Egeberg\(^1\), L. Schneider\(^1\), A. Byskov\(^2\), S. T. Christensen\(^1\); \(^1\)Department of Biology, University of Copenhagen, Copenhagen, Denmark, \(^2\)Department of Reproductive Biology, University Hospital, Copenhagen, Denmark

Ovarian cancer is the fourth leading cause of death among women in industrialized countries. Around 80-90% of these cancers stem from the ovarian surface epithelium (OSE). Yet the molecular mechanisms as to how the cancer arises are poorly understood. Here we investigated the relationship between primary cilia in cultures of normal human OSE cells isolated from 20-34 year old women and in human ovarian adenocarcinoma cell lines (OVCAR3 and SKOV3), which are derived from human OSE of ovarian cancer patients. Initially we show by immunofluorescence microscopy analysis that primary cilia protrude from normal OSE, and that about 80% of human OSE cells in culture form primary cilia after serum starvation to induce growth arrest. In contrast, only about 20% of OVCAR3 and SKOV3 cells were ciliated during growth arrest, indicating that defects in ciliogenesis are linked to ovarian cancer. Induction of quiescence was verified by dephosphorylation of retinoblastoma protein and nuclear loss of PCNA and Ki67, such that growth-arrested cells were e.g. Ki67 negative. In normal OSE cells, components in signaling pathways that are defective in tumor cell formation and invasion localized to primary cilia, including PDGFR\(\alpha\) and Hedgehog (Hh) components. Upregulation and activation of PDGFR\(\alpha\) was reduced in OSE cancer cells compared to normal OSE, whereas Hh signaling measured by Ptc-1 expression was greatly upregulated in cancer cells compared to normal cells. Preliminary data further suggest that inhibition of AurA - either by specific inhibitors or siRNA - stimulates ciliary formation in cancer cells, and this increase may be associated with partly restoration of the normal ciliary signaling pathways. These results support the model by which primary cilia are associated with malignant transformation of OSE that may represent a novel drug target with therapeutic potential in epithelial cancers. Further analysis will be required to understand the importance of AurA and its upstream regulators in ciliary disassembly and regulation of signalling pathways in malignant cell transformation.

**Cell Stiffness Correlates with Invasive Potential in Ovarian Cancer: A Magnetic Tweezer Study.**

V. Swaminathan\(^1\), M. Karthikeyan\(^3\), E. T. O'Brien\(^2\), G. Blobe\(^3\), R. L. Superfine\(^2\); \(^1\)Curriculum in Applied Sciences and Engineering, University of North Carolina at Chapel Hill, Chapel Hill, NC, \(^2\)Department of Physics and Astronomy, University of North Carolina at Chapel Hill, Chapel Hill, NC, \(^3\)Department of Medicine and Pharmacology, Duke University, Durham, NC

In cancer, genetic changes produce phenotypes that have altered responses to signals specific to the tissue of origin, leading to increased proliferation, migration and invasion to surrounding tissues. The specific process of migration and invasion in the context of cancer progression relies on alterations in cell biomechanical properties including cell stiffness, morphology, cytoskeletal changes and alterations in signaling pathways that regulate the same. We hypothesized that during ovarian cancer progression alterations in the actin cytoskeleton resulting in increased invasiveness also result in a reduction in cell compliance/stiffness. To test the hypothesis we used ovarian cancer cell lines, and primary ovarian cancer cells obtained from ascites of patients with advanced stage disease and characterized their invasive potential using a transwell invasion assay, and simultaneously examined cell stiffness using the 3D Force Microscope (3DFM). The 3DFM produced ~100 pN pulses using 2.8 um fibronectin-coated beads. Force-response curves were analyzed for compliance and compared between cell lines. We found that there is a remarkable correlation between stiffness and invasion with the stiffest cell type being the least invasive and vice versa. Conversely, reducing invasiveness by expressing T\(\beta\)RIII, a previously demonstrated modulator of cell invasion and migration in non-expressing cancer cells reduced cell stiffness, thereby strongly correlating with reduction in invasive potential. Hence, we propose the presence of a distinct cytoskeletal and biomechanical signature of cancer cells during cancer progression that can be measured using 3DFM.

Cellular and Molecular Mechanisms Involved in the Anti-Metastatic Effect of Pomegranate Juice in Prostate Cancer Cells.
L. Wang, A. Alcon, H. Yuan, M. Martins-Green; Cell Biology & Neuroscience, University of California Riverside, Riverside, CA

Prostate cancer is the most common invasive malignancy and the second leading cause of cancer-related deaths among U.S. males. Pomegranate juice from tree Punica granatum has been identified as a natural product that inhibits the growth and reduces the invasiveness of prostate cancer cells. However, the underlying mechanisms involved in the anti-metastatic effect of Pomegranate Juice remain unclear. We have recently found that, in addition to causing cell death of hormone-refractory prostate cancer cells, Pomegranate Juice also increases cell adhesion and decreases cell migration of the cells that do not die. We hypothesize that Pomegranate Juice inhibits the migratory and metastatic properties of hormone refractory prostate cancer cells by stimulating the expression and/or activation of molecules that alter the cytoskeleton and the adhesion machinery of the cell, resulting in enhanced cell adhesion and reduced cell migration. To test this hypothesis, we used both Affimetrix gene arrays to study gene expression and microRNA arrays to study the non-coding RNAs, which are molecules known to have profound regulatory effects on gene expression in normal cells and to be disregulated in cancer cells. We found that several genes involved in cell adhesion such as E-cadherin, CD44, and Myristoylated alanine-rich protein kinase c (MARCKS) were up-regulated and several genes involved in cell migration such as type I collagen, tenascin C and chimerin 1 were down-regulated after Pomegranate Juice treatment. Discovery of the mechanisms by which this enhanced adhesion and reduced migration are accomplished can potentially lead to more specific and effective treatments of the disease in particular when the components of the juice responsible for these effects are identified.

Maintenance of Stem Cell Properties in Prostate Cancer-Derived CD133+MDR1+ Cells.
S. Rentala, L. Mangamoori, P. Yalavarthy; Department of Biotechnology, IST, Jawaharlal Nehru Technological University, Hyderabad, India

CD133 (prominin-1), a 5-transmembrane glycoprotein, has recently been considered an important marker that represents the subset population of cancer stem-like cells. The purpose of the present study is to isolate cancerous stem-like cells from normal healthy volunteers and prostate cancer patients (CD133+) which also express MDR1 and to ascertain the influence of Oct-4 on ‘stemness’ and differentiation of these CD133+ cells towards epithelium. In the present study, CD133+ cells were isolated using magnetic beads from normal healthy volunteers and prostate cancer patients (NV-CD133+ and PC-CD133+). The isolated cells were analyzed using flow cytometry and western blot technique for CD133, MDR1 and Oct-4. CD133+MDR1+ cells were cultured in presence and absence of antihuman Oct-4 blocking antibody. Our results showed higher Oct-4 expression in PC-CD133+ cells with the ability to self-renew and may represent a reservoir with differentiation potential for generating prostate cancer cells. Furthermore, PC-CD133+ cells highly co-expressed the multiple drug-resistant marker MDR1. The treatment with Oct-4 blocking antibody can specifically block the capability of PC-CD133+ cells to differentiate into prostate epithelial cells bearing CD57. So finally we conclude that PC-CD133+ cells displayed a higher Oct-4 expression with the ability to self-renew and may represent a reservoir with differentiation potentials for progression of prostate cancer. The MDR1 expression of PC-CD133+ cells In Vitro and In Vivo is partially due to preferential activation of Oct-4 gene expression.

80/B27
Identification and Characterization of FKBP52-Specific Inhibitors for Prostate Cancer Treatment.
Introduction: Prostate cancer is a leading cause of death among African American males in USA. Androgens are the major stimulator of prostate tumor growth. Androgen-independent tumor growth during the late stage of the disease renders the current anti-androgen therapy futile since these treatments depend on androgen antagonists which compete with hormone for binding the Androgen Receptor (AR) hormone binding domain (HBD). Thus, drugs that target AR regulatory mechanisms and prevent prostate cancer cell growth are promising alternatives for the treatment of hormone-refractory prostate cancer (HRPC). The FK506-Binding Protein 52 (FKBP52) is proven to be an important regulator of AR receptor-mediated signal transduction in cellular and animal models and represents a potential target for treatment of HRPC. These studies are aimed at inhibiting endogenous androgen-dependent gene expression and FKBP52 association with the receptor complex. Methodology: A modified receptor-mediated reporter assay in yeast and mammalian cells was used to screen a natural compound library for FKBP52 inhibitors. AR-HBD-compound cocrystallographic structures were performed, as well as Surface Plasmon Resonance in order to determine the binding of the compounds to AR. Results: We identified molecules that efficiently and specifically inhibit FKBP52-mediated regulation of AR function by binding to a regulatory surface on the AR-HBD. We have demonstrated that these compounds do not compete with hormone for binding the HBD, nor do they compete with coactivator peptides. In addition, these compounds inhibit AR function by preventing hormone-dependent dissociation of the FKBP52-AR complex which results in low levels of hormone-bound receptor in the nucleus. Preliminary assays in LNCaP (prostate cancer) cells have demonstrated that the compounds inhibit Prostate-Specific Antigen expression and androgen-dependent proliferation. At the half-lethal dose (LD50) none of the compounds displayed cellular toxicity within the effective concentration range. Conclusion: We have identified molecules that inhibit AR function and represent an exciting new approach for HRPC treatment. In addition, these studies will lead to FKBP52-receptor interaction models.

D. M. Grice¹, H. M. Faddy¹, P. A. Kenny², G. R. Monteith¹, S. J. Roberts-Thomson¹; ¹School of Pharmacy, University of Queensland, St Lucia, QLD, Australia, ²Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, New York, NY

Calcium transport proteins, including calcium ATPases, are responsible for maintaining cytosolic calcium homeostasis and calcium levels in intracellular organelles. Deregulation of global calcium homeostasis can modulate cellular proliferation. The Golgi-associated calcium ATPases maintain Golgi calcium levels via sequestration of cytosolic calcium into the Golgi secretory pathway. These ATPases may also influence global cellular calcium regulation by calcium sequestration and/or alterations in the post-translational modifications of proteins important in the regulation of intracellular calcium. We initially queried a microarray database of 295 clinical breast cancer samples for expression of Golgi-associated calcium ATPases and found differential expression amongst transcriptional breast cancer subtypes. To understand the role upregulated ATPases may have in breast cancer, ATPase expression was silenced in breast cancer cell lines. We used a low density siRNA transfection protocol and Dharmacon OnTarget plus Smartpool siRNA. Silencing (~95%) was confirmed 24 - 120 h post transfection using real time RT-PCR and resulted in a significant decrease in cellular proliferation. Altered cellular proliferation can be associated with the induction of endoplasmic stress (ER). However, in breast cancer cell lines, Golgi-associated calcium ATPase-mediated proliferation was independent of ER stress induction (tunicamycin 0.1 - 10 µg/mL) and Golgi-associated calcium ATPase silencing did not sensitize the cells to ER stress. To assess the role of Golgi-associated calcium ATPases on cytosolic free calcium regulation we used a FLIPRTETRA Imaging System. We examined the effects of siRNA on calcium responses initiated by cyclopiazonic acid and in the presence of different calcium mobilising agents (ATP, thrombin and trypsin). This study suggests that some breast cancers are...
associated with remodelling of calcium homeostasis through alterations in the transcription of Golgi-associated calcium ATPases. The aberrant overexpression of these calcium pumps, and their contribution to cellular proliferation, suggests these transporters may represent a novel and specific target for therapeutic treatment for some breast cancer subtypes.

M. M. Chen1, C. Lee1, H. A. Leland1, G. Lin2, S. Silletti1; 1Moores UCSD Cancer Center, La Jolla, CA, 2Pathology, UCSD, La Jolla, CA

We have identified the neural cell adhesion molecule L1 (L1-CAM, CD171) as a marker of “dedifferentiation” and mediator of malignancy in pancreatic ductal adenocarcinoma (PDAC). L1 has been described as a mediator of the malignant phenotype or indicator of poor prognosis in melanoma, breast, ovarian and colon cancer, with roles in regulating signaling and experimental metastasis, however previous reports on L1 expression in PDAC range from absent to high. Our data demonstrate that L1 is expressed in poorly-differentiated PDAC cells in situ. Moreover, our data demonstrate steady-state saturated phosphorylation of threonine-1172 (T1172) in the L1 cytoplasmic domain in PDAC cells In Vitro and in situ, in contrast to melanoma and neural cells. Although blockade of PKC and CKII activity caused T1172 dephosphorylation in PDAC cells, only CKII was capable of phosphorylating T1172 of recombinant L1 cytoplasmic domain in vitro. Importantly, L1 phosphorylation drives a change in the extracellular structure of L1, whereby membrane-proximal epitopes become obscured and distal epitopes become exposed, suggesting a shift from the previously described closed conformation to the open and putatively multimerized conformation. The multimerization of L1 has been demonstrated previously to regulate integrin binding, and we demonstrate that L1 bound to integrins αvβ3 and αvβ5 exhibits differential anti-L1 antibody epitope availability, suggesting that T1172 phosphorylation is involved in regulating these ectodomain conformations and associated integrin binding. We further demonstrate that phosphorylation of T1172 is required for the ADAMs-mediated shedding of the L1 ectodomain that drives tumor cell migration. These data define a specific role for T1172 in regulating L1 activity in pancreatic ductal adenocarcinoma cells.

miR-200c Modulates EGFR Signaling by Targeting Negative Feedback Regulator MIG-6/ERRFI1 in Breast Cancer.
A. Schwaeger, J. Zhang, S. Uhlmann, S. Wiemann, O. Sahin; Division of Molecular Genome Analysis, German Cancer Research Center, Heidelberg, Germany

Fine-tuning of epidermal growth factor receptor (EGFR) signaling is crucial for maintaining cellular homeostasis and preventing unrestrained proliferation. Several negative feedback mechanisms have been shown to play major roles in this process. Mitogen-inducible gene 6 (MIG-6) is a central feedback inhibitor of kinase-active ERBB receptors and it is found to be down-regulated or lost in several human tumors, indicating a tumor-suppressor function. MicroRNAs are a class of small regulatory RNAs, which down-regulate their target genes by destabilization of the mRNA or repression of translation. Several miRNAs have been shown to be overexpressed in tumors, exerting an oncogenic function by suppressing tumor-suppressor genes. This study aimed at identifying oncogenic miRNAs targeting MIG-6, thus enhancing mitogenic signaling, to represent them as therapeutic targets. Whole genome miRNA/mRNA expression profiles followed by qRT-PCR and Western blot experiments in different breast cancer cell lines identified miR-200c as the most probable regulator of MIG-6 out of all predicted miRNAs. Ectopic expression of miR-200c in MDA-MB-231 breast cancer cell line substantially decreased MIG-6 protein level. Noteworthy, luciferase reporter assay revealed MIG-6 as a direct target of miR-200c. MDA-MB-231 cells were shown to be more responsive to EGF stimulation after miR-200c overexpression or MIG-6 knockdown, reflected by increased and more sustained phosphorylation of ERBB2 and its downstream kinase AKT. Additionally, miR-200c could notably increase proliferation of cells stimulated with EGF as reflected with higher percentage of cells in S and G2/M phase of cell
SUNDAY

cycle. As miR-200c has been known to regulate epithelial-mesenchymal transition (EMT) by targeting the TGF-β induced E-cadherin repressors ZEB1 and ZEB2, our results could implicate miR-200c as a key regulator of the cell’s decision between migration and proliferation. Further study will include analysis of breast cancer patient samples for miR-200c and its targets MIG-6/ZEB1/ZEB2 as well as the possible role of miR-200c in resistance against ERBB receptor-targeted drugs e.g. gefitinib and trastuzumab.

84/B31 ABSTRACT WITHDRAWN

85/B32

Breast cancer is the most common malignancy among women in developed countries, affecting more than a million women per year worldwide. Of these, triple negative breast carcinoma represents 10-17%. Triple negative breast carcinomas, characterized by estrogen, progesterone and HER2 receptor negativity are very aggressive tumors with poor prognosis. Breast Cancer Stem derived from triple negative parental Breast Cancer tumors, are a subpopulation of cells within the parental breast cancer population within the individual which are positive for the following markers: CD133+CD44+CD24+ESA+SSEA-1+TRA-1-61+ & TRA1-81+ and Oct ¾ these Breast Cancer Stem cells are highly tumorigenic and possess the stem cell-like properties of self-renewal and the ability to produce differentiated progeny. Breast Cancer Stem cells also demonstrate up regulation of SSEA3+,SSEA4+ upon differentiation into parental cancer phenotype. Individualized treatment (tailored therapy) based on molecular biology markers of tumor and patient is the trend in clinical practice these days. However, molecular targets and predictors for the treatment of triple negative breast carcinoma do not currently exist. With the identification and characterization of Breast Cancer Stem Cells from parental triple negative tumors, enables one to screen novel drug candidates for potential development of therapeutics for triple negative Breast Cancer Patients. In this study we have utilized Breast Cancer Stem Cells from triple negative Tumors to screen potential drug candidates. The Breast Cancer Stem Cell based assay system may provide novel therapeutic approaches into treatment of triple negative breast cancer patients, which are resistant to standard chemotherapy and radiation.

Werb1; 1Anatomy, University of California, San Francisco, San Francisco, CA, 2Stanford University, Stanford, CA, 3The Prostate Centre, Vancouver General Hospital, Vancouver, BC, Canada

The 20q13 region of the human genome is highly amplified in 20-30% of early stage human breast cancers, and this amplification correlates with poor prognosis. Several groups identified the human ZNF217 transcription factor gene as one of two candidate oncogenes in 20q13.2 that correlates with breast cancer and gastric adenocarcinomas, and overexpression of ZNF217 leads to immortalization of human mammary epithelial cells. We find that high ZNF217 expression correlates with poor survival in human breast tumors. In addition, patients with basal subtype primary tumors have lower expression levels of ZNF217 than do patients expressing other breast cancer subtypes. To further characterize downstream pathways affected by ZNF217 in breast cancer progression, we overexpressed mouse Znf217 in mouse primary cells and immortalized mouse mammary epithelial cell lines. Microarray expression profiling in these cells identified a number of downstream genes including other genes found in human 20q13.2, genes repressed by transcriptional repressor complexes known to be associated with Znf217, genes that play a
role in differentiation in other tissues, and genes that play a role in stem cell expansion. If ZNF217 is a target gene in 20q13.2 driving breast cancer progression, then it is a candidate for targeted drug development. We identified drugs from the Developmental Therapeutics database that have the best correlation in NCI60 tumor cell lines between their IC50s and increased ZNF217 expression levels. To validate the drug that best correlated with cell death in overexpressing ZNF217 cell lines, we tested it on human breast tumor cells with low level expression of ZNF217. Cells overexpressing ZNF217 become resistant to doxorubicin treatment, but treatment with our candidate ZNF217 inhibitor overcomes the ZNF217-induced resistance to doxorubicin-induced cell death. Therefore, ZNF217 is a potential drug target for breast cancer.

**Human HER2+ Breast Cancer Stem Cells Utilized for Drug Discovery Therapeutics for HER2+ and Estrogen & Progesterone Negative Breast Cancer Patients.**

Breast cancer is the most common malignancy among women in developed countries, affecting more than a million women per year worldwide. The HER2+, Estrogen and Progesterone negative breast carcinoma is characterized by estrogen, progesterone receptor negativity and HER2 receptor positive are a sub-classification of HER2+ breast Cancers. Breast Cancer Stem derived from HER2+ and double negative parental Breast Cancer tumors, are a subpopulation of cells within the parental breast cancer population within the individual which are positive for the following markers: CD133+CD44+CD24+ESA+SSEA-1+TRA-1-61+& TRA1-81+ and Oct ¾ these Breast Cancer Stem cells are highly tumorigenic and possess the stem cell-like properties of self-renewal and the ability to produce differentiated progeny. Breast Cancer Stem cells also demonstrate up regulation of SSEA3+,SSEA4+ upon differentiation into parental cancer phenotype. Individualized treatment (tailored therapy) based on molecular biology markers of tumor and patient is the trend in clinical practice these days. However, molecular targets and predictors for effective treatment of HER2+ double negative breast carcinoma do not currently exist. With the identification and characterization of Breast Cancer Stem Cells from parental HER2+ double negative tumors, enables one to screen novel drug candidates for potential development of therapeutics for HER2+ double negative Breast Cancer Patients. In this study we have utilized Breast Cancer Stem Cells from HER2+ double negative Tumors to screen potential drug candidates. The Breast Cancer Stem Cell based assay system may provide novel therapeutic approaches into treatment of HER2+ double negative breast cancer patients, which are resistant to standard chemotherapy and radiation.

**Estrogen Activates G-Protein Inwardly Rectifying Potassium Channels (GIRK) in MCF-7 Breast Cancer Cells.**

H. K. Plummer, M. W. Hance; Pathobiology, U Tennessee, Knoxville, TN

Breast cancer is the second leading cause of cancer death. Previous work from our laboratory has indicated the importance of G-protein inwardly rectifying potassium channels (GIRK) in breast cancer. Estrogen, a major risk factor for breast cancer, has been correlated with potassium channel function in the brain. Accumulating evidence has shown that many of these ion channels are essential for cell proliferation and cell survival, which are key events in cancer progression. In the present study, we investigated the chronic effects of estrogen in MCF-7 breast cancer cells. We found a dramatic increase in GIRK1 and GIRK2 protein levels in response to 10 nM estrogen treatment, as well as an increase in intracellular potassium accumulations and increased cellular proliferation after 24-48 hours of treatment. Protein levels were monitored by western blotting, proliferation was measured by 5-Bromo-2’ deoxy-uridine (BrdU) assay, and PBFI potassium-specific florescent dye was used to measure potassium accumulation. GIRK1 RNA interference knockdown decreased estrogen receptor alpha protein levels and activation. In addition, estrogen treatment resulted in increased phosphorylation of specific members of G-protein couple receptor
(GPCR) and MAPK signaling pathways, which have been shown to be responsive to GIRK1 knockdown by our laboratory in MDA-MB-453 breast cancer cells. Our data indicates that GIRK1- and GIRK2-specific channels are the predominant functional subunits in MCF-7 cells. Our data also links GIRK function to the major breast cancer risk factor of estrogen and suggest that GIRK may have relevance as a therapeutic target, especially in concert with already approved treatment options such as anti-estrogen and anti-aromatase compounds.

Effects of PKCδ and PLC-γ1 on MCP-1 Expression in Taxol-Induced Breast Cancer Cell Death.
H. An¹, Y. Kim², J. Ko¹; ¹Life Sciences and Biotechnology, Korea University, Seoul, Korea, South, ²Biomedical laboratory science, Yonsei University, Wonju, Korea, South

Monocyte chemotactic protein-1 (MCP-1) is a CC chemokine that plays an important role in immune cell migration. It has been reported that chemokines including MCP-1, are involved in angiogenesis and metastasis. However, the exact role of chemokines in cancer development is still obscure. We investigated the involvement of MCP-1 in taxol-induced breast cancer cell death. The anti-cancer drug taxol induced MCF-7 breast cancer cell death. Treatment with taxol increased the mRNA expression level of MCP-1 in a dose and time dependent manner. Up-regulation of MCP-1 by taxol was augmented in cells treated with rottlerin, a specific inhibitor of protein kinase Cδ (PKCδ). In addition, taxol-induced MCP-1 expression was reduced by the ectopic expression of PKCδ in a dose dependent manner, indicating that PKCδ plays a negative role in taxol-induced MCP-1 expression in MCF-7 cells. On the other hand, taxol-induced up-regulation of MCP-1 was reduced in cells treated with U73122, an inhibitor of phospholipase C (PLC), and ectopic expression of PLC-γ1 increased the expression of MCP-1 in taxol-treated MCF-7 cells, indicating PLC-γ1 functions as a positive regulator in taxol-induced MCP-1 expression. These results indicate that MCP-1 is involved in taxol-induced breast cancer cell death and we propose that taxol induces up-regulation of MCP-1 by affecting both positive and negative regulatory signaling pathways.

Rho GTPases in Disparate Effects of Soy Isoflavones on Breast Cancer Metastasis.
E. Otero-Franqui¹,², M. Martinez-Montemayor², W. Torres-Rivera², A. De La Mota², L. Cubano², S. Dharmawardhane¹,²; ¹Biochemistry, University of Puerto Rico-Medical Sciences Campus, San Juan, PR, ²Anatomy and Cell Biology, Universidad Central del Caribe, Bayamon, PR

Breast cancer is a major cause of death from cancer. Death from breast cancer is usually due to metastasis. The role of soy foods in breast cancer prevention is known but their effects on metastatic breast cancer remain to be understood. The objective of investigating a role for soy isoflavones in established breast cancer was achieved by testing the effect of the major soy isoflavones on progression of mammary tumors in nude mice created from green fluorescent protein (GFP) tagged-MDA-MB-435 bone metastatic variant. Following tumor establishment, mice were orally gavaged with vehicle or soy isoflavones: genistein (10 mg/kg body weight (BW)), daidzein (10 mg/kg BW), or genistin (50%), daidzein (40%), and glycitein (10%) three times per week. Tumor progression was quantified by whole body fluorescence image analysis twice a week followed by microscopic image analysis of excised organs for metastases. Results show that daidzein significantly increased while genistein decreased mammary tumor growth by 38% and 33% respectively, compared to vehicle. Daidzein increased lung, heart, and kidney metastases while genistein decreased bone and liver metastases. Combined soy isoflavones did not affect mammary tumor growth but increased metastasis. Phosphoinositide-3-kinase (PI3-K) pathway real time PCR array analysis on excised tumors demonstrates that genistein significantly downregulated 26% of the genes tested, including Rho GTPases ROH1, RAC1, and CDC42, and their downstream effector PAK1. Daidzein upregulated 14% of the genes including CCND1, GRB2, MAPK1, JUN, CTNNB1, IRS1, EIF4G1, and GSK3B that regulate proliferation and protein synthesis. Western blotting of mammary tumor extracts or breast cancer cell lysates following genistein or daidzein treatment show that genistein downregulated RhoA, Rac1, and Cdc42 while
daidzein upregulated Rac1 protein expression. Differential regulation of Rho GTPases may account for the disparate responses of breast cancers to genistein and daidzein diets. Thus, soy diets may exert complex effects on breast cancer patients and survivors. This research was supported by grant numbers AICR IIG 03-31-06 and NIH/NIGMS SC3GM084824 to SD and NCCR/NIH 2G12RR003035 and S06GM050695 to UCC.

How Does MenaINV Sensitize EGF Receptor to EGF?
D. Pesen1, S. K. Alford2, L. Ritsma3, J. E. Segall1, J. van Rheenen3, F. Gertler2, J. Condeelis1; 1Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, 2Koch Institute, Massachusetts Institute of Technology, Cambridge, MA, 3Hubrecht Institute-KNAW & Academic Medical Center, Utrecht, Netherlands

Invasive breast tumor cells have been shown to uniquely express the MenaINV isoform of Mena. MenaINV has been shown to enhance the sensitivity of breast tumor cells to EGF and correspondingly, increased metastatic potential. To determine the molecular mechanism that mediates the MenaINV-elicited increase in sensitivity to EGF, we studied the localization and dynamics of the EGF receptor (EGFR) in MenaINV expressing tumor cells. Using TIRF imaging of E11 cells (MTLn3 cells stably transfected with EGFR-GFP) transiently transfected with mCherry-MenaINV, we found that EGFR and MenaINV colocalize at focal adhesions. Consistent with this observation, EGFR-GFP also colocalized with mCherry-Paxillin, a focal adhesion component. When EGFR clusters were counted in E11 cells with or without mCherry-MenaINV expression, cluster numbers were found to be independent of mCherry-MenaINV, but increased along with the increased EGFR expression levels. In addition, fluorescence recovery after photobleaching (FRAP) measurements of EGFR-GFP dynamics in E11 cells revealed no differences in recovery half time (15 sec) and mobile fraction (60%) that correlated with mCherry-MenaINV expression. Therefore, while EGFR and MenaINV colocalize at focal adhesions, EGF clustering and dynamics in the plasma membrane are not affected by MenaINV expression in cells that overexpress the EGFR. MenaINV may increase sensitivity to EGF through interactions with a subpopulation of EGFR that is in focal adhesions. Nevertheless, it remains possible that clustering of EGFR in sub-resolution-clusters (<250nm) in the plasma membrane that are not in focal adhesions contribute to the increased EGFR sensitivity observed in cells expressing MenaINV. Initial EM data indeed suggests that EGFR clusters in small domains.

Benzyl Isothiocyanate Inhibits Metastasis of Breast Cancer Cells In Vitroand In Vivo.
E. Kim2, J. Hong1, S. Eom2, H. Shin1,2, J. Park1,2; 1Department of Food Science and Nutrition, Hallym University, Chuncheon, Korea, South, 2Center for Efficacy Assessment and Development of Functional Foods and Drugs, Hallym University, Chuncheon, Korea, South

Benzyl isothiocyanate (BITC) is a hydrolysis product of glucotropaeolin found in cruciferous vegetables, and has been reported to have anti-cancer properties. To examine the effect of BITC on metastatic capacities of breast cancer cells in vitro, MDA-MB-231 human and 4T1 mouse breast cancer cells were cultured in the presence of 0 - 4 μmol/L with or without 10 ng/mL hepatocyte growth factor (HGF). BITC inhibited basal and HGF-induced cell migration, invasion, and adhesion in dose-dependent manners in both MDA-MB-231 and 4T1 cells. However, BITC did not affect the viability of these cells at these concentrations. BITC decreased basal and HGF-stimulated secretion and activity of urokinase-type plasminogen activator (uPA) in MDA-MB-231 cells. By contrast, BITC increased protein expression of plasminogen activator inhibitor-1 in MDA-MB-231 cells. BITC decreased basal and HGF-induced secretion of tissue inhibitor of metalloproteinase (TIMP)-1, but increased TIMP-2 secretion by MDA-MB-231 cells. However, BITC did not affect secretion of matrix metalloproteinase (MMP)-2 or MMP-9. Furthermore, BITC inhibited HGF-stimulated phosphorylation of cMet and Akt, and reduced basal and HGF-stimulated translocation of p65 to the nucleus and NF-κB DNA binding activities in MDA-MB-231 cells. To examine whether BITC inhibits cancer metastasis in vivo, 4T1 cells (50,000 cells) were injected into the inguinal mammary fat pad of syngeneic female BALB/c mice. One day later, the
mice were divided into 3 groups and subjected to gavage with 0 - 10 mg BITC/kg body weight/day for 4 weeks. Oral administration of BITC significantly decreased the numbers of pulmonary tumor nodules and total pulmonary metastatic volume. The present results indicate that BITC has potential as an anti-metastatic agent for breast cancer patients.

Her2 and K-RasG12D Dependent Centrosome Regulatory Targets Are Critical to Centrosome Amplification in Mammary Epithelial and Breast Cancer Cells.
M. Harrison, X. Zeng, A. M. Adon, H. I. Saavedra; Radiation Oncology, Emory University, Winship Cancer Institute, Atlanta, GA

Over 80% of breast cancers and ductal hyperplasias harbor elevated frequencies of centrosome amplification (CA), a process leading to defective and multipolar mitotic spindles, aneuploidy and chromosome instability. To date, the signaling pathways that generate CA in breast cancers remain a mystery. We hypothesized that Her2, Ras and c-Myc, proto-oncogenes constitutively active in breast cancers and which oncogenic versions trigger mouse mammary cancers, initiate mammary cancers by inducing CA and chromosome breaks, precursors to chromosome instability. To test this hypothesis, we selectively expressed K-RasG12D and c-Myc in mouse mammary epithelial cells for five days using the MMTV-rtTA; tetO inducible transgenic model. Addition of doxycycline to the diet of K-RasG12D and/or c-Myc transgenic mice resulted in elevated expression of the oncogenes and various degrees of hyperplasia and dysplasia; K-RasG12D exhibiting more severe dysplasia. Both K-RasG12D and c-Myc led to increased S phase fractions, apoptosis and double strand breaks. Remarkably, only K-RasG12D resulted in elevated frequencies of CA. K-RasG12D exclusively induced expression of cyclin D1, while K-RasG12D and c-Myc led to over-expressed Nek2A. Abolishing expression of cyclin D1, Cdk4, and Nek2 in MCF10A mammary epithelial cells abrogated H-RasG12V-induced centrosome amplification. This suggests that H-RasG12V plays an important role in CA. To evaluate the clinical relevance of our results, we assessed whether breast cancer cells over-expressing Her-2 resulted in CA. We showed that these cancer cells harbor CA relative to MCF10A cells. These cells also show Nek2A, Plk-4, p27, cyclin D1, E2F3a, and E2F1 upregulation. siRNA knockdown of Cdk4, cyclinD1’s catalytic partner, greatly reduces CA in Her-2 over-expressing cells. These results suggest that the Her-2/Ras pathway is critical to the induction of CA in both mouse and human mammary cancers.

Circulating Tumor Cells in Primary Breast Cancer.
T. Ueno, S. Tanaka, M. Toi; Breast Surgery, Kyoto University, Kyoto, Japan

Objective: Circulating tumor cells (CTCs) are considered to be responsible for cancer metastasis in the distant organs. Elucidating mechanisms underlying CTC release will lead to a new strategy for cancer treatment. CTCs in metastatic breast cancer have been reported to reflect status of systemic cancer activity. However, CTCs in primary breast cancer remain to be studied. In this study, we examined CTCs in primary breast cancer patients to elucidate characters of CTCs in primary breast cancer. Methods: Forty-five primary breast cancer patients before preoperative systemic chemotherapy were enrolled in this study. CTCs were assessed in 7.5ml blood by the immunomagnetic detection system, CellSearch system (Veridex, LLC, NJ). CTCs were defined by the phenotype, Ep-CAM+, CK8/18/19+, DAPI+, CD45-. Viable and apoptotic CTCs were separated using FITC-M30 antibody (PEVIVA, Sweden). Results: Thirty five percents of the patients showed more than 2 CTCs in 7.5ml blood. When the patients were categorized by the intrinsic subtypes, patients with HER2 subtype cancers showed a higher number of CTCs than the other subtypes (p < 0.01). There was no difference in the ratio between viable and apoptotic CTCs among cancer subtypes. We analyzed CTC count in association with the response to preoperative systemic chemotherapy. There was no correlation between CTC count and tumor response. However, higher rates of apoptotic CTCs were associated with better response to the treatment (p = 0.02), suggesting that apoptotic CTC rates may predict treatment response to chemotherapy. Conclusions: There was a significant difference in CTC count among intrinsic
subtypes of breast cancer, which may explain the difference in clinical outcome of breast cancers with different intrinsic subtypes. Separating viable and apoptotic CTCs may be useful to predict treatment response to chemotherapy.

A. V. Timoshenko; Biology, University of Western Ontario, London, ON, Canada

Production of vascular endothelial growth factor C (VEGF-C), a most potent lymphangiogenic factor, by normal and cancer cells can be linked to the activation of Toll-like receptors (TLRs) because the promoter region of the gene contains the putative NF-κB binding site. To test this hypothesis, we examined the effect of TLR2 ligand chitin on VEGF-C production by MDA-MB-231 human breast cancer cells, which have been recently reported to secrete constitutively high levels of VEGF-C in cell culture medium (Timoshenko et al, 2006) and to express abundantly TLR2 (Xie et al, 2009). The 80-90% confluent cell monolayers were treated with serum-free DMEM containing either chitin hydrolysate at serial dilutions corresponding 0.25-8 mM of total N-acetylglucosamine (GlcNAc) or NaCl (13.75-220 mM) for 24 h and the concentration of VEGF-C was measured in cell culture media using a solid phase sandwich ELISA kit. Cells treated with GlcNAc-specific lectin wheat germ agglutinin (WGA) were used as a positive control. Chitin hydrolysate was found to induce an immense dose-dependent increase in VEGF-C accumulation in cell culture medium of MDA-MB-231 cells, which was at a chitin GlcNAc concentration of 4 mM up to 10 folds more than the basal production. A moderate increase of VEGF-C secretion was also observed in the presence of hypertonic doses of NaCl, which mimicked the matrix of chitin hydrolysate stock solution, and in the presence of WGA. When chitin hydrolysate was added to cells together with WGA with an intention to inhibit the lectin effect, the overproduction of VEGF-C was sustained indicating that WGA-independent receptors were responsible for chitin-mediated stimulation of VEGF-C synthesis. To the best of our knowledge, this is the first study demonstrating that chitin hydrolysate serves as a strong inducer of VEGF-C synthesis by breast cancer cells activating most likely TLR2-mediated signaling pathway.

96/B43
Effects of Canola Oil on Breast Cancer Cell Growth and Multi-Drug Resistance.
K. Cho, L. Mabasa, S. Bae, A. W. Fowler, C. Park; Animal Sciences, North Dakota State University, Fargo, ND

Canola oil, a naturally well balanced omega-6/omega-3 containing oil, has a very low level of saturated fat and relatively high levels of monounsaturated and polyunsaturated fatty acids. The beneficial effects of alpha-linolenic and oleic acids in canola oil are widely accepted in human health, particularly cardiovascular disease, but limited data are available regarding cancer, including breast cancer. We previously reported that canola oil has anti-proliferative effects on the cell growth of estrogen positive human breast cancer cells in vitro. The objective of the study was to investigate the effects of canola oil on breast cancer cell growth and multi-drug resistance. Three estrogen receptor positive breast cancer cell lines T47D, MCF7, MCF7/doxorubicin-resistant were cultured with media containing various combinations of canola oil and anti-estrogen drug tamoxifen or fatty acid synthase inhibitor cerulenin. Cell proliferation and caspase-3 activity were measured (1-4 days). Canola oil significantly inhibited the growth of both T47D and MCF7 cancer cells with tamoxifen (28.6% and 6.3% respectively) and cerulenin (25.1% and 6.5% respectively) on day 4, compared with tamoxifen or cerulenin alone. Canola oil also showed increased drug susceptibility on anti-cancer drug doxorubicin multi-drug resistant cells. Canola oil decreased the cell growth of MCF7/doxorubicin-resistant cells (8.9%) and increased the expression of caspase-3 activity (16.7%) on day 4, one of the crucial enzymes regulating the apoptosis pathway. The consistent and significant inhibition of canola oil, on the growth of these cancer cells appears to be due to increased apoptosis. Canola oil leads to breast cancer cell apoptosis, acts synergistically with anti-cancer drugs, and alleviates multidrug resistance. These results could be useful in the development of improved nutritional strategies for drug resistant breast cancer.

Extracellular Proton Promotes the Migration of Breast Cancer Cells through the Activation of the Proton Sensing Receptor, oGPCR X.
Y. Lee1, K. Heo2, S. Ryu1, P. Suh1; 1Pohang University of Science and Technology(POSTECH), Pohang, Korea, South, 2National Cancer Center, Goyang-si, Korea, South

G-protein-coupled receptors (GPCRs) are the largest family of cell-surface molecules that regulate many cell functions. Recently, several GPCRs have emerged as critical players in tumor growth, angiogenesis and metastasis. Of 800 GPCRs, a half of them are orphan GPCRs, which has no known ligands or functions. Orphan GPCRs is a highly active area of research that already led to the identification of many ligands for previously orphaned GPCRs. However, little is known about the tumor-specific expression profiles and their roles in specific human cancers. Here, we profile expression of orphan GPCRs in breast cancer which is the most common malignant disease in women world. We selected 90 orphan GPCRs as targets and performed quantitative PCR analysis in non-transformed breast derived cell (MCF 10A) and breast cancer cell (MCF7 and MDA-MB 231). As a result, we newly found an orphan GPCR, oGPCR X is highly up-regulated in breast cancer cell and breast cancer tissues, suggesting that oGPCR X may be involved in the breast cancer progression and metastasis. To elucidate functions, we down-modulate the expression of oGPCR X in highly malignant breast cancer cell (MDA-MB-231) by using shRNA-Lenti virus system. Upon acid stimulation, oGPCR X did not effect on breast cancer cell proliferation. In contrast, acid-induced breast cancer cell migration was significantly impaired by oGPCR X knockdown cell lines compared with wild-type cell lines on acidic condition. Take together, our results suggest oGPCR X is aberrantly over-expressed in breast cancer and promotes acid-induced breast cancer cell migration. In addition, we expect that these novel finding provide a foundation for further studies for identifying the functions of novel orphan GPCRs in breast cancer.

98/B45
The Role of Genetic Polymorphisms of DNA Repair Gene RAD23B and Breast Cancer Risk in Puerto Rican Women.
J. Perez-Mayoral1, C. Colon1, A. L. Pacheco-Torres1, J. Matta2, J. Dutil1; 1Dpt. Biochemistry, Ponce School of Medicine, Ponce, PR, 2Physiology and Pharmacology, Ponce School of Medicine, Ponce, PR

Breast cancer is the most commonly diagnosed cancer among women in the United States and Puerto Rico. Susceptibility to breast cancer is influenced by several factors, including age, DNA repair capacity and genetics. Rare high penetrance mutations in the breast cancer genes BRCA1 and BRCA2 only explain a small number of breast cancer cases. Low penetrance mutations in other DNA repair genes may confer higher risks of developing the disease in the general population. Previous studies have linked polymorphisms in the DNA Repair gene RAD23B with laryngeal cancer, lung cancer and breast cancer susceptibility. Our objective was to assess the contribution of single nucleotide polymorphisms (SNP) in RAD23B to breast cancer risk in Puerto Rican women. We genotyped three SNPs of the RAD23B gene rs10521083, rs10739234 and rs1805329 using the TaqMan PCR assay. Allelic and genotype frequencies were compared between 152 breast cancer cases and 251 controls recruited through breast surgery and oncology practices in Puerto Rico. Allele and genotype frequencies at rs10521083 and rs10739234 were not associated with breast cancer risk. However, the T allele at rs1805329 was more frequent in women with breast cancer than in healthy women (X2= 6.723, p<0.01). In conclusion, we provide evidence that genetic variants in the nucleotide excision repair gene RAD23B are associated with a higher risk of breast cancer in Puerto Rican women. Knowledge of the genetic basis to breast cancer susceptibility is likely to impact on personalizing breast cancer screening and preventive strategies.
Grape Polyphenols Inhibit Breast Cancer Progression through Regulation of the PI3K/Akt Pathway.
L. Castillo-Pichardo¹, E. Otero-Franqui², S. Dharmawardhane¹²; ¹Biochemistry, University of Puerto Rico - Medical Sciences Campus, San Juan, PR, ²Anatomy and Cell Biology, Universidad Central del Caribe, Bayamón, PR

Grape and red wine polyphenols have been widely studied due to their cancer preventive properties. However, much of these studies have focused on individual polyphenols at concentrations too high to be achieved via dietary consumption. We recently reported that combined grape polyphenols resveratrol, quercetin, and catechin (RQC) at physiologically relevant concentrations induced apoptosis and inhibited breast cancer cell proliferation, cell cycle progression, cell migration, and primary mammary tumor growth and metastasis to bone and liver (Schlachterman et al., 2008. J. Translat. Oncol. 1:19-27; Castillo et al., 2009. Clin. Exp. Met. 26:505-516). Herein, we used human phospho-kinase antibody arrays and Western blot analyses to investigate the molecular mechanisms of RQC action on breast cancer. Phosphorylation levels, and thus the activity, of Akt and its downstream effector endothelial nitric oxide synthase (eNOS) were decreased in breast cancer cells treated with 5µM RQC. Western blotting of excised tumors from mice following dietary RQC treatment showed an increase in phospho and total levels of IκBα, i.e. the inhibitor of the Nuclear Factor kappa-B (NFkB). Akt is activated by phosphatidylinositol 3-kinase (PI3K) and plays a central role in tumor development by inducing cell proliferation and survival pathways. eNOS also inhibits apoptosis and induces cell proliferation, angiogenesis, invasion, and metastasis. Moreover, the PI3K/Akt pathway activates NFkB, a transcription factor commonly hyperactivated in cancer to promote cancer cell survival and proliferation, that has been specifically implicated in cancer metastasis to the bone. Taken together, these results suggest that RQC treatment inhibits breast cancer progression and site-specific inhibition of metastasis to the bone by downregulation of Akt signaling to eNOS and NFkB. This study was funded by AICRIIG 03-31-06 and DoD BCRP W81XWH-07-1-0330 to S.D.; NIH/RCMI 2G12RR003035 to UCC; NIH/RCMI G12-RR03051 to UPR; and DOD BCRP W81XWH-08-1-0258 to LCP.

A Potential Mechanism for Omega 3 Polyunsaturated Fatty Acids to Inhibit Growth of Breast Cancer: Alteration of Location of G Protein in Plasma Membrane Microdomains (Lipid Rafts).
J. Yu¹, S. Panda¹, L. Zhang¹, M. M. Rasenick¹²; ¹Physiology and Biophysics, University of Illinois at Chicago, Chicago, IL, ²University of Illinois at Chicago, Chicago, IL

The omega-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), inhibit the growth of human breast cancer cells. In order to explore the modulation of breast cancer cell growth by omega-3 fatty acids, we observed the effects of EPA and DHA on proliferation of MCF-7, the human breast cancer cell line. Three days treatment of MCF-7 cells with EPA and DHA inhibited cell proliferation, and DHA significantly decreased proliferation of MCF-7 cells about 25% compared to control group. Furthermore, activation of the G protein coupled estrogen receptor, GPR30, increased the proliferation of MCF-7 cells around 15% compared to control group. This was attenuated by DHA treatment. Previous studies suggested translocation of activated Gαs into lipid rafts (allen et al, 2005). DHA and EPA treatment reduced lipid rafts association of Gαs in MCF7 cells. Fluorescence recovery photo bleaching showed that omega-3 fatty acids treatment reduced the movement of Gαs on cell plasma membrane. These results give rise to the possibility that altered subcellular localization of Gαs and the subsequent change in Gαs signaling may be one mechanism whereby omega 3 fatty acids decrease breast cancer cell proliferation. (Supported by DOD)F

Twist: A Potential Novel Therapeutic Target to Prevent Breast Cancer Metastasis.
The transcription factor, Twist, is a crucial regulator of epithelial-mesenchymal transition (EMT) during embryogenesis and tumorigenesis, regulates breast cancer cell invasion and metastasis, and it is highly expressed in malignant breast tumors. Our objective is to design dominant-negative (DN) Twist mutants to inhibit wild type Twist activity and reduce Twist-mediated invasion of breast cancer cells. Deletion of the last 20 C-terminal amino acids ($\Delta$183-202) resulted in a non-functional Twist protein, as shown by lack transcriptional activity. Amino acid substitutions, S144K/R145E, did not result in lack of transcriptional activity, whereas a triple mutation, S144K/R145E/$\Delta$183-202, resulted in a further decrease of transcriptional activity, compared to $\Delta$E183-202 only. Moreover, the $\Delta$183-202 and S144K/R145E/$\Delta$183-202 mutants, acted as DNAs, as indicated by their ability to inhibit the transcriptional activity of wild type Twist. The mutants were also tested for their ability to inhibit Twist-mediated IL-8 production and migration/invasion of the Twist-expressing BT-549 breast cancer cell line in vitro. All three mutants, as well as silencing of Twist expression with shRNA, resulted in decreased IL-8 release. However, only the $\Delta$183-202 deletion resulted in decreased In Vitro invasion. Transcription factors are difficult targets of therapy due to their nuclear localization. To facilitate transfer into the nucleus of target cells, the mutants were fused to VP22, a protein transduction domain, which possesses membrane translocation properties. The VP22:Twist mutants will be tested in the same way as the Twist mutants and used to produce adenovirus carrying the transgene under the Tet-response element (TRE). Neural stem cells (NSCs), which naturally home to tumor sites, will be transduced and injected into tumor bearing mice. Once the stem cells have arrived to the tumor sites, the mice will be injected with doxycycline for VP22:DN Twist expression, which should be released from NSCs and taken up by target cancer cells. Given the role of Twist as a master regulator of breast cancer metastasis, delivery of DN Twist to tumor sites represents a promising therapeutic strategy to prevent breast cancer metastasis.

NEDD9 Is Required for Activation of Oncogenic Signaling Pathways in Mammary Tumor Development.

J. L. Little, E. Izumchenko, M. K. Singh, S. Seo, M. Kurokawa, E. N. Pugacheva, B. Egleston, A. Klein-Szanto, E. Golemis; Fox Chase Cancer Center, Philadelphia, PA; Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva, Israel; Department of Hematology and Oncology, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; Mary Babb Randolph Cancer Center, West Virginia University, Morgantown, WV

Neural precursor cell-Expressed Developmentally Downregulated gene 9 (NEDD9; HEF1, CASL) is a scaffolding protein regulating mitosis, survival, and migration. within the last 3 years, NEDD9 has been implicated in the progression and metastasis of several cancers. In addition, NEDD9 interacts with and positively regulates activity of key oncogenic signaling proteins such as Aurora-A kinase (AURKA) and Src. Recently, a viable and fertile Ned9 knockout strain has been developed that enables evaluation of the In Vivo role of NEDD9 in cancer initiation and progression. Interestingly, loss of Ned9 significantly limits age at tumour formation in the MMTV-Polyoma Virus middle T antigen (PyV(m)T) model of mammary tumorigenesis (Izumchenko, et al. Cancer Res., In Press.). In MMTV-PyV(m)T mice, there are few differences in invasion and apoptosis between Ned9 genotypes, but early tumors of MMTV-PyV(m)T;Ned9/- tumors had reduced markers of proliferation compared to MMTV-PyV(m)T;Ned9+/+ mice. Further, tumors harvested from MMTV-PyV(m)T;Ned9/- mice had generally reduced activation of key oncogenic signaling proteins, with the lowest levels of activation correlating with the greatest delays in tumor onset. To explore the role of NEDD9 in a second highly physiological model of mammary tumorigenesis, Ned9/- mice were crossed to MMTV-neu (HER2; ErbB2) transgenic mice, and compared with MMTV-neu;Ned9+/+ counterparts. Strikingly, by 18 months, 88% of MMTV-neu;Ned9+/+ mice developed tumors, in contrast to only 18% of MMTV-neu;Ned9/- mice. This indicates a novel role for NEDD9 in the initiation of mammary tumorigenesis. This is in contrast to the role of NEDD9 in progression and metastasis that is largely ascribed to NEDD9 cooperation...
with oncogenes focal adhesion kinase (FAK) and Src and indicates the relationship between NEDD9 and other oncogenic partners may be important in mammary tumor initiation.

**Modulatory Effects of Adipocyte-Conditioned Media on Calcium Homeostasis in Isolated Cardiac Ventricular Myocytes.**

T. J. Herron1,2, R. P. O'Connell1, X. Lin2, J. Mertens2, W. P. Cawthorn1, O. A. MacDougald1,2, J. Anumonwo2,1; 1Molecular and Integrative Physiology, University of Michigan, Ann Arbor, MI, 2Internal Medicine (Cardiovascular), University of Michigan, Ann Arbor, MI

Bioactive factors secreted by adipocytes (adipokines) play an important intermediary role in communication with many other cell types. However, effects of adipokines on cardiac myocyte electrophysiology and function are largely unknown. We have used a combination of optical as well as the whole-cell patch-clamp technique to examine the effects of adipocyte-conditioned media on myocyte contraction and calcium homeostasis in adult rat cardiac myocytes. Ventricular myocytes were isolated and plated on laminin-coated cover slips. To test the effects of adipokines, myocytes were cultured in adipocyte-conditioned media (ACM) for 24 hours. for control experiments, myocytes were cultured in non-conditioned media (NCM) or in HEK293 cell-conditioned (HCM) media. After 24 hours in culture (ACM, HCM or NCM), myocytes were loaded with a fluorescent calcium indicator (fluor-4AM, 10 µM) for simultaneous measurements of intracellular calcium transients and cell shortening. Cells were initially field stimulated at a low frequency (0.5 Hz, 40 V, 37°C) and only myocytes that showed no spontaneous contractions were studied. Compared to the control conditions (NCM or HCM), myocytes in ACM demonstrated a higher incidence of spontaneous calcium transients and contractions when pacing frequency was increased to 1 Hz. for example, in NCM 0/16 (0%) cells displayed spontaneous activity compared to 2/8 cells (25%) in HCM, and to 7/14 cells (50%) in ACM. Patch-clamp analysis of the L-type calcium current showed that compared to NCM controls, ACM treated cells had a reduced peak inward current (Ip) at 0 mV. Ip (pA/pF) was -3.31 ± 0.39 (NCM, n=7) vs -1.92 ± 0.39 (ACM, n=9); p = 0.03). Voltage-dependent channel inactivation was also changed; mid points of channel inactivation (V1/2) were -35.3 ± 2.2 mV (ACM) and -41.1 ± 1.6 mV (NCM) (p < 0.05). The ACM had no effect on voltage-dependent current activation; V1/2 was -12.98 ± 0.3 mV in NCM and -14.43 ± 0.56 mV in ACM (p =NS). These results suggest that paracrine factor(s) in the ACM predispose cardiac myocytes to calcium overload, and these factors may be important for understanding the role of adipokines in the pathophysiology of the myocardium in obesity.

**Diacylglycerol Generated by Lipin Acts in Packaging Neutral Lipids into Cytoplasmic Droplets.**

O. Adeyo, S. Lee, A. S. Chandrahas, J. M. Goodman; Pharmacology, UT Southwestern, Dallas, TX

An important aspect of lipogenesis in adipose tissue is the assembly of lipid droplets, a process that is incompletely understood. Lipin, a phosphatidic acid phosphohydrolase, is known to be involved in lipogenesis through providing the substrate diacylglycerol (DAG) for triglyceride (TAG) synthesis, as well as to directly affect gene transcription of lipogenic factors. Mice with lipin mutations display a lipodystrophy-like syndrome which has certain similarities to lipodystrophy caused by mutations in seipin in humans. We show in Saccharomyces cerevisiae that the absence of PAH1 (encoding yeast lipin) results in defective neutral lipid packaging into droplets; instead, neutral lipids accumulate laterally in the ER although a few droplets remain. (Other phosphatidic acid phosphatases can provide the necessary DAG for generating TAG for filling the droplets). The droplet-packaging defect depends on the lack of phosphatidic acid phosphatase activity of Pah1p, and it is not a result of an altered triglyceride/steryl ester ratio. The packaging defect can be mimicked by overexpression of DGK1 (DAG kinase), but not by overexpression of
CDS1 (phosphatidate cytidyltransferase), indicating that the defect is caused by lack of DAG rather than a toxic effect of an excess of phosphatidic acid. This was further supported by the fact that a double knockout of both DGK1 and PAH1 restores neutral lipid packaging into droplets; this strain has the same number of droplets as wild type. We also show that Nem1p, which is known to activate Pah1p on microsomal membranes, is found in punctate structures on the ER, and most of these colocalize with seipin, which is found at ER-droplet junctions. In the absence of PAH1, much of seipin is no longer found at the ER-droplet junctions. Our data suggest that PAH1 promotes lipid droplet packaging by either introducing a shape change (via DAG) in the ER outer leaflet and/or by localizing seipin at ER-droplet junctions.

**Analysis of Hormone Sensitive Lipase Activity within Adipocytes via High Content Analysis Techniques.**

P. McDonough1, P. Loy1, R. Ingermanson1, P. Gehalot2,1, B. M. Buehrer3, C. Lars1, J. H. Price2,1; 1Vala Sciences Inc, San Diego, CA, 2Burnham Institute for Medical Research, La Jolla, CA, 3Zen-Bio, Research Triangle Park, NC

Lipid droplets are the defining feature of adipocytes and the basis for obesity, which is a worldwide health issue. Lipolysis of triglycerides occurs via lipases including Hormone Sensitive Lipase (HSL) which is phosphorylated by kinases including cAMP-dependent protein kinase (PKA, Ser 563, Ser 565, Ser 659, Ser 660), ERK-MAPK (Ser 660), glycogen synthase kinase-4 (Ser 563), Ca2+/calmodulin dependent kinase II (Ser 565) and AMP-activated kinase (Ser 565). In the basal state, HSL is found distributed throughout the cytoplasm, but HSL translocates to the lipid droplets upon activation. In this study, high content assay techniques were used to quantify HSL and lipid droplets in 3T3L1 adipocytes exposed to the β-adrenergic agonist, isoproterenol (ISO). Following treatment, the cells were fixed, labeled for nuclei, lipid droplets, & HSL (or for phosphoHSL) and then imaged with an automated digital fluorescence workstation. The images were analyzed in an automated fashion for lipid droplets and HSL on a cell by cell basis via an image analysis program which included colocalization algorithms (Pearson’s Correlation, Pr, and the Manders’ M1 coefficient). Control cells exhibited Pr values of 0.16 to 0.23, for cells visualized for HSL, signifying little association of HSL with the droplets. Exposure to 1 or 10 µM ISO led to much stronger colocalization of HSL with the droplets (Pr values of approx. 0.40). Phosphorylation of HSL on Serine 660 was dramatically increased by ISO, and the phospho-HSL Serine 660 label colocalized tightly with the lipid droplets. Z’ values > 0.6 were obtained for the effect of ISO on Pr and M1 for phospho-HSL Serine 660. The number, size, and intensity of the lipid droplets diminished upon exposure to ISO consistent with action of HSL. The high Z’ values suggest that high content analysis and phospho-HSL:lipid droplet colocalization could be used to screen chemical or genomic libraries for potential activators of HSL, furthering our understanding of the lipolysis and leading to identification of compounds with anti-obesity properties.

**Mitochondrial Dysfunction and Insulin Resistance in Adipocytes.**

X. Shi, A. Burkart, S. M. Nicoloro, M. P. Czech, J. Straubhaar, S. Corvera; molecular medicine, Umass medical school, worcester, MA

Adipose tissue is an important endocrine organ which stores excess energy as triglycerides and secretes adipokines to regulate whole body energy homeostasis. We previously found that mitochondrial biogenesis occurs during adipogenesis and that impaired mitochondrial function in adipose tissue is correlated with insulin resistance in rodents and human. To study the cause-effect relationship between mitochondrial dysfunction and insulin resistance in adipose tissue, we used the 3T3-L1 adipocytes as a model. siRNA knock-down of the mitochondrial transcription factor a (Tfam), a crucial factor for mitochondrial DNA integrity and transcription, resulted in impaired mitochondrial function in 3T3-L1 adipocytes without interfering with adipogenesis. Tfam-depleted adipocytes showed no significant morphological or global gene expression profile alteration and they were normal in many aspects of adipocyte function. However, Tfam-depleted adipocytes showed impaired mitochondrial respiratory function, reflected by reduced oxygen
consumption and slower ATP synthesis rate. Insulin-stimulated GLUT4 translocation to the cell membrane and glucose transport was impaired in these adipocytes, resembling insulin resistance in adipose tissue. These results suggest that mitochondrial dysfunction could be a direct cause of insulin resistance in adipose tissue. The mechanism by which impaired mitochondrial function causes insulin resistance seems not to be a result of impaired insulin signal to AKT, since the insulin-stimulated phosphorylation of AKT in these adipocytes was, paradoxically, enhanced relative to controls. To attempt to determine the mechanism by which mitochondrial dysfunction impairs glucose transport, we analyzed gene expression profile using Affymetrix expression array. Several genes are altered in Tfam-depleted adipocytes. Among these is Rab21, a small GTPase that is localized to endocytic pathway. Preliminary data show there is a definite requirement for Rab21 in insulin-stimulated glucose uptake in 3T3-L1 adipocytes.

Serum- and Glucocorticoid-Inducible Kinase 1 (SGK1) Regulates Adipocyte Differentiation via Forkhead Box O1.

V. Panel1, N. Di Pietro3, S. Hayes1, A. Bagattin1, S. Meruvu1, A. Pandolfi3, L. Hungendubler1, G. Fejes-Toth1, A. Naray-Fejes-Toth1, E. Mueller1; 1NIDDK, NIH, Bethesda, MD, 2Physiology, Dartmouth Medical School, Lebanon, NH, 3Biomedical Sciences, University “G. D’Annunzio”, Chieti, Italy

Dexamethasone priming of preadipocytes is necessary for their adipogenic commitment and differentiation, but the mechanisms through which glucocorticoids stimulate adipogenesis have not been fully elucidated. We investigated the potential role of serum and glucocorticoid-inducible kinase 1 SGK1, as a mediator of glucocorticoid-initiated signals in adipocytes. Here we show that SGK1 is expressed in white adipose tissue and that its levels are induced in the conversion of preadipocytes into fat cells. Adipocyte differentiation is significantly diminished via siRNA inhibition of endogenous SGK1 expression, while ectopic expression of SGK1 in mesenchymal precursor cells promotes adipogenesis. The SGK1-mediated phenotypic effects on differentiation parallel changes in the mRNA levels for critical regulators and markers of adipogenesis, such as PPARγ, C/EBPα and fatty acid binding protein aP2. We demonstrate that SGK1 affects differentiation by direct phosphorylation of FoxO1 thereby changing its cellular localization from the nucleus to the cytosol. In addition we show that SGK1-/- cells are unable to relocalize FoxO1 to the cytosol in response to dexamethasone. Together these results show that SGK1 influences adipocyte differentiation by regulating FoxO1 phosphorylation and reveal a potentially important function for this kinase in the control of fat mass and function. We are tempted to speculate that SGK1 specific inhibitors could reduce adipogenic conversion in Cushing patients and become potentially useful therapeutic agents in the treatment of their obesity.

Transcriptional Activation of Peroxisome Proliferator-Activated Receptor-γ during Adipocyte Differentiation.

J. Ha, S. Yun, E. Kim, S. Lee, Y. Kim, I. Jin, C. Kim, S. Bae; pharmacology, Pusan National University, Yang san, Korea, South

Peroxisome proliferator-activated receptor-γ (PPAR-γ) is widely known as a transcription factor that is important for the induction of adipogenesis. We demonstrate that transcriptional activity of PPAR-γ is regulated by both protein kinase a (PKA) and phosphatidylinositol 3-kinase (PI3K)/Akt signaling pathways. Transcriptional activity of PPAR-γ was markedly increased by isobutylmethylxanthine (IBMX) whereas insulin and dexamethasone was not effective. IBMX-induced activation of PPAR-γ was completely blocked by either PKA inhibitor (H89) or exchange protein activated by cAMP inhibitor (Epac, GTI-298). Furthermore, PI3K inhibitor (LY294002) completely blocked IBMX-induced transcriptional activation of PPAR-γ. Transcriptional activation of PPAR-γ was observed in the presence of both PKA agonist (6-MB-cAMP) and Epac agonist (8-pCPT-2′-O-Me-cAMP). In addition, Epac agonist strongly induced the phosphorylation of Akt. Finally, knock-down of Akt1 resulted in blunting of PPAR-γ transcriptional activation. Given these
results, we suggest here that both PI3K/Akt and PKA signaling pathways are necessary for the transcriptional activation of PPAR-γ.

Decreased PPARγ Expression Compromises Perigonadal Specific Fat Deposition and Insulin Sensitivity.
Y. Tsai1, P. Tsai2, M. Jiang1, T. Chou3, N. Maeda4; 1Institute of Clinical Medicine, National Cheng Kung University, Tainan, Taiwan, 2Department of Medical Laboratory Science and Biotechnology, National Cheng Kung University, Tainan, Taiwan, 3Institute of Molecular Medicine, National Cheng Kung University, Tainan, Taiwan, 4Department of Pathology and Laboratory Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC

Mutations and polymorphisms in PPARG have been linked to adiposity and partial lipodystrophy in humans. However, how disturbances in PPARG lead to depot-specific effects on adipose tissue, as shown by the characteristic aberrant fat distribution in patients, remains unclear. By manipulating the 3'-untranslated region of the PPARγ gene, we have generated mice with PPARγ gene expression ranging from 25% to 100% normal. Basal levels of PPARγ transcripts between 50%~100% had no significant effect on body weight, fat mass, and insulin sensitivity. In contrast, mice with 25% normal PPARγ expression exhibited reduced body weight and total fat mass, insulin resistance, and dyslipidemia. Interestingly, fat mass was selectively reduced in perigonadal depot without significant changes in inguinal and other depots. Expression of adipogenic factor C/EBPα and some other metabolic genes containing peroxisome proliferator response element were reduced in a perigonadal depot-specific fashion. This was further associated with depot-specific reduction in the expression of adipokines, increased expression of TNFα, and increased ectopic lipid deposition in muscles. Together, these results underscore the differential sensitivity of the individual fat depots on PPARγ availability as an underlying mechanism of partial lipodystrophy.

Automated Analysis of Steatosis in Hematoxylin/Eosin Stained Human Liver Biopsies.
P. McDonough2, R. Ingermanson2, Z. D. Goodman3, J. Price1,2; 1Burnham Institute for Medical Research, La Jolla, CA, 2Vala Sciences Inc, San Diego, CA, 3Armed Forces Institute of Pathology, Washington, D.C., DC

Excess lipid droplets (steatosis) in the liver is the defining characteristic of non-alcoholic fatty liver disease. Hepatic steatosis is also prominent in patients infected with hepatitis C virus, a disease that afflicts over 100 million people worldwide. Steatosis often progresses to fibrosis, cirrhosis, and hepatocellular carcinoma, and liver biopsies are often taken from patients to aid in diagnosis of liver dysfunction and from subjects undergoing clinical trials relevant to these disease states. Sections obtained from the biopsies are stained with hematoxylin plus eosin (H & E staining), and are commonly evaluated for steatosis by pathologists utilizing a 0, 1, 2, 3, or 4 scoring system. The goal of this study was to develop an automated algorithm for quantification of steatosis in images obtained from human liver biopsies visualized with an Aperio slide scanner. To do this, an algorithm, previously developed to quantify of lipid droplets in images obtained from cultured cells by fluorescence microscopy, was adapted for use with bright field images obtained from H & E staining procedures. After calibration with reference images, the algorithm was able to predict the steatosis score by a qualified pathologist with an accuracy of 85% (51 of 60 biopsies). A second algorithm was also developed which accurately identified nuclei within the images (the % error between automated analysis and counting of nuclei by the pathologist averaged 3% over 14 images). The development of a steatosis algorithm will enable researchers to quantify lipid droplets and predict the steatosis score from images derived from the livers of human and animal models of fatty liver and related afflictions.

Disruptions in Sphingolipid Metabolism Induce Obesity-Like Phenotypes in Drosophila Melanogaster.
The objective of our study was to determine whether disruptions in sphingolipid metabolism affect energy homeostasis using flies as a model organism. We used a systems biology approach, utilizing lipidomics, high-throughput biochemical assays, and DNA microarrays to analyze sphingolipid (SL) mutant flies of interest. Using electrospray ionization liquid chromatography tandem mass spectrometry (ESI/LC/MS/MS), we profiled the sphingolipidome of SL mutant flies. The sphingolipidome included measurements of ceramide, sphingoid bases and their derivatives. Obesity-like phenotypes were characterized using classic hallmarks of obesity. These included increased triglyceride levels, fat body cell size, adiposity and resistance to starvation induced death. Finally, DNA microarray analysis was performed to identify potential changes in transcriptional programs related to energy homeostasis. Our results show that obesity-like phenotypes correlated with ceramide accumulating SL mutants. Furthermore, these mutants exhibit changes in their transcript expression profiles that suggest a program shift towards lipid storage and/or increased nutritional uptake. Based on these results, we conclude that SL metabolism plays an important role in regulating energy homeostasis.

Peripheral Serotonin Enhanced Bile Acids Circulation and Accelerated Lipid Metabolism.

Serotonin is a neurotransmitter synthesized in the raphe nuclei of the brain stem and involved in the central control of food intake, sleep and mood. Serotonin is also a peripheral hormone produced by enterochromaffin cells in the intestine and involved in vasoconstriction, haemostasis and immune system. Serotonin is synthesized by two distinct tryptophan hydroxylase (TPH) rate-limiting enzyme in brain (TPH2) and in peripheral (TPH1). As serotonin is inability to cross the blood-brain barrier, there are two serotonin systems in brain and periphery with independent functions. We revealed that serotonin decreased the body-weight gain of mice fed a high fat diet. However, the functions of serotonin in periphery have not yet been fully elucidated. In this study, we investigated the physiological effect of serotonin on plasma metabolites and liver functions. After fasted mice were intraperitoneally injected with 1 mg serotonin, plasma glucose level was elevated. In contrast, plasma triglyceride, cholesterol and NEFA concentrations decreased following serotonin injection. Next, we evaluated the effect of serotonin on liver functions and bile acids circulation. The hepatic glycogen content and expression of glycogen synthase 2 (GYS2) mRNA was significantly highest at 240 min after injection. at the same time, the hepatic triglyceride content was significantly lowest. Furthermore, serotonin stimulated the contraction of gallbladder and the excretion of bile, and the bile volume at 60 min was smallest. at the same time, the plasma bile acids concentration increased. In contrast, the content of fecal bile acid excretion decreased at first and second days after injection. The mRNA and protein expression of apical sodium-dependent bile acid transporter (ASBT) in ileum was significantly increased at 30 min and 240 min after injection, respectively. These data indicated that serotonin induced physiological actions in periphery via enhancing of bile acids circulation.

Plasmin/Plasminogen Facilitates Uptake of agLDL by Macrophages.

Macrophage uptake of aggregated matrix-anchored LDL leads to foam cell formation and progression of atherosclerotic lesions. Urokinase plasminogen activator receptor (uPAR) is expressed at elevated levels in atherosclerotic human arteries, primarily in macrophages. Correlations between increased plasminogen activation and accelerated atherosclerosis are also
reported in several human studies. However, a coherent picture of the role of the uPAR/plasminogen system in atherogenesis has not emerged. In order to understand the mechanisms through which the uPAR/plasminogen system accelerates atherosclerosis, we employed an In Vitro cell culture model to examine the effects of plasmin on macrophage agLDL interactions. In this system, agLDL is retained for prolonged times in surface-bound membrane invaginations termed surface-connected compartments (SCCs). Data will be presented that demonstrates plasmin treatment results in proteolysis of agLDL inducing dramatic changes in SCC morphology. Specifically, plasmin proteolysis causes surface-associated agLDL to become partially or completely internalized in an actin-dependent manner. This results in the delivery of a significant amount of cholesterol to the macrophage. Additionally, surface expression of uPAR increases during incubation of macrophages with agLDL resulting in an increased capacity to convert plasminogen into plasmin. Our preliminary data suggest a model for the mechanism of plasmin accelerated atherosclerosis in which proteolysis of agLDL causes changes in SCC morphology which facilitates cholesterol uptake by macrophages and consequent foam cell formation.

A Novel Marker (PC-Cholesterol Complex) for Foam Cell Death Can Be Related to Oxidized Phospholipid Production.
M. Mori, N. Yamaguchi, S. Kikuchi, M. Takahashi, M. Fujimoto; Applied Pharmacology, Chiba Institute of Science, Chiba, Japan

[Objective] Phosphatidylcholine (PC)-cholesterol (FC) complex structures, a unique atheroma related antigen related to foam cell death. To elucidate the role of antigen in the development of atherosclerosis, the relationship among PC-FC complex, FC increase and Oxidized lipid production in cultured foam cell were investigated. [Method] J774 cells incubated in the presence of hyperlipidemic sera or modified LDL for 24 hr, then cultured up to 3-13 days. PC-FC complex and Oxidized Phospholipid were detected by immunofluorescent microscopy using specific monoclonal antibodies. Cell Apoptosis was detected by Annexin V binding. [Results & Discussion] Using human or WHHL rabbit hyperlipidemic sera and J774 cells, we succeeded to express PC-FC complex as a apoptosis marker on the surface of FC-rich lipid droplets. After apoptosis of the foam cells, residual lipid droplets can be accumulated to another preparation of macrophage(2nd stage). Oxidized lipids significantly increased during the foam cell culture detected by DPPP. Oxidized phospholipids specifically accumulated in the 2nd stage foam cells whereas, no significant increase of oxidized one can be observed after treatment with U18666A in 1st stage foam cells in order to block cellular cholesterol transport. This phenomena would be related to the PC-cholesterol complex formation as well as the foam cell death. This antigen expression can be related to oxidized lipid production. Oxidized lipid accumulation might be related to the foam cell death and the expression of PC-cholesterol complex. There were significantly relationship between the PC-FC complex formation, foam cell death and oxidized lipid accumulation in 2nd stage foam cells

Decreased Expression of N-Cadherin in Microvascular Pericytes and Endothelial Cells: Implications for Altered Vascular Permeability in Diabetic Retinopathy.
S. Rangasamy1, J. Maestas1, A. Das2, P. McGuire1; 1Cell Biology and Physiology, University of New Mexico School of Medicine, Albuquerque, NM, 2Surgery/Ophthalmology, University of New Mexico School of Medicine, Albuquerque, NM

N-cadherin is an integral membrane protein that plays an important role in microvascular function by mediating the homophilic interaction between endothelial cells and pericytes. In diabetic retinopathy, pericyte loss is considered to be an important mechanism that leads to altered blood retinal barrier function and neovascularization. Loss of N-cadherin in microvascular pericytes and endothelial cells in diabetic conditions may alter the ability of the cells to adhere with each other, resulting in pericyte loss and altered endothelial cell behavior. The objective of this study was to examine changes in the expression of N-cadherin in human microvascular endothelial cells and
pericytes exposed to high glucose (30.5 mM) that mimics the In Vivo diabetic condition. Analysis of endothelial cells and pericytes by real time PCR and western blot analysis revealed a greater than 30% reduction in the expression of N-cadherin mRNA and protein when cells were grown in high glucose compared to normal physiological glucose levels (5mM). Recently, Angiopoietin-2 (Ang-2) has been shown to be up regulated in cells in response to high glucose treatment and increased Ang-2 induces pericyte loss in animal studies. Our studies have revealed that treatment of both pericytes and endothelial cells with Ang-2 for a minimum of 48 hours leads to reduced expression of N-cadherin. In addition, rats receiving an intraocular injection of Ang-2 revealed a significant (26%) decrease in the level of N-cadherin 24 hours following the injection. Further studies utilizing immunocytochemical analyses demonstrated that the expression of N-cadherin by endothelial cells is regulated in part by the presence of pericytes in the local environment. Results from these studies suggest that high glucose and increased levels of Ang-2 in the diabetic condition could lead to altered N-cadherin expression in microvascular cells. Reduced N-cadherin may further lead to modification of endothelial cell/pericyte interactions and alteration of the blood-retinal-barrier.

Improvement of Mouse Embryo Progenitor-Derived Insulin-Producing Cells for Type 1 Diabetes Therapy.
S. Shao, G. Li; National University Medical Institutes, National University of Singapore, NUS, Singapore

Generation of functional insulin-producing cells from stems cells is a promising approach for cure of type 1 diabetes. We have been able to differentiate mouse embryonic stem and progenitor cells into highly pure and expansible insulin-producing cells which could reverse hyperglycemia in diabetic animals. However, these cells revealed the features of immaturity and unphysiological insulin secretory response to glucose stimulation. It is known that some transcription factors act as master regulators for expression of the genes key to various aspects of islet β-cell function. One such transcription factor, v-maf musculoaponeurotic fibrosarcoma oncogene homolog a (MafA), plays important roles in promoting differentiation of mature β-cells and regulating insulin expression for maintaining β-cell phenotype. This work aimed to examine potential benefits after overexpression of MafA in our mouse embryo progenitor-derived insulin-producing (MEPI)-1 cells since MafA expression in these cells was much lower than that in isolated islets. By using a lentivirus expression system, MafA could be up-regulated by 2-fold in MEPI-1 cells after 72-h transfection. MafA-overexpressed cells exhibited better signal transduction responses to glucose stimulation as reflected by the higher glucose metabolic rate and enhancement of both membrane potential depolarization and intracellular Ca2+ concentration rises upon high glucose challenge. More importantly, MafA up-regulation markedly improved glucose-stimulated insulin secretion (GSIS) profile by suppressing the basal release and increasing the high glucose effect, displaying a dose-response curve similar to that observed in isolated islets. Meanwhile, the insulin content was increased. Real-time PCR found that the lower expression of GLP-1R, glucose transporter 2, glucokinase, NK6 transcription factor-related locus 1 and Kir6.2 in MEPI-1 cells in comparison with primary β-cells, was significantly up-regulated upon MafA overexpression. Taken together, our data demonstrated that normalization of MafA levels could enhance the β-cell relevant gene expression profile in MEPI-1 cells toward promoting maturation and substantially improve GSIS by acting on multiple signaling cascade events.

Effect of Administration of Ethanol Extracts of Bidens Odorata, Eryngium Carlinae and Loeselia Mexicana on Diabetic Rats.
R. Noriega-Cisneros, O. Ortiz-Avila, M. Arellano-Plaza, M. Clemente-Guerrero, S. Manzo-Avalos, R. Salgado-Garciglia, A. Saavedra-Molina; Instituto de Investigaciones Químico-Biológicas, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mexico

Diabetes mellitus is a metabolic disorder of multiple etiologies, characterized by chronic hyperglycemia. This chronic hyperglycemia is directly related to the development of long-term
complications, diabetic nephropathy, among others, which determine the quality of life of diabetic patients. Because of this, there is the need to investigate new alternatives to treat diabetes based on plants known since ancient times. The aim of this study was to investigate the effect of administration of the ethanol extracts of Bidens odorata (BO), Eryngium carliniae (EC) and Loeselia mexicana (LM), plants of the forest area of the indigenous community of San Juan Nuevo Parangaricutiro, Michoacán, México in diabetic rats. We measured glucose levels in blood and weight of the rats, likewise, was measured the food and water intake for 30 days, during which conducted oral administration (in drinking water) of the three extracts in a dose of 150 mg/kg. Diabetes was induced by a single injection (ip) of streptozotocin (40 mg/kg). Rats with glucose levels above 300 mg/L were used to shape the diabetic groups. The administration of extracts of BO, EC and LM had no hypoglycemic effect; however, its use was able to reduce the weight loss characteristic of diabetic model. The symptoms of polyphagia and polydipsia were present in the diabetic groups, as evidenced by the high consumption of food and water, compared with a no diabetic group (p<0.01) despite receiving treatment with different extracts. Although, the results of the evaluated parameters did not show a clear effect of extracts of the diabetic condition, believe that their consumption is beneficial, since extracts help to overcome the suffering, the end of treatment the rats in diabetic group who received no treatment died, unlike those who did receive any of the extracts which have survived several weeks after treatment. Due to the results, currently being tested by varying the route of administration and dose of BO and EC extracts to find effective dose is also possible to evaluate the antioxidant activity of extracts in different organs. Acknowledgements: The authors appreciate the partial economic support of CIC-UMSNH (2.16, 2009) grant.

A Novel Role for the Centrosomal Protein, Pericentrin, in Regulation of Insulin Granule Docking.

The centrosome is important for microtubule organization and cell cycle progression in animal cells. Recently, mutations in the centrosomal protein, pericentrin, have been linked to human microcephalic osteodysplastic primordial dwarfism (MOPD II), a rare genetic disease characterized by severe growth retardation and early onset of type 2 diabetes among other clinical manifestations. Case reports of children with MOPD II describe abnormalities in glucose homeostasis, yet the mechanism linking pericentrin mutations with dysregulated glucose homeostasis and diabetes is unknown. We have observed abundant expression of pericentrin in pancreatic β-cells of normal animals which led us to hypothesize that pericentrin may have a critical function during insulin secretion. Here we report an essential role for the integral centrosomal protein, pericentrin, in docking of vesicles in professional secretory pancreatic islets and insulinoma cells. In addition to the typical centrosome localization, pericentrin was also enriched with secretory vesicles in the cytoplasm. Pericentrin co-localized and co-immunoprecipitated with syntaxin-1, a core component of the SNARE complex that regulates vesicle trafficking and tethering to the plasma membrane. Pericentrin overexpression in β-cells resulted in aggregation of insulin-containing secretory vesicles with cytoplasmic pericentriolar material and an increase in the levels of intracellular insulin. RNA mediated silencing of pericentrin in secretory β-cells caused dysregulated secretory vesicle docking at the plasma membrane and hypersecretion of insulin into the media. Mice transplanted with pericentrin-depleted islets had abnormal fasting hypoglycemia. This previously unrecognized function for centrosomal protein in protein secretion illustrates the utility of these scaffolding proteins to regulate diverse cellular processes and identifies a novel target for modulating protein secretion in disorders such as diabetes.

Identification and Characterization of a Proinsulin Interacting Protein, TMP21/P23.
Insulin is synthesized in the Endoplasmic Reticulum (ER) of pancreatic beta cells as proinsulin, transported through the secretory pathway, processed and stored in granules along with other proteins until stimulated for secretion. In order to identify proteins that interact and facilitate transport of proinsulin in the early secretory pathway, a yeast two hybrid screen was performed against a mouse pancreatic islet cDNA library. We identified and focused our studies on TMP21, or p23, a type I transmembrane protein of the p24 family of proteins that play an important but not well understood function in vesicular trafficking between the ER and Golgi. Our immunofluorescence analyses of mouse and rat insulinoma cell lines, MIN6 and INS-1 cells respectively, demonstrated that TMP21 co-localizes with proinsulin, suggesting a potential initial site of interaction. Over-expression and coimmunoprecipitation studies of various deletion mutants of TMP21 with proinsulin in COS-1 cells suggested that the luminal GOLD domain of TMP21 is sufficient to mediate this interaction. In order to analyze the functional significance of this interaction we made stable cells of MIN6 cells that had reduced expression of TMP21 as well as other isoforms of TMP21. These cells had slightly fragmented Golgi as had been seen before for cells with low levels of TMP21, but had marginal effect on the processing of proinsulin to insulin. We are currently exploring the possible function of TMP21 in post-Golgi insulin granule biogenesis, quality control in secretory granules and/or regulated insulin secretion. Our results for the first time add proinsulin to the list of other proteins such as Golgi matrix proteins (GRASP55 and GRASP65) that interact with TMP21.

The Effect of Angelica Sinesis on Improving Renal Functions and Increasing BMP-7 Expression in Diabetic Nephropathy.
C. Yeh1, C. Hsing2; 1Graduate Institute of Medical Sciences, Chang Jung Christian University, Tainan, Taiwan, 2Department of Medical Research and Department of Anesthesiology, Chi-Mei Medical Center, Tainan, Taiwan

Hyperglycemia induced reactive oxygen species (ROS) generation is believed as major factors leading to diabetic nephropathy (DN). Angelica sinensis (AS) is mentioned to show renal protective effect in combination with other herbs. Bone morphogenetic proteins-7 (BMP-7) is also produced merit in protection of DN. The role of BMP-7 in AS-induced renal improvement is not clear. The present study investigated the effects of AS on renal functions, BMP-7 expression, and the levels of ROS in streptozotocin (STZ)-induced diabetic rats and high glucose exposed rat mesangial cells (RMCs). After one- or four-week treatment, AS improved renal functions and increased renal BMP-7 expression in diabetic rats. The BMP-7 expression in RMCs was reduced by high glucose treatment and this could be reversed by AS. Moreover, RMCs exposed to high glucose were expired by BMP-7 RNAi transfection but those cells remained alive by scramble transfection. Thus, we employed regular RMCs to knock down BMP-7 with RNAi and we found that AS increased BMP-7 expression in these RMCs. Direct activation of BMP-7 expression by AS could be considered. The results of DPPH assay, DHE stain, and lucigenin assay indicated that AS could inhibit high glucose-induced ROS in RMCs. These results suggest that AS has an ability to improve renal functions in STZ-diabetic rats through increasing endogenous BMP-7 expression and decreasing oxidative stress in kidney. The present study suggests that AS could be applied to improve renal functions in diabetic disorders.

A Functional Screen Using High Content Analysis Reveals miRNA’s That Are Involved in Regulating the Intracellular Lipid Content of Hepatocytes.
R. Whittaker1, P. Loy1, P. McDonough1, E. Sisman2, P. Aza-Blanc2; 1Vala Sciences Inc., San Diego, CA, 2Burnham Institute for Medical Research, La Jolla, CA, CA

Objective: Studies have demonstrated that 75% of obese individuals develop hepatic steatosis independent of alcohol abuse, a condition known as Non-Alcoholic Fatty Liver Disease (NAFLD).
NAFLD is progressive and can eventually lead to liver failure. Microarray studies have demonstrated more than 100 microRNA’s (miRNA’s) are misregulated in NAFLD. However, a causative link between miRNA misregulation and development of NAFLD has not been shown. Therefore, this study was undertaken to identify miRNA’s that have the ability to regulate intracellular lipid content in hepatocytes and may be involved in the development of NAFLD. Methods: Huh-7 cells, which were derived from a human hepatoma, are spontaneously steatotic under normal cell culture conditions, demonstrating several fold higher levels of triglycerides and cholesterol, when compared to normal immortalized human hepatocytes. Increased de novo lipogenesis in HUH-7 cells mimics one of the underlying causes of NAFLD, making them an ideal model for this study. Huh-7’s, were transfected with a library of 327 human miRNA’s, in duplicate 384 well plates and incubated under normal cell culture conditions for 4 days. Following incubation, the cells were fixed and stained for nuclei and lipid droplets. The well plates were then imaged using an automated microscopy platform and analyzed using automated image analysis software. for the primary screen, hits were defined as those miRNA’s which altered intracellular lipid content by +/- 30%. Hits from the primary screen were included in a secondary screen and compared to a scrambled miRNA control. miRNA’s that altered lipid content +/- 40% from the control were considered hits. Results: The screen revealed 11 miRNA’s that increased or decreased intracellular lipid content by 40% or more. The effective miRNA’s were able to increase lipid content up to 170% or decrease lipid content to 48% of control levels. Conclusions: This study demonstrates a causative link between alterations in the expression levels of certain miRNA’s and their effects on hepatocyte lipid content. Follow up studies are underway to determine the mechanism of action underlying the effects of our identified miRNA’s.

**Chondrogenic Potential of Mesangial Cells in Diabetic Nephropathy.**

S. Kishi, H. Abe, H. Akiyama, T. Doi; 1Department of Nephrology, Graduate School of Medicine, Faculty of Medicine, The University of Tokushima, Tokushima, Japan, 2Department of Orthopaedic surgery, Kyoto University, Kyoto, Japan

Objective—Phenotypic changes of mesangial cells (MCs) are key pathologic findings during the process of progressive diabetic nephropathy (DN). MCs showed activated smooth muscle and acquired fibroblast phenotypes in addition to increased basement membrane components. This study investigated whether MCs can differentiate into chondrocytes in developing diabetic glomerular injury. Methods and Results—DN mice exhibited the induction of both SOX9, a master transcriptional factor of chondrogenesis and its downstream target, type II collagen (COL2). Positivity of COL2 was detected in sclerotic lesions in diabetic renal glomeruli shown by immunohistochemistry. So we explored this mechanism in vitro. A glomerular mesangial cell line was established from glomeruli isolated from normal, 4 week-old mice (C57BL/6JxSJL/J). Advanced glycation end-products stimulation induces the expression of BMP-2 and BMP-4 (BMP-2/4) in MCs. When cultured under micromass culture method in the presence of BMP-2/4 which triggered chondrogenesis of pluripotent C3H10T1/2 stem cells, MCs formed well-defined pellets comprising cells embedded in an extracellular matrix (ECM). In the ECM, highly expressed sulfated proteoglycans and COL2 were confirmed by Alcian blue (AB) and immunocytochemistry. The expression of SOX9 and COL2 was upregulated by BMP-2/4 in western blotting. SOX9 was also upregulated by hypoxic condition. COL2 was suppressed by treatment with a p38 kinase inhibitor, SB203580. Overexpression of SOX9 caused ectopic expression of sulfated proteoglycans and COL2 proven by RT-PCR, and western blot analysis, AB and immunocytochemistry. Conclusions—our present data showed ectopic BMP-2/4 expressions promote differentiation of MCs into chondrocytes by induction of SOX9 expression. It provide a new aspects in the progression of glomerular injury—MCs have a chondrogenic potential. As chondrocytes are unique cells that locate at avascular and hypoxic condition, it is implied that the transdifferentiation of MCs into chondrocytes is an accommodation response to chronic pathological hypoxia in kidney. And our data also suggest under pathological states, impaired differentiation of MCs may contribute to the progression of DN.
Glucose-6-phosphate dehydrogenase (G6PD), one of the NADPH producing enzymes, plays crucial roles in lipid metabolism and cellular redox regulation. Recently, we have reported that overexpression of G6PD in adipocytes stimulates lipogenesis and insulin resistance via increase in reactive oxidative species (ROS) generation and inflammatory response (Mol. Cell. Biol. 25:5146-5157, 2005; Diabetes 55:2939-2949, 2006). The fact that chronic oxidative stress causes pancreatic b-cell failure prompts us to elucidate whether alteration of G6PD is also linked with pancreatic b-cell dysfunction. In this study, we observed that G6PD expression was greatly increased in the pancreatic islets of several diabetic animal models including db/db mice and OLETF rats. In addition, G6PD expression was increased by FFAs and TNFα, which are mediated in metabolic syndromes. Furthermore, SREBP-1c, a well known transcription factor for lipogenesis and b-cell dysregulator, directly regulated expression of G6PD. When G6PD was overexpressed in INS-1 insulinoma cells, b-cell specific gene expression including PDX-1, insulin, and Glut2 was significantly down-regulated. Furthermore, G6PD overexpressing INS-1 cells exhibited increased expression of pro-oxidant enzymes with a little change of expression of antioxidant enzymes, resulting in ROS accumulation. Subsequently, enhanced G6PD expression led to apoptosis of pancreatic b-cells, concomitant with increases of pro-apoptotic gene expression as well as NF-kB activation. Taken together, these findings suggest that increased G6PD expression in pancreatic b-cells would elevate cellular ROS accumulation and activate NF-kB signaling, resulting in a b-cell dysregulation, which is frequently found in type 2 diabetic subjects.

Increased Fat Due to Estrogen Deficiency Induces Bone Loss by Elevating MCP-1 Production.

Growing evidence links fat and bone metabolism. Increased adipose tissue mass is associated with changes in the endocrine and metabolic function of adipose tissue. Altered production of adipokines by adipose tissue has been implicated in metabolic consequences associated with obesity. Adipose tissue of obese mice expressed increased level of monocyte chemoattractant protein-1 (MCP-1, CCL2), compared with that lean mice (Sartipy and Loskutoff, 2003). Ovarian involution and estrogen deficiency induce postmenopausal bone loss through effects on bone marrow and bone cells. Steady-state bone mass depends upon a balance between rates of bone formation and bone resorption. The most relevant consequence of estrogen deficiency due to ovariectomy (OVX) is elevated cytokine-induced osteoclast (OC) formation (Weizmann and Pacifici, 2006). We have investigated the relationship between the increased fat and the bone loss associated with OVX-induced estrogen withdrawal. We have focused on the effect of fat has on OC formation by releasing MCP-1. Ciliary Transition Zone Proteins Are Required for Proper Basal Body Positioning, Structural Integrity of the Ciliary Gate, and Proper Formation of the Axoneme.
Cilia are organelles with motile and/or sensory-signaling functions that protrude from most metazoan cell types and are important for a wide array of physiological and developmental processes. The most proximal section of the ciliary axoneme, which adjoins the basal body (the organelle required for ciliary axoneme elongation), is termed ‘transition zone’. Approximately 12 different proteins localise within this region, most of which are implicated in so-called ‘ciliopathies’ (e.g., Meckel syndrome, nephronophthisis, Joubert syndrome) that are characterised by retinal degeneration, kidney disease, brain and skeletal malformations, and other ailments. Remarkably, the function of these transition zone-associated proteins remains enigmatic. Here we use C. elegans to demonstrate functional interactions between many of these proteins, and show that they are required for several aspects of ciliogenesis. Various double mutant combinations, analysed by both fluorescence microscopy of ciliary markers and transmission electron microscopy, reveal defects in basal body positioning, formation of the ciliary gate formed by transitional fibers and Y-links at the base of cilia, and axoneme formation. Our findings expand the interaction network of ciliary proteins, describe previously unknown ciliogenic roles for the transition zone region, and point to the importance of ciliopathy-associated proteins in early ciliogenic processes.

Restriction of Access into the Ciliary Membrane Requires MKS and NPHP Proteins.
C. L. Williams, B. K. Yoder; Cell Biology, University of Alabama at Birmingham, Birmingham, AL

Cilia are microtubule-based and membrane-bound organelles that serve diverse functions in various organisms and tissues. The ciliary membrane is a tightly regulated region that is enriched with many proteins not found throughout the rest of the cell membrane. Likewise, many proteins found in the cell membrane are excluded from the cilium. The mechanisms by which the cell membrane and ciliary membrane are differentially regulated are unknown. It is proposed that proteins at the base of the cilium participate in cell/ciliary membrane protein sorting, but the molecular identities of such proteins have not been uncovered. Here, we demonstrate that cilia Basal body proteins implicated in the human developmental disorders Nephronophthisis (NPHP) and Meckel-Gruber Syndrome (MKS) function in this capacity in Caenorhabditis elegans. Using a combination of gene mutations and fluorescence-tagged transgenes, we find that NPHP-1, NPHP-4, MKS-1, MKSR-1, MKSR-2, MKS-3, and MKS-6 function redundantly in the worm to maintain proper cilia morphology such that mutations in single genes have little or no effect on ciliogenesis while certain combinations of mutant genes are detrimental to cilia formation. Although singularly not required to build cilia in C. elegans, these genes influence cilia sensory signal transduction. We propose that at least part of this influence is through maintaining the compositional integrity of the ciliary membrane. We find that in the absence of NPHP-1, NPHP-4, MKSR-1, MKSR-2, or MKS-6, transmembrane and membrane-associated proteins normally excluded from the ciliary membrane are allowed to freely access or accumulate within the cilium. Such proteins we observed abnormally entering the cilium include TRAM-1a, RP2, and MKS-3. These results contrast previous studies in which disruption of other cilia-associated disease proteins resulted in the loss of some normally cilia-localized proteins from the cilium. These data provide important insight into a mechanism by which ciliary membrane composition and signal transduction is regulated and may underlie the molecular basis of phenotypes observed in NPHP and MKS patients.

In Polycystic Liver Disease (PCLD), benign hyperproliferation of cystic cholangiocytes and cell cycle dysregulation contribute to hepatic cystogenesis. We showed recently that dysregulation of cholangiocyte cycle in PCK rats (animal model of PCLD) results from Cdc25A overexpression due to decreased miR-15a levels. In many cancers, abnormal cell cycle is associated with p53-dependent centrosome hyperamplification. However, no data exist on centrosome hyperamplification and mechanisms involved in this process in benign proliferative conditions such as PCLDs. Our aims were to analyze: (i) centrosome morphology and numbers; (ii) expression of p53 and its targets: p21, Cdk2/CyclinE; (iii) role of Cdc25A in centrosome hyperamplification; and (iv) effect of Cdc25A modulation by miR-15a on centrosome amplification in PCK-CCL (cholangiocyte cell line derived from PCK rats). Centrosome morphology and numbers were assessed by confocal or transmission electron microscopy In Vivo (normal and PCK rat livers) and In Vitro [PCK-CCL and normal rat cholangiocytes (NRC)]; expression of proteins by Western blot; and cell cycle by flow cytometry. PCK-CCL was transfected with a miR-15a precursor to decrease Cdc25A level and analyze effect of this manipulation on centrosome numbers. 30% of PCK-CCL had amplified centrosomes compared to 6% in NRC. Majority of PCK-CCL were in G2/M phase in contrast to NRC (mostly present in G0/G1 phase). Centrosomes in cystic cholangiocytes were longer, improperly positioned, with additional appendages; cells with multiple spindles were observed. Levels of p53 and p21 were not different between PCK-CCL and NRC and no mutations were found in p53 gene. However, Cdk2 and Cyclin E levels were ~2-times higher, likely due to Cdc25A over-expression (by 75%). Transfection of PCK-CCL with a miR-15a precursor inhibited Cdc25A up to 50% and decreased the number of cells with hyperamplified centrosomes by 10% (p<0.05). In the PCK-CCL, centrosome hyperamplification is linked to Cdc25A overexpression. Experimental suppression of Cdc25A by miR-15a reduces the number of cells with hyperamplified centrosomes. The data suggest that centrosome hyperamplification in PCLD appears to be Cdc25A but not p53-dependent.

Activation of Trpv4 Reduces the Hyperproliferative Phenotype of Cystic Cholangiocytes from an Animal Model of ARPKD.
S. A. Gradilone, T. Masyuk, J. M. Banales, B. Radtke, B. Huang, A. Masyuk, P. L. Splinter, N. LaRusso; Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, Rochester, MN

In the polycystic liver diseases, formation of hepatic cysts involves benign hyperproliferation of cholangiocytes. In PCK rats, an animal model of autosomal recessive polycystic kidney disease (ARPKD), cholangiocytes have decreased [Ca^{2+}]i levels that contribute to cholangiocyte hyperproliferation. We recently showed that Trpv4, a calcium entry channel, is expressed in normal rat cholangiocytes and its activation leads to an increase in [Ca^{2+}]i. Thus, we hypothesized that pharmacological activation of Trpv4 might reverse the hyperproliferative phenotype of PCK cholangiocytes. Methods: Trpv4 expression was examined in liver tissue from normal and PCK rats and from normal humans and patients with both autosomal dominant polycystic kidney disease (ADPKD) and ARPKD. Trpv4 expression was examined in liver tissue from normal and PCK rats and from normal humans and patients with both autosomal dominant polycystic kidney disease (ADPKD) and ARPKD. The effect of Trpv4 activation on PCK cholangiocyte proliferation and cyst formation was assessed in cultured cholangiocytes derived from normal and PCK rats. Results: We found Trpv4 was overexpressed ~8 times at the mRNA level and ~3 times at the protein level in PCK cholangiocytes. Confocal and immunogold electron-microscopy supported Trpv4 overexpression in cholangiocytes of PCK rats and human samples of patients with ARPKD or ADPKD. Treatment of PCK cholangiocytes with Trpv4 agonists (4oPDD, 5',6'-EET and nifedipine+arachidonic acid) increased [Ca^{2+}]i levels by ~30% resulting in inhibition of cell proliferation by ~25%-50% and cysts growth in 3-D-culture by ~70%. The inhibitory effects of Trpv4 activators on cyst growth were blocked when Trpv4 was silenced with a specific siRNA. Attenuation of cell proliferation and cyst growth in response to the increase in [Ca^{2+}]i was associated with activation of Akt and inhibition of β-Raf and Erk1/2. Conclusions: Cholangiocytes from PCK rats and humans with ARPKD and ADPKD overexpressed the calcium channel, Trpv4. Pharmacologic activation of Trpv4 by three different agonists increases levels of [Ca^{2+}]i in cystic cholangiocytes from PCK rats, leading to inhibition of cholangiocyte hyperproliferation and In Vitro
cyst growth via a mechanism involving Akt activation and inhibition of β-Raf/Erk pathway. These data suggest that TRPV4 may represent a potential therapeutic target in the polycystic liver diseases.

Novel Cellular Distribution of Foxj1.
U. Singh; Non Clinical Safety, Hoffmann-La Roche Inc., Nutley, NJ

Objective: to confirm Foxj1 as a specific marker of ciliated epithelial cells, we evaluated the cellular localization of Foxj1 in the mouse lung. Method: NBF fixed tissues were embedded in paraffin & sectioned to 5-µm thickness. Sections were deparaffinized then antigen retrieval was performed. Sections were blocked in 10% serum, rabbit α-Foxj1, goat α-CC10 & mouse α-β tubulin IV were incubated with sections for 1h (IHC) & O/N (immunofluorescence or IFA) then in IHC to visualize the signal anti-rabbit & anti-goat ABC kits were used along with Nova red substrate. For IFA after primary antibody Alexa 488 donkey anti-rabbit or Cy3 anti-goat or Alexa 488 anti-mouse were used. Stained sections were imaged using Nikon fluorescence microscope. For western blot lung lysate was prepared by homogenizing the whole lung then cytoplasmic & nuclear fractions were separated using BioVision extraction kit. Samples were run on 10% SDS-PAGE and transferred on to PVDF membrane. The membrane was incubated with odyssey blocker for 1 hr then with anti-Foxj1 antibody & anti-CC10 antibody for O/N at 4°C. These membranes were incubated with IRDye 800-anti-rabbit & IRDye-800 anti-goat antibody then imaged using Li-Cor Odyssey imaging system. Summary: Foxj1 is a transcription factor, involved in the regulation of ciliogenesis & expressed in the nucleus of ciliated cells of various tissues including respiratory tract. The distribution of Foxj1 in FFPE lung tissues using a harsh antigen retrieval method was nuclear as previously reported, but we found its also cytoplasmic & associated with the cilia. These findings were confirmed using double immunofluorescence which demonstrated colocalization of Foxj-1 & β-tubulin IV in the cilia & cytoplasm of respiratory ciliated epithelial cells. CC10, a marker of Clara cells & Foxj1 were mutually exclusive in their expression by IFA. Western blots of the cytosolic & nuclear fractions of mouse lung identified two forms of Foxj1: a ~45 KD almost exclusively nuclear form, and ~50 KD nuclear and cytoplasmic form. Conclusion: Foxj1 can be used to identify specifically ciliated cells in the mouse lung. A novel pattern of sub-cellular distribution of two forms of Foxj1 in the mouse lung was established.

Valdoni”, University of Rome “La Sapienza”, Rome, Italy

Cholangiocytes, the epithelia lining the biliary epithelium, are the target cells of several human liver diseases defined as cholangiopathies. Autosomal dominant polycystic kidney disease (ADPKD) represents an important example of a genetic cholangiopathy, since it is caused by mutations in PKD genes with an abnormal formation of multiple renal and biliary cysts. Biliary hyperplasia is regulated by a number of factors including sex hormones such as estrogens, progesterone and follicle-stimulating hormone (FSH). We have previously shown that FSH stimulates cholangiocyte growth by activation of cAMP signaling. Here, we tested the hypothesis that FSH regulates the growth of ADPKD biliary cysts by an autocrine mechanism. Methods: We evaluated: (i) the expression of FSH and FSH receptor (FSHR) by immunofluorescence and real-
time PCR; and (ii) cholangiocyte proliferation in a. liver sections from normal and ADPKD patients (by immunohistochemistry for PCNA) and b. immortalized normal human cholangiocyte lines (H69) and immortalized cell lines obtained from the epithelium lining the hepatic cysts from patients with ADPKD (LCDE) by immunoblots for PCNA. In H69 and LCDE cells we assessed FSH secretion in short-term cultures (6 hours) by EIA kits and intracellular cAMP levels by RIA kits. Also, we used siRNA to knockdown FSH expression in LCDE and H69 cells before evaluating cAMP levels and proliferation by PCNA immunoblots. Results: There was: (i) a higher expression of FSH (~60%) and FSHR (~30%); and (ii) elevated cholangiocyte proliferation in sections from ADPKD patients compared to normal patients and in LCDE cells compared to normal H69 cells. There was increased FSH secretion (~40%) in cultures of LCDE compared to H69 cells. Silencing of FSH induced a decrease in cAMP levels and cholangiocyte proliferation in ADPKD samples and LCDE cells. Conclusion: FSH is an important autocrine trophic factor for biliary growth in the course of ADPKD. Modulation of cholangiocyte FSH secretion may be important in the control of the formation and the progression of hepatic cystogenesis.

**The NPHP Cystic Suppressor Proteins Form a Centriolar Compartment Required for Formation of the Primary Cilium.**

J. J. Miller2, L. Sang1, P. K. Jackson1; 1Cell Regulation, Genentech, Inc, S. San Francisco, CA, 2Chemical and Systems Biology, Stanford University School of Medicine, Stanford, CA

Nephronophthisis (NPHP) is an autosomal recessive, cystic kidney disease, caused by mutations of nine known genes. NPHP patients also show cerebellar defects, situs inversus, and retinitis pigmentosa. The molecular mechanism suppressing formation of cysts is poorly understood, but may include changes in the apical-basal polarity of cells, cell cycle, or secretory behavior of cells. Recent studies suggest that specific changes in ciliary signaling mechanisms may be important for cyst suppression. Using a recently reported system for high-throughput protein tagging and proteomic analysis (PMID: 19405035), we have generated inner medullary collecting duct (IMCD) and fibroblast cell lines stably expressing GFP (LAP)-tagged forms of NPHP1, NPHP2/Inversin, NPHP3, NPHP4, NPHP5, NPHP6/CEP290, and NPHP8/RPGRIP1L. We have identified a network of high confidence interaction proteins placing the NPHP proteins in three subnetworks. In the first network, strong interactions among NPHP1, NPHP4, and NPHP8 are linked to a cortical network of actin binding proteins and show apical localization in IMCD3 cells, but are not strongly required for ciliation. In the second network, NPHP6 binds to and directs NPHP5 proteins to the centriole. NPHP5 also binds NPHP2, which localizes to both centriole and cilium. NPHP5 is organized at the cortex by association with the exocyst proteins Sec3/Sec8, calmodulin, and NPHP1. NPHP5 binds to the deubiquitinating enzyme USP9X/Fat Facets. Both NPHP5 and USP9X are required for ciliation in RPE cells, suggesting ubiquitin-dependent control of ciliation. In the third network, NPHP6/CEP290 associates with MKS1 and MKS6, proteins mutated in the related Meckel-Gruber syndrome. MKS proteins participate in pathways important for neural tube closure and Hedgehog signaling. We did not observe direct interactions among the NPHP subnetworks and proteins associated with intraflagellar transport complexes IFT-A or IFT-B, nor proteins important in the Bardet-Biedl syndrome (BBS) or ciliopathy. We suggest that NPHP proteins participate in a centriolar-cortical anchoring mechanism.

**Planar Cell Polarity (PCP) Proteins Regulate a Novel Apical Localization of Polycystin-1.**

I. Tsai, Z. Lan, F. Qian, G. G. Germino; Johns Hopkins University, Baltimore, MD

Autosomal dominant polycystic kidney disease (ADPKD), which leads to forming cyst instead of developing proper renal tubules, is one of most common inherited diseases of humans. at least 85% of all cases of ADPKD result from mutation of the PKD1 gene, encoding the protein polycystin-1 (PC-1). However, the mechanisms by which PC-1 regulates the diameter of renal tubules and the reasons why ADPKD patients with mutations of PKD1 develop kidney cysts remain obscure. Recent studies suggest that cysts may result from improper establishment or maintenance of planar cell polarity (PCP). As a first step in determining the role of PC-1 in this
process, we examined the cellular localization of PC-1 with respect to a set of known PCP proteins. Because endogenous levels of PC-1 are too low to detect with certainty, we developed an MDCK cell culture system with inducible expression of EGFP-tagged PC-1. Using this system, we identified a previously undescribed apical pool of PC-1 that co-localizes with Dishevelled (Dvl) and Vangl2. Interestingly, the apical localization of PC-1 appears to be inhibited by over-expressing dominant negative Dvl or knocking down Vangl2, suggesting that Dvl and Vangl2 may play a role in regulating PC-1 sub-cellular localization. This localization appears to be essential for proper tubule formation since a PC-1 mutant that does not localize apically is also defective in forming tubules in vitro. Finally, we investigated PC-1 signaling downstream of PC-1 and found enhanced RhoA activation, localized to the apical membrane near PC-1.

**Aurora-A Kinase Regulates the PKD2 Calcium Channel.**

O. V. Plotnikova, E. Pugacheva, E. Golemis; 1Basic Science, Fox Chase Cancer Center, Philadelphia, PA, 2Mary Babb Randolph Cancer Center, West Virginia University, Morgantown, WV

Autosomal dominant polycystic kidney disease (ADPKD) is a common condition, affecting 1 in 800 live births from all ethnic groups. The majority of the cases arise from inherited mutations in the PKD1 and PKD2 genes, which encode the proteins polycystin 1 and 2 (PC1 and PC2). PC2 belongs to the transient receptor potential (TRP) superfamily of transmembrane ion channels, and functions at the endoplasmic reticulum (ER) as a Ca2+ release channel. PC2 also heterodimerizes with PC1 at the membrane of the primary cilium, where it acts as mechanosensitive channel. Downregulation of PC2 calcium channel activity is associated with PKD pathogenesis. Aurora a (AurA) is a centrosomal kinase that is best known for a role regulating mitotic entry and promotes progression through the stages of mitosis. We have now shown that AurA directly binds the C-terminal cytoplasmic domain of PC2 and phosphorylates a unique residue an S829 residue. AurA phosphorylation negatively regulates PC2 channel activity. Small molecule inhibition of AurA phosphorylation or depletion of AurA by specific siRNA increases Ca2+ release through the PC2 channel, while AurA overexpression decreases Ca2+ release. Physiological stimuli that normally transiently increase PC2 activation and intracellular calcium level also rapidly and transiently induce AurA activation, with a time course appropriate for AurA limitation of PC2 activity. Our data suggest that AurA is activated by the cytoplasmic Ca2+ released from ER stores, then binds and phosphorylates PC2 to suppress further PC2 channel activity. AurA is abundantly expressed in human and murine kidneys and activated phAurA is present in the kidneys cells lining ADPKD cysts. Our work provides the first evidence that AurA acts as a rapid response environmental sensor in mammalian cells. We conclude that AurA is novel regulator of PC2 activity, and hypothesize that AurA inhibition may have therapeutic benefit in ADPKD treatment.

**Purinergic Signaling Can Regulate the Cell Surface Delivery of Polycystin-1.**

H. C. Chapin, C. Hueschen, M. J. Caplan; 1Cell Biology, Yale University, New Haven, CT, 2Yale College, New Haven, CT, 3Cellular and Molecular Physiology, Yale University, New Haven, CT

Polycystin-1 (PC1) is a mechano- or chemosensory receptor that localizes to the plasma membranes and cilia of epithelial cells. Mis-localization of PC1 may be associated with cystic kidney disease, and a variety of partner proteins and intracellular conditions are likely to regulate PC1 expression and delivery to the plasma membrane. The ion channel polycystin-2 (PC2) and PC1 interact with one another through their C-terminal tails. PC2 is known to modify the localization of PC1 in cultured cells, and PC1 may affect PC2 channel function. Using a quantitative surface immunofluorescence assay, we found that PC1 requires co-expression with PC2 to reach the plasma membrane in cultured HEK293 cells. PC1 surface localization requires functional PC2 channel activity, as demonstrated by the failure of a channel-defective PC2 mutant to support surface delivery. Interestingly, surface delivery does not require a stable
interaction between PC1 and PC2, since C-terminally truncated versions of either protein do not negatively affect PC1 localization. The delivery of PC1 to the surface is correlated with an increase in the cleavage of PC1 at the G-protein coupled receptor proteolytic site (GPS), a cleavage that is necessary but not sufficient for surface delivery. We find that extracellular ATP acting through cell surface purinergic receptors potentiates the effect of PC2 on PC1 localization. Adding extracellular ATP increases the amount of PC1 that reaches the surface in the presence of PC2, while the purinergic receptor blocker suramin abrogates the effect and reduces the amount of surface PC1, even in the presence of PC2. ATP seems to affect steps late in the secretory pathway, since the ATP-induced increase in surface PC1 is not accompanied by an increase in the GPS cleavage. In summary, our data indicate that PC1 localization to the plasma membrane depends on the channel activity of PC2 and that extracellular ATP, acting through purinergic receptors, may regulate this delivery.

Ciliary Membrane Protein Trafficking in C. elegans.
J. Wang, S. Warburton-Pitt, M. Barr; Genetics, Rutgers University, Piscataway, NJ

Cilia are sensory organelles that protrude like antennae off eukaryotic cells. Receptors and signaling transduction molecules dynamically localize to the cilium in a tightly regulated process. Defects in ciliary development, formation, or function may result in human genetic diseases, or ciliopathies. We are using the nematode Caenorhabditis elegans to study ciliary receptor trafficking [1] and also to model human ciliopathies. A group of ciliopathies including Meckel-Gruber Syndrome (MKS), Joubert’s syndrome, and nephronophthisis (NPHP) display overlapping clinical manifestations and causal genes. The C. elegans genome encodes homologs for several of the MKS, Joubert’s, and NPHP genes, and these gene products specifically localize to the cilia base. We hypothesize that these proteins act at the ciliary base and function in membrane protein localization. PKD2 (Polycystic Kidney Disease gene 2) encodes a conserved TRP polycystin (TRPP) channel that localizes to cilia and may act as a mechanosensor. We have been looking at the role of the MKS, Joubert’s, and NPHP genes on the localization of PKD-2 and other ciliary components in C. elegans. Mammalian INPP5E mutations cause Joubert’s syndrome [2, 3], whereas, the C. elegans inositol 5-phosphatase CIL-1 is required for normal PKD-2::GFP localization [4]. C. elegans NPHP-1 and NPHP-4 are required for cilia development and morphology in PKD-2 expressing neurons [5]. In C. elegans sensory neurons, MKS-3 localizes to the ciliary base. In an mks-3 mutant, PKD-2::GFP accumulates abnormally at the cilia base. These findings suggest that these ciliary base-localized proteins might play a general role in regulating ciliary protein localization. We are therefore examining interactions among these genes regarding to ciliary protein localization regulation. 1 Bae YK et al 2008 Dev Dyn 237:2021-9. 2 Bielas SL et al 2009 Nat Genet. 41:1032-6. 3 Jacoby M et al 2009 Nat Genet. 41:1027-31. 4 Bae YK et al 2009 The CIL-1 phosphoinositide 5-phosphatase regulates ciliary localization of the TRP polycystins and sperm function in C. elegans. New Roles for Ciliary Kinesins in Male-Specific CEM Sensory Neurons.
N. Morsci1, M. Barr2; 1Genetics, Rutgers University, Piscataway, NJ, 2Cell and Molecular Biology, University of Wisconsin - Madison, Madison, WI

The cilium is a specialized organelle used by a cell to detect and convert extracellular sensory stimuli into appropriate intracellular responses. Although all cilia are built by a conserved kinesin-2-driven process, termed intraflagellar transport (IFT), their structural and functional diversity is conferred by cell-specific modulation of IFT by additional motors and/or signaling proteins. Our objective is to explore the roles of multiple kinesins in specializing cilium length and shape in C.elegans nematode. We employed In Vivo fluorescent microscopy to examine CEM cilia morphology in wild-type males and mutants defective in the IFT kinesins KLP-11 and OSM-3 and male-enriched kinesin-3 KLP-6. Cilia axoneme reporter β-Tubulin-4::GFP shows that cilia length is similar in wild-type, osm-3(p802) and klp-6(my8) males (~3.4µm). Surprisingly, klp-11(tm324)
mutation resulted in changed shape and elongation of the CEM cilia to 5±9µm. Double mutant klp-11 osm-3 males had variable phenotype with missing, short or long CEM cilia. Additional removal of KLP-6 (in klp-11 osm-3; klp-6 triple mutants) suppressed the long cilia category and resulted in stunted or absent CEM cilia. These results provide important insight to mechanisms controlling ciliary length and indicate that a) OSM-3 is not required for CEM cilia formation and maintenance, b) KLP-11 and OSM-3 act partly redundantly in CEM cilia biogenesis, and c) KLP-6 acts with the IFT kinesins to regulate CEM ciliary length. We hypothesize that KLP-6 may regulate ciliary length via vesicular transport-mediated delivery of membrane to the ciliary base. Additionally, we propose that KLP-11 plays a CEM cilia-specific role in length restriction and shape definition. We are utilizing In Vivo time-lapse imaging to measure IFT particle velocity using cargo protein OSM-6::GFP to assess the effect of klp-11, osm-3 and klp-6 mutations on dynamics of intraflagellar transport in CEM cilia.

Systems-Level Control of Longevity in Yeast: Aging Is a Developmental Program.
A. Goldberg, P. Kyryakov, S. Bourque, T. Boukh-Viner, M. Burstein, A. Beach, V. Richard, M. Juneau, M. Belanger, B. Patel, V. Titorenko; Biology Department, Concordia University, Montreal, QC, Canada

The yeast Saccharomyces cerevisiae is a valuable model for unveiling the mechanisms of cellular aging in multicellular eukaryotes. Yeast aging can be slowed down by calorie restriction (CR), a low-calorie dietary regimen that extends life span in a wide spectrum of organisms and delays the onset of age-related disorders in rodents. To define a specific pattern of metabolism and organelle dynamics that is responsible for the anti-aging effect of CR and to establish the mechanisms underlying such effect, we assessed the effect of a CR diet and numerous mutations extending life span on the age-dependent dynamics of cellular and organelar proteomes and lipidomes, carbohydrate and lipid metabolism, interorganellar metabolic flow, concentration of reactive oxygen species, frequencies of nuclear and mitochondrial DNA mutations, mitochondrial morphology, stress response, and apoptosis. We show that yeast merge a number of cellular processes, which we call modules, into a metabolic longevity network. Our findings suggest a model for the spatiotemporal dynamics of this network. This model envisions that 1) yeast establish a diet- and genotype-specific configuration of the network by setting up the rates of the processes taking place within each of its modules; 2) the establishment of a network’s configuration occurs before yeast enter a non-proliferative state; and 3) different network’s configurations established prior to entry into a non-proliferative state define different rates of survival following such entry. Thus, by designing a specific configuration of the metabolic longevity network prior to reproductive maturation, yeast define their life span. We concluded that the chronological aging of yeast is a developmental program. Implementing our knowledge and using systems biological analysis, we identified five groups of novel anti-aging small molecules that extend yeast longevity by targeting 1) mitochondrial fusion and mitochondria-controlled, age-related apoptosis; 2) the protein kinase Rim15p, an essential component of the evolutionarily conserved nutrient-signaling network governed by protein kinase a and TOR complex; and 3) lipid metabolism in the endoplasmic reticulum, peroxisomes and lipid bodies.

Adult-Onset Inhibition of SNF1A/dAMPKα Reduces Stress-Resistances and Shortens Lifespan in Drosophila Melanogaster.
D. Tohyama, A. Yamaguchi; Department of Neurobiology, Graduate School of Medicine, University of Chiba, Chiba, Japan

Energy homeostasis and stress resistance are closely linked to aging and longevity. AMPK (AMP-activated protein kinase), a sensor of cellular energy status, is activated by metabolic stresses that accelerates AMP/ATP ratio, regulating energy balance in whole organism. Recently AMPK is recognized as attractive therapeutic target for cancer, diabetic mellitus and obesity, providing a link to the metabolic syndrome. However little is known how functional deficiency of AMPK during adulthood affects aging and longevity In Vivo due to its redundancy and critical role.
in the development. Drosophila SNF1A/dAMPKα (CG3051) is a single orthologue for its mammalian counterparts. Using time- and tissue-specific RNAi system in Drosophila, we examined whether adult-onset dAMPKα RNAi affects lifespan and which tissue is responsible for its effect on longevity. We show that adult-onset inhibition of dAMPKα, especially in muscle, shortens lifespan. Further, inhibition of dAMPKα during adulthood enhances sensitivity to paraquat and starvation stress. Real-time PCR studies showed that adult-onset inhibition of SNF1A/dAMPKα decreased the expression levels of stress-resistant genes. Our results raise a possibility that dAMPKα could be one of master regulators integrating aging/longevity, metabolic hemostasis and stress resistance in whole organism.

**Analysis of Yeast Lifespan Mediated by the Ca\(^{2+}\)-Signaling Pathways.**

R. Tsubakiyama, M. Mizunuma, K. Kume, T. Miyakawa, D. Hirata; Graduate School of Advanced Sciences Matter, Hiroshima University, Hiroshima, Japan

The \(zds1\Delta\) strain of the *Saccharomyces cerevisiae* shows the sensitivity to Ca\(^{2+}\) and the Ca\(^{2+}\)-induced, Swe1p- and Cln2p-mediated G2 cell cycle arrest, and polarized bud growth. To clarify a overview of the cell cycle and the growth control, we screened for suppressor mutants of the Ca\(^{2+}\)-sensitive phenotypes of \(zds1\Delta\) cells. Recessive mutants so far isolated have been classified into 14 genetic complementation groups (scz mutant). Of these mutants, we identified mutant allele of *SIR3* as *scz14*. In the recent research, it has been reported that Sir3 is involved in silencing of mating loci/telomeric, stress response, and aging. Therefore, we focused on the relationship aging with Ca\(^{2+}\)-signaling. Because other SCZ had been expected to be involved in aging, we examined the lifespan of *scz* mutants to understand the molecular mechanism by which Ca\(^{2+}\) involved in aging through the analysis of SCZ. The replicative lifespan in budding yeast is defined as the number mitotic cycles completed by a mother cell before senescence. We first examined the replicative lifespan of wild-type, \(zds1\Delta\), *swe1\Delta/scz1*, *mpk1\Delta/scz2*, *bck1\Delta/scz3*, *cnb1\Delta/scz4*, *ssn2\Delta/scz5*, *pkc/scz6*, *scz7*, *mck1\Delta/scz10*, *alg9\Delta/scz13*, and *sir3\Delta/scz14*. All *scz* strains had a shorter lifespan than wild-type, suggesting that SCZ is involved in the regulation of yeast lifespan. Next, we investigated the telomere length, known to be related to the lifespan, of these strains by Southern blot analysis. As a result, the telomere length of most strains were shorter than wild-type. These results suggested that SCZ genes are related to the aging and the telomere length. Thus, we proposed that Ca\(^{2+}\)-signaling is important for the regulation of aging and the maintenance of the telomere length.

**Mechanical Characterization of Schlemm’s Canal Endothelial Cells In Vitro.**

E. H. Zhou\(^1\), W. D. Stamer\(^2\), R. Krishnan\(^1\), K. Perkumas\(^2\), C. R. Ethier\(^2\), J. J. Fredberg\(^1\), M. Johnson\(^3\); \(^1\)Environmental Health, Harvard University, Boston, MA, \(^2\)Ophthalmology and Vision Science, University of Arizona, Tucson, AZ, \(^3\)Bioengineering, Imperial College London, London, United Kingdom, \(^4\)Biomedical Engineering, Northwestern University, Evanston, IL

Background: The elevated intraocular pressure (IOP) associated with primary open angle glaucoma is caused by dysfunction of the tissues of the aqueous humor outflow pathway. However, the cellular and molecular basis of this dysfunction remains unknown. The bulk of aqueous humor outflow must traverse the endothelial lining of Schlemm’s canal (SC). We therefore hypothesize that the mechanical properties of the SC endothelium may contribute to the regulation of IOP. Objective: Systematic characterization of the mechanical properties of SC cells isolated from healthy donors. Methods: Using a micro rheological assay, optical magnetic twisting cytometry (OMTC), we focus on the baseline cell rheology, pharmacological responses to relaxing and contractile agonists, and how these measurements vary with In Vitro passage number. Results: Similar to other adherent animal cells in culture, the SC cells were found to exhibit weak power-law rheology with a median shear modulus of ~ 400 Pa (at 0.75 Hz), similar to that measured for other endothelial cell types. The baseline cell stiffness was nearly constant from passage 2 (p2) to p6; the contractile response to fetal bovine serum (1%) was constant from p2 to p4 but decreased appreciably in p5 and p6; the relaxing response to isoproterenol (100 uM)
were found the same between p2 and p3, but decreased in p4, p5 and p6. We also report the
dose response for contractile/relaxing agonists, including LPA, histamine, isoproterenol, and Y-
27632. Conclusion: Our measurements begin to define the mechanical phenotype of SC cells In
Vitro and could contribute to a better understanding of the cellular basis of glaucoma
pathogenesis.

Genetics, Berlin, Germany, 3Cologne Center for Genomics, University of Cologne, Cologne,
Germany, 4Cancer Research Centre, University of Liverpool, Liverpool, United Kingdom, 5Berlin-
Brandenburg Center for Regenerative Therapies, Berlin, Germany

Wrinkling of the skin and reduction in bone density are natural consequences of aging. Since
osteoporosis is a severe health problem impeding the life quality of an ever increasing number
of elderly people it is of utter importance to understand the intracellular and physiological aspects of
bone formation and maintenance. Gerodermia osteodysplastica (GO) is an autosomal recessive
disorder characterized by wrinkly skin due to elastic fibre defects and osteoporosis with increased
fracture rate. It is caused by loss-of-function mutations in GORAB (golgin, RAB-6 interacting),
which is most prominently expressed in skin and osteoblasts (Hennies HC et al, Nature Genetics
40, 2008). The protein GORAB localizes to the Golgi apparatus and has been shown to interact
with the small GTPase RAB6 (Ras-related in brain) by yeast 2-hybrid and In Vitro pulldown
assays. This identifies GORAB as a golgin. In further assays we found evidence for an interaction
with the small GTPase ADP-ribosylation factor 5 (ARF5), which is also Golgi localized.
Knockdown of neither RAB6 nor ARF5 causes GORAB to dissociate from the Golgi apparatus.
The interaction of RAB6 maps to the central part of GORAB and the in silico identification of a
GRIP-like domain in the C-terminus, known to relate interaction with ARF- like 1 (ARL1) or ARF1
(Panic B et al, Mol Cell. 12, 2003; Gillingham AK et al., J Cell Biol. 167, 2004), hint at an
intriguing mechanism of cooperative binding of these two small GTPases. Electron and
epifluorescence microscopy showed that acute knockdown of GORAB in HeLa cells causes a
mild disruption in the Golgi structure. While Golgi morphology in non-confluent cultured skin
fibroblasts from GO patients was not altered, the Golgi structure became disturbed when the cells
reached confluency. In this state, cells secrete high amounts of extracellular matrix and the
intracellular trafficking machinery is highly taxed. These findings show that disturbance of Golgi
function and intracellular trafficking can cause diseases with aberrations of the extracellular
matrix in skin and bone.

They Will Survive: Novel akt Mutants Have Extended Lifespan during Amino-Acid
Starvation.
J. D. Slade, B. E. Staveley; Biology, Memorial University of Newfoundland, St. John’s, NF,
Canada

The protein kinase akt, a central component of the insulin signalling pathway, has been
implicated in the control of cell growth and cell survival through a variety of mechanisms,
including the negative control of apoptotic targets. Up-regulation of akt leads to an increase in
growth, while reducing akt activity decreases growth, and can be lethal. Several Drosophila akt
mutant lines were created through the mobilization of a P-element located within the upstream
control region of the gene. Characterization of the mutants showed variability in development and
overall growth. The time required for the mutants to reach eclosion is delayed when compared to
tROLS. Consistent with previously analyzed hypomorphic alleles, analysis of both mutant eyes
and somatic clones of the eye reveal that altered akt activity leads to a reduction in cell number
and size. Interestingly, these mutants have a moderate decrease in lifespan when aged upon
standard media, yet they show an increase in lifespan upon amino-acid deprived media when compared to the control. Replacement of akt activity in the mutants is sufficient to suppress this extension in lifespan, indicating it is the reduction in akt activity which produces this phenotype. These experiments can lead to a better understanding of the mechanisms that control survival during conditions of starvation, which can aid in understanding the progression of diseases which affect feeding behaviours, such as anorexia and other eating disorders. Support contributed by an Natural Sciences and Engineering Research Council of Canada (NSERC) PGS-D3 to J.D. Slade and an NSERC Discovery Grant to B.E. Staveley.

Epigenetic Regulation of iPS Reprogramming in Premature Aging Mouse Model–Zmpste24 Deficient Mice.
J. Zhou, Z. Zhou; Biochemistry, The University of Hong Kong, Hong Kong, China
Zmpste24−/− mouse is a premature aging mouse model for human Hutchinson-Gilford progeria syndrome (HGPS). Zmpste24−/− MEFs and fibroblasts from HGPS patients are more sensitive to DNA-damaging agents and exhibit defective repair and delayed checkpoint response. HGPS cells and normal aged cells show decreased levels of H3K9 trimethylation and increased levels of H4K20 methylation. In addition, trimethylation of H3K27 is reduced in female HGPS cells. Our recent data indicates that acetylation of H4K16 is decreased in Zmpste24−/− MEFs. All these findings drove us to ask whether accelerated senescence could be a barrier to iPS reprogramming and whether the epigenetic changes observed in Zmpste24−/− MEFs could be reprogrammed. I utilized fibroblasts derived from Zmpste24−/− mice to carry out the iPS induction by introducing c-Myc, Klf4, Oct4 and Sox and found similar induction efficiency of reprogramming between Zmpste24−/− and wild-type MEFs. Furthermore, H4K16 acetylation in Zmpste24−/− MEFs derived IPS was found to be similar to wild-type MEFs derived iPS. These data provide an explanation for the similar efficiency between aging cells and wild-type cells and suggest that aging associated epigenetic changes can be reprogrammed during the iPS induction.

Tenascin C Protects Aortic Tissue from Multiple Insults against the Development of Aortic Aneurysm.
H. Aoki1,2, T. Kimura2,4, K. Yoshimura2, K. Imanaka-Yoshida3, T. Yoshida3, K. Aonuma4, M. Hiroe3, T. Imaizumi1, M. Matsuzaki2; 1Cardiovascular Research Institute, Kurume University, Kurume, Japan, 2Department of Molecular Cardiovascular Biology, Yamaguchi University School of Medicine, Ube, Japan, 3Department of Pathology and Matrix Biology, Mie University Graduated School of Medicine, Tsu, Japan, 4Division of Cardiovascular Medicine, University of Tsukuba, Tsukuba, Japan, 5Department of Nephrology and Cardiology, International Medical Center of Japan, Tokyo, Japan
Aortic aneurysm (AA) is a common disease in the elderly people, caused by a segmental weakening of the aortic walls, which leads to the progressive aortic dilation under hemodynamic stress and eventually causes sudden death by the rupture of aorta. Recently, we reported that c-Jun N-terminal kinase (JNK) works as an integrator of multiple insults on aortic walls and regulates tissue response toward the destruction. Little is known, however, about the protection mechanism of aortic tissue against the development of AA. Tenascin-C (TN-C) is a member of large oligomeric extracellular glycoprotein family that regulates the cell migration, inflammation and fibrotic changes and healing of the tissue. In the current study, we tested the hypothesis that TN-C protects aortic tissue from the development of AA. We found that TN-C is expressed in aortic walls where the tissue destruction is most active both in human AA and in mouse model of AA. Systemic infusion of angiotensin II (AngII) and infrarenal periaortic application of CaCl2, representative insults to induce AA in mice, induced systemic and local expression of TN-C, respectively, in aorta. Simultaneous application of systemic AngII and infrarenal CaCl2 enhanced the suprarenal expression of TN-C in aorta, suggesting this segment of aorta experiences greater stress upon the combined insults than a single insult. Strikingly, combined insults with AngII and CaCl2 caused the development of large aneurysm in the suprareal aorta that resembles the
human disease only in TN-C knockout mice, while single treatment either with AngII or CaCl2 showed comparable effect on wild type and TN-C knockout mice. Transcriptome analysis showed that TN-C suppresses the inflammatory mediators and elastolytic enzymes in vascular smooth muscle cells. Therefore, TN-C is an integrator of multiple tissue insults that protects the aortic walls from the development of AA.

Towards a Molecular Understanding of the Association of Desmin and Nebulin Filaments.
G. M. Conover1, S. Sharma2, H. Herrmann2; 1Veterinary Pathobiology, Texas A&M University, College Station, TX, 2Cell Biology, German Cancer Research Center, Heidelberg, Germany

Desminopathies constitute a newly identified myopathy manifesting a wide range of symptoms that are frequently present in cardiac sudden death. Over 45 mutations in desmin have been identified in humans as causative for desminopathy, characterized by dissolution of myofibrils, streaming Z-discs, and accumulation of protein aggregates. Desmin, the main intermediate filament (IF) protein in striated muscle, binds to nebulin establishing a direct link with the basic muscle contractile unit the sarcomere. Our studies aim to temporally elucidate the binding of desmin to nebulin during distinct stages of IF assembly. Our results show that multiple desmin domains bind to a high-affinity nebulin fragment encompassing modules 160-164 by blot overlay assays, but displayed no binding to keratins or lamins. Consistent with these findings, our in Vitro assembly and cosedimentation assays demonstrated that the nebulin fragment was pelleted with desmin headless and tailless truncation constructs but to a lesser extent than with rod domain, indicating that the rod domain is important for the interaction. Electron microscopy revealed that this nebulin fragment integrated into the mature desmin filaments. Analysis by cosedimentation assays of the binding of mutant desmin E245D to nebulin, a residue previously shown to interfere with the ability of nebulin to precisely regulate thin filament lengths, revealed a strong binding as compared to wild-type protein. Taken together, our data suggest that the binding site of nebulin for desmin is not a single, linear binding site but instead encompasses multiple residues, and that the E245D mutation appears to alter the in Vitro binding of nebulin for desmin filaments. We propose a working model to explain our data by which desmin wraps around the Z-disc and binds to nebulin with multiple residues, some of which are buried and exposed upon stretch during actinomyosin activation.

Host-Pathogen Interactions I (146 – 163)

146/B93
NS1 of H5N1 Interacts with SAP-97 in a PDZ-Dependent Manner to Disrupt Epithelial Barrier Integrity.
V. G. Conoley1, W. Zhang1, A. C. Boon2, C. D. Johns3, C. Li4, H. Penmatsa1, A. L. Kulkarni2, M. Zhang2, R. K. Rao3, R. J. Webby2, A. P. Naren1; 1Department of Physiology, University of Tennessee Health Science Center, Memphis, TN, 2Department of Infectious Diseases, St. Jude Children's Research Hospital, Memphis, TN, 3Department of Pathology and Laboratory Medicine, University of Tennessee Health Science Center, Memphis, TN, 4Department of Biochemistry and Molecular Biology, Wayne State University School of Medicine, Detroit, MI, 5Department of Biochemistry, The Hong Kong University of Science and Technology, Hong Kong, China

The ability of influenza a virus to cause global pandemics has been a great concern throughout history. Since the beginning of the H5N1 outbreak in 1996, there have been 436 reported human cases resulting in 262 deaths. The pathology of H5N1 infection includes pulmonary edema and diarrhea. Large scale sequencing of avian influenza a viruses revealed that nonstructural protein 1 (NS1) contains a class I PDZ motif. The NS1 proteins of influenza viruses of avian origin contain the PDZ motif ESEV which has been found to bind several PDZ domain proteins, while NS1 of human influenza viruses contain the PDZ motif RSKV that does not bind PDZ proteins. The interaction of NS1 and host proteins via the PDZ motif, is a determinate in the virulence of influenza viruses of avian origin. It is our hypothesis that the NS1 protein of H5N1 increases
pathogenicity by interacting with host proteins through the PDZ motif. We are the first to show that the NS1 protein of A/chicken/Vietnam/C58/04 binds synapse associated protein-97 (SAP-97), an adherens junction protein, in a PDZ motif-dependent manner. In H5N1 infected tissues, the SAP-97 distribution is reorganized as evidenced by fluorescent immunostaining. Functionally, the interaction of NS1 and SAP-97 results in the loss of epithelial barrier function as measured by calcium switch and inulin flux assays. Disease pathology of the tissues of mice infected with H5N1 is more severe when infected with virus in which the NS1 protein contains the PDZ motif than those infected with virus which lacks the NS1 PDZ motif. The interaction of NS1 and SAP-97 helps explain the mechanism of why the two disease states, pulmonary edema and diarrhea, in which epithelial barrier is compromised, are both common in human H5N1 infection.

Role of L-SIGN and DC-SIGN for Entry of Junin Arenavirus into Host Cells.
M. G. Martinez1, S. Belouzard2, N. Candurra1, G. Whittaker2; 1Biological Chemistry, FCEyN, University of Buenos Aires, Buenos Aires, Argentina, 2Microbiology and Immunology, College of Veterinary Medicine, Cornell University, Ithaca, NY

Target cell tropism of enveloped viruses is regulated by interactions between viral and cellular factors during its replication cycle. Binding of viral envelope glycoproteins to specific cell-surface receptors determines susceptibility to viral entry. The entry and dissemination of viruses in several families can be mediated by C-type lectins such as hDC-SIGN and hL-SIGN. DC-SIGN is expressed in dendritic cells and has been identified as a receptor for different enveloped viruses. We used JUNV GPC pseudotyped particles or JUNV to study their ability to be internalized by hDC- or hL-SIGN. Results from transduction with JUNV pseudovirus show that infection of relatively non-permissive CHO cells was markedly enhanced when we over expressed hDC or hL-SIGN. Experiments using non-permissive mouse 3T3 cells showed that they become susceptible to JUNV pseudovirus transduction when they stable express DC-SIGN, or its homologue hL-SIGN, and that transduction of 3T3 stable expressing hDC-or hL-SIGN is blocked by anti-hDC/hL-SIGN antibodies and mannan. In addition, transduction of permissive CRFK was also enhanced when they were stable expressing DC-SIGN. Immunofluorescence assays with JUNV showed that infection of Vero cells was significantly enhanced by the over expression of hDC-SIGN or hL-sign, whereas infection of non-permissive murine cell line, 3T3, can be rescued by the expression of hDC-or hL-SIGN. Mannan treatment considerably reduced infection, in immunofluorescence and PFU assays, of lectin expressing cell lines, whereas anti-hDC/hL-SIGN antibodies showed reduction of infection as seen by PFU assay. Therefore DC- and L-SIGN can act as a novel attachment factors that mediate entry of JUNV. However, a number of cell-surface molecules bind viral envelope glycoproteins without mediating entry. Instead, they serve as capture receptors that disseminate viral particles to susceptible cells. We also demonstrate that the human C type lectins hL-SIGN and hDC-SIGN enhances transduction by JUNV pseudovirus particles in cells devoid of the JUNV receptor, hTfR1, indicating that C-type lectins can mediate virus entry in the absence of the virus cellular receptor.

The HCV IRES Is a Potent Activator of PKR but Resistant to Eif2 Phosphorylation.
T. Shimoike1, S. A. Mckenna2, D. A. Lindhout2, Y. Okada3, J. D. Puglisi4; 1Virology II, National Institute of Infectious Diseases, Musashi-murayama, Japan, 2Chemistry, University of Manitoba, Winnipeg, MB, Canada, 3Safety Research on Blood and Biologics, National Institute of Infectious Diseases, Musashi-murayama, Japan, 4Structural Biology, Stanford University, Stanford, CA

Translation of hepatitis C virus (HCV) is initiated at an internal ribosome entry site (IRES) located at the 5’end of its RNA genome. The HCV IRES is highly structured and greater than 50% of its nucleotides form based-paired helices. We report here that the HCV IRES is an activator of PKR, an interferon-induced enzyme that participates in host cell defense against viral infection. Binding of HCV IRES RNA to PKR leads to a greatly increased (20-fold) rate and level (4.5-fold) of PKR autophosphorylation compared to previously studied dsRNA activators. We have mapped the domains in the IRES required for PKR activation to domains III-IV and demonstrate that the N-
terminal double-stranded RNA binding domains of PKR bind to the IRES in a similar manner to other RNA activators. Addition of HCV IRES RNA inhibits cap-dependent translation in HeLa S10 lysates via phosphorylation of PKR and elf2α. However, HCV IRES-mediated translation is not inhibited by the phosphorylation of PKR and elf2α. The results presented here suggest that hydrolysis of GTP by elf2 is not an essential step in IRES-mediated translation. Thus, HCV can use structured RNAs to its advantage in translation, while avoiding the deleterious effects of PKR activation.

*Regulation of HIV Protein Levels by Two Cellular Pathways Provides New Insight into Control of HIV Replication.*

G. Ambrus-Aikelin1, S. Naji1, E. Singer1, J. Reyes2, Q. Lin4, J. Johnson3, J. Yates3, A. Saphire2, W. Sundquist4, L. Gerace1; 1Cell Biology, The Scripps Research Institute, La Jolla, CA, 2Immunology and Microbial Sciences, The Scripps Research Institute, La Jolla, CA, 3Chemical Physiology, The Scripps Research Institute, La Jolla, CA, 4Biochemistry, University of Utah, Salt Lake City, UT

Human immunodeficiency virus (HIV)-1 Rev is essential in the late phase of viral gene expression and replication. It regulates nuclear export, translation and encapsidation of Rev-response element (RRE) containing HIV mRNAs. In a proteomic study we have recently identified 95 human proteins that selectively interact with Rev and the RRE in vitro. Based on a probable role in RNA trafficking and other functions, we have selected a group of 17 proteins for further study in RNAi experiments. Silencing eight of these proteins caused specific loss of Rev functions in a Rev dependent Gag expression reporter assay. We have selected three of these: the E3 ligase Huwe1 and the RNA binding proteins ILF2 and ILF3. We have shown that these proteins are required not only for Rev functions, but also for viral replication, as silencing these proteins resulted in a 10 to 20 fold drop in p24 protein levels in HIV transfected cell supernatants. Surprisingly, the loss of Rev functions in siRNA knockdowns of Huwe1 and ILF2/3 is a result of the loss of the Rev protein itself. In each of these cases cytoplasmic Rev mRNA remains intact, however, Rev loss occurs through two distinct pathways. A Rev mutant where the lysine residues are replaced by arginine can rescue Rev dependent Gag expression in Huwe1 silenced cells, but not in ILF2/3 silenced cells. This suggests that Huwe1 regulates Rev levels via a ubiquitin related mechanism, whereas ILF2/3 regulation of Rev follows a different route. The description of the molecular mechanisms of Rev regulation via the Huwe1 and ILF2/3 proteins offers important insight into HIV replication and might eventually open up novel therapeutic avenues.

*Streptococcal Collagen-Like Surface Protein 1 Promotes Adhesion to the Respiratory Epithelial Cell.*

P. Tsai1, S. Chen2, C. Wu3, L. Wu1, Y. Tsai4; 1Dep. Lab. Med. and Biotech., Med. College, NCKU, Tainan, Taiwan, 2Graduate Institute of Clinical Medical Sciences, Chang Gung University, Tao-Yuan, Taiwan, 3Department of Cell Biology and Anatomy, Med. College, NCKU, Tainan, Taiwan, 4Institute of Clinical Medicine, Med. College, NCKU, Tainan, Taiwan

Collagen-like surface proteins Scl1 and Scl2 on Streptococcus pyogenes contain contiguous Gly-X-X triplet amino acid motifs, the characteristic of human collagen structure. The potential role of Scl1 in adhesion has been studied but yielded conflicting results. To explore the role of Scl1 in adherence to epithelial cells, we constructed a non-polar scl1 isogenic mutant from Scl2-defective S. pyogenes strain and a Scl1-expressed Escherichia coli. The loss of Scl1 resulted in a three-fold decrease in binding to human epithelial cells, HEP-2. Expression of Scl1 on the surface of a heterologous host E. coli significantly increased adhesion to HEP-2. Adhesion was abrogated when Scl1-expressed E. coli was pre-incubated with proteases or antibodies against recombinant Scl1 (rScl1) protein. Treatment of HEP-2 cells with rScl1 protein or pronase drastically reduced the binding capability of Scl1-expressed E. coli. These suggest that the adhesion is mediated through Scl1 on bacterial surface and protein receptor(s) on epithelial cells. However, blocking of potential integrins did not affect Scl1-mediated adhesion of bacteria to epithelial cells. Together, these
results underscore the importance of Scl1 in the virulence of S. pyogenes and imply that Scl1 may act as an adhesin during pathogenesis of streptococcal infection.

Er Stress-Induced Conversion of Brucella-Replicative Organelles into Late Endosomal Vacuoles.

T. Starr, J. Celli; Laboratory of Intracellular Parasites, RML/NIAID/NIH, Hamilton, MT

Following uptake by phagocytes or entry into non-phagocytic cells, the intracellular pathogen Brucella abortus resides within a membrane-bound compartment, the Brucella-containing vacuole (BCV). The maturation of the BCV requires the Type IV secretion system VirB as a means of establishing a replicative niche in the endoplasmic reticulum (ER). During maturation the intermediate BCV traffic along the endocytic pathway and interacts with lysosomes, a process required to induce VirB functions and promote trafficking towards the ER. Although these stages of the intracellular cycle have been well characterized, little is known about post-replication events and how bacterial egress may occur. Here we show that at late times post-infection (2-3 days) in both primary macrophages and HeLa cells, Brucella infection induced ER stress via the Unfolded Protein Response (UPR). Concomitantly, BCVs re-acquired LAMP-1 positive endosomal membranes, suggesting a reassociation with the endocytic pathway, but did not display the autophagy marker MAP-LC3. Instead, this relocation was enhanced in either Atg5 -/- macrophages or HeLa cells treated with siRNA directed against both Atg5 and MAP-LC3, suggesting that Atg5 and LC3-dependent stages of autophagy interfere with the formation of these vacuoles. Characterization of the trafficking kinetics and identification of the host factors involved in Brucella survival late in infection will allow us to not only further characterize the pathway used by the bacteria to subvert normal host defense, but also understand the bacteria’s ability to egress, reinfect neighboring cells, and ultimately establish a chronic infection.

FipA Is a Francisella tularensis Surface Protein Required for Intracellular Replication and Survival in Murine Macrophages.

A. Chong1, T. D. Wehrly1, R. Child1, B. Hansen2, J. Celli1; 1Laboratory of Intracellular Parasites, Rocky Mountain Laboratories, NIAID, NIH, Hamilton, MT, 2Electron Microscopy Unit, Research Technologies Section, Rocky Mountain Laboratories, NIAID, NIH, Hamilton, MT

Francisella tularensis is a faculative intracellular pathogen that causes tularemia, a zoonotic disease with potentially lethal consequences in humans. The ability of F. tularensis to reside within host phagocytes is essential to the bacterium’s pathogenesis. Following phagocytosis, F. tularensis rapidly escapes its original phagosome into the host cytosol where it replicates extensively. Transcriptional profiling of the highly virulent F. tularensis subsp. tularensis strain Schu S4 at different stages of its intracellular cycle in murine bone-marrow derived macrophages (BMMs) revealed novel upregulated genetic determinants required for intracellular growth in macrophages and virulence in mice (Wehrly et al., 2009, Cell. Micro., 11(7):1128). One of these determinants, FipA (for Francisella lipoprotein A; FTT1676), encodes for a 330 amino acid with a putative lipoprotein signal sequence. Deletion of FipA in Schu S4 delayed phagosome disruption. ΔFipA mutant bacteria were replication deficient even after eventual escape into the host cytosol. Ultimately, a portion of the bacteria were found in membrane bound compartments labeled with the late endosomal marker LAMP1 and the autophagosomal membrane protein LC3, indicative of killing by an autophagy mediated mechanism. Immunofluorescence microscopy, surface protein biotinylation, and cell fractionation studies show that FipA localizes to the surface of Schu S4 during macrophage infection. Exposure on the bacterial surface situates FipA where it could potentially interact with the macrophage cytosolic compartment to impact the intracellular fate of F. tularensis.

A Family of Salmonella Virulence Factors Functions as a Novel Class of Autoregulated E3 Ubiquitin Ligases.
Salmonella encodes at least two Type III Secretions systems, which function to deliver bacterial effector proteins into the cytosol of host cells. These effector molecules modulate the activities of several host signaling pathways leading to virulent infection. Here we show that the Salmonella effector protein SspH2 belongs to a growing class of bacterial effector proteins that harness and subvert the eukaryotic ubiquitination pathway. SspH2 possesses ubiquitination activity that is dependent on a conserved cysteine residue. A crystal structure of SspH2 reveals a canonical leucine rich repeat (LRR) domain that interacts with a unique E3 ligase (which we have termed NEL for Novel E3 Ligase) C-terminal fold distinct to that of previously observed HECT or RING-finger E3 ligases. Interestingly, the LRR domain partially occludes the catalytic cysteine residue contained in the NEL domain, and our data suggests that a substantial conformational change is required for optimal E3 ligase activity. In addition, we show that the N-terminal domain targets SspH2 to the plasma membrane of polarized epithelial cells, and propose a model whereby binding of the LRR to proteins at the target site releases the ligase domain for site-specific function.

154/B101 Subtilase Cytotoxin Cleaves Newly Synthesized Bip and Blocks Antibody Secretion in B Lymphocytes.
C. A. Hu1, S. K. Dougan1, S. Virreira Winter1, A. W. Paton2, J. Paton2, H. L. Ploegh1; 1Whitehead Institute for Biomedical Research, Cambridge, MA, 2Research Centre for Infectious Diseases, School of Molecular and Biomedical Science, University of Adelaide, Adelaide, SA, Australia

Shiga-toxigenic Escherichia coli (STEC) uses subtilase cytotoxin (SubAB) to interfere with adaptive immunity. Its inhibition of immunoglobulin secretion is both rapid and profound. SubAB favors cleavage of the newly synthesized immunoglobulin heavy chain-binding protein (BiP) to yield a C-terminal fragment that contains BiP’s substrate binding domain. In the absence of its regulatory nucleotide binding domain, the SubAB-cleaved C-terminal BiP fragment remains tightly bound to newly synthesized immunoglobulin light chains, resulting in retention of light chains in the endoplasmic reticulum (ER). Immunoglobulins are thus detained in the ER, making impossible the secretion of antibodies by SubAB-treated B cells. The inhibitory effect of SubAB is highly specific for antibody secretion, because other secretory proteins such as IL-6 are released normally from SubAB-treated B cells. Although SubAB also causes BiP cleavage in HepG2 hepatoma cells, (glyco)protein secretion continues unabated in SubAB-exposed HepG2 cells. This specific block in antibody secretion is a novel means of immune evasion for STEC. The differential cleavage of newly synthesized versus ‘aged’ BiP by SubAB in the ER provides insight into the architecture of the ER compartments involved.

155/B102 Essential and Selective Interaction of the Chlamydial Inclusion with the Transferrin Recycling Pathway.
S. P. Ouellette, R. Carabeo; Centre for Molecular Microbiology and Infection, Imperial College London, London, United Kingdom

Chlamydia is an obligate intracellular pathogen that resides within a parasite-defined vacuole termed an inclusion. The inclusion has selective interactions with host vesicular transport pathways, but the significance of these observations remains unclear. For example, a prominent feature of the chlamydial inclusion is its proximity to transferrin (Tf)-containing vesicles and the recycling endosomal markers Rab4 and Rab11, but there are no data demonstrating the essentiality of these interactions. We demonstrate that the Tf-containing vesicles surrounding the chlamydial inclusion are of the slow pathway of Tf recycling. Inhibitors known to arrest or delay this arm of Tf recycling were found to be potent inhibitors of chlamydial growth. In addition, quantitative analysis of Tf transport revealed that the inhibitors prevented the transport of Tf from
Rab11 vesicles to the Rab4/Rab11 intermediate compartment. This observation implied a requirement for the hybrid compartment in chlamydial growth. Indeed the apparent requirement for the Rab4/11 hybrid vesicle was confirmed by the observed partial growth inhibition of chlamydiae in cells co-expressing the dominant negative forms of Rab4 and Rab11. This report is the first demonstration of the biological relevance of and specific interactions with the TF recycling pathway by the inclusion. Findings provide insight into possible non-siderophore dependent mechanism of iron acquisition by this intracellular pathogen.

A Novel Method to Track the Dynamic Interplay between Bacterial and Host Factors during Pathogen-Induced Vacuolar Rupture in Real Time by Fluorescence Microscopy.
A. Bobard, K. Ray, G. Tran Van Nhu, J. Enninga; BCI, Institut Pasteur, Paris, France

A common feature of the infection of eukaryotic cells by pathogens is their capacity to hijack host cellular processes. Gram-negative bacteria such as Shigella flexneri and Salmonella enterica are able to trigger their own entry via the needle-like type three secretion system. The formation of a bacteria containing endocytic vacuole within the cytosol of host cell is the subsequent and common step for both pathogens after internalization. Shigella escapes very quickly from this niche to reach the cytosol within minutes, however Salmonella remains multiple hours inside the vacuole forming filamentous structures called "sifs". In order to decipher molecular events involved in the rapid rupture of Shigella’s vacuole, we developed a novel approach based on fluorescence microscopy allowing us to follow the escape of Gram-negative pathogens from a vacuolar compartment into the cytosol with very accurate spatial and temporal resolution. Using small chemical inhibitors that interfere with host cellular processes, we show that the dynamics of vacuolar rupture by Shigella can be modified. This indicates the involvement of the host cell in this process. Concerning this, it is also of note that no bacterial factor has been identified to be directly involved in the rupture of the vacuole. Performing high-content/high-throughput approaches we are now delineating the precise molecular mechanisms exploited by Shigella to escape into the host cellular cytoplasm. Moreover, this will help finding new therapeutic target in order to develop drugs against pathogens infection.

Limited Actin Proteolysis Mediates Invasion of Bacteria Serratia sp. in Eukaryotic Cells.
E. S. Bozhokina¹, O. A. Tsapлина¹, I. V. Demidyuk², S. V. Kostrov², L. V. Kever³, Y. Y. Komissarchik³, T. N. Efremova¹, S. Khaitina¹; ¹Department of Cell Cultures, Institute of Cytology, Russian Academy of Sciences, St.Petersburg, Russia, ²Department of Molecular Basis for Biotechnology and Protein Engineering, Institute of Molecular Genetics, Russian Academy of Sciences, Moscow, Russia, ³Group of Ultrastructure of Cell Membranes, Institute of Cytology, Russian Academy of Sciences, St. Petersburg, Russia

Virulence of bacterial pathogens depends on their ability to attach and invade the host cell. Penetration of bacteria into eukaryotic cell is based on the interaction of bacterial factors with cytoskeleton and signaling system of the host. Earlier we have shown that synthesis of bacterial protease ECP32/grimelysin displaying specific activity towards actin correlates with the invasive activity of the host bacteria. Grimelysin from Serratia grimesii has been shown to be highly homologous to proteolysin from Serratia proteamaculans that differs from grimelysin by only 8 amino acid substitutions. In this work, we describe limited proteolysis of actin with proteolysin and invasive properties of the host bacteria S. grimesii DZMO 30063 and S. proteamaculans 94. Furthermore, taking into account that actin may be a natural substrate for these proteases, we address the question of a direct involvement of actin-specific proteases grimelysin and proteolysin in the process of bacterial invasion. To determine the role of grimelysin and proteolysin in capability of the bacteria to invade eukaryotic cells, human larynx carcinoma Hep-2 cells were incubated with recombinant bacteria E. coli K-12 and E. coli BL21DE3, expressing grimelysin and proteolysin genes, respectively. The cells were analyzed by confocal and electron microscopy. The noninvasive bacteria strains E. coli K-12 and E. coli BL21DE3 bearing plasmids without inserts of grimelysin or proteolysin gene were used as a control. Incubation of both
recombinant bacteria strains with Hep-2 cells affected confluence of the cells monolayer, the cells altered the shape, their membranes had numerous actin containing protrusions. The bacteria were found in cytoplasm of approximately 10% of cells. EM confirmed the presence of bacteria in cytoplasm, often located in vacuoles. In contrast, the control bacteria were not found in cytoplasm. The recombinant bacteria were further subjected to quantitative invasion analysis. In summary, expression of grimelesin or proteasins genes leads to appearance of invasive phenotype of normally noninvasive bacteria strains suggesting an active role of these proteases and limited actin proteolysis in the *Serratia* invasion.

**Specific Innate Immunity: The Itam-Containing Ceacam3 Is a Molecular Mimic That Elicits Opsonin-Independent Activation of Neutrophil Bactericidal Responses against Neisseria gonorrhoeae.**

H. Sarantis¹, M. P. Amin¹, C. Chan², C. P. Stanners², S. D. Gray-Owen¹; ¹Molecular Genetics, University of Toronto, Toronto, ON, Canada, ²Biochemistry, McGill University, Montreal, QC, Canada

Infection with *Neisseria gonorrhoeae* promotes a massive infiltration of polymorphonuclear neutrophils (PMNs) to the infected urogenital tract. The gonococci interact directly with these bactericidal leukocytes in an opsonin-independent manner, via interactions between bacterial Opa proteins and members of the human carcinoembryonic antigen related-cellular adhesion molecule (CEACAM) family. While PMNs from wild-type mice do not bind or engulf *N. gonorrhoeae*, PMNs from transgenic mice expressing human CEACAMs effectively bind, engulf, and mount a bactericidal oxidative burst and degranulation response. Using a transfection-based approach, we show that all Opa-binding CEACAMs of PMNs (CEACAM1, CEACAM3 and CEACAM6) allow PMN capture and engulfment of *N. gonorrhoeae*. However, only the immunoreceptor tyrosine-based activation motif (ITAM)-containing CEACAM3 elicits the neutrophil’s degranulation and oxidative burst responses. Bacterial binding to CEACAM3-triggers the phosphorylation of Syk tyrosine kinase and its downstream effector, Vav, which is a guanine exchange factor for Rho family GTPases. Since Vav has been implicated in a variety of neutrophil functions, we bred CEACAM transgenic mice with those lacking the Rac isoforms of neutrophils, Rac1 or Rac2, to discern the contribution of these proteins in the CEACAM3-dependent responses. Unexpectedly, we show that genetic ablation of either Rac1 or Rac2 in PMNs is not sufficient to abolish CEACAM3-dependent phagocytosis, oxidative burst or degranulation, suggesting either a redundancy in function or the involvement of another GTPase. We also show that CEABAC neutrophils, but not neutrophils from wild-type littermates, can produce the proinflammatory chemokines MIP-1 and MIP-2 in response to neisserial infection, providing an avenue for the rapidly progressing inflammation during gonorrhea. Consistent with this finding, a substantial defect in neutrophil influx is evident in CEACAM3-expressing mice exposed to *N. gonorrhoeae* in the absence of Rac. Together, these results define CEACAM3 as a molecular mimic of intercellular adhesion molecules commonly targeted by bacterial pathogens, allowing induction of a potent specific innate immune response by neutrophils.

159/B106
**The Rickettsia Outer Membrane Protein Sca2 Is an Actin Nucleator.**

C. M. Haglund, M. D. Welch; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Many species of the bacterial genus *Rickettsia* utilize actin-based motility to move within and between infected host cells. *Rickettsia* actin tails contain long, unbranched actin filaments, in contrast to the short, branched networks generated by other intracellular pathogens. The current model of *Rickettsia* motility, in which the rickettsial protein RickA activates the host Arp2/3 complex, does not account for the unique ultrastructure of *Rickettsia* actin tails, the absence of RickA from the genome of the motile species *Rickettsia typhi*, or conflicting evidence regarding the localization of Arp3. These data suggest that additional motility factors remain to be defined. We searched *Rickettsia* genome databases for sequences with similarity to the well-characterized...
WH2 actin-binding motif and identified three such motifs in the outer-membrane protein Sca2 (surface cell antigen 2), which is present in all known motile *Rickettsia* species. Using In Vitro pyrene-actin polymerization assays, we show that the WH2-like part of Sca2 from *Rickettsia parkeri* binds actin monomers and inhibits actin filament assembly. Expressed separately, the N-terminal part of Sca2 promotes actin polymerization in vitro, binds filament barbed ends, and has distant sequence similarity to the formin family of actin nucleators. Expressed together, these two parts of Sca2 modulate actin filament dynamics, inhibiting assembly at lower Sca2 concentrations and promoting assembly at higher concentrations. Immunofluorescence microscopy reveals that Sca2, unlike RickA, is abundant on the surface of *R. parkeri* and is enriched at the actin-associated pole. These results suggest that multiple activities of Sca2 - monomer binding, filament nucleation, and protection of barbed ends - contribute to the formation of *Rickettsia* actin tails. We propose a new model in which Sca2, independently of RickA and the Arp2/3 complex, nucleates actin filaments and enables filament elongation during *Rickettsia* actin-based motility.

*Alternaria alternata* Induces Ca$^{2+}$ Signaling and Cytokine and Growth Factor Release from Human Airway Epithelial Cells via the Protease Activated Receptor 2.

S. Boitano$^{1,2,3}$, R. Campbell$^{2,3}$, S. Schulz$^{1,2,3}$, C. L. Sherwood$^{2,3}$, M. J. Halonen$^{4,2,3}$, 1Physiology, Arizona Health Sciences Center, Tucson, AZ, 2Arizona Respiratory Center, Arizona Health Sciences Center, Tucson, AZ, 3Bio5 Collaborative Research Institute, Arizona Health Sciences Center, Edinburgh, United Kingdom, 4Immunobiology, Arizona Health Sciences Center, Tucson, AZ, 5Medical Pharmacology, Arizona Health Sciences Center, Tucson, AZ, 6Cell Biology and Anatomy, Arizona Health Sciences Center, Tucson, AZ

From examination of the environmental exposures most closely tied to childhood asthma worldwide (housedust mite, fungi, cockroaches, and pet-related constituents), a concept is developing that these disparate entities with myriad different constituents do have a few commonalities, including the production of proteases with trypsin-like function. In this report we examine *A. alternata* filtrates and their ability to activate human bronchial airway epithelial cells (16HBE14o-) as measured by Ca$^{2+}$ signaling and proinflammatory cytokine and growth factor release. We show that *A.alternata* filtrates induce transient Ca$^{2+}$ changes consistent with activation of Ca$^{2+}$ release from intracellular stores. These Ca$^{2+}$ transients are blocked by heat inactivation, protease inhibitor cocktails and a serine-specific protease inhibitor (AEBSF) pretreatment of *A. alternata*. To more closely evaluate receptors involved in *A.alternata*-driven activation, we have developed a HeLa cell line that stably expresses the protease activated receptor 2 (PAR-2) protein. *A. alternata* filtrates produce Ca$^{2+}$ transients in PAR-2 transfected cells, whereas they are ineffective on untransfected HeLa cells. To better evaluate physiological responses to *A. alternata*, we repeated stimulation of 16HBE14o- and monitored cytokine and growth factor secretion. *A. alternata* filtrate stimulation of 16HBE14o- cells induced increased proinflammatory cytokine release (IL1$\alpha$, IL6, IL8, and TNFa) and growth factor release (GMCSF, GCSF, VEGF and FGF) within 3 hours. To better examine the role of PAR-2 in these responses, we used the PAR-2 peptide agonist, SLIGRL to activate the 16HBE14o- cells and noted a similar proinflammatory cytokine release pattern by 3 hours of incubation, however, only GMCSF and GCSF displayed significant increases among the growth factors. These data support the hypothesis that *A. alternata* proteases induce rapid increases in human airway epithelial intracellular Ca$^{2+}$ concentration and proinflammatory cytokine release that occurs in part via PAR-2 and that these responses may be critical early steps in the development of asthma.

A Novel Mechanism for Generation of Antibodies against a Xeno-Auto-Antigen Involving Bacterial Scavenging and Expression of a Dietary Glycan.

R. E. Taylor$^{1}$, C. Gregg$^{1}$, V. Padler-Karavani$^{1}$, H. Yu$^{2}$, R. U. Sorensen$^{5}$, X. Chen$^{2}$, J. Inostroza$^{3}$, V. Nizet$^{4}$, A. Varki$^{1}$, 1Glycobiology Research and Training Center and Departments of Medicine and Cell and Molecular Medicine, University of California, San Diego, La Jolla, CA, 2Department of Chemistry, University of California, Davis, Davis, CA, 3Department of Basic Sciences, Medical School of University of La Frontera, Santiago, Chile, 4Glycobiology Research and Training
All humans have circulating antibodies against N-glycoly neuraminic acid (Neu5Gc), a sialic acid that cannot be synthesized by humans. Red meat and milk contain large amounts of Neu5Gc that, when ingested, can be metabolically incorporated into human tissues, especially carcinomas. Thus, the potential exists for circulating anti-Neu5Gc antibodies to react against endogenous Neu5Gc, which we call a "xeno-auto-antigen", as it is a foreign antigen that can become immunoreactive self. Indeed, we have recently demonstrated that anti-Neu5Gc antibodies contribute to chronic inflammation in the promotion of tumor progression. Here we show that anti-Neu5Gc antibodies appear in infants at 6-12 months of age and that their timing of appearance correlates with the introduction of Neu5Gc in the diet. The timing of the appearance of anti-Neu5Gc antibodies also appears coincident with antibodies against Nontypeable Haemophilus influenzae (NTHi), an obligate human commensal and pathogen that is a major cause of otitis media in infants and children. NTHi has been shown by others to scavenge N-acetylneuraminic acid (Neu5Ac), a sialic acid synthesized by humans, in order to mask it’s lipooligosaccharide (LOS) glycans and evade host immune attack. We show that, in addition to Neu5Ac, NTHi can also scavenge exogenously administered free Neu5Gc in vitro and express it on it’s LOS. Furthermore, we demonstrate that Neu5Gc-deficient mice infected with NTHi expressing Neu5Gc generate anti-Neu5Gc antibodies. Finally, purified human anti-Neu5Gc antibodies specifically recognize Neu5Gc expressing NTHi but not Neu5Ac-expressing or nonsialylated NTHi. Based on our findings we propose a novel model for the generation of human anti-Neu5Gc antibodies in which dietary Neu5Gc is taken up and expressed by colonizing bacteria, which provide the immunogenic stimulus required to produce antibodies against Neu5Gc.

162/B109

Antibody-Mediated Immune Responses against Crude Schizont Extract Are Comparable to Responses of AMA-1, GLURP, MSP1-19, and MSP3.

A. R. Aikins¹, H. Lamptey², M. Ofori², K. A. Kusi², Y. D. Osei¹, E. Remarque³, M. Theisen⁴, D. Dodoo²; ¹Biochemistry, University of Ghana, Accra, Ghana, ²Noguchi Memorial Institute for Medical Research, University of Ghana, Accra, Ghana, ³Parasitology, Biomedical Primate Research Centre, Lange Kleiweg, Netherlands, ⁴Infectious Diseases Immunology, State Serum Institute, Copenhagen, Denmark

Many blood-stage malaria vaccine candidate antigens have been identified and it is likely that a malaria vaccine candidate will consist of more than one candidate antigen. The objective of the study was to assess the immune responses to the crude schizont extract which contains many antigens, in relation to some blood-stage vaccine candidate antigens which are AMA-1, GLURP, MSP1-19 and MSP3. Plasma samples were obtained from a cohort of 352 children, aged, 3 to 10 years, in Ghana at the beginning of a nine-month morbidity surveillance which coincided with the beginning of the malaria transmission season. Crude schizont extract was prepared by continuously culturing the malaria parasites and harvesting the schizont-rich RBCs using the magnetic-activated cell sorting system and lysing the schizont-rich RBCs to release the parasite antigens into solution. The supernatant of the suspension contained the crude schizont extract. IgG and IgM responses against the crude schizont extract and the recombinant antigens were measured by indirect ELISA. The proportion of the participants that had asymptomatic parasitemia was fairly constant throughout the surveillance (50-65%), while the incidence of malaria rose from March, peaking in July and then with a general decline through November. The proportion of IgM and IgG responders to the four recombinant antigens and the crude schizont extract ranged from 30%-95% with that of schizont extract being 83% and 87% respectively. Antibody levels increased with age and protection with the median age for susceptible children (5 years) being significantly lower than that for protected children (8 years) (p=0.001). After adjusting for the confounding effect of age, the data showed a significant association between age and IgM and IgG responses to all the antigens tested with p-values between 0.002 and 0.03.
In conclusion, immune responses against the crude schizont extract which contains numerous antigens presented by the schizont at the blood-stage was comparable to AMA-1, GLURP, MSP1-19 and MSP3, and further studies must be done to confirm its correlation with protection.

163/B110
A Novel Erythrocyte Targeted Parasite Protein Is Important for the Survival of Plasmodium Falciparum.
S. Kumar; Cell Biology, The Scripps Research Institute, La Jolla, CA

Plasmodium falciparum cause the most severe malaria called cerebral malaria, which accounts for more than 1.5 million deaths annually. In humans the malaria related clinical symptoms arises due to the erythrocytic cycle where the parasite resides in the parasitophorous vacuole inside the red blood cells. During the progression of the erythrocytic cycle the parasite extensively modifies the infected RBC (iRBC) by recruiting ~ 400 proteins in the iRBC cytoplasm and surface. Apart from few characterized exported proteins, majority of them are of unknown functions, and lack homology with any known proteins. Mature RBC completely lacks the transport pathway so to facilitate export of the proteins and nutrients the parasite develops extensive membranous structures in the iRBC cytoplasm spanning form the parasite confines to the RBC membrane called as Maurer’s clefts and Tubo-vesicular network (TVN). So far, no consensus motif has been found in the Plasmodium secretome and the mechanism of transport is very poorly known. In the present work we have identified a novel conserved membrane protein, PFI0160w previously known as hypothetical protein, which is expressed at early trophozoite stage and reaches its maxima in the schizont stage. By indirect immunofluorescence microscopy, electron microscopy and biochemical assays we have shown that this protein is exported from the parasite and localizes in the Maurer’s clefts before reaching to the iRBC surface. We have named it as “Parasite exported conserved membrane protein” (PEMP). The antibody against PEMP strongly inhibits the parasite growth with IC50 value of 40 μg/ml. The export of the protein is sensitive to brefeldin a (BFA) suggesting that it is exported following the classical secretory pathway. Our data projects PEMP as a potential drug as well as vaccine candidate against the deadly malaria pathogen.

Cell Biology of the Immune System I (164 – 174)

FRET Reporters for Imaging MMP12 Activity as a Marker for Lung Inflammation.
C. Schultz1,2, A. Cobos-Correa1,2, M. Mai1,2; 1Cell Biology & Biophysics Unit, EMBL, Heidelberg, Germany, 2Molecular Medicine Partnership Unit, EMBL & Univ. Heidelberg, Heidelberg, Germany, 3Pediatric Pulmonary and Cystic Fibrosis Center, University of Heidelberg, Heidelberg, Germany

Chronic obstructive pulmonary disease (COPD) is accompanied by destruction of the extracellular matrix of alveolar airspaces of the lung and emphysema. It is believed that the destructive cause is an imbalance between proteases and antiproteases induced by an up-regulation of enzymes such as elastases and collagenases. A prime candidate is macrophage elastase also called matrix metalloprotease 12. Here we introduce a series of FRET-based peptide reporters for monitoring macrophage secreted MMP12 activity in lavage fluids from mice as well as on the surface of cells isolated form these lavages. To address the localization of the active enzyme on the cell surface, we prepared lipidated FRET-based reporters that reside on the plasma membrane. The synthesis of the peptidic backbone, the attachment of the fluorophores and the lipidation was achieved on a solid phase support. The lavage reporter LaRee1 inserted spontaneously into the plasma membrane of RAW macrophages and cells from lung lavages. Upon enzymatic cleavage, the acceptor was released but the lipidated donor fragment was sufficiently lipophilic to be internalized by endocytosis. The latter produced a memory signal that permitted us to identify activated macrophages in lung lavages of mice instilled with particulate matter, i.e. A model of acute pulmonary inflammation. The reporters are therefore useful to detect
MMP12 activity in pulmonary inflammation and may thus be useful to evaluate for emphysema formation at an early stage, thus providing important information for the diagnosis of lung diseases. In addition, we could demonstrate that secreted MMP12 activity resides exclusively on the surface of macrophages while MMP12 released into the supernatant or the lung lumen remained in the inactive pro-form. This implies that MMP12-induced damage to the extracellular matrix requires direct contact of macrophages which makes the mobility of these cells a prime target for a potential treatment for COPD.

Overexpression of HO-1 Protects against TNF-α-Mediated Airway Inflammation by Down-Regulation of TNFR1-Dependent Oxidative Stress.
I. Lee, C. Yang; Graduate Institute of Basic Medical Science, Chang-Gung University, Tao-Yuan, Taiwan

Oxidative stresses are considered to play an important role in the induction of cell adhesion molecules and proinflammatory cytokines, a key event in inflammatory processes. Heme oxygenase-1 (HO-1) exerts as an antioxidant which protects against tissue injury. Here, we report that HO-1 was induced in cultured human tracheal smooth muscle cells (HTSMCs) by treatment with a potent inducer of HO-1 activity, cobalt protoporphyrin IX (CoPP IX), or infection with a recombinant adenovirus carrying the human HO-1 gene. Overexpression of HO-1 protected against TNF-α-mediated airway inflammation by down-regulation of oxidative stress, adhesion molecules, and IL-6 in HTSMCs and the airways of mice. HO-1 overexpression inhibited TNF-α-induced ICAM-1 and VCAM-1 expression, THP-1 cells adherence, IL-6 generation, p47phox translocation, and NF-κB activation. HO-1 overexpression also attenuated TNF-α-induced oxidative stress, which was abrogated in the presence of the HO-1 inhibitor, zinc protoporphyrin IX (ZnPP IX) and CO scavenger. In addition, HO-1 overexpression reduced the formation of a TNFRI/c-Src/p47phox complex. These results suggested that HO-1 functions as a suppressor of TNF-α signaling, not only by inhibiting adhesion molecules expression and IL-6 generation but also by diminishing intracellular ROS production and NF-κB activation in HTSMCs and the airways of mice.

Amelioration of Asthmatic Inflammation by an Aqueous Extract of Spinacia Oleracea Linn.
J. Heo, M. Son, C. Park, H. Lee, S. Lee; Food Enzyme Bio-Technology, Kyung Pook National University, Daegu, Korea, South

Inflammation of the respiratory tract is a crucial process in immune diseases, including asthma, and atopic rhinitis. To establish whether an aqueous extract of Spinacia oleracea Linn (SoL) has a beneficial influence in terms of anti-asthmatic activity, we examined its effects on an ovalbumin-induced asthmatic model. Mice sensitized to ovalbumin were orally administered the SoL extract, and their lungs examined by Haematoxylin-Eosin staining to determine IL-4/13 cytokine expression. The SoL extract exerted strong anti-asthmatic effects by inducing a decrease in the CD4+ cell number, IL-4/13, and other molecular markers in the lung. Our results collectively indicate that the aqueous SoL extract ameliorates asthmatic symptoms effectively in a mouse ovalbumin-challenge model.

Caveolin-1 Regulates Monocytes Recruitment in Fibrotic Lung Disease.
E. Tourkina1, M. Richard1, J. Oates1, A. Hofbauer1, M. Bonner1, R. P. Visconti2, J. Zhang2, R. M. Silver1, S. Hoffman1,2; 1Medicine, Rheumatology, Medical University of SC, Charleston, SC, 2Cell Biology and Anatomy, Medical University of SC, Charleston, SC

The reduced caveolin-1 level in scleroderma lung fibroblasts and the lungs of bleomycin-treated mice promotes collagen overexpression and lung fibrosis. We now evaluate whether caveolin-1 is also deficient in monocytes from bleomycin-treated mice and scleroderma patients and examine the consequences of this deficiency and its reversal. Mice or cells received the CSD (caveolin-
1scaffolding domain) peptide to reverse the pathological effects of reduced caveolin-1 expression. In bleomycin-treated mice, caveolin-1 expression was reduced and CXCR4 expression was increased in circulating monocytes. Systemic treatment with the CSD peptide reversed these effects as well as the accumulation of monocytes in lung tissue. To validate our results in human disease, we examined caveolin-1 and CXCR4 expression in circulating monocytes and lung tissue from scleroderma patients. We found that scleroderma monocytes contain less caveolin-1 and significantly more CXCR4 than their normal counterparts and that there is a massive increase in CXCR4 in the tissue of scleroderma patients with lung involvement. We also determined the molecular mechanisms regulating CXCR4 and caveolin-1 expression in scleroderma monocytes. The overexpression of CXCR4 in scleroderma monocytes is due to the low level of caveolin-1 in these cells as evidenced by the fact that CSD peptide treatment of scleroderma monocytes inhibits CXCR4 expression. The pro-inflammatory cytokine TNFα and the pro-fibrotic cytokine TGF-β cause normal monocytes to adopt the scleroderma phenotype: low caveolin-1 and high CXCR4. In summary, exposure of monocytes to TNFα and TGFβ reduces their caveolin-1 expression; in turn, reduced caveolin-1 expression upregulates CXCR4 expression. These results support the idea that using the CSD peptide to compensate for low caveolin-1 levels in scleroderma monocytes may be a useful treatment for scleroderma because this treatment will inhibit CXCR4 expression and thereby inhibit the accumulation of monocytes and monocyte-derived cells in injured lung tissue.

Amelioration of Airway Inflammation via the Blockade of Lymphotoxin Signaling.
H. Lee, E. Lee, H. Kang; School of Biological Sciences and Technology, Chonnam National University, Gwangju, Korea, South

Lymphotoxin (LT) has been known to be essential for IgE production, and a physiological role of IgE in the airway may consist of maintaining the balance of Th1 and Th2 responses to prevent aberrant inflammation. To investigate whether LT signaling involved in airway inflammation, anti-inflammatory reactions were examined by administration of LTbR-Ig from OVA (ovalbumin)/Alum (aluminium hydroxide) and HDM (house dust mite)-treated mice. The blockade of LT signaling by administration of LTb receptor (R)-Ig induced the reduction of the infiltration of inflammatory cells to airway. IgE levels in serum and bronchoalveolar lavage fluid (BALF) of those mice were markedly decreased by administration of LTbR-Ig compared with mice treated with human Ig. In addition, LTbR-Ig suppressed the expression of proinflammatory cytokines in the lung of OVA/Alum and HDM-treated mice. Furthermore, the LTbR-Ig-treated mice showed the ameliorated allergic symptoms in morphology. These results suggested that blockade of LTb receptor signals might be helpful to reduce the more increased airway inflammatory responses.

TNF-α Decreases Aquaporin-3 Expression in Keratinocytes.
I. Horie, A. Hisatsune, H. Katsuki, Y. Isohama; Chemico-Pharmacological Sciences, Graduate School of Pharmaceutical Sciences, Kumamoto University, Kumamoto city, Japan

[Objective] Aquaporin-3 (AQP3) is selectively expressed in the basal layer of keratinocytes in skin. Although AQP3 is believed to be important to maintain physiological hydration and wound repair in skin, expression or function of AQP3 in inflammatory conditions has not been understood. In the present study, we examined the effect of TNF-α, an inflammatory cytokine, on AQP3 expression in keratinocytes. [Methods] DJM-1 human keratinocyte cell line was cultured in MEM containing 10% FBS and antibiotics. The expression of AQP3 protein and mRNA was assessed with western blotting and real-time quantitative RT-PCR, respectively. AQP3 promoter (-990/+88) activity was measured by luciferase assay. [Results] TNF-α decreased the level of AQP3 protein in DJM-1 cells, in time- (0-24 h) and concentration- (0.02-20 ng/ml) dependent manners. The level of AQP3 protein in TNF-α treated (20 ng/ml, 24 h) cells was decreased to 50% of that in control cells. This decrease in AQP3 protein was correlated to the decrease in plasma membrane water permeability, assessed by stopped-flow method. TNF-α also decreased AQP3 mRNA and AQP3 promoter activity, without changing the stability of AQP3 mRNA,
suggesting that TNF-α decreased AQP3 transcription. The decrease in AQP3 by TNF-α was abolished SB203580 and PD98059, p38 and ERK inhibitors respectively, but not by CAPE, an NF-κB inhibitor. It is, therefore, suggested that TNF-α decreased AQP3 expression via MAPK-dependent pathways. [Conclusion] We demonstrated that TNF-α decreased AQP3 expression via ERK- and p38-dependent pathways. These data strongly suggests that AQP3 expression in keratinocytes may be decreased in inflammatory conditions. Considering the function of AQP3 in skin, TNF-α-induced decrease of AQP3 expression may be related to impaired skin hydration and wound repair in inflammatory conditions.

170/B117
Smad7 and Smad6 Use Distinct MH2 Subdomains to Bind to Discrete Regions of Pellino-1, Mediating TGF-Beta1-Induced Negative Regulation of IL-1R/TLR Signaling.
Y. Lee, J. Kim, H. Lee, S. Park; SungKyungKwan University, Suwon, Korea, South

The molecular mechanism by which transforming growth factor-beta (TGF-beta) suppresses inflammation is not well characterized. Here, we demonstrate that complete suppression of Interleukin-1 receptor/Toll-like receptor (IL-1R/TLR) signaling requires the concerted efforts of TGF-beta-induced Smad6 and Smad7. Upon treatment of TGF-beta 1, Smad6 and Smad7 simultaneously bind to distinct regions of Pellino-1, an adaptor protein of interleukin-1 receptor associate kinase (IRAK1), via two different secondary structural elements in their MH2 domains. These interactions abrogate NF-kappaB activity by blocking formation of the IRAK1-mediated signaling complex downstream of IL-1R/TLR signaling. Double knock-down of endogenous Smad6 and Smad7 genes by RNA interference further reduced the anti-inflammatory activity of TGF-beta1 than when compared with single knock-down of either Smad6 or Smad7, suggesting that both Smad6 and Smad7 are required for maximal suppression of IL-1R/TLR signaling. Thus, we show that both Smad6(beta-sheet)and Smad7(alpha-helix) simultaneously bind to distinct regions of Pellino-1 via non-overlapping regions in their MH2 domains, and act as critical mediators for effective TGF-beta 1-mediated suppression of IL-1R/TLR signaling.

171/B118
Roles for the Protein Agrin in Regulating Inflammation In Vitro.
M. Mencel1, C. Jacobson1,2; 1Biology, University of Waterloo, Waterloo, ON, Canada, 2Mechanical and Mechatronics Engineering, University of Waterloo, Waterloo, ON, Canada

Agrin is a heparan sulfate proteoglycan best known for its role in the organization and stabilization of numerous molecules, including acetylcholine receptors (AChR), during the formation of the neuromuscular junction. Interestingly, both agrin and AChRs are broadly expressed molecules, present in a variety of cells, including immune cells. Macrophages, phagocytes of the immune system that are primarily responsible for the eradication of infection, have been known to express AChRs and be involved in regulating inflammation. The cholinergic anti-inflammatory pathway is widely accepted as one mechanism of regulating inflammatory response. This pathway, termed the neuro-immune axis, is dependent on the acetylcholine (ACh) secreted by the vagus nerve. ACh inturn activates the α7 nicotinic acetylcholine receptors (α7-nAChRs) present on macrophages regulating the further production and synthesis of pro-inflammatory cytokines, such as tumor necrosis factor α (TNF-α) by inhibiting the nuclear factor kappa B (NF-xB) transcription factor. Using SDS-PAGE, immunoblotting, immunocytochemistry and ELISA techniques we find here that agrin increases α7-nAChRs expression in the macrophage cell line RAW264.7 and appears to aggregate surface α7-nAChRs in this cell line. Importantly, agrin alone does not appear to affect pro-inflammatory cytokine synthesis. The addition of ACh appears to diminish the effects of agrin, suggesting that agrin may play a role upstream of ACh signaling through α7-nAChRs. Together, these findings suggest a role for agrin in modifying an inflammatory response in the innate immune system by regulating the efficacy of vagus derived ACh.

Inhibition of Cellular Response to Sphingosine-1-Phosphate by Human Plasma Gelsolin.
R. Bucki1, A. Kulakowska2, F. Byfield1, M. Baranowski3, M. Zendzian-Piotrowska3, A. Sadzynski4, M. Marzec1, W. Drozdowski5, R. Bittman5, P. Janmey1; 1Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, PA, 2Department of Neurology, Medical University of Białystok, Białystok, Poland, 3Department of Physiology, Medical University of Białystok, Białystok, Poland, 4Suwałki’s District Hospital, Suwałki, Poland, 5Department of Chemistry and Biochemistry, Queens College of City University of New York, New York, NY

Sphingosine-1-phosphate (S1P) is a potent and pleiotropic bioactive lipid mostly released by haematopoietic cells, that acts as an extracellular agonist and an intracellular second messenger. Cell activation by S1P requires precise control, as an acute increase in its plasma concentration is sufficient to induce sudden cardiac death through an S1P receptor-mediated mechanism. Here we report that human plasma gelsolin (hpGSN) acts as an S1P buffer, as it binds S1P and its synthetic structural analog (S)-FTY720-phosphate. The optical density at 280 nm of hpGSN decreased following the addition of S1P or (S)-FTY720-phosphate and hpGSN’s ability to depolymerize F-actin decreases progressively with increasing addition of phosphatidylinositol 4,5-bisphosphate (PIP2) and S1P at similar molecular ratios. Both the transient increase in phosphorylation of extracellular signal regulated kinase (ERK) and nuclear factor kB (NF-kB) cytosol-nucleoplasm translocation in bovine aortic endothelial cells (BAEC) after S1P treatment were inhibited by hpGSN. Evaluation of gelsolin and S1P levels in cerebrospinal fluid reveals a low concentration of gelsolin and high concentration of S1P in samples obtained from patients suffering from lymphatic meningitis and multiple sclerosis. These findings indicate that gelsolin-mediated buffering of S1P activity may be important to keep immunomodulatory balance at inflammatory sites.

173/B120
IL-1β-Activated Macrophages Stimulate Differentiation of Mesenchymal Stem Cells to Smooth Muscle Cells via Paracrine Mechanism.
M. Kim, H. Song, E. Jeon, J. Kim; Pusan National University, Gyeongsangnam-do, Korea, South

Mesenchymal stem cells (MSCs) have been known to be useful for regeneration of inflamed or injured tissues. Macrophages are involved in acute or chronic inflammatory diseases and IL-1β, a pro-inflammatory cytokine, plays a key role in the activation of macrophages. In order to explore the crosstalk between MSCs and macrophages within inflammatory environment, we examined the effects of conditioned media from macrophages in the differentiation potential of MSCs to vascular smooth muscle cells. We demonstrate here that IL-1β-conditioned media from macrophages (IL-1β CM) stimulate differentiation of MSCs to vascular smooth muscle cells, as evidenced by increased expression of smooth muscle-specific markers, including alpha-smooth muscle actin (α-SMA), smooth muscle-myosin heavy chain, and calponin. The IL-1β CM-induced expression of α-SMA was abrogated by pretreatment of MSCs with the MEK/ERK-specific inhibitor U0126. Moreover, pretreatment of MSCs with the Rho kinase-specific inhibitor Y27632 or over-expression of the dominant negative mutants of RhoA or Rho kinase blocked the IL-1β CM-stimulated α-SMA expression, indicating a pivotal role of ERK and Rho kinase in the IL-1β CM-induced differentiation of MSCs to SMCs. Taken together, these results suggest that IL-1β-activated macrophages promote differentiation of MSCs to vascular SMCs, which are crucial for vascular regeneration of injured tissues, through paracrine mechanism.

Interleukin-1β Modulation of Intestinal Epithelial Tight Junction Barrier Requires Activation of p38 Kinase.
R. Al-Sadi, T. Y. Ma; University of New Mexico, Albuquerque, NM

Interleukin-1β (IL-1β) has been shown to play an essential role in mediating intestinal inflammation of Crohn’s disease (CD) and other inflammatory conditions of the gut. The IL-1β-induced increase in intestinal epithelial tight junction (TJ) permeability has been postulated to be an important pathogenic mechanism contributing to intestinal inflammation. However, the intracellular pathways that mediate the IL-1β modulation of intestinal TJ barrier function remain...
unclear. In these studies, we show that activation of p38 MAP kinase signaling cascade is required for the IL-1β induced increase in Caco-2 intestinal epithelial TJ permeability. The IL-1β caused a time-dependent increase in p38 activation as measured by phospho-p38 immunoblotting. Inhibition of p38 by specific inhibitor SB-203580 (25 μM) prevented the IL-1β induced drop in Caco-2 transepithelial resistance (TER) and also abolished the IL-1β induced increase in permeability to paracellular marker inulin. To further validate the role of p38 signaling pathway in mediating the IL-1β effect on Caco-2 TJ permeability, p38 expression was selectively knocked-down by transfection of p38 siRNA. The transfection of p38 siRNA resulted in a near-complete knock-down of p38 in filter-grown Caco-2 monolayers. The siRNA-induced knock-down of p38 prevented the IL-1β induced drop in Caco-2 TER and increase in inulin flux. IL-1β also caused a time-dependent increase in myosin light chain kinase (MLCK) activity and expression. Inhibition of MLCK by ML-7 (10 μM) prevented the IL-1β induced increase in Caco-2 TJ permeability. Moreover, inhibition of p38 by SB203580 prevented the IL-1β induced up-regulation of MLCK. p38 silencing by siRNA transfection also abolished the IL-1β induced increase in MLCK expression and activity. In conclusion, our data data suggest that the IL-1β modulation of intestinal epithelial TJ barrier is regulated by p38 signaling cascade induced up-regulation of MLCK activity and protein synthesis.

**Developing New Angiogenic Models Based on a Novel, Stable, Fluorescently Labeled Endothelial Cell Line.**

A. Heisel, K. Wei, E. Hunter, P. Ruiz-Lozano, J. Price, N. Prigozhina; Burnham Institute, La Jolla, CA

Formation of new blood vessels, or angiogenesis, has been implicated in many physiological processes and diseases and is, therefore, an important target for drug development. Recapitulation of vessel formation In Vitro by human cells not only allows investigating cell-cell and cell-matrix interactions in a controlled environment, but is also a crucial step in developing High Content Screening (HCS) assays that search for novel stimulators or inhibitors of angiogenesis. The typical cell type used in most angiogenic assays today is Human Umbilical Vein Endothelial Cells (HUVECs). However, because HUVECs are primary cells, their use is limited to 6-8 passages. To overcome this limitation, we have developed a 96-well HCS assay using HMEC-1, immortalized human microvascular endothelial cells (Ades et al., 1992). We showed that HMEC-1 cells, by themselves and in co-culture with Epicardial Mesenchimal Cells (EMC), are able to form branching networks on Matrigel. Moreover, we created HMEC-1 and EMC cell lines stably expressing nuclear-localized Histone-2B (H2B) fused with eGFP or mCherry fluorescent proteins, thus allowing easy cell tracking and screening by automated algorithms. We characterized the networks formed by these cells and showed them to be comparable to those formed by HUVECs in timing of vessel formation, number of branching nodes, branch length, and other angiogenic features. We propose to use these fluorescent HMEC-1 and EMC lines as a viable cell choice for future angiogenic assays.

**Regulation of Endothelial Senescence by the Homeodomain Transcription Factors MEOX1 and MEOX2.**

J. Douville1,2, D. Cheung1,2, J. Wigle1,2; 1Institute of Cardiovascular Sciences, St. Boniface General Hospital Research Centre, Winnipeg, MB, Canada, 2Biochemistry & Medical Genetics, University of Manitoba, Winnipeg, MB, Canada

The mesenchyme homeobox genes, MEOX1 and MEOX2, encode homeodomain transcription factor proteins. In the adult, MEOX2 expression is maintained in the vasculature. MEOX2 is expressed in both vascular smooth muscle and endothelial cells where it blunts proliferation by inhibiting cell cycle progression. To date there are only two confirmed target genes of MEOX2;
the cyclin-dependent kinase inhibitors p21 CIP1/WAF1 (CDKN1A) and p16 INK4a (CDKN2A). The Meox1/Meox2 knockout mice have shown that the Meox proteins can partially compensate for one another during development; however the role of MEOX1 has yet to be studied in the vasculature. The objectives of our study were to: 1) Determine whether MEOX1 and MEOX2 play a role in endothelial cell senescence and 2) Identify novel target genes of MEOX1 and MEOX2 in endothelial cells. To fulfill these aims, the MEOX proteins were expressed in primary human umbilical vein endothelial cells (HUVEC) via adenoviral transduction. Expression of the p21 and p16 genes was measured by western blot and quantitative real-time PCR analysis. Cellular proliferation and senescence were assessed by analyzing bromodeoxyuridine (BrdU) incorporation and senescence associated beta-galactosidase (SA-β-gal) staining, respectively. Novel target genes were identified using the GeneChip Human Genome U133 Plus 2.0 Array (Affymetrix) expression microarray and verified via qRT-PCR. Both MEOX1 and MEOX2 activated p21 gene transcription in HUVECs. However, only MEOX2 induced a significant increase in p21 at the protein level. Surprisingly, the increased p21 expression induced by MEOX2 did not correlate with decreased BrdU labeling. MEOX1 and MEOX2 both activated p16 gene transcription in HUVECs which corresponded with increased SA-β-gal staining. Taken together, we conclude that both MEOX1 and MEOX2 are key regulators of cellular senescence in vascular endothelial cells.

Involvement of Rho-Kinase in LPA-Mediated Inflammatory Response through Activation of NF-κb and AP-1 in Endothelial Cells.

H. Shimada, L. E. Rajagopalan; Global Research 7 Development, Pfizer, Chesterfield, MO

Endothelial cells play an important role in the recruitment of immune cells through the induced expression of chemokines and cell adhesion molecules. The proinflammatory lipid mediator, LPA (lysophosphatidic acid) has been shown to induce IL-8, MCP-1, ICAM-1 and VCAM-1 expression in endothelial cells. However, the pathways involved in LPA-mediated inflammatory signaling in endothelial cells are not fully understood. The present study was undertaken to investigate the LPA-mediated inflammatory signaling in endothelial cells. LPA induced expression of IL-8, MCP-1, ICAM-1 and phosphorylated NF-κb p65 (Ser536), JNK/SAPK (Thr183/Tyr185), and c-Jun (Ser63) in HUVEC. LPA also increased c-Jun expression. Based on literature, linking LPA to ROCK activation, we examined the phosphorylation status of downstream substrates of Rho-kinase (ROCK), MLC (Thr19/Ser18) and MYPT1 (Thr850). LPA-mediated phosphorylation of MLC (Thr19/Ser18) and MYPT1 (Thr850) was blocked by a ROCK inhibitor (H-1152P) but not by a NF-κB inhibitor (Bay11-7082) or JNK inhibitor (SP600125). LPA-mediated phosphorylation of NF-κB p65 (Ser536) and translocation of NF-κB into nucleus were inhibited by H-1152P and Bay 11-7082, but not by SP600125. H-1152P and SP600125 inhibited LPA-mediated phosphorylation of JNK/SAPK (Thr183/Tyr185) and c-Jun (Ser63). LPA-induced c-Jun expression was inhibited by H-1152P but not by SP600125 and Bay 11-7082. In addition, H-1152P suppressed LPA-induced IL-8, MCP-1, ICAM-1, and VCAM-1 expression in HUVEC. These results indicate that ROCK plays a critical role in LPA-mediated inflammatory response through activation of NF-κB and AP-1 in endothelial cells.

Interleukine-23 Activates Endothelial Cells Causing Intracellular Signalling and Morphological Changes.

S. S. Petersen1, A. J. Hansen2, K. Tritsaris1, S. Dissing1; 1Inst. Cell. and Mol. Med., University of Copenhagen, Copenhagen, Denmark, 2Cytokine Biology, NOVO Nordisk A/S, Måløv, Denmark

Interleukin 23 (IL-23) stimulates survival and proliferation of Th17 cells that are implicated in autoimmune inflammatory diseases and IL-23 also serves as an important cytokine regulator for these diseases. IL-23 is reported to activate a complex consisting of the IL-12Rβ1 as well as the IL-23 receptor. Here we report, using RT-PCR on mRNA from human dermal microvascular endothelial cells (HDMEC), that these cells possess the IL-12Rβ1 receptor. We therefore studied to which extent IL-23 could activate endothelial cell signalling and the possible consequences
with regard to migration, spheroid sprouting and morphological changes. In HDMEC, IL-23 caused a transient increase in p-Akt and p-mTOR with maximal phosphorylation between 10 and 20 min. GTP-Rac was formed after 1 min and we found enhanced polymerizations of actin filaments as well as cell shape changes after 2 hrs. Time laps experiments with phase contrast microscopy also revealed cell shape changes induced by IL-23 when cells were followed for 6 hrs. We did not see enhanced migration with IL-23 or activation of angiogenesis in a mouse cornea assay. Microarray analysis revealed upregulation of mRNA coding for SMADs that are important regulators of transcription. IL-23 caused a considerable increase in spheroid sprouting of pig aorta endothelial cells (PAE) as measured in a collagen gel assay. IL-23 also stimulated phosphorylation of Akt near the perinuclear area as well as phosphorylations of JAK2, STAT3, STAT5 and Erk1/2. These data show that IL-23 activates endothelial cells, not as a classical angiogenic factor, but as a regulator of cell shape, transcription and possibly also a modulator of capillary wall integrity.

179/B126
Angiopoietin-1/Tie2 Signal Inhibits Inflammation through Expression of Krüppel-Like Factor 2.
S. Fukuhara, K. Sako, N. Mochizuki; Department of Structural Analysis, National Cardiovascular Center Institute, Osaka, Japan

Angiopoietin-1 (Ang1) is a ligand for endothelium-specific receptor tyrosine kinase Tie-2. In adult vasculature, Ang1/Tie2 signaling is thought to regulate both maintenance of vascular quiescence and promotion of angiogenesis. However, it has been unknown how Tie2 signal regulates these distinct biological functions. Recently, we have reported that Ang1 assembles distinct Tie2 signaling complexes in the presence or absence of cell-cell junctions (Nat. Cell Biol. 2008). Ang1 bridges Tie2 at cell-cell contacts, resulting in trans-association of Tie2 in the presence of cell-cell contacts. In clear contrast, in the isolated cells, extracellular matrix (ECM)-bound Ang1 locates Tie2 to cell-substratum interface. Furthermore, Tie2 activated at cell-cell or cell-ECM contacts leads to preferential activation of Akt and Erk, respectively. In this study, we further performed DNA microarray analyses to identify the genes regulated by trans-associated Tie2 and ECM-anchored Tie2. Ang1 regulated distinct sets of genes in the presence or absence of cell-cell contacts. Interestingly, in the presence of cell-cell contacts, Ang1 up-regulated the genes involved in vascular stabilization, which include Krüppel-like factor 2 (KLF2), zinc finger protein 36, C3H type-like 2, connexin 40, delta-like1 and delta-like 4. We also revealed that Ang1 induces KLF2 expression through a phosphoinositide 3-kinase (PI3K)/Akt-dependent activation of myocyte enhancer factor 2 (MEF2), and that Ang1-induced KLF2 expression attenuates inflammation. Collectively, trans-associated Tie2 stimulates transcriptional activity of MEF2 through a PI3K/AKT pathway, thereby inducing KLF2 expression and contributing to the maintenance of vascular quiescence.

180/B127
The Roles of PML Nuclear Bodies in Endothelial Cell Physiology.
X. Cheng, Y. Liu, H. Kao; Biochemistry, Case Western Reserve University, Cleveland, OH

Promyelocytic leukemia protein (PML) nuclear bodies (NBs) are dynamic sub-nuclear compartments that play roles in several cellular processes including transcriptional regulation, apoptosis, and DNA repair. We have previously shown that tumor necrosis factor alpha (TNFα) induces formation of PML NBs and promotes the expression of matrix metalloproteinase-10 (MMP-10) in human umbilical vein endothelial cells (HUVECs). We have also found that inflammatory cytokines, such as TNFα, interferon alpha (IFNα) and interferon gamma (IFNγ), are inhibitory to angiogenesis in HUVECs and human microvascular endothelial cells (HMVECs). In addition, knockdown of PML significantly compromises TNFα- and IFNa-mediated inhibition of tube formation and cell migration. We further demonstrate that TNFα and IFNα induce Stat1 expression in HUVECs, and that knockdown of Stat1 inhibits TNFα- and IFNα-induced PML mRNA accumulation. Chromatin immunoprecipitation (ChiP) assays indicated that Stat1 associates with PML promoter. These data suggests that Stat1 is a candidate transcription factor
involved in cytokines-induced PML expression. Finally, we show that integrin beta1 (ITGB1) was significantly up-regulated in PML-knockdown cells at both mRNA and protein levels and that TNFα, IFNα and IFNγ treatment decreased ITGB1 expression at both mRNA and protein levels. Based on these data, we hypothesize that PML negatively regulates tube formation in endothelial cells, in part by regulating cell migration through inhibition of ITGB1 expression. Taken together, our data supports a model in which PML NBs are important players that mediate TNFα and IFNα activity to control endothelial cell fate.

181/B128
Caveolae Mediate Protease-Selective Signaling by Protease-Activated Receptor-1.
U. J. Soh¹, A. Russo², J. Trejo¹; ¹Department of Pharmacology, School of Medicine, University of California, San Diego, La Jolla, CA, ²Department of Pharmacology, College of Medicine, University of Illinois, Chicago, Chicago, IL

Protease-activated receptors (PARs) are a family of G protein-coupled receptors (GPCRs) that elicit cellular responses to extracellular proteases. The coagulant protease thrombin contributes to inflammatory responses associated with vascular injury and thrombotic disease, whereas the anti-coagulant protease activated protein C (APC) promotes cytoprotective and anti-inflammatory signaling. Moreover, both thrombin and APC signal through PAR1 but elicit opposite effects on endothelial barrier permeability. APC and thrombin also differentially regulate Rac and RhoA signaling, small GTPases that control endothelial barrier permeability. The mechanism by which two different proteases activate the same receptor to elicit distinct cellular responses is not known. Strikingly, pre-incubation of endothelial cells with APC ablates thrombin-stimulated signaling and increased endothelial barrier permeability. However, in cells stably expressing caveolin-1 siRNA, APC cytoprotective signaling was abrogated, whereas thrombin-induced cellular signaling remained intact, suggesting that receptor localization to caveolar microdomains is critical for protease-selective signaling. Our studies further indicate that APC-activated PAR1 is retained at the cell surface, while thrombin induces rapid receptor internalization through clathrin-coated pits and lysosomal degradation. Interestingly, APC pre-incubation does not affect thrombin-induced PAR1 internalization or degradation. These findings suggest that thrombin and APC activate distinct PAR1 subpopulations that utilize distinct processes for regulation of receptor signaling and trafficking. Towards understanding the mechanisms responsible for APC-induced signal regulation we examined the distribution of PAR1 and signaling effectors in caveolae by detergent-free sucrose density fractionation. PAR1 and signaling components of cytoprotective pathways were found largely in caveolin-1 enriched fractions, while inflammatory signaling mediators were detected mainly in heavy fractions. Collectively, these findings suggest that spatial and temporal distribution of PAR1 and signaling effectors contribute to the ability of different proteases to selectively signal through PAR1.

182/B129
Role of AKAP12 in Endothelial Cell Wound Healing In Vitro.
B. Roy, B. D. Grove; Anatomy and Cell Biology, Univ of North Dakota, Grand Forks, ND

AKAP12 (gravin), a 300kD multivalent A-kinase anchoring protein, is localized at the cell periphery and may participate in cell signaling events at that location. Based on previous studies linking AKAP12 to cell motility and cell spreading, the aim of this study was to determine if AKAP12 plays a role in endothelial cell wound healing. To test this hypothesis, mechanical scratch wounds were induced in confluent human umbilical vein endothelial cells (HUVEC) in 8-well plates, after which the wounded cultures were treated with different concentrations of antisense and missense oligonucleotides for 48 hours. The effect of oligonucleotide treatment on gravin expression was assessed by western blot. In addition, the pattern of AKAP12 expression in wounded HUVEC monolayers was examined using immunofluorescence microscopy and AKAP12 expression in active, sub-confluent cultures and quiescent, confluent cultures of HUVEC was compared by western blotting. Cultured HUVEC demonstrated a density dependent profile of AKAP12 expression. Low density, proliferating HUVEC cultures showed high AKAP12 expression whereas confluent contact inhibited cultures exhibited weak expression. Furthermore, the
expression of AKAP12 was up-regulated at the wound edge in wounded HUVEC monolayers. Finally, the level of gravin expression and the extent of wound closure after 48 was reduced in HUVEC treated with antisense oligonucleotides as compared to control cells treated with missense oligonucleotides. The pattern of expression in cultured HUVEC and the results of the antisense experiments conducted in this study suggest that AKAP12 may play role in cellular activities associated with endothelial cell wound healing.

183/B130
Apoptosis Induction in HUVECs by Acocostatin.
N. M. Crittenden, A. Seoane, T. Takelemariam, J. G. Soto; Biology, San Jose State University, Santa Clara, CA

Disintegrins are proteins isolated from viper snake venom and are capable of inducing apoptosis through competitive ligand-binding to integrins. We isolated a PIII disintegrin-like protein (Acocostatin) containing disintegrin and cysteine-rich regions from the copperhead snake Agkistrodon contortrix contortrix. Our hypothesis is that acocostatin will induce apoptosis in Human Umbilical Vein Endothelial Cells (HUVECs). Acocostatin was cloned into a pGEX-KG bacterial vector and the resultant recombinant protein was purified using glutathione sepharose beads. Apoptosis was detected with Annexin-V-FITC and nuclear fragmentation assays on HUVECs. Camptothecin, a known inducer of apoptosis, was the positive control, while glutathione-S-transferase (GST) treated cells served as the negative control. Groups of 100,000 cells were treated with 5 \( \mu \)M camptothecin, acocostatin, or GST for 24 hours. Another subset of cells was left untreated. Results were analyzed through flow cytometry and FACSCalibur software. The following results support our hypothesis: acocostatin induced 32.8% apoptosis, camptothecin 41.2%, GST 5.4%, and untreated cells exhibited 3.0% apoptosis. To test for nuclear fragmentation, 200,000 cells were grown on slides and treated with 2.5\( \mu \)M GST or acocostatin for 24 hours. One slide was left untreated. Cells were then fixed for 1 hour with 3% formaldehyde solution and stained with 1\( \mu \)M Hoechst stain for 15 minutes. When the slides were viewed at 100x under epifluorescent microscopy, the acocostatin treated cells demonstrated nuclear fragmentation, which was not observed in the other cells. Current experimentation is underway to determine which region of the acocostatin gene is responsible for the induction of apoptosis in HUVECs.

Cell Phone Radiation Activates p38MAPK/Hsp27 Stress Pathway.
H. Tammio, S. Heinävaara, N. Kuster, D. Leszczynski; 1STUK-Radiation and Nuclear Safety Authority, Helsinki, Finland, 2IT'IS Foundation, Zurich, Switzerland

Induction of biological effects by mobile phone radiation (RF-EMF) remains a controversial issue. We have earlier demonstrated that RF-EMF (900 MHz GSM signal) alters gene and protein expression and activates stress response (phosphorylation of p38MAPK and Hsp27) in human endothelial cell line EA.hy926 (Leszczynski et al., Differentiation 2002, 70:120-129; Leszczynski et al., Proteomics, 2004, 4:426-431; Nylund & Leszczynski, Proteomics 2004, 4:1359-1365; Nylund & Leszczynski, Proteomics 2006, 6:4769-4780). We have also shown that this radiation might alter protein expression in the skin of human volunteers (Karinen et al. BMC Genomics 2008, 9:77). In the present study we have further examined effects of RF-EMF (1800 MHz GSM signal) on stress response in EA.hy926 cells by determining effects on the expression of stress proteins and on the expression and phosphorylation (activity) of several kinases located upstream of Hsp27. Cells were exposed to RF-EMF at specific absorption rate (SAR) of 2.0 W/kg & 5.0 W/kg for 15, 30 and 60 minutes. After the exposure expression of stress proteins (Hsp27, Hsp40, Hsp60, Hsp70, Hsp90, Hsp110) and expression/activity of kinases (M KK3/6, p38MAPK, MAPKAPK2) were examined by western blot. Temperature of cells during the exposure was continuously monitored and it remained throughout the experiments at 37 ± 0.2 deg. C. from 3 to 5 experiments were performed for each protein, time-point and SAR. Statistical analysis was performed using Kruskal-Wallis test. Obtained results show that RF-EMF had no effect on the expression heat shock proteins (activity was not examined). Stress kinases MKK3/6 and
MAPKAPK2 appeared to be activated at 5.0 W/kg but not at 2.0 W/kg SAR. Expression but not activity of p38MAPK was also altered at 5.0 W/kg. In conclusion, the obtained results support a notion that RF-EMF might activate cellular stress response.

J. T. Morgan1, E. R. Pfeiffer2, T. L. Thirkill3, G. C. Douglas4, D. Starr4, A. I. Barakat1; 1Mechanical and Aeronautical Engineering, University of California, Davis, Davis, CA, 2Biomedical Engineering, University of California, Davis, Davis, CA, 3Cell Biology and Human Anatomy, University of California, Davis, Davis, CA, 4Molecular and Cellular Biology, University of California, Davis, Davis, CA

Arterial endothelial cells (ECs) actively respond to biochemical and biomechanical stimuli, and these responses regulate normal vascular function and the progression of atherosclerotic disease. The nesprins are large Klarsicht, ANC-1, Synex Homology (KASH) domain-containing proteins that directly link cytoskeletal elements to the nuclear envelope in mammalian cells. Nesprin-1 and -2 associate with the actin cytoskeleton, while nesprin-3 interacts with the intermediate filament network via plectin, a cytoskeletal cross-linker. Because the cytoskeleton modulates biochemical and biomechanical signal transduction in ECs, understanding the interdependence of nesprins and cytoskeletal elements is critical to elucidating the potential role of nesprins in EC signaling. To interrogate nesprin-cytoskeletal connections, we used a variety of techniques including pharmacological disruption of specific cytoskeletal elements, siRNA-mediated knockdown of nesprin-3 (siN3), and a dominant negative KASH protein plasmid (dnKASH) which displaces nesprins from the nuclear envelope. Disruption of filamentous actin using cytochalasin-D elicited a ~40% decrease in whole-cell nesprin-1 intensity while having no significant effect on nesprin-3 intensity. Intermediate filament disruption with acrylamide led to doubling in nesprin-3 intensity relative to untreated cells. Preliminary data suggests that transfection with the dnKASH plasmid increased the distance between the microtubule organizing center (MTOC) and the nucleus. Transfection with siN3 also increased MTOC-nucleus distance (compared to reagent alone). When HAECs were subjected to a steady shear stress of 15 dyne/cm² for 2 hrs, the MTOC polarized upstream of the nucleus, and this was unaffected by treatment with either dnKASH or siN3. These findings suggest that the cytoskeletal filament network in HAECs modulates nesprin expression and that KASH domain proteins regulate MTOC positioning relative to the nucleus.

A Novel Role of Substance P as an Injury Messenger for BMSC Mobilization.
Y. Son1, H. Hong1,2, E. Lee1, E. Lee1, J. Kim3, M. Jiang4, Y. Kwon4, W. Ahn1; 1Genetic Engineering, Kyung Hee University, Yong In, Korea, South, 2R&D Institute, Cell & bio, Seoul, Korea, South, 3Ophthalmology, Chung-Ang University, Seoul, Korea, South, 4College of Veterinary Medicine, Kyungbuk University, Taegu, Korea, South

Tissue injury may create a specific microenvironment for inducing the systemic participation of bone marrow stromal cells (BMSC) in the repair process. Here we show that Substance P (SP) is an early injury-inducible factor, regulated by wound size, and induces the CD29+ cell mobilization. This function of SP was proved in uninjured mice, rats, and rabbits by its intravenous injection. Those SP-mobilized CD29+ cells were characterized to be BMSC by binding of intravenously injected biotin-SP on BMSCs in vitro and their multipotent differentiation capacities In Vitro and ectopic bone marrow formation in vivo. Both SP injection and transfused SP-mobilized BMSCs accelerated wound healing, particularly, epithelial-entraftment of the transfused cells in the injured tissue. Finally, we showed that SP stimulated transmigration of human BMSCs, cell proliferation, Erk1/2 activation, and nuclear translocation of beta-catenin in vitro. This finding highlights a novel function of SP as a systemically acting messenger of injury and a mobilizer of BMSC to participate in wound healing. This study was supported by grants SC3120 given to Dr Y Son.

Identification of a New Angiogenic Factor Secreted from Osteoblasts.
J. Kim, S. Yun, J. Kim, Y. Kim, S. Cha, S. Lim, S. Ryu, P. Suh; 1Life Science, Pohang University of Science and Technology (POSTECH), Pohang, Korea, South, 2University of Virginia, Charlottesville, VA, 3National Cancer Center, Goyang, Korea, South, 4Korea Ocean Research and Development Institute (KORDI), Ansan, Korea, South

In bone fracture repair process, cell-to-cell communication between osteoblasts and endothelial cells is considered as important event. Though its importance, cellular communicator between osteoblasts and endothelial cells is a little known. We focused on secretary molecules from osteoblasts might be involved in endothelial cell angiogenesis. To find secretary molecule specifically increased in osteoblasts with angiogenic activity, we compared activity of conditioned medium from undifferentiated mesenchymal stem cells and osteoblasts on endothelial cells angiogenic functions. As a result, we could observe that secretary molecules from osteoblasts showed significant increases in endothelial cells migration. To identify migration-inducing molecule, RP-HPLC and ESI LC-MS/MS analysis were conducted. Among the several candidate molecules, we selected protein C. Many intracellular functions of protein C have been known and there are some reports about protein C secretion to extracellular region. But, there is no report about extracellular function of protein C, especially related to function as a ligand. First, we checked chemotactic activity of protein C on endothelial cells. We could observe that protein C-induced endothelial cells migration in dose-dependent manner. Also, another property of angiogenesis, tube structure formation was induced by protein C treatment. These activities of protein C were mediated by FGFR-1 activation and its downstream signaling molecules activation. SU5402, FGFR antagonist, and siRNA for FGFR-1 abolished protein C-induced endothelial cell migration and activation of signaling molecules by protein C. Based on this study, identification of protein C as a new angiogenic factor for endothelial cell will be helpful for understanding of the communications between osteoblasts and endothelial cells and applications in bone-related disease such as bone fracture.

The Role of LSECS in the Thrombocytopenia Caused by Liver Xenotransplantation.

There are over 17,000 people on the waiting list to receive a liver for transplantation. In order to bridge the gap between the number livers needed and the number of livers available for transplantation, sources of liver other than deceased human must be examined. The pig liver seems optimal, since pigs are easily raised, metabolically similar to people, are accurate in size, and are more ethically acceptable than non-human primates. We have observed that a pig’s liver perfused with human blood will bind and remove human platelets from circulation. Our goal is to identify what causes platelet binding and block the interaction. In this study porcine livers were perfused with human platelet rich plasma ex vivo. Following addition of PRP, The number of platelets in circulation decreased by over 90% at 15 minutes. Needle biopsies and samples of the perfusate were taken over 3 hours. Western blot analysis revealed that there was no sign of platelet activation or lysis during perfusion. Fluorescently labeled platelets were taken up by liver sinusoidal endothelial cells (LSEC) and compartmentalized in LAMP1 positive phagosomes based on confocal analysis. To confirm our ex vivo findings, we isolated primary LSECs from the pigs liver and found that they phagocytosed human platelets In Vitro independent of antibody binding and Fc receptor mediated phagocytosis. We have discovered that LSECs in the pig liver contribute significantly to the thrombocytopenia that occurs after xenotransplantation.

Direct and Indirect Roles of Placental Macrophages in Early Vascular Development.
J. C. Fitzsimmons, M. Westwood, J. D. Aplin; Maternal and Fetal Health Research Group, University of Manchester, Manchester, United Kingdom
Establishment of the placental circulation early in pregnancy is essential to allow the developing fetus access to maternal oxygen and nutrients. Placental vessels are believed to form in situ by the differentiation of endothelial precursors within the villous stroma; placental macrophages or Hofbauer cells (HCs) are abundant within stroma of early villi but their functions are not well understood. Here we use In Vitro cultures of primitive placental mesenchymal cells (PMCs) to test the hypothesis that HCs contribute to placental vascular development. HC in first trimester placental villi express CD163. Cultures of mixed PMCs generated from first trimester placenta (n=4) were separated into CD163+ (HC) and CD163- populations using immuno-magnetic beads. These were cultured separately or as a recombined population overnight on collagen I or MatrigelTM in the presence of EGF (10ng/ml) and FGF (20ng/ml) and monitored using time-lapse imaging. HCs were observed in close association with early placental vessels. CD163+ HCs cultured on MatrigelTM exhibited an elongated tubular morphology compared with those cultured on collagen I and became organised into primitive vascular structures (PVSs). Mixed CD163+/CD163- cultures formed significantly more PVSs than CD163- (HC depleted) cultures (p=0.014). Time-lapse imaging of mixed cultures on MatrigelTM revealed a close association of HCs with other stromal cells, and an apparent role for HCs in the co-ordination of network formation. These data support the hypothesis that these cells have the capacity both to stimulate and contribute to placental vasculogenesis and angiogenesis. Time-lapse investigations indicate that direct contact with PMCs may be important in the co-ordination of vascular patterning. Furthermore, our finding that HCs are capable of integrating into vascular-like networks In Vitro allows us to make the novel suggestion that they play a direct role in placental vessel formation through incorporation into vessels. Improved understanding of the mechanisms involved in placental vascular development will help identify therapeutic targets for diseases of pregnancy, such as Fetal Growth Restriction, in which vascular development is compromised.

A Drosophila Model for Seamless Tube Formation.
J. Schottenfeld, A. Ghabrial; Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

Objective: to identify the genetic and molecular mechanisms controlling seamless tube formation. The Drosophila tracheal system is composed of a network of tubes that sprout from 10 pairs of epithelial sacs. The network forms by a series of successive branching and fusion events. During this process, specialized tip cells lead the migration of new branches and mediate their interconnection. During the branch fusion process, some tip cells become specialized as “fusion cells” and convert themselves into seamless tubes that span the branch fusion joint. Other tip cells become specialized as “terminal cells” that go on to form branched, blind-ended seamless tubes that ramify extensively on target tissues, like muscle, and act as the site of gas exchange. Similar to tracheal terminal and fusion cells, endothelial tip cells that connect new sprouts to other tubes in the vascular network during angiogenesis have been shown to form seamless tubes. So-called “seamless endothelial cells” are believed to create seamless tubes by a cell hollowing process in which vesicles and vacuoles are trafficked to the center of the cell and coalesce and fuse to form an intracellular lumen bounded by apical membrane. A forward genetic screen for defects in seamless tracheal tubes has identified novel factors, such as whacked, that are involved in membrane trafficking. The primary defect in whacked mutants is the overgrowth of tubes at the distal tip of terminal branches. Positional cloning of whacked revealed that it encodes a RabGAP protein. Interestingly, overexpression of Whacked results in a striking phenotype, causing the overgrowth of tubes proximal to the terminal cell nucleus. Additional work has revealed that Rab35 is the key target of Whacked RabGAP activity: expression of a constitutively active isoform of Rab35 phenocopies whacked loss of function and expression of a dominant negative isoform of Rab35 (Rab35DN) phenocopies the Whacked overexpression defect. Moreover, expression of Rab35DN in the tracheal system can suppress whacked terminal cell morphogenesis defects and rescue whacked mutant animals to viability. Thus, we predict that Rab35, and its regulator Whacked, direct polarized tube growth.

Assembly Dynamics and Stabilization of Actin-Like Parm Filaments from Plasmid R1.
L. Brun1, S. Chen1, G. Fink1, J. Hou1, R. D. Mullins1,2; 1Physiology Course, Marine Biological Laboratory, Woods Hole, MA, 2Cellular and Molecular Pharmacology, UCSF School of Medicine, San Francisco, CA

In bacteria many low-copy plasmids are actively transported through the cytoplasm by the assembly of cytoskeletal polymers. In the case of Type II plasmid segregation the polymer is an actin-like protein, ParM, and the free energy of its assembly is harnessed by a DNA protein complex composed of the repressor protein, ParR, and the centromeric DNA sequence, parC. We investigated the assembly dynamics of ParM using Total Internal Reflection Fluorescence (TIRF) microscopy combined with stochastic modeling of polymer assembly. Modeling indicates that filaments must be stabilized by a cap of at least three ATP bound protomers at the end of the filament. Using TIRF microscopy of quantum dot-labeled ParR/parC with various combinations of wildtype and nonhydrolyzing ParM mutants we tested the hypothesis that the ParR/parC complex forms a sliding collar that fits around the ParM filament and that it tracks growing ends of ParM filaments by binding more tightly to newly incorporated, ATP-bound ParM subunits than to older subunits that have hydrolyzed ATP. This test was based on our prediction that the ParR/parC complex will bind tightly to clusters of non-hydrolyzing mutants and be displaced from the growing end of the filament.

Origin of Twist-Bend Coupling in Actin Filaments.
E. M. De La Cruz1, J. Roland2, L. Blanchoin3,2, J. Martiel2; 1MB&B, Yale University, New Haven, CT, 2TIMC-IMAG Laboratory, Université Joseph Fourier, Grenoble, France, 3Commissariat à l'Energie Atomique, Centre National de la Recherche Scientifique, Institut National de la Recherche Agronomique, Grenoble, France

Actin filaments are semi-flexible polymers on cellular length scales that display large scale conformational twisting and bending motions. Modulation of filament bending and twisting elasticity has been linked to regulatory actin binding protein function, filament assembly dynamics, force generation and motility (work output). The coupling between bending and twisting modes is a critical determinant of overall polymer elasticity and mechanics, but has not been evaluated for actin filaments. We have adopted a coarse-grained description of an actin filament that captures key documented features of actin filaments including the protomer subunit structure, geometrical constraints coming from filament helicity and twist, interaction energies and bending and twisting elasticities. We have used this computational model to predict the degree of coupling between filament bending and twisting motions. Comparison with a "single-stranded" actin protofilament indicates that bend-twist coupling in actin originates from the double protofilament structure.

Force Regulates Actin Subunit Interactions through Catch-Slip Bonds Switchable by Formin.
C. Lee1, J. Lou1, S. Ono2, S. Eskin1, C. Zhu1, L. V. McIntire1; 1Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, 2Pathology, Emory University, Atlanta, GA

It has been shown that cyclic uniaxial stretch induces the cell and its actin stress fiber to align in two ways: 1) with RhoA, and its effector, formin, the cell aligns perpendicular to the direction of stretch; 2) if RhoA or formin is inhibited, it aligns parallel to stretch. This suggests that the way actin cytoskeleton dynamics respond to force in-vivo is modulated by the RhoA/formin pathway. To pursue the molecular mechanism underlying this observation, we studied the bond lifetime-force relationship of G-actin/G-actin interactions by atomic force microscopy (AFM). Both AFM
probes, the cantilever tip and the polystyrene surface, were functionalized with G-actin by incubating sequentially with biotinylated BSA, streptavidin, and biotinylated G-actin. The working buffer for lifetime measurements is F-buffer. The measured binding was specific to G-actin/G-actin interactions as the binding frequency was significantly suppressed by not coating the cantilever tip with G-actins, by using G-buffer as working buffer, or by adding latrunculin a to prevent G-actin/G-actin interactions. Without formin, the bond lifetime of G-actin/G-actin interaction first increases then decreases as the force increases, with a maximum of 0.63 sec occurring at 10.5 pN, which is a "catch-slip" mechanism. This behavior can be explained by force-induced formation of new interactions between G-actins, a structural mechanism provided by steered molecular dynamics simulations. When the FH2-containing formin construct, mDia1(FH2-DAD) is involved, the catch-slip bonds are switched to slip bonds, in which the bond lifetime monotonically decreases with the increasing force. The slip bonds are further reversed back to catch-slip bonds by the DID domain-containing N-terminal construct of mDia1, which inhibits FH2 via DAD-DID interaction, an auto-inhibition which can be removed by RhoA. Our study suggests how actin dynamics can be regulated by force and how this regulation is modulated by formin and RhoA, thus potentially explain how the force-induced cell alignment is regulated by the RhoA/formin pathway. It indicates a possible crosstalk mechanism bridging the actin-mediated mechanotransduction and the biochemical signal transduction pathways.

A Role for an Antiparallel Actin Dimer in Cells.
U. Silvan1, H. Mannherz2, C. Mittelholzer1, P. Burkhard3, B. M. Jockusch4, U. Aebi1, C. Schoenenberger1; 1M.E. Müller Institute for Structural Biology, Biozentrum, University of Basel, Basel, Switzerland, 2Department of Anatomy and Embriology, Ruhr University, Bochum, Germany, 3The Institute of material Science, University of Connecticut, Storrs, CT, 4Cell Biology, Zoological Institute, Technical University of Braunschweig, Braunschweig, Germany

In the cytoplasm, actin is a major component of the cytoskeleton and its coordinated assembly of filaments from monomers drives fundamental biological processes including cell motility, division and membrane dynamics. During the past decade, actin has been identified as an essential component of several nuclear machines that regulate gene expression and chromosome architecture. It may also contribute to the structural integrity of the nucleus, and mediate intranuclear movement of viruses, nuclear organelles, and even chromosomal sites. Despite the involvement in numerous nuclear mechanisms, the polymerization status of actin in the nucleus is still under debate. At the onset of actin polymerization in vitro, two types of dimers are detected. First, an antiparallel dimer ("lower dimer" or LD) occurs (1). As polymerization proceeds, LD decreases, while a parallel filament dimer ("upper dimer") appears. It has been proposed that the ragged and branched filaments observed during the early stages of polymerization might be attributed to a transitory LD incorporation (2). However, because of its transient nature, LD has so far evaded detection in vivo. Because a previous study demonstrated that antibodies are suitable tools to examine different forms of actin (3), we set out to raise LD-specific to study the functional significance of this actin conformation. Activity against monomeric actin was depleted from serum of rabbits immunized with crosslinked LD, resulting in a serum that was highly enriched for LD-reactivity. Immunoelectron microscopy of In Vitro polymerized actin filaments revealed specific labeling of filament branches. Moreover, for the first time the presence of LD in cells was demonstrated by immunofluorescence. The labeling pattern indicates that this unconventional form of actin is present in the cytoplasm and in the nucleus and is distinct from the actin forms described so far. Characterizing the Steric Effects of a Yeast/Muscle V76i Substitution in Actin.
K. Wen, J. Fields, M. McKane, P. A. Rubenstein; Biochemistry, University of Iowa, Iowa City, IA
Actin inter-subdomain interactions are important for controlling actin conformational dynamics and consequently its ability to reversibly polymerize. Yet the intramolecular allosteric interactions responsible for conformational regulation are largely unknown. Studies of a series of yeast actins containing muscle residues in subdomains 1 and 2 showed that the replacement of V76 in yeast actin with I in muscle actin results in a substantial retardation of nucleotide exchange rate. This result coupled with the actin structure led us to hypothesize that hydrophobic interactions involving the residue at position 76 coordinate the interaction of subdomains 1 and 2 with the interdomain nucleotide cleft. We thus altered the degree of packing by constructing V76I, W79Y and W79F mutant yeast actins and V76I/W79Yor F double mutants to relieve the crowding introduced by I76. Of the single mutants, only W79Y showed abnormal growth characteristics which were rescued by the addition of I76. As with the hybrid actins, I76 alone resulted in a nucleotide exchange rate half that of WT actin. W79F in addition to I76 partially rescued this retardation. I76 slows nucleation and polymerization, but these effects are exacerbated, not rescued, in the double mutant. Although yeast profilin binds both V76I and the V76I/W79F double mutant with an affinity similar to that of WT actin, it only accelerates their nucleotide exchange rates to a level half of that achieved with WT actin. Thus, profilin cannot compensate for the steric effects imposed by the introduction of I76. Interestingly, profilin retards polymerization of these two mutant actins, especially V76I/W79F actin to a much greater extent than it does WT actin. Together, our results suggest that the extent of hydrophobic interactions provided by residue 76 plays a major role in regulating the interaction between subdomain 1 and 2 of actin and consequently its nucleotide exchange and polymerization properties.

Cytoplasmic Actin Isoforms Perform Distinct Functions in Stereocilia.
B. Perrin, K. J. Sonnemann, J. M. Ervasti; BMBB, University of Minnesota, Minneapolis, MN

About 100 actin-rich stereocilia sprout from the top of auditory hair cells and are arranged like a choir in rows of increasing height with members of a given row nearly the same height. In addition to adopting a precise morphology, stereocilia must be maintained for life because hair cells are not regenerated. Stereocilia are largely made of β- and γ-actin, which are encoded by Actb and Actg1, respectively. These actin proteins are nearly identical, differing by only four biochemically-similar amino acids. Nevertheless, Actb and Actg1 knockout mice have distinct phenotypes. Actg1−/− mice developed progressive hearing loss corresponding with disruptions in stereocilia F-actin. In addition, individual stereocilia became shortened or lost while neighboring stereocilia appeared unaffected. (Belyantseva IA, Perrin BJ, Sonnemann KJ, et al. PNAS (2009) 106:9703). Hair cell-specific Actb knockout mice also developed progressive hearing loss, but did so more rapidly than Actg1−/− mice. Furthermore, β-actin-deficient stereocilia had a distinct phenotype. Most prominently, the first row of stereocilia in the hair cell bundle became dramatically shorter coincident with the onset of hearing loss. In addition, stereocilia within a row lost precise height registration with neighboring stereocilia. Together, these data are consistent with γ-actin strengthening stereocilia or repairing damage while β-actin maintains stereocilia length.

Differential Arginylation of Actin Isoforms Is Regulated by a Novel Degradation Mechanism Coupled to the Translation and Folding Dynamics In Vivo.
F. Zhang, A. Kashina; Animal Biology, University of Pennsylvania, Philadelphia, PA

Actin cytoskeleton in non-muscle cells is composed of beta and gamma isoforms that differ only by four N-terminal amino acid residues, but perform distinct functions in vivo. One of the insights into the underlying mechanisms maintaining this functional distinction came with the recent discovery that beta, but not gamma actin can be posttranslationally arginylated on its N-terminus, and that this modification bears important regulatory role in actin dynamics and maintaining the integrity of the actin network. Here we addressed the question of how the preferential arginylation of only one of the highly similar actin isoforms can be achieved, by examining the metabolic fate of exogenously expressed arginylated and non-arginylated actin in non-muscle cells. We found that arginylated gamma actin is highly unstable In Vivo compared to the arginylated beta actin,
and that it degrades selectively by a proteasome-dependent mechanism. Remarkably, in addition to the difference in amino acid sequences, this instability is regulated at the nucleotide level at the translation level. Further investigation suggests that preferential degradation of gamma actin is coupled to its slower translation rate compared to beta, leading to a slower folding, that exposes a lysine residue normally hidden in the actin structure, for ubiquitination. Our data suggest a novel mechanism of protein regulation by degradation coupled with translation/folding dynamics, likely employed for the differential regulation of arginylation in vivo. Our data is the first demonstration that beta and gamma actin are synthesized with different rates and that these rates likely confer differences in their posttranslationally modified states, important for their in vivo functions.

198/B145
Ion-Dependent Polymerization Differences between β- and γ-Nonmuscle Actins.
S. E. Bergeron1, S. Korrapati2, M. Zhu2, P. A. Rubenstein1; 1Biochemistry, University of Iowa, Iowa City, IA, 2Dept. of Microbiology & Molecular Genetics, Michigan State University, East Lansing, MI

Eight different point mutations in mammalian γ-nonmuscle actin cause autosomal dominant deafness, and many of these mutations are in regions that may affect binding sites for proteins that regulate filament formation and stability. Hair cells contain β- and γ-nonmuscle actin and are one of the few cell types in which the γ isoform predominates over the β-form (2:1 ratio). The molecular mechanism(s) leading to this actin-dependent deafness phenotype is unknown. As a model system for assessing the biochemical effects of these mutations, we previously showed that five of the six mutations in yeast actin demonstrate near normal polymerization kinetics. This result led us to hypothesize that the deafness phenotype largely results from altered actin/actin-binding-protein interaction(s). Although yeast and γ-actins are 90% identical, the remaining difference may be important for assessing the effects of these mutations in humans. We thus established a baculovirus expression system to allow us to begin an initial characterization of human β- and γ-nonmuscle actin before studying the effects of the deafness mutations in the γ isoform. The two nonmuscle actins differ by only 4 amino acids, three of which are in the amino-terminus and none of which are near a polymerization interface. Negatively-stained samples of pure β- and γ-actins show essentially the same morphology. Surprisingly, β-nonmuscle actin in the Ca form polymerizes and releases phosphate over twice as fast as γ-nonmuscle actin. In the Mg form, these differences become much smaller. Mixing assays show the two actins co-polymerize and demonstrate that the difference in polymerization results largely from an elongated γ-actin nucleation phase. In the hair cell stereocilia, a phalloidin-staining core of bundled β-actin filaments is surrounded by a shell of γ-actin that does not stain with phalloidin. The stereocilium also contains about 1 mM calcium-binding proteins including parvalbumin which could provide an ionic environment favoring the Ca-actin form. Our polymerization results are consistent with the disposition of the two isoactins in the hair cell stereocilium.

199/B146
Identification of a Novel γ-Actin Transcript Enriched in Muscle.
M. C. Drummond1,2, K. H. Friderici1,2,3, 1Genetics Program, Michigan State University, East Lansing, MI, 2Microbiology and Molecular Genetics, Michigan State University, East Lansing, MI, 3Pediatrics and Human Development, Michigan State University, East Lansing, MI

Cytoplasmic actins are among the most ubiquitous and abundant proteins in the nucleated cell. Most vertebrates express two isoforms of cytoplasmic actin, β and γ (ACTB and ACTG1, respectively), which differ by only four amino acids in the N-termini of the proteins. The coding sequence of these two isoforms is remarkably well conserved, whereas the introns and UTRs demonstrate significantly less conservation. Although much is known about their general function, tissue specific distribution and relative expression levels, distinctly different functional roles for these two isoforms have not yet been determined. In most tissues, β-actin is expressed at >2:1 ratio relative to γ-actin, with the exception of the cochlea and gut epithelia where γ-actin is the predominant isoform. Expression of ACTG1 is thought to be controlled in part by limiting the splicing of intron 3 from the RNA transcript. Using PCR we have identified a novel γ-actin
transcript that is present in mouse cDNA from muscle, brain, eye, intestine, and cochlea. This novel transcript is particularly enriched in muscle where it is present at a level nearly equal to that of the standard isoform. This transcript includes a novel 45 bp exon located in the middle of ACTG1 intron 3 that introduces a premature stop codon. This 45 bp segment is flanked by canonical splice sites and shows a high degree of conservation between species. Likewise, we have demonstrated the presence of this alternative transcript in mouse cDNA from humans, cats, and dogs. A protein product corresponding to either a truncated protein or read-through of the stop codon is not present in the tissues. We therefore postulate that ACTG1 regulation is not controlled by the splicing of intron 3 from the RNA transcript, but rather involves the inclusion of a stop codon-containing pseudoexon/alternative exon. Lloyd C, Gunning P. β- and γ-actin genes differ in their mechanisms of down-regulation during myogenesis. J Cell Biochem. 2002;84(2):335-42.

Actin Conformational Changes Induced by Profilin Binding Observed with H/D Exchange and Mass Spectrometry.
E. Stokasimov, P. A. Rubenstein; Biochemistry, University of Iowa, Iowa City, IA

Profilin binds to actin’s barbed end across subdomains 1 and 3 leading to an increased rate of exchange of the adenine nucleotide bound in actin’s inter-domain cleft. However, the mechanism by which this increase is achieved is not understood. There is also an actin isoform-specific difference in actin’s ability to bind to different profilins leading to a differential enhancement of nucleotide exchange. Again, the mechanism underlying this functional specificity is not well understood. We used amide proton hydrogen/deuterium (HD) exchange detected by mass spectrometry to analyze conformational changes induced by profilin binding to yeast and muscle actins. Areas of yeast actin affected by binding of yeast profilin (YPF) or human profilin 1 (HPF) at saturating conditions are subdomain 1 peptides 8-31, 95-104 and 356-375, subdomain 4 peptide 208-218, and subdomain 3 peptide 154-176. All five peptides exhibit less exchange when YPF is bound compared to actin alone. On the other hand, YPF increases HD exchange in peptide 326-340 in the area connecting subdomains 1 and 3. A comparison of HD exchange of yeast actin bound to YPF or HPF shows differences in peptide 347-355 in subdomain 1. Furthermore, peptide 154-176 exchanges more when HPF rather than YPF is bound. Binding of HPF1 to muscle actin leads to an increased exchange over actin alone in peptide 145-155 in subdomain 3 and peptide 326-340 connecting subdomains 1 and 3. Conversely, HPF decreases exchange in peptide 208-218 in subdomain 4. Interestingly, binding of YPF to muscle actin causes greater HD exchange in the area connecting subdomains 1 and 3 than does HPF. The results demonstrate possible differential interaction of specific profilin isoforms to specific actin isoforms. They also show YPF-dependent propagation of conformational change through subdomains 1 and 3 onto subdomain 2 of yeast actin, while HPF seems to affect mostly subdomain 3 in muscle actin. Many of the changes observed are in peptides that line or contact the nucleotide cleft, consistent with profilin’s ability to alter the kinetics of nucleotide exchange.

RAGE Regulation of F-Actin Remodeling and Membrane Repair/Permeability in Endothelial Cells.
F. Xiong, Y. Hong, S. Xiong, Z. Zhou, L. Mei, W. Xiong; IMMAG, Medical College of Georgia, Augusta, GA

Receptor for Advanced Glycation End products (RAGE), an immunoglobulin superfamily transmembrane protein, is a receptor for multiple ligands. Ligands of RAGE include AGE (advanced glycation end product), s100, HMGB1, and b-amyloid (Ab). Thus, RAGE is implicated in the pathogenesis of multiple disorders, including diabetic complications, Alzheimer’s disease, and chronic inflammations. However, the underlying mechanism for RAGE induced cellular dysfunction remains largely unknown. Here, we present evidence for RAGE regulation of F-actin remodeling and membrane repair/permeability in endothelial cells. An endothelial cell line expressing RAGE showed a defective membrane repair activity and a decrease of F-actin stress
fibers and associated focal adhesions as compared with the parental cell line. The RAGE effects appeared to require serum in the culture and the intracellular domain of RAGE. These results suggest a new cellular function of RAGE in regulating plasma membrane permeability, an event that may underlie its pathogenesis of multiple disorders, including Alzheimer’s disease.

**Peritubular Myoid Cells Contract in Both the Parallel and Transverse Axes.**  
*L. Lopez, A. Losinno, A. Morales, J. Cavicchia; IHEM, UNCuyo, Mendoza, Argentina*

Testicular peritubular myoid cells (PMCs), the main cellular component of the seminiferous tubule (ST) wall, are contractile cells that express cytoskeletal markers of true smooth muscle, such as alpha-isoactin, F-actin, and myosin. The contractile activity of PMCs is responsible for the contraction of STs underlying the transport of spermatozoa and testicular fluid and, at least in part, for sperm release during spermiation. PMCs from isolated ST segments VII-VIII of rat testis, either relaxed (control ST) or contracted with endothelin-1 (E-1 ST) were analyzed by confocal and electron microscopy to visualize the actin filament cytoskeleton (AF). PMC areas from control and E-1 ST were 938 ± 64 and 760 ± 81 (µm² ± SEM) respectively and x, y diameters from control and E-1 ST were x: 36 ± 1; 30 ± 2 and y: 30 ± 2; 23 ± 3 (µm ± SEM) respectively. PMCs from these segments contain two layers of actin filaments. One layer is localized underneath the nucleus and close to the basal membrane of the seminiferous epithelium and is oriented transversally to the major ST axis. The other layer is localized above the nucleus and oriented parallel to the ST axis. Contraction reduced the area of the PMCs, and the x and y axes and also shortened both the parallel and transverse layer of AF. These results lead us to conclude that the particular organization of actin filaments in PMCs allow them to contract the cell in both parallel and transverse axes.

**Modulation of β Actin Filament Network Associated to Sertoli Cell Ectoplasmic Specializations along the Rat Seminiferous Epithelium Cycle.**  
*J. C. Cavicchia¹², F. Capani², M. Foscolo²; ¹Medical School, Cuyo University, Mendoza, Argentina, ²Histology Embryology Institute, CONICET, Mendoza, Argentina*

The term blood-testis barrier (BTB) originated by early physiological studies on the mammalian testis that demonstrated a differential transport of ions and metabolites between the basal areas of the seminiferous tubules (basal compartment), and the apical areas (adluminal one). Its morphological correlate was found to be located in specialized junctional devises found between the adjacent Sertoli (sustentacular) cells, integrated by occluding or tight junctions, which seal each inter-Sertoli space and by adherens junctions conformed by a highly organized circumferential belt of β actin filaments close to Sertoli cell membranes. Another junctional device, the tubular bulbar complexes (TB) completes this arrangement. These structures were termed ectoplasmic specializations (ES) by L. Russell(1977).OBJECTIVE: The aim of this study was to evaluate the distribution and arrangement of β actin and the implicated Sertoli membranes using confocal or electron microscopy, colocalization of beta actin with prosaposin (that specifically stains Sertoli cytoplasm) and freeze fracture (to observe Sertoli membranes and TB complexes).RESULTS: A clear, differential spatial organization of β actin filaments together with a differential arrangement of TB complexes along the spermatid cycle were observed. CONCLUSION: Significant interrelations between the actin network, the junctional complexes of the BTB and TB complexes were detected at different stages of the seminiferous cycle. Supported by Cuyo University and CONICET (National Research Council) grants from Argentina.

**Analysis of Domain(s) of LASP-2 Responsible for Actin-Binding Activity and Localization in Filopodia and Focal Adhesions.**
Lasp-2 concentrates to lamellipodial actin bundles in neural cells and focal adhesions in fibroblastic cells. Lasp-2 has three structural regions: a LIM domain, a nebulin-repeat region, and an SH3 domain. Lasp-2 is a splicing variant from the LASP2/NEBL gene, which concurrently encodes nebulette, an actin-binding protein expressed specifically in cardiac muscle. Various nebulin repeats of nebulin superfamily (nebulin, nebulette, and N-RAP) have been shown to associate with F-actin, and it has been proposed that the repeats participate in the association of lasp-2 with F-actin; however, the domain(s) responsible for actin-binding activity and the localization are still unclear. To determine the region responsible for the actin-binding activity of the lasp-2 molecule, we prepared recombinant fragments of lasp-2 in order to subject them to a co-sedimentation assay with F-actin. We expressed the fragments examined in the co-sedimentation assay with F-actin in NG108-15 neuroblastoma cells to confirm the relationship between the actin-binding activity and subcellular localization of lasp-2. The fragments was also transfected in C2C12 myoblasts to analyze localization in focal adhesions visualized by interference reflection microscopy. We revealed that the domains responsible for actin-binding activity showed a similar subcellular localization to full-length lasp-2 in NG108-15. However, the domains did not primarily contribute to its recruitment to focal adhesions in C2C12. Actin filament binding activity may be a major contributor to the subcellular localization of lasp-2 to filopodia but is not crucial for lasp-2 recruitment to focal adhesions.

Dissection of Functional Domains of GSNL-1, a Gelsolin-Like Protein in C. elegans.
Z. Liu, T. Klaavuniemi, S. Ono; Department of Pathology, Emory University, Atlanta, GA

The Caenorhabditis elegans gelsolin-like protein-1, GSNL-1 (475aa), is a new member of the gelsolin family of actin-regulatory proteins (Klaavuniemi et al., 2008). It is an unconventional gelsolin-related protein with four gelsolin-like domains (G1 to G4), unlike typical gelsolin-like proteins with six or three G domains. Sequence alignment suggests that GSNL-1 lacks two G domains that are equivalent to fourth and fifth G domains of gelsolin. GSNL-1 severs actin filaments and caps the barbed end in a calcium-dependent manner similarly to gelsolin. In contrast, GSNL-1 has different properties from gelsolin in that it remains bound to F-actin, and does not nucleate actin polymerization. To understand the mechanism by which GSNL-1 regulates actin dynamics, we investigated domain-function relationship of GSNL-1 by analyzing activities of truncated forms of GSNL-1. For actin filament severing activity, G1 plus the linker between G1 and G2 was sufficient, whereas the presence of G2 greatly enhanced the activity. This is similar to gelsolin. Effects on the critical concentration of actin suggested that G1-G2 was necessary and sufficient for barbed-end capping activity. G-actin binding assays by non-denaturing electrophoresis demonstrated the presence of at least two G-actin binding sites in G1 and G3-G4. By contrast, F-actin co-sedimentation assays indicated that G3-G4 was sufficient for binding to F-actin, which is different from gelsolin that has an F-actin binding site in G2. Interaction of gelsolin with actin was inhibited by direct binding of gelsolin with polyphosphoinositides (PIP2). Actin severing activity of GSNL-1 was also inhibited in the presence of PIP2. Two PIP2-sensitive domains were mapped to G1 and G2. These results suggest that G domains of GSNL-1 play distinct roles in regulation of actin dynamics and that F-actin binding sites are located in different G domains between GSNL-1 and gelsolin.

Kinetic Analysis of the Binding of Cofilin, 14-3-3y and AZX100.
D. Derkach, K. Perkins, M. Sheller; R&D, Capstone Therapeutics, Tempe, AZ

Pathological scarring, such as keloid and hypertrophic, is characterized by the presence of myofibroblasts, which are distinguished from fibroblasts by the expression of α Smooth Muscle
Actin (αSMA) and Connective Tissue Growth Factor (CTGF). Previous data have shown that AZX100, a 24 amino acid phosphopeptide analog of HSP20 linked to a protein transduction domain, can reduce the expression of αSMA and CTGF in keloid-derived myofibroblasts. AZX100 binds the intracellular scaffolding protein 14-3-3γ, which displaces bound cofilin and results in actin depolymerization and reversal of TGF-β1-induced myofibroblast differentiation. In this study, Surface Plasmon Resonance (SPR) and immunoprecipitation (IP) studies were used to determine whether AZX100 can displace bound cofilin from 14-3-3γ. The interaction of 14-3-3γ and AZX100 was examined using SPR. 14-3-3γ binds to AZX100 in a phosphorylation-dependent manner with two distinct KD’s of 642±40 nM and 803±51 nM. No binding of 14-3-3γ to unphosphorylated or scrambled AZX100 was observed. Similarly, binding of 14-3-3γ to cofilin was phosphorylation-specific, as no binding to unphosphorylated cofilin was observed. Analysis of the interaction between 14-3-3γ and cofilin revealed two distinct KD’s of 42±6 nM and 267±75 nM. Most importantly, the ability of AZX100 to displace bound 14-3-3γ from phosphorylated cofilin was demonstrated by SPR analysis as well as by immunoprecipitation experiments. These results demonstrate that although 14-3-3γ has a lower binding affinity for AZX100 versus cofilin, a molar excess of AZX100 can displace bound cofilin, leading to actin depolymerization in the myofibroblast. Thus, AZX100 may be of therapeutic benefit for the prevention of abnormal scarring.

Overlapping and Distinct Functions for Cofilin, Coronin and Aip1 in Actin Dynamics In Vivo.
M. Lin, B. Gelletta, J. A. Cooper; Washington Univ, St Louis, MO

Actin filament disassembly is critical for actin-based motility, to control filament network architecture and to regenerate subunits for assembly. Here, we examined the roles of three actin cytoskeletal proteins, coronin, cofilin and Aip1, which have been implicated as combining in various ways to control actin dynamics by promoting or regulating disassembly. We studied their functions during the endocytosis process in budding yeast, where actin filament dynamics at the cortical actin “patch” contribute to the formation and movement of endocytic vesicles. We found that all three proteins were recruited during the late phase of the actin patch life. They all arrived at the same time, when actin and other actin-associated proteins were leaving the patch. Their peak molecular stoichiometry per patch was 500 cofilin molecules, 90 coronin molecules and 45 Aip1 molecules. We found that mutations in genes encoding one protein could influence the proper localization of another protein. Using quantitative patch motion analysis and comparing mutant alleles, we found commonalities and differences in the phenotypes for mutations of the three genes. Together, the results are consistent with all three proteins working to promote actin disassembly, but not in a simple way and not with equal importance.

All Three Vertebrate Iqgaps Interact with Actin Filaments.
X. Fang1, R. Luzes2,3, H. Kan1, L. C. Cameron2,3, G. S. Bloom1; 1Department of Biology, University of Virginia, Charlottesville, VA, 2Laboratorio de Bioquímica de Proteínas, Universidade Federal do Estado do Rio de Janeiro, Rio de Janeiro, Brazil, 3Instituto de Genética e Bioquímica, Universidade Federal de Uberlândia, Uberlândia, Brazil

The IQGAP family comprises scaffolding proteins that regulate actin assembly, exocyst function, and cellular motility, morphogenesis, adhesion and division. Vertebrates express 3 family members, IQGAP1, IQGAP2 and IQGAP3, which are ~60-70% identical to each other in amino acid sequence and are organized into a common set of functional domains. Prior work has shown that IQGAP1 binds directly to F-actin (Bashour et al. 1997. J CELL BIOL 137: 1555-1566), and stimulates nucleation of branched actin filaments through N-WASP and the Arp2/3 complex following direct binding to cytoplasmic domains of ligand-activated growth factor receptors (Benseñor, et al. 2007. J CELL SCI 120: 658-669). IQGAP1 thus spatially and temporally couples growth factor signaling to actin assembly, and by extension, the plasma membrane expansion that defines cell migration and shape change. By contrast to IQGAP1, very little is known about
interactions between IQGAP2 or IQGAP3, and actin. To begin addressing this issue we used actin filament binding assays and fluorescent fusion protein expression in cultured mammalian cells. Purified his-tagged IQGAP2(full length) and IQGAP2(2-528), an N-terminal fragment corresponding to ~1/3 of the full length protein, bound directly to purified F-actin by high speed centrifugation assays. Furthermore, IQGAP2(full length)-YFP and IQGAP3(full length)-YFP, as well as the N-terminal fragments, IQGAP2(1-528)-YFP and IQGAP3(1-531)-YFP, all targeted to F-actin rich domains, including lamellipodia and cell-cell junctions, when expressed in mammalian cells. Similar observations were made for IQGAP1(full length)-YFP, IQGAP1(1-522)-YFP and GFP-IQGAP1(1-550). With 2 exceptions, IQGAP2(full length)-YFP and IQGAP2(1-528)-YFP, none of the fluorescent fusion proteins associated with stress fibers. Fluorescent fusion proteins of the middle and C-terminal thirds of each IQGAP failed to target to actin filaments. Based on these observations, we hypothesize that all 3 mammalian IQGAPs interact directly with actin filaments in vivo via their N-terminal regions, and that the unique localization of IQGAP2 on stress fibers signifies functional heterogeneity among the IQGAPs. Supported by NIH grant NS051746 to GSB.

Distinct Functional and Structural Interactions between Iqgap1 and Cdc42 Versus Rac1.
H. Wallrabe1, Y. Cai1, R. Luzes2,3, H. Kan1, L. C. Cameron2,3, G. S. Bloom1; 1Department of Biology, University of Virginia, Charlottesville, VA, 2Laboratorio de Bioquímica de Proteínas, Universidade Federal do Estado do Rio de Janeiro, Rio de Janeiro, Brazil, 3Instituto de Genética e Bioquímica, Universidade Federal de Uberlândia, Uberlândia, Brazil

IQGAP1 stimulates nucleation of branched actin filaments by activating N-WASP, which in turn activates the Arp2/3 complex (Benseñor, et al. 2007. J CELL SCI 120: 658-669). N-WASP can be activated by other factors, including GTP-bound forms of Cdc42 and Rac1, which also bind IQGAP1. We report here the use of purified proteins for In Vitro polymerization and binding assays, and of FRET microscopy of cultured cells to illuminate functional interactions involving IQGAP1, N-WASP, and either Cdc42 or Rac1. Pyrene-actin assembly assays were used to compare how activated Cdc42 and Rac1, alone and in combination with IQGAP1, affected actin assembly in the presence of N-WASP and the Arp2/3 complex. Cdc42 (100-200 nM) and IQGAP1 (45 nM) cooperatively stimulated actin filament nucleation, primarily by reducing the lag time before Vmax for assembly was reached. This nucleation cooperativity reflected dose-dependent stimulation by Cdc42 of IQGAP1 binding to N-WASP. Under otherwise identical conditions, Rac1 and IQGAP1 behaved quite differently. at low (100 nM) Rac1, the two proteins cooperatively reduced the lag time before assembly Vmax was reached, but at high (200 nM) Rac1 Vmax was faster and was reached more quickly for Rac1 alone than for either IQGAP1 alone, or the combination of Rac1 and IQGAP1. This negative cooperativity reflected dose-dependent inhibition by Rac1 of IQGAP1 binding to N-WASP. These results imply that IQGAP1 interacts by distinct mechanisms with Cdc42 versus Rac1 to fine tune actin filament assembly in vivo. To address this possibility, quantitative FRET microscopy fully corrected for spectral bleedthrough was used to study interactions of GFP-IQGAP1 with mOrange-Cdc42 versus mOrange-Rac1 in live MDCK cells. Robust corrected energy transfer was observed for both FRET pairs, but the average distance between IQGAP1 and Cdc42 was 0.7 nm with a range of 0.65-0.77 nm, whereas IQGAP1 and Rac1 were 0.74 nm apart on average, with a range of 0.70-0.80 nm. The differential interactions of IQGAP1 with Cdc42 versus Rac1 that we observed In Vitro were thus recapitulated in live cells, and both sets of data support a higher affinity of IQGAP1 for Cdc42 as compared to Rac1. Supported by NIH grant NS051746 to GSB.

Roles of Ena/VASP and Capping Protein in Drosophila Development.
S. Nowotarski1, R. Banerjee1, J. Gates1, M. Peifer2; 1Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, NC, 3Department of Biology, Bucknell University, Lewisburg, PA
Proper development requires cells to build a range of different actin-based structures. Each actin structure presumably arises from differing underlying actin geometries resulting from the effect of different suites and levels of actin regulators. We use Drosophila morphogenesis and oogenesis as models for understanding In Vivo requirement of proper actin regulation, specifically focusing on two integral actin regulators: Enabled/VASP (Ena) and Capping Protein (CP). In oogenesis we found Ena plays important roles in cortical integrity of germ-line nurse cells, and in proper formation of bundled actin filaments in nurse cells during the dumping process. Ena localizes to barbed ends of these specialized actin structures. Ena appears to be negatively regulated by Abelson kinase in this context. Analysis of ena mutants affecting different domains suggests the EVH1 domain is not as critical as the oligomerization and EVH2 domains in oogenesis. Further insight into the contribution and importance of individual domains of Ena during morphogenesis and oogenesis is currently being pursued through a protein structure function approach. We found CP is important for nurse cell dumping, and also plays a surprisingly critical role in oocyte specification perhaps as part of the dynactin complex. Together these data support an antagonistic relationship between Ena and CP in oogenesis. We are continuing to explore the relationship between these two proteins in morphogenesis.

**Actin Polymerization in Differentiated Vascular Smooth Muscle Cells Requires Vasodilator-Stimulated Phosphoprotein (VASP).**

H. Kim¹, P. Graceffa², F. Ferron², C. Gallant¹, M. Boczkowska², R. Dominguez², K. G. Morgan¹,³; ¹Department of Health Sciences, Boston University, Boston, MA, ²Department of Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA, ³Boston Biomedical Research Institute, Watertown, MA

Our group has previously shown that vasoconstrictors increase net actin polymerization in differentiated vascular smooth muscle cells (dVSMC) and that increased actin polymerization is linked to contractility of vascular tissue. However, the underlying mechanisms are largely unknown. Here, we evaluated the possible functions of the Ena/VASP family of actin filament elongation factors in dVSMC. Inhibition of actin filament elongation by cytochalasin-D decreases contractility without changing the level of myosin light chain phosphorylation, suggesting that actin filament elongation is necessary for dVSM contraction. VASP is the only Ena/VASP protein highly expressed in aorta tissues and VASP knockdown decreased smooth muscle contractility. VASP partially colocalizes with both alpha-actinin and vinculin in dVSMC. Profilin, known to associate with G-actin and VASP, also colocalizes with alpha-actinin and vinculin, potentially identifying both the dense bodies and the adhesion plaques as hot spots of actin polymerization. Differential centrifugation and imaging results indicate that VASP may undergo subtle positional changes in response to stimuli. The EVH1 domain of Ena/VASP is known to target these proteins to their sites of action. Introduction of an expressed EVH1 domain as a dominant negative inhibits stimulus-induced increases in actin polymerization. We also directly visualized, for the first time, the incorporation of rhodamine-labeled actin in dVSMC cells, and identified “hot spots” of actin polymerization in the cell cortex that colocalize with VASP. These results indicate a role for VASP in actin filament assembly at the cell cortex that modulates contractility in dVSMC.

**Remodeling of the Actin Cytoskeleton by Vasodilator-Stimulated Phosphoprotein Regulates the Formation of Dendritic Spines and Synaptic Strength.**

W. Lin¹, B. R. Anderson¹, C. A. Nebhan¹, D. J. Webb¹,²; ¹Biological Sciences, Vanderbilt University, Nashville, TN, ²Cancer Biology, Vanderbilt University, Nashville, TN

Reorganization of the actin cytoskeleton is critical for the formation and plasticity of dendritic spines, which are actin-rich structures that constitute the postsynaptic sites of excitatory synapses. Alterations in the density and morphology of spines, which can be attributed to actin remodeling, are associated with neuronal disorders, including mental retardation, Fragile-X syndrome, Down’s syndrome, Alzheimer’s disease, and epilepsy. This points to a central role for these structures and the regulation of actin in cognitive function. Despite the importance, the
mechanisms that regulate actin reorganization in dendritic spines are currently not well understood. Here, we show that the multifunctional actin-binding protein vasodilator-stimulated phosphoprotein (VASP) is enriched in spines and functional synapses in hippocampal neurons. Knockdown of endogenous VASP using siRNA leads to a significant decrease in the number of spines and synapses. Expression of GFP-VASP results in an increase in the number of spines and the size of spine heads with a higher concentration of filamentous actin and more available barbed ends in these structures. In addition, VASP promotes an increase in the synaptic expression of α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA)-type glutamate receptors at the membrane, suggesting that VASP strengthens synaptic efficacy. Expression of VASP lacking the Ena/VASP homology domain2 (EVH2), which binds G- and F-actin, results in a reduction in synaptic targeting, spine density, and spine head size. Deletion of the coiled-coil domain, which mediates VASP tetramerization, within EVH2 decreases the number and size of spines. Interestingly, the EVH1 domain, but not the proline-rich region, is also important for VASP function in spines. Collectively, our results suggest that actin polymerization and bundling, which are mediated by VASP, regulate the density, size, and morphology of dendritic spines. Therefore, VASP-regulated remodeling of the actin cytoskeleton is critical for the formation and expansion of dendritic spines and for modulating synaptic strength.

213/B160  
The Role of Cyclase-Associated Protein 1 (CAP1) in Actin Dynamics.  
M. Makkonen, E. Bertling, P. Lappalainen; Institute of Biotechnology, University of Helsinki, Helsinki, Finland

The actin cytoskeleton is essential for many cellular processes such as morphogenesis, motility, endocytosis and cytokinesis. The structure and dynamics of the actin cytoskeleton are regulated by various actin binding proteins. Cyclase-associated proteins (CAPs) are highly conserved actin monomer binding proteins found in all eukaryotes studied. Two CAP isoforms are found in mammalian cells, CAP1 is widely expressed in non-muscle cells and CAP2 is found mainly in developing and mature striated muscles. Budding yeast has only one CAP protein (called Srv2), which binds ADP-actin monomers and profilin through its C-terminal domain, and cofilin/ADP-G-actin complex through its N-terminal domain. By mutagenesis analysis, we show here that mouse CAP1 binds ADP-G-actin, profilin and cofilin/ADP-G-actin by similar mechanisms to yeast Srv2. However, unlike yeast Srv2, mouse CAP1 binds also ATP-G-actin with high affinity through its WH2 domain. We are also currently carrying out RNAi and rescue experiments with mutant versions of CAP1 to reveal the roles of these various protein-protein interactions in morphogenesis and motility of mammalian cells. In conclusion, here we show that mammalian CAP1 binds profilin, ADP-G-actin, ATP-G-actin and cofilin/actin through distinct sites.

214/B161  
CAP2, Cyclase Associated Protein 2, Is a Dual Compartment Protein with WH2 Domains.  
V. Peche1,2, R. Schröder1,6, G. Pfitzer5, C. Clemen1,2, I. Karakesisoglou1,7, T. Holak4, M. Schleicher3, A. A. Noegel1,2; 1Institute for Biochemistry-I, University of Cologne, 50931, Cologne, Germany, 2Center for Molecular Medicine Cologne, Medical Faculty, University of Cologne, 50931, Cologne, Germany, 3Institute of Cell Biology, Ludwig-Maximilians-Universität, 80336, München, Germany, 4Max-Planck-Institute of Biochemistry, 82152, Martinsried, Germany, 5Institute of Vegetative Physiology, Medical Faculty, University of Cologne, 50931, Cologne, Germany, 6Institut für Neuropathologie Schwabacheranlage 6, Universitätsklinikum Erlangen, 91054 Erlangen, Germany, 7School of Biological and Biomedical Sciences, University of Durham, South Road, Durham, DH1 3LE, United Kingdom

CAPs are evolutionary conserved proteins that have roles in regulating the actin cytoskeleton and in signal transduction. Mammals have two CAP genes that code for related proteins, CAP1 and CAP2. With specific antibodies for both proteins we studied their distribution and subcellular localisation. CAP1 shows a broad tissue distribution, whereas CAP2 is significantly expressed only in brain, heart and skeletal muscle, and in skin. CAP2 is found in the nucleus in undifferentiated myoblasts and at the M-line of differentiated myotubes. In PAM212, a mouse
keratinocyte cell line, CAP2 is enriched in the nucleus. By contrast, CAP1 localises to stress fibers and F-actin rich regions such as lamellipodia in PAM212 cells. In human skin CAP2 is present in all living layers of the epidermis where it localises to the nuclei and to cell-cell junctions. ChIP analysis revealed that CAP2 could effectively bind to chromatin. Moreover, like other CAPs, CAP2 can sequester actin through its C-terminal domain. This sequestering activity presumably resides in the WASP homology domain 2 (WH2 domain), a short stretch of amino acids between the N- and C-terminal domain of CAP2. Immunofluorescence studies with mouse whole mount embryos revealed the expression of CAP2 at E12.5, specifically in the developing heart. Thus CAP2 is an important actin binding protein, which sequesters actin through its WH2 domain, with a dual compartmental distribution and may play an important role during heart development in mouse embryogenesis.

**Selective Disruption of the Actin Cytoskeleton but Not the Muscle Sarcomere by Targeting Cytoskeletal Tropomyosin.**

T. T. Bonello¹, J. Stehn¹, T. Butler², D. Winlaw², S. Palmer³, E. Hardeman³, M. Allanson⁴, V. Reeve⁵, P. Gunning¹; ¹Department of Pharmacology, School of Medical Sciences, University of New South Wales, Sydney, NSW, Australia, ²Kids Heart Research, The Children’s Hospital at Westmead, Sydney, NSW, Australia, ³Department of Anatomy, School of Medical Sciences, University of New South Wales, Sydney, NSW, Australia, ⁴Faculty of Veterinary Science, University of Sydney, Sydney, NSW, Australia

The actin cytoskeleton represents a promising target for the design of cancer chemotherapeutics, but to date no anti-actin compounds have reached the clinic. Directly targeting actin is associated with unacceptable toxicity due to the central role of actin in striated muscle contraction. To maintain cardiac and respiratory function, compounds which disrupt actin filaments must discriminate between the actin cytoskeleton of tumor cells and the specialized actin-based structures of the striated muscle sarcomere. Muscle and non-muscle actin filaments are associated with distinct tropomyosin (Tm) isoforms which regulate filament function. Our laboratory has designed novel anti-Tm compounds which specifically target non-muscle Tms relied upon by cancer cells. OBJECTIVE: to investigate the specificity of anti-Tm compounds by assessing their impact on cardiac function In Vitro and In Vivo. SUMMARY OF RESULTS: The structural integrity of isolated rat cardiomyocytes (CMs) was maintained with exposure to the lead anti-Tm compound, TR100, at a concentration (10 μM) which disrupted adhesion and viability of the neuroblastoma tumor cell line, SKN-Be2C. To assess function following TR100 treatment, sarcomere shortening of contracting isolated adult rat CMs was measured in real time using the IonOptix system. Acute perfusion with 10μM or 50μM TR100 did not alter the contractile properties of the CM, measured as peak shortening, duration of contraction and maximal rate of shortening and relengthening. In contrast, all contractile parameters were significantly depressed with exposure to the actin destabilizing compound, Cytochalasin-D (20μM). In Vivo cardiac data was derived from a B16/F10 murine melanoma model, treated with 30mg/kg TR100. at this dose, tumor growth was suppressed, but no obvious signs of hypertrophy or heart damage were observed as measured by changes to interventricular septum thickness, heart weight or blood troponin I levels. CONCLUSIONS: These results demonstrate that it is possible to target the actin cytoskeleton to achieve tumor-specific cytotoxicity without consequent cardiac toxicity.

**Tropomyosin 4 Affects Neuronal Morphogenesis and Differentiation.**

N. Curthoys¹, G. Schevzov², P. Gunning¹, T. Fath¹, ¹Oncology Research Unit, Discipline of Paediatrics and Child Health, University of Sydney, Sydney, NSW, Australia, ²Oncology Research Unit, School of Medical Sciences, University of New South Wales, Sydney, NSW, Australia

The actin cytoskeleton regulates cellular structure and a range of functions such as cell motility, cytokinesis, and vesicle formation. Tropomyosins regulate these functions by attenuating effects of other actin binding proteins on actin filaments. at least 40 Tropomyosin isoforms are produced
from four genes (αTm, βTm, γTm, and δTm). Tm4 is the single known mammalian product of the δTm gene, with similar distributions along membrane junctions in many tissues, including synapses. Tm4 function in brain is largely unknown. We have identified a potential alternative product from the δTm gene, which is immunoreactive with the Tm4 antibody. We aim to identify and characterise this product, and to investigate the function of Tm4 in neural cells. Methods Rat neuroblastoma cells (B35s) were stably transfected with a mammalian vector containing Tm4 cDNA. We are using proteomics approaches to identify which proteins are affected in their expression by Tm4 overexpression. We have optimized the purification of the Tm4 antibody immunoreactive product, and are currently preparing samples to sequence this product. Results Endogenous and exogenous Tm4 associates with actin cables in B35s, and Tm4 overexpression induces morphological changes normally associated with differentiation. The alternative novel product of Tm4 has been immunoprecipitated along with Tm4 and is resistant to heat treatment, indicating it may be a Tropomyosin. Conclusion Overexpression of Tm4 profoundly alters the actin cytoskeleton. We are currently investigating the molecular pathways through which Tm4 induces these changes. Identification of a potentially novel Tropomyosin isoform will be followed by characterization of the function of this isoform.

Binding of Human Angiogenin Inhibits Actin Polymerization.
M. Pyatibratov1,2, D. Tolkatchev3, J. Plamondon3, P. Xu3, F. Ni3, A. Kostyukova1; 1Neuroscience & Cell Biology, RWJMS, Piscataway, NJ, 2Institute Of Protein Research, RAS, Pushchino, Moscow Region, Russia, 3Biotechnology Research Institute, NRCC, Montreal, QC, Canada

Angiogenin is a potent inducer of angiogenesis, a process of blood vessel formation. It interacts with endothelial and other cells and elicits a wide range of cellular responses including migration, proliferation, and tube formation. One important target of angiogenin is cell-surface actin that has been shown to act as a receptor for angiogenin in endothelial cells and their interaction might be one of essential steps in angiogenin-induced neovascularization. We used pyrene-actin fluorescence, co-precipitation and electron microscopy to study the binding interactions between angiogenin and actin in a wide range of conditions. We showed that at physiological KCl concentrations, angiogenin inhibits polymerization of G-actin. At low KCl concentrations angiogenin induces formation of unstructured aggregates, which, as shown by NMR, may be caused by angiogenin’s propensity to form dimers and higher oligomers in solution. Angiogenin binds to F-actin. This binding does not cause depolymerization of actin filaments though it causes straightening of filaments. We tested if the presence of tropomyosin, an actin filament binding protein, can prevent angiogenin binding and vice versa. Binding of tropomyosin and angiogenin to F-actin appears to be independent therefore these proteins do not share the same binding interface on F-actin. These observations suggest that angiogenin binding to G-actin as well as to F-actin may cause drastic changes in the cell cytoskeleton by inhibiting polymerization of G-actin and changing the mechanical properties of F-actin.

Conventional Myosin (218 – 234)

Myosin-II as an Active Force Sensor That Converts Mechanical Inputs into Chemical Signals.
Y. Kee1,6, R. A. Firtel6, P. Iglesias2, D. Robinson1,3,4; 1Cell Biology, Johns Hopkins School of Medicine, Baltimore, MD, 2Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD, 3Pharmacology and Molecular Sciences, Johns Hopkins School of Medicine, Baltimore, MD, 4Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, 5Section of Cell and Developmental Biology, University of California San Diego, San Diego, CA, 6Department of Biophysics, Johns Hopkins University, Baltimore, MD

Mechanosensing is important in many physiological processes such as hearing and blood pressure regulation. However, the mechanisms by which cells sense mechanical inputs are not
well understood. Previous studies from our lab showed that cellular mechanosensing is crucial for regulating cytokinesis shape change. We use micropipette aspiration (MPA) to generate stress on the cell cortex. Using this assay, we discovered that mechanical stress stimulates the accumulation of myosin-II (a contractile force generating protein) and cortexillin-I (an actin bundling protein) to the deformation site to correct cell shape. Both myosin-II and cortexillin-I are required for this active mechanosensory system during cytokinesis. Recently, we demonstrated that this mechanosensory response is tunable by varying the lever arm length of myosin-II heavy chain, showing that myosin-II is an active force sensor in this mechanosensory system. In our new study, we focus on how mechanical inputs mediated through myosin-II lead to changes in biochemical signaling pathways, specifically the cortexillin-I regulatory and spindle signaling pathways. Rac1A (a small GTPase), IQGAP1, and IQGAPA (GTPase effectors) can form complexes with cortexillin-I. In the absence of both IQGAP1 and IQGAPA, cortexillin-I does not localize normally to the cleavage furrow during cell division. Using MPA, we found that IQGAPA, but not IQGAP1, is essential for myosin-II mechanosensing during cell division. Consistently, only IQGAPA is responsive to mechanical perturbation. Kif12, a mitotic-kinesin-like protein in Dictyostelium cells, is part of the chromosomal passenger complex, including INCENP and Aurora kinase. Kif12 is also recruited to the cell cortex inside the micropipette in a myosin-II-dependent manner. Thus, some of the mitotic spindle signaling machinery is responsive to the mechanical stress sensed by myosin-II. Overall, these results indicate that myosin-II is a key element for mechanosensing and for translating mechanical inputs into biochemical signaling pathways.

Analysis of Conformation of the Skeletal Muscle Myosin Modified by Bifunctional Reagents Using FRET.
M. D. Yamada1, K. Ishiyama1, E. Katayama2, Y. Kimori3, S. Maruta1; 1Soka University, Hachioji, Japan, 2Inst. of Med. Sci., The Univ. of Tokyo, Shiroganedai, Japan, 3Nat'l Inst. of Neurosci., Nat'l Ctr of Neurol. and Psych., Kodaira, Japan

Previously biochemical studies have demonstrated that the highly reactive cysteine residues SH1 and SH2 can be crosslinked by variety of bifunctional reagents with different spans (3-14 Å) in the presence of nucleotides, suggesting that the region is highly flexible. The SH1-SH2 region is believed to play a key role in the conformational changes that occur in the myosin head during the force generation coupled to ATP hydrolysis. We have previously shown that the HMM, which SH1-SH2 was crosslinked by p-Phenylenedimaleimide (pPDM) and 1,5-difluoro-2,4-dinitrobenzene (F2DNB) in the presence of ADP, have a novel conformation using quick freeze deep etch electron microscopy (QFDE-EM). We have also demonstrated that conformational change of the myosin motor domain during ATP hydrolysis can be monitored by measuring the FRET using fluorescent ATP analogue NBD-ATP. In the present study, we analyzed the conformation of the myosin crosslinked by pPDM and F2DNB using FRET between the ATP binding site and the A1 essential light chain (ELC). We prepared skeletal muscle myosin subfragment-1 (S1), which ELC was labeled by 6-bromoacetyl-2-dimethylaminonaphthalene (BD) at the Cys 177. And fluorescent ADP analogue NBD-ADP was trapped within the ATPase site of S1 labeled by BD. The FRET efficiency was estimated by measuring the change of fluorescence intensity of BD comparing with control BD-S1. The FRET efficiency of pPDM-S1-ADP and F2DNB-S1-NBD-ADP were lower than S1-NBD-ADP state. This suggests that the pPDM-S1-ADP and F2DNB-S1-ADP states form more kinked conformation

Tropomyosin and Myosin-II Cellular Levels Promote Actomyosin Interactions and Contractile Ring Assembly in Fission Yeast.
B. C. Stark, T. E. Sladewski, M. Lord; Molecular Physiology & Biophysics, University of Vermont, Burlington, VT

The actin-based myosin-II motor (Myo2p) and the actin-binding protein tropomyosin (Cdc8p) are essential for contractile ring formation and cytokinesis in fission yeast. Yet how these proteins
operate in the contractile ring is not well understood. We used a combination of genetics, live cell imaging, and biochemical assays to understand the roles of Myo2p and Cdc8p in ring assembly. We found that rings form prematurely in cells engineered to carry an extra copy of myo2 suggesting that changes in Myo2p cellular levels can influence ring assembly. Mutations in the Myo2p motor or Cdc8p delay ring formation, indicating a role for both proteins in ring assembly. Doubling Myo2p levels suppressed ring assembly and cytokinesis defects associated with a cdc8 mutation suggesting that Cdc8p contributes to effective Myo2p function in the cell. In Vitro assays revealed that Cdc8p regulates Myo2p directly. Actin-activated ATPase assays showed that association of Cdc8p with actin increases Myo2p's ATP hydrolysis rate by promoting its affinity for actin. In the presence of Cdc8p, Myo2p's ability to support actin filament gliding in motility assays was enhanced, despite a two-fold reduction in velocity. We found that Cdc8p promotes actomyosin interactions by favoring the strong actin-bound state of Myo2p. This new mode of regulation relies on the ability of tropomyosin to selectively alter myosin kinetics to maximize actomyosin interactions, which favors contractile ring assembly in the fission yeast system.

Characterization of the Effects of Streptozotocin-Induced Diabetes on Expression of Myosin-LIB in Rat Brains Using Calmodulin Affinity Chromatography.
L. K. Calábria¹, G. Costa Nunes da Cruz², N. Moura de Gouveia³, F. Vieira Alves¹, F. Barcelos Furtado¹, M. Valle de Souza², F. S. Espindola¹; ¹Instituto de Genética e Bioquímica, Universidade Federal de Uberlândia, Uberlândia, Brazil, ²Universidade de Brasília, Instituto de Biologia, Brasília, Brazil

The Ca+2/calmodulin complex interacts with and regulates various enzymes and target proteins, known as calmodulin-binding proteins (CaMBPs). This group of proteins includes molecular motors such as myosins. Myosin-II binds calmodulin in a Ca+2-independent manner and was showed in our study to be overexpressed in the brains of diabetic rats. In this study, we compared the calmodulin affinity chromatography-purified CaMBPs isolated from the brains of streptozotocin-induced diabetic rats and non-diabetic rats. Proteins eluted with EGTA and urea were separated on an SDS-PAGE gel, digested and submitted to peptide mass fingerprinting. The gel revealed similar protein profiles for the CaMBPs from the brains of diabetic rats and non-diabetic rats. There were sixteen intense bands for the diabetic brain and fifteen for the non-diabetic brain. Four proteins were found exclusively in diabetic brains, two were found exclusively in non-diabetic brains and thirteen were found in both types of rat brains. Moreover, the fraction eluted with 6 M urea contained myosin-IIB and cytoplasmic actin and showed that these proteins were strongly expressed in diabetic brains. Protein sequences were then analyzed for the presence of the calmodulin-binding sites. A large fraction of the proteins present (83%) had putative IQ motifs or calmodulin-binding sites. This is the first study to identify calmodulin-binding proteins in the brains of diabetic and non-diabetic rats through a comparative proteomic study, and it opens up new areas of study related to the link between myosin-IIB levels in the brain and diabetes mellitus.

Conditional Ablation of Nonmuscle Myosin II-B in Mice Results in Arrhythmogenic Right Ventricular Cardiomyopathy Associated with Defects in the Coronary Circulation.
X. Ma¹, M. Ikebe², S. Anderson¹, R. S. Adelstein¹; ¹Laboratory of Molecular Cardiology, NHLBI/NIH, Bethesda, MD, ²U. Mass. Med Ctr, Worcester, MA

Global ablation of nonmuscle Myosin II-B (NM II-B; B¹⁻¹ B¹⁺⁻) in mice results in lethality during embryonic development with cardiac associated defects. In an effort to produce a mouse model for human cardiac disease, we generated a NM II-B conditionally ablated mouse in which Cre-recombinase is under the control of the transgelin/SM22α promoter (B¹⁺⁻SM22α B¹⁻⁻SM22α mice). NM II-B was ablated in almost all cardiac myocytes, the majority of epicardial cells, and smooth muscle cells of the aorta as early as E11.5. Unlike B¹⁻⁻ B¹⁺⁻ mice, B¹⁺⁻SM22α B¹⁻⁻SM22α mice survive up to 5 months of age. MRI analyses of the mouse hearts show severe dysfunction and dilation of the right ventricle at 4 months, while the contractile activity of the left ventricle is not impaired.
EKG analyses of B<sup>SM22<sub>a</sub></sup> mice at 1 month and later show cardiac arrhythmias, including defects in conduction such as atrial-ventricular dissociation and the presence of numerous premature ventricular beats indicating a blockage in cardiac conduction. Sectioning of B<sup>SM22<sub>a</sub></sup> hearts at 3 months demonstrates marked cardiac myocyte hypertrophy and interstitial fibrosis in the right ventricle. Cardiac myocyte hypertrophy is also observed in the left ventricle, but no obvious interstitial fibrosis is seen. In addition, B<sup>SM22<sub>a</sub></sup> hearts show defects in coronary vessel development during the early embryonic stages. Large size coronary arteries are missing in the right ventricle of adult B<sup>SM22<sub>a</sub></sup> hearts. Many of these mice die suddenly between 3-5 months of age due to cardiac arrhythmias. In addition both the systemic and pulmonary blood pressure of B<sup>SM22<sub>a</sub></sup> mice were significantly lower compared to their control littermates consistent with the idea that NM II-B in vascular smooth muscle is contributing to maintain the vascular tone.

Cell migration of human oral keratinocytes is a highly regulated and coordinated process that is dependent upon dynamic changes in the actin cytoskeleton. In a previous study, we showed that virulence factors secreted by Candida albicans targets the keratinocyte actin cytoskeleton and stimulates cell migration by ~2-fold. In this study, we examined the dynamic distribution of non-muscle myo2A and B during stimulated keratinocyte migration to determine their roles in this process. We used human oral keratinocytes (OKF6/TERT-2) co-cultured with hyphae-forming wild-type C. albicans. Rates of keratinocyte migration and the cellular redistribution of myo2A and B were determined at 0, 3 and 6 hours by multi-mode high resolution microscopy and quantitative image analysis. First we observed that the protrusive activity at the leading edge, analyzed kymographically, was significantly greater in C. albicans treated cultures than in untreated cultures. In addition, cell migration increased and the distribution of myo2A and B changed. Myo2A, which was localized throughout the cytoplasm in untreated cells, localized to newly formed actin stress fibers and focal adhesions (FAs) after 3 h of treatment. Myo2A was excluded from the leading edge of the lamellipodia that formed after 6 h of treatment. In contrast, Myo2B, detectable at the rear and the center of untreated cells, was mostly absent from actin stress fibers and FAs that formed at 3 h, but localized at the leading edge of newly formed lamellipodia at 6 h. Fluorescence intensity profiles illustrated both the coordinated redistribution of myo2 isoforms and their colocalization with the actin cytoskeleton. Cell migration and the localization of myo2 a and B were not affected with the C. albicans mutant SAP4-6Δ/SAP4-6Δ and non-pathogenic Saccharomyces cerevisiae. We conclude that infection with C. albicans activated cell migration through the simultaneous reorganization of the actin cytoskeleton and the redistribution of myo2A and B, findings that differs from published results with other cell types. C. albicans, a pathogenic fungus that infects the human epithelium may stimulate changes in the actin cytoskeleton as part of its invasion strategies.

Non-Muscle Myosin II Regulation via Inhibitory Site Phosphorylation.
J. Beach<sup>1,2</sup>, T. Egelhoff<sup>1</sup>; <sup>1</sup>Department of Cell Biology, Cleveland Clinic Foundation, Cleveland, OH, <sup>2</sup>Department of Physiology and Biophysics, Case Western Reserve University, Cleveland, OH

Non-Muscle Myosin II (NM-II) interacts with filamentous actin to produce force. This acto-myosin cytoskeleton is involved in many different cellular processes, including cytokinesis and migration. A "monomer" of NM-II consists of two myosin heavy chains (MHC), two essential light chains (ELC) and two regulatory light chains (RLC). A vast number of studies have investigated the NM-II regulation via phosphorylation of the RLC at residues T18 and S19. This phosphorylation leads to NM-II activation and assembly. However, more recent work has uncovered putative "inhibitory"
sites on both the RLC (S1, S2, and T9) and MHC IIA (S1917 and S1944). In vitro studies have suggested that phosphorylation at these sites shift the equilibrium of NM-II towards the disassembled, inactive state. Our current studies utilize phosho-specific antibodies and GFP-tagged NM-II constructs containing phospho-mimetic and non-phosphorylatable point mutations to investigate the mechanism by which these sites are phosphorylated in live cells and the effect that this phosphorylation has on NM-II localization and function.

Residues in the Hydrophobic Seam of the Myosin S2/LMM Hinge Impart Myosin Rod- and Muscle-Specific Properties.

A. Cammarato1, X. Li2, J. Suggs1, Q. Yu1, C. Lee1, P. Li2, W. Lehman2, S. I. Bernstein1; 1Biology, San Diego State University, San Diego, CA, 2Physiology and Biophysics, Boston University School of Medicine, Boston, MA

The subfragment 2/light meromyosin "hinge" region of Myosin II rods forms a less stable coiled-coil than flanking regions. Different hinge sequences may contribute to muscle specific properties. Transgenic replacement of a portion of fast muscle myosin hinge a (encoded by exon 15a) in Drosophila melanogaster indirect flight muscle (IFM) with slow muscle hinge B (exon 15b) increases rod coiled-coil propensity, rod and sarcomere lengths and decreases flight performance. Using confocal microscopy we confirmed an ~8% sarcomere length increase in hinge B-substituted IFM myofibrils. To characterize the hinges' nano-mechanical properties, we determined persistence length (PL) differences via electron microscopy and molecular dynamic (MD) simulations. Rotary shadowed 15b myosin molecules showed an ~22% increase in PL relative to 15a (64.2 vs. 50.3 nm) while MD simulations revealed an ~39% greater PL for 15b relative to 15a (85 vs. 52 nm). These data are consistent with a high coiled-coil propensity of exon 15b-containing rods potentially stiffening the hinge and a substantial portion of the tail. To determine hinge residues critical for imparting muscle, myofibrillar and molecular properties, we transgenically replaced either 2 charged (line 15aCh) or 2 polar (line 15apH) amino acids of 15a with uncharged or with hydrophobic residues, respectively, from 15b. PCOILS structure-prediction software estimates a low (8%) coiled-coil propensity for both 15a and 15aCh-expressing molecules. However, the coiled-coil propensity for 15apH molecules is predicted to be 60%, nearly the value for 15b-containing hinges (82%). Flight indices (4.1 of a possible 6.0) and myosin rod contour lengths (149.8 nm) for 15aCh were similar to 15a control flies, while 15apH flies showed dramatically compromised flight ability (1.8 of a possible 6.0) and expressed longer myosin rods (154.1 nm) as with 15b. We are determining sarcomere lengths from 15aCh and 15apH myofibrils and PLs of the myosin tails to quantify the stiffness of the hinges/rods. Our data suggest certain hydrophobic residues are critical for establishing rigid coil-coils and, in turn, hinge-specific properties that dramatically influence molecular and muscle-specific properties.

226/B173

Effects of the Alternatively Spliced Surface Loops on the Kinetics of NMHC-2C.

S. M. Heissler, D. Manstein; Institut für Biophysikalische Chemie, Medizinische Hochschule Hannover, Hannover, Germany

Nonmuscle myosins are widely distributed and play important roles in the maintenance of cell morphology and cytokinesis. Until now, little is known about the function of NMHC-2C and its three splice variants. Here, we present the detailed kinetic and functional characterization of the three alternatively spliced isoforms of human nonmuscle myosin-2C. NMHC-2C is alternatively spliced both in loop-1 and loop-2. An 8 aminoacid (aa) insert in the loop-1 region is present in isoforms 1 and 3. Isoform 3 additionally displays a 33 aa insert in the loop-2 region. Isoform 2 contains no inserts in either of the loops and represents the shortest isoform. Baculovirus expression of the gene constructs encoding the motor domains of the NMHC-2C isoforms fused to an artificial lever arm results in the production of soluble and functional protein. Transient kinetic experiments indicate a more than 100-fold decrease in the affinity of isoform 3 for F-actin in the absence of nucleotide, which can be attributed to the loop-2 extension. ADP binding shows only minor differences for the three splice variants. In contrast, larger differences are observed for
the rates of ADP release both in the absence and presence of actin. The largest differences are observed between isoforms 2 and 3. Isoform 3 displays a 5-fold increase in $K_D$ and 12-fold increase in $K_{AD}$. Isoform 1 shows intermittent behavior. Additionally, our results indicate that the ADP release kinetics of all three isoforms are modulated by physiological changes in the concentration of free Mg$^{2+}$-ions. This work defines the functional properties and regulatory mechanisms for the NMHC-2C isoforms.

Novel Mechanism of S100A4 Inhibition: Trifluoperazine-Induced Protein Oligomerization.

V. Malashkevich$^1$, N. G. Dulyaninova$^1$, M. Liriano$^2$, K. M. Varney$^2$, D. Knight$^1$, M. Brenowitz$^1$, D. J. Weber$^2$, S. C. Almo$^1$, A. R. Bresnick$^1$; $^1$Biochemistry, Albert Einstein College of Medicine, Bronx, NY, $^2$Biochemistry and Molecular Biology, University of Maryland School of Medicine, Baltimore, MD

S100A4, a member of the S100 family of Ca2+-binding proteins, regulates carcinoma cell motility via interactions with myosin-IIA. Numerous studies indicate that S100A4 is not simply a marker for metastatic disease, but rather has a direct role in metastatic progression. These observations suggest that S100A4 is an excellent target for therapeutic intervention. Using a novel biosensor-based assay, trifluoperazine (TFP) was identified in a screen for small molecule inhibitors as a compound that disrupts the S100A4/myosin-IIA interaction. To examine the interaction of S100A4 with TFP, we determined the 2.3 Å crystal structure of human Ca2+-S100A4 bound to TFP. Two TFP molecules bind within the hydrophobic target binding pocket of Ca2+-S100A4 in solution. Remarkably, TFP binding results in the assembly of ten Ca2+-S100A4/TFP dimers into a tightly packed pentameric ring. Within each pentamer most of the contacts between S100A4 dimers occurs through the TFP moieties. Equilibrium sedimentation and cross-linking studies demonstrate the formation of a similarly sized S100A4/TFP oligomer in solution, and an examination of the Hill coefficient indicates that TFP-mediated S100A4 oligomerization is cooperative. Assays examining the ability of TFP to block S100A4-mediated disassembly of myosin-IIA filaments, demonstrate that significant inhibition of S100A4 function occurs only at TFP concentrations that promote S100A4 oligomerization. These studies support a novel mode of inhibition in which TFP disrupts the S100A4/myosin-IIA interaction by sequestering S100A4 via small molecule-induced oligomerization.

228/B175

Regulation of Lamellipodial Persistence by S100A4 during Macrophage Chemotaxis.

Z. Li, N. G. Dulyaninova, M. Pozzuto, R. P. House, S. C. Almo, A. R. Bresnick; Biochemistry, Albert Einstein College of Medicine, Bronx, NY

S100A4, a member of the S100 family of Ca2+-binding proteins, is directly involved in tumor metastasis. In addition to its expression in tumor cells, S100A4 is expressed in normal cells and tissues, including fibroblasts and cells of the immune system. To examine the contribution of S100A4 to normal physiology, we created S100A4-deficient mice by gene targeting. Homozygous S100A4-/- mice are fertile, grow normally and exhibit no overt abnormalities; however, bone marrow macrophages (BMMs) derived from these mice display significant defects in chemotactic motility. S100A4-/- BMMs exhibit a random walking path as compared to wild-type macrophages due to altered protrusive activity and a failure to form stable lamellipodia. Biochemical studies indicate that these changes are the consequence of myosin-IIA overassembly and associated perturbations on adhesion complexes. The loss of S100A4 expression also reduced the invasive capability of macrophages and did not support macrophage-dependent invasion of tumor cells into a collagen gel. These studies establish S100A4 as a regulator of physiological macrophage motility, and suggest a role for S100A4 in regulating macrophage recruitment and chemotaxis in vivo.

*Myosin-Specific Chaperone UNC-45 Is Required for Drosophila Cardiac Function and Myocardium Integrity.*  
G. C. Melkani1,2, K. Ocorr2, R. Bodmer2, S. I. Bernstein1; 1Department of Biology, Molecular Biology and SDSU Heart Institute, San Diego State University, San Diego, CA, 2Development and Aging Program,, Burnham Institute for Medical Research, La Jolla, CA

Using Drosophila melanogaster as a model organism we are defining the role of UNC-45, a putative myosin chaperone, in maintaining striated muscle function and integrity. UNC-45 belongs to the UCS (UNC-45, CRO1, and She4p) domain protein family, whose members interact with various myosins and are required for myosin function. The In Vivo RNAi approach using the Gal4/UAS system permits us to knock down Drosophila unc-45 (dunc-45) transcripts in a tissue-specific manner. DUNC-45 knock-down in the heart allows survival to adulthood, but lifespan is dramatically reduced, with ~90% dead within three weeks. Optical heartbeat analysis of semi-intact hearts from various age adults was carried out using high-speed video and movement analysis algorithms. Analysis of several cardiac parameters (e.g., diastolic and systolic diameters, heart period and arrythmicity index) showed severely compromised cardiac function. For example ~80% of 1, 2 and 3 week old knock-down hearts do not show contraction or relaxation of normally highly-contractile regions (primarily in abdominal segment three). The remainder of the heart shows a greatly reduced and irregular beating pattern. Another striking response to DUNC-45 knock-down was dilation of the third segment of the heart. For example, the average diastolic diameter for one week old control fly heart is 76 µm. However, in the 1 week old knock-down heart the average diastolic diameter is 128 µm. Cardiac arrhythmias were observed in one-week-old flies, whereas arrhythmias were only observed after three weeks of age in wild type flies. Immunofluorescent images of relaxed hearts using myosin antibody showed irregular heart muscle patterning and missing myofibrils in DUNC-45 knock-down adults. Structural and functional defects of the dunc-45 knock-down heart were rescued to some extent by transgenic over-expression of DUNC-45. As UNC-45 prevents folding and accumulation of myosin, the heart displays myofibrillar disarray and reduced contraction, which may account for the observed premature lethality.

**230/B177**  
*Structure of the Putative Myosin Chaperone, UNC-45.*  
C. F. Lee1, A. V. Hauenstein2, W. C. Gasper1, B. Sankaran3, S. I. Bernstein1, T. Huxford2; 1Department of Biology and Molecular Biology Institute, San Diego State University, San Diego, CA, 2Department of Chemistry and Biochemistry, San Diego State University, San Diego, CA, 3Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA

UNC-45 is a chaperone that may be responsible for folding the myosin motor domain into its correct conformation. Mutations in UNC-45 cause muscle defects and dysfunction, due to the importance of myosin in muscle structure and contraction. UNC-45 is composed of an N-terminal tetra-tricopeptide (TPR) domain, a C-terminal UCS (UNC-45/Cro1/She4 homology) domain, and a central region that links these. As Drosophila melanogaster is a model organism for muscle research, we are using it to investigate UNC-45’s role in muscle development and function. Here we present a 3.0 Å resolution x-ray crystal structure of Drosophila UNC-45 (dUNC-45), which should serve as a basis for attaining a detailed understanding of its mechanism of action. Bacterially expressed recombinant His-tagged dUNC-45 was purified sequentially using immobilized metal affinity chromatography and size exclusion chromatography. The protein eluted as a single peak, indicating a homogeneous population of protein suitable for crystallization. Crystals were prepared by hanging drop vapor diffusion and x-ray diffraction data were collected to a limit of 3.0 Å resolution. For phase determination, a seleno-methionine derivative dUNC-45 crystal was prepared for single wavelength anomalous dispersion (SAD) experiments. Synchrotron data were collected at the Berkeley National Laboratory Advanced Light Source. The diffraction data were processed in HKL2000. Selenium positions were determined and refined in Phenix. The resulting structure was refined against native data using Phaser and maximum-likelihood refinement with Refmac5. Model building was carried out in
The current model of dUNC-45 has $R$-cryst and $R$-free values of 0.24 and 0.28 respectively. The TPR domain is not visible in the model, likely due to flexibility of the domain within the crystal. The protein consists of multiple $\alpha$-helixes that form specific hydrophobic surface patches which could be involved in substrate binding. Currently, we are pursuing structure-based biochemical assays to determine the precise protein surfaces that are involved in the binding and chaperone activities of dUNC-45.

231/B178

**Cellular Characterization of the Last of the Dictyostelium Myosin II Heavy Chain Kinases - MHCK-D.**

J. Greene, P. Steimle; Biology, University of North Carolina at Greensboro, Greensboro, NC

Contractile processes such as cytokinesis and cell migration rely on the proper assembly and localization of Myosin II bipolar filaments. In *Dictyostelium discoideum*, as well as in mammalian cells, Myosin II filament disassembly can be driven by phosphorylation of the Myosin II heavy chain (MHC) “tail”, preventing myosin-mediated contraction. In *Dictyostelium*, MHC phosphorylation is catalyzed by at least three kinases (MHCK-A, -B, and -C) that share homologous $\alpha$-kinase catalytic and WD-repeat domains. Another *Dictyostelium* protein, tentatively named MHCK-D, is predicted to have the same domain organization as the aforementioned MHCKs but its function in the cell is unclear. Previous studies showed that disrupting MHCK-D expression has little effect on Myosin II filament turnover in vegetative *Dictyostelium* cells. To examine further the role of MHCK-D in the regulation of Myosin II, we generated *Dictyostelium* cell lines over-expressing an amino-terminal truncation of MHCK-D that possesses both the kinase catalytic and WD-repeat domains (MHCK-D** cells). We found that MHCK-D** cells exhibited slowed growth in suspension culture and became large and multinucleated over time, with an average of 2.9 nuclei/cell after 5 days, compared with 1.2 nuclei/cell for AX2 cells grown under the same conditions. Analysis of cells expressing this same truncation of MHCK-D, but with a GFP tag, revealed a diffuse distribution of the kinase in the cell. RT-PCR studies indicate that MHCK-D is expressed constitutively throughout the developmental cycle of *Dictyostelium*. In summary, the Myosin II-null phenotype associated with MHCK-D over-expression suggests that this kinase can function as a MHCK that catalyzes MHC phosphorylation and drive Myosin II filament disassembly in the cell. We have also generated bacterial and *Dictyostelium* cell lines for the expression and purification of fusion-tagged MHCK-D for biochemical studies of the kinase’s activity.

**Characterization of a Novel Myosin Regulatory Light Chain in Mice.**

I. Park, C. Cho; Life Science, Gwangju Institute of Science and Technology, Gwangju, Korea, South

Previously, we systematically identified a number of novel, authentic genes abundantly transcribed in mouse cardiac muscle through in silico and In Vitro analyses. In the present study, we characterized one of such genes, Mm.261329. The Mm.261329 gene, currently named myosin light chain regulatory B-like (Mylrbl), is located on mouse chromosome 17, composed of 4 exons and transcribed into 1779-nucleotide mRNA encoding 172 amino acids. During the course of our study, we found the presence of a gene highly homologous to the Mm.261329/Mylrbl gene. This gene, designated as myosin light chain 12B (Myl12B), is adjacent to the Mm.261329/Mylrbl gene on the same chromosome. The Myl12B gene transcribes into 939-nucleotide mRNA encoding 172 amino acids of which sequence is remarkably similar (98%) to that of the Mm.261329/Mylrbl gene. Since none of these genes have been investigated at the protein and functional levels, we analyzed the biochemical and cellular characteristics of these proteins. The Mm.261329/Mylrbl protein was found to contain a Ca$^{2+}$ binding activity. We generated an antibody recognizing both the Mm.261329/Mylrbl and Myl12B proteins. Tissue distribution analysis showed that these proteins are expressed in diverse tissues including cardiac, smooth and non-muscle tissues. Proteomic analysis of proteins immunoprecipitated with the antibody in mouse heart revealed that interacting proteins are various myosin components different from
SUNDAY

those involved in muscle contraction. Immunostaining analysis of NIH3T3 cells showed that the Mm.261329/Mylrbl and Myl12B proteins are co-localized with the phalloidin-staining actin cytoskeleton. Thus, our results suggest implication of the Mm.261329/Mylrbl and Myl12B proteins in diverse cellular processes other than muscle contraction.

Thrombin Regulation of Myosin Light Chain Phosphorylation in Retinal Pigment Epithelial Cells.
A. Ruiz-Loredo, E. López, A. López-Colomé; Universidad Nacional Autónoma de México, Distrito Federal, Mexico

The retinal pigment epithelium (RPE) forms a monolayer of quiescent cells that acts as an outer blood-retina barrier (BRB) between the choriocapillaries and the photoreceptors. An early event in the establishment of most retinal diseases involves BRB breakdown, whereupon serum components, thrombin among them, directly contact RPE cells. The serine protease thrombin activates cell signaling via G protein-coupled proteinase-activated receptors (PARs). Responses triggered by PAR stimulation include the activation of cytoskeletal targets which regulate cell shape and adhesion by inducing the formation of actin stress fibers, focal adhesion complexes and acto-myosin contraction. Thrombin-induced changes on the actin cytoskeleton could further compromise the barrier function of RPE cells, exacerbating the disease process. In order to support a role for thrombin in RPE cell cytoskeleton reorganization we analyzed its effect on the signal transduction pathways leading to myosin light chain (MLC) phosphorylation and actin polymerization in rat RPE cells in primary culture. The phosphorylation state of the MLC was determined by western blot analysis, changes in the RPE cytoskeleton were visualized using immunofluorescent staining for F-actin, and the activation of Rho GTPase was measured using an enzyme-linked immunosorbent assay. Our results show that thrombin induces the time-dependent phosphorylation of the MLC through the specific activation of PAR-1. Pharmacological analysis showed that this effect is mediated by at least four intracellular pathways: Rho/Rho kinase, protein kinase C (PKCζ), phosphatidylinositol-3 kinase/PKCζ and MLC kinase. Moreover, thrombin promoted actin stress fiber formation, which was significantly prevented by blockage of the pathways leading to MLC phosphorylation. Based on these results, we conclude that cellular contraction triggered by the increase in MLC phosphorylation, together with actin stress fiber formation, may be involved in RPE barrier dysfunction. This work was partially supported by Grant IN203507 from PAPIIT, U.N.A.M., and by Grant CB-80398 from CONACyT to A.M.L.C.

Mouse Models of Human MYH9-Related Diseases.
Y. Zhang, M. Conti, S. Kawamoto, Y. Schmist, R. S. Adelstein; Molecular Cardiology, NHLBI, NIH, Bethesda, MD

Humans with point mutations in MYH9, the gene encoding nonmuscle myosin heavy chain IIA (NMHC IIA), develop a variety of syndromes with defects in their platelets (macrothrombocytopenia), kidneys (glomerulonephritis), eyes (cataracts), hearing (deafness) and granulocytes (inclusion bodies). The purpose of the present study is to gain insight into the pathological mechanism of the diseases by generating mouse models for two of these mutations and characterizing the resultant mouse phenotypes. We have produced both R702C and D1424N mutant mice by using homologous recombination to replace wild type NMHC IIA with mutant R702C or D1424N in NMHC IIA. Breeding of heterozygous R702C mutant mice has not produced homozygous mutant offspring. The homozygotes die between embryonic day 8.5 and 10.5. on the other hand, breeding of heterozygous D1424N mutant mice produced homozygous mutant offspring at close to normal ratios, suggesting that mutations in the motor domain of NMHC IIA may have a more severe effect than mutations in the rod during embryonic development. Interestingly, giant platelets were found in the blood smears from both R702C and D1424N adult heterozygous mice. Both mutants also have significantly higher mean platelet volumes compared to their wild type littermates (6.12 +/- 0.62 fl, wt; 10.17 +/- 1.50 fl, heterozygous R702C; 10.13 +/- 1.66 fl, heterozygous D1424N). Kidney function was studied by examining the
albumin/creatinine ratio in urine samples. Some but not all adult heterozygotes of both mutant lines have higher albumin/creatinine ratios at 8-9 weeks, indicating that kidney impairment may develop in some heterozygous mutants at an early age. These preliminary results suggest that these mouse models should be useful in understanding the pathophysiology of human MYH9-related diseases.

**Tubulin Interaction with G Protein-Coupled Receptors Directs Receptor Transport from the Endoplasmic Reticulum to the Cell Surface.**

*M. T. Duvernay, X. Zhang, G. Wu; Pharmacology, LSU Health Sciences Center, New Orleans, LA*

The C-termini of G protein-coupled receptors (GPCRs) are required for their export from the endoplasmic reticulum (ER) to the cell surface. However the molecular mechanisms remain poorly understood. To address this issue, we searched for proteins interacting with the C-termini of GPCRs. By using peptide-conjugated Agarose affinity columns combined with proteomics, we identified α- and β-tubulin interacting with the C-terminus of α2B-adrenergic receptor (α2B-AR). The interaction was confirmed by GST-fusion protein pull down assays using purified tubulin and brain cytosolic extracts. Site-directed mutagenesis of the C-terminus identified the basic residue cluster in the membrane proximal amphipathic α-helix 8 as the tubulin docking site. This basic residue cluster is structurally similar to the tubulin-binding sites in the microtubule-associated proteins such as cytoplasmic linker protein-170, the end binding protein-1, CLIP170, XMAP215 and EB1. Interestingly, the positively charged Arg/Lys residues are highly conserved in the membrane proximal regions of the C-termini amongst family a GPCRs and indeed, tubulin interacted with the C-terminal positively charged motif in angiotensin II type I receptor (AT1R). Furthermore, mutation of the Arg/Lys clusters dramatically inhibited α2B-AR and AT1R transport to the cell surface and receptor-mediated ERK1/2 activation, and the mutated receptors were extensively arrested in the ER. These data provide the first evidence indicating that the basic residue clusters direct GPCR interaction with microtubules which coordinates receptor traffic from the ER to the cell surface (GM076167).

**Characterization of Plant γ-Tubulin: Unique Amino Acid Residues and Function.**

*Y. Miyamoto1,2, T. Horio1,3, D. Yamauchi4, T. Okada4, S. Sekita4, N. Futamura5, K. Shinohara5, Y. Fujimoto1, T. Nakai1, T. Shimmer6, T. Saruwatari1,2, M. Shimamura7, T. Akashi8, Y. Mineyuki1,2; 1Graduate School of Life Science, University of Hyogo, Himeji, Japan, 2Sentan, JST, Himeji, Japan, 3Department of Molecular Biosciences, University of Kansas, Lawrence, KS, 4Faculty of Pharmaceutical Sciences at Kagawa Campus, Tokushima Bunri University, Sanuki-city, Japan, 5Department of Molecular and Cell Biology, Forestry and Forest Products Research Institute, Tsukuba, Japan, 6Graduate School of Life Science, University of Hyogo, Kamigori, Japan, 7Department of Biological Science, Hiroshima University, Higashi-Hiroshima, Japan, 8Division of Molecular Mycology of Medicine, Nagoya University, Nagoya, Japan*

Plant microtubules are organized without obvious converging centers, while animal and fungal microtubules are mostly organized from focused organizing centers. How these plant-specific microtubule organization systems became established during plant evolution remains unknown. We and other groups have shown that γ-tubulin, a conserved microtubule nucleator protein, localizes to the microtubule nucleation sites in plant cells. We also have reported that the function of plant γ-tubulin is somewhat different from that of fungus (and presumably of animals) (Horio and Oakley, 2003, Plant Physiol.). We investigated the origin of plant-specific microtubule organization in terms of changes in amino acid residues and those in functions of various plant γ-tubulins. Among the plant lineage, gymnosperms are especially interesting, because only a primitive group of gymnosperms produce centrioles in their life cycle. Comparison of amino acid
residues of γ-tubulins showed that gymnosperm γ-tubulins were more similar to those of bryophytes/pteridophytes than to those of angiosperms irrespective of whether the plants have centrioles or not. These data clearly showed that γ-tubulins of land plants fall into two groups, angiosperm and non-angiosperm types. Next, we tested whether γ-tubulins of Ginkgo (non-angiosperm type) and of Chara (green algae) can replace the endogenous γ-tubulin in the fission yeast Schizosaccharomyces pombe, because severe defects occur when an Arabidopsis γ-tubulin (angiosperm type) is expressed in S. pombe. A strain expressing Ginkgo γ-tubulin grew much better at low temperatures and exhibited less morphological abnormality. A strain expressing Chara γ-tubulin showed even fewer defects. These results suggest that green plant γ-tubulins have gradually lost functions that are important for the cell growth of S. pombe, and, presumably, they were replaced by specific functions required for plant microtubule organization. This work was supported by JSPS grant 17207006 and SENTAN, JST.

O-GlcNAc Modification on Tubulin Is Involved in Neurite Outgrowth of Dopaminergic Neuronal Cells.
S. Ji, J. Kang, S. Park, J. Cho; Biology, Yonsei University, Seoul, Korea, South

β-O-linked N-acetylglucosamine (O-GlcNAc) is a nucleocytoplasmic post-translational modification on serine and threonine residues that is dynamically regulated by O-GlcNAc transferase and O-GlcNAcase. Many proteins are O-GlcNAcylated in response to various cellular processes, including transcription, proliferation, apoptosis and signal transduction. In the case of neuronal cells, there are many O-GlcNAcylated proteins that are related to neurodegenerative diseases. Neuronal differentiation process is largely studied, but it is rarely known the relationship between O-GlcNAcylation and neuronal differentiation. To examine whether O-GlcNAc modification is involved in neuronal cell differentiation process, we utilized neurite outgrowth model system induced by all trans retinoic acid (tRA) in dopaminergic neuronal cell line. Total O-GlcNAcylation patterns were changed during tRA-induced neuronal cell differentiation. In addition, O-GlcNAc modification on neuron-specific tubulin beta 3 was decreased during neurite outgrowth. We confirmed O-GlcNAcylated peptide of tubulin alpha and beta using ESI Q-TOF. Also, increased O-GlcNAcylation of tubulin inhibits its heterodimerization and polymerization. Therefore, O-GlcNAcase inhibitors are co-treated with tRA to prevent the decrement of intracellular O-GlcNAcylation level, and the extent of neurite outgrowth was decrease 17% compared to tRA-treated neurons. Thus, our data indicate that O-GlcNAc modification on tubulin seems to be related to neurite outgrowth in cultured dopaminergic neuronal cells.

Identification of a Novel Posttranslational Modification of Neuronal Tubulin by Transglutaminase and Polyamines.
Y. Song1, A. Schilling2, L. Kirkpatrick3, B. Lee4, S. T. Brady1; 1Anatomy and Cell Biology, University of Illinois at Chicago, Chicago, IL, 2Proteomics and Informatics Services Facility, University of Illinois at Chicago, Chicago, IL, 3Lexicon Pharmaceuticals, Houston, TX, 4Protein Lab, University of Illinois at Chicago, Chicago, IL

Neurons contain large numbers of microtubules which support intracellular transport, facilitate axon growth, and form the structural basis of neuronal morphology. While microtubules in non-neuronal cells are generally quite dynamic and can be depolymerized by cold, calcium, or antimitotic drugs, a significant portion of neuronal microtubules, particularly axonal microtubules, are resistant to such treatments and are unusually stable. Though the biochemical basis for such stability is still not clear, isoelectric focusing suggests that neuronal cold-stable microtubules contain biochemically distinct tubulins that are more basic in nature. Posttranslational addition of polyamines is one of the few posttranslational modifications that add positive charges to protein. Polyamines (putrescein, spermine and spermidine) are abundant cations in brain and transglutaminase can modify proteins by incorporating polyamines onto select glutamine residues via gamma-glutamyl amine covalent bonds. To test the hypothesis that transglutaminase-catalyzed polyamination of tubulins may contribute to microtubule stability, endogenous
polyamine levels were lowered in rats with DFMO, an irreversible inhibitor of polyamine synthesis. Significant decreases in neuronal cold-stable tubulin levels were observed. In Vivo labeling of tubulin with 3H-putrescine and an In Vitro transamidation assay using the fluorescent polyamine analogue monodansylcadaverine indicated that neuronal tubulin is a transglutaminase substrate and can be polyaminated. Further, the modification sites were mapped using LC-MS-MS which suggested a sequence specific incorporation of polyamines on neuronal tubulins in the presence of transglutaminase activity. Additional experiments demonstrated that endogenous brain transglutaminase-catalyzed polyaminated tubulins mimic neuronal stable microtubules regarding their resistance to cold and calcium, and 2D-PAGE of polyaminated tubulin showed a basic shift for modified tubulin. Together, these experiments suggested that axonal tubulin may be polyaminated upon activation of transglutaminase, and that this modification may contribute to the stability of axonal microtubules.

A Hypothesis on the Origin and Evolution of Tubulin.
R. F. Luduena¹, J. McIntosh²; ¹Biochemistry, University of Texas Health Science Center at San Antonio, San Antonio, TX, ²MCD Biology, University of Colorado, Boulder, CO

Tubulin, the protein subunit of microtubules, is an α/β heterodimer. Other isoforms of eukaryotic tubulin include γ, δ, ε, η, and ζ. All these proteins are related to the eubacterial protein FtsZ, which is involved in cytokinesis, so the genes that encode all these proteins probably evolved from a common ancestor in the forebear of these two branches of current life. Of these proteins, only α, β and γ are known to participate in microtubule formation, although η and δ may bind to microtubule minus ends. Thus, the property of forming microtubules occurs in only one part of the tubulin family tree. Hence, a tubular assembly geometry is unlikely to have characterized the tubulin/FtsZ ancestor. FtsZ, α, β, and γ can all polymerize to form curving filaments or rings. Filaments of FtsZ are thought to change their curvature to constrict the bacterial membrane at the cell equator, and γ rings help to nucleate microtubules. α/β heterodimers form curved filaments whenever a microtubule is depolymerizing, and the same proteins can form rings during microtubule depolymerization in the presence of either high Mg2+ or certain drugs. Curving protofilaments of α and β tubulin appear to be connected via fibrils to the inner kinetochore, so their changes in curvature may help microtubule depolymerization to pull chromosomes toward the poles of a eukaryotic spindle during mitosis. In the case of FtsZ and α/β tubulin, GTP binding and hydrolysis appear to play a role in protein structure changes and thus in curvature changes. In short, it is likely that the common ancestor of the tubulin superfamily and FtsZ was a protein that polymerized to form curving filaments that exerted intracellular forces by a mechanism involving GTP.

Myc-Nick Is Cytoplasmic Form of Myc That Promotes Tubulin Acetylation and Accelerates Muscle Cell Differentiation.
M. Conacci-Sorrell, C. Ngouenet, R. Eisenman; Fred Hutchinson Cancer Research Center, Seattle, WA

The oncoprotein Myc is a basic HLH transcription factor essential for embryonic development, and a critical regulator of major biological processes such as proliferation, growth, apoptosis, and differentiation. Myc controls these processes by regulating specific target genes and promoting global chromatin changes. While transcriptional regulation of Myc target genes is being extensively studied, potential transcription-independent functions of Myc are just beginning to be explored and may explain some of the biological effects induced by Myc. In the process of investigating non-nuclear functions of Myc, we discovered Myc-nick, a cytoplasmic form of Myc that contains an intact N-terminus but lacks the C-terminal region (nuclear localization signal, Max dimerization domain and DNA binding domain). Myc-nick is generated by a proteolytic cleavage of full-length Myc that is carried out in the cytoplasm by calcium dependant calpains. Ectopic expression of Myc-nick in myc-null fibroblasts caused major changes in the cytoskeleton and promoted dramatic changes in cell morphology marked by the induction of cell protrusions. Using
In Vitro systems we demonstrated that Myc-nick directly binds to tubulins and regulates α-tubulin acetylation, by recruiting histone acetyl transferases to microtubules. Because induction of tubulin acetylation, calpain activation and decreased levels of full-length Myc all occur during terminal differentiation, we decided to investigate the role of Myc-nick in cell differentiation. We found that Myc-nick levels are elevated during muscle cell differentiation and in adult mouse muscles such as quadriceps. The ectopic expression of Myc-nick in myoblasts accelerated cell fusion and the expression of myogenic markers. Based on our results, we propose a model for Myc regulation and function during terminal differentiation in which calcium influx promotes calpain activation that in turn converts full-length Myc into Myc-nick. The cleavage of Myc by calpains has 2 roles: first to abrogate the transcriptional blockade to differentiation caused by full-length Myc, and second to generate Myc- nick, which influences cytoskeletal organization and facilitates terminal differentiation.

241/B188
The Expression of Tubulin Cofactor A (TBCA) Is Regulated by a Noncoding Antisense TBCA RNA.
S. Nolasco1,2, J. Bellido2, J. Goncalves1, J. Zabala2, H. Soares1,3,4; 1Instituto Gulbenkian de Ciência, Apartado 14, Oeiras, Portugal, 2Departamento de Biología Molecular, Facultad de Medicina, IFIMAV-Universidad de Cantabria, 39011, Santander, Spain, 3Escola Superior de Tecnologia da Saúde de Lisboa, Lisboa, Portugal, 4Centro de Química e Bioquímica, Departamento de Química e Bioquímica, Faculdade de Ciências, UL, Ed C8, Lisboa, Portugal

TBCA is a β-tubulin folding cofactor that is not required for tubulin folding in vitro. However, we showed that TBCA knockdown decreased the amount of α- and β-tubulin, causing G1 cell cycle arrest and cell death in human cell lines. Tbca gene expression was analyzed in different murine tissues being more abundantly expressed in testis, where it is progressively up-regulated from the onset of meiosis reaching the highest levels in differentiating spermatids. The Tbca expression pattern seems to be more associated to microtubule cytoskeleton rearrangements, dynamics and β-tubulin processing through spermatogenesis rather than with meiosis. In this context a close correlation was observed between the Tbca expression waves and the testis specific tubulin isotypes β3 and α3/7, suggesting that the Tbca role in the testis might be associated to β-tubulin isotypes’ maturation and/or interchange. To clarify the Tbca role, we decided to study the expression regulation of the mouse Tbca gene during testis maturation. During these studies we identified two transcribed closely related Tbca genes localized in chromosome 13 and 16 (Tbca13 and Tbca16, respectively). Interestingly, we observed that both genes were expressed constitutively, but they presented opposite patterns during testis maturation. The testis Tbca13 steady state levels increased, whereas those of Tbca16 were progressively decreased from 14 to 25 post-natal days. This data suggested the existence of a regulatory mechanism between the two genes in testis, which prompted us to characterise the respective encoding proteins. Unexpectedly, using mass spectrometry, we were not able to identify the TBCA16 protein in any stage of testis maturation. Thus, we put forward the hypothesis that the Tbca16 transcript was involved in the regulation of Tbca13 gene expression. Indeed we detected that Tbca16 gene is a non-coding anti-Tbca gene, transcribed in a reverse complementary orientation. These data and the fact that the Tbca16 knockdown leads to an increase of the Tbca13 mRNA levels in GC-2spd(ts)-spermatocyte mouse cell line lead us to postulate that Tbca16 is involved in the regulation of the Tbca13 expression during spermatogenesis.

242/B189
Phosphor-Regulation of γ-Tubulin Nucleation Activity in Budding Yeast.
D. Chen1, J. Vogel1,2; 1Biology, McGill University, Montreal, QC, Canada, 2DBRI, McGill University, Montreal, QC, Canada

Phosphorylation has been showed to be an important post-translational modification to modulate the activity of γ-tubulin in microtubule organization. In budding yeast the direct kinase (s) for γ-tubulin (Tub4) has not been proved In Vivo and only one phosphorylation residue (Tyr445) has been confirmed. SerXXX is a putative Cdk1/Cdc28 phosphorylation residue on Tub4p. Site-
directed mutagenesis analysis reveals that SerXXX is an important residue for normal function of γ-tubulin. When SerXXX is mutated to Asp, cells exhibit growth defect with delayed mitosis. SXXXD mutant dies under restrictive temperature instead of arresting. GFP-Tub1 fusion protein is used to monitor the microtubules In Vivo and this demonstrates that SXXXD mutant has longer cytoplasm microtubule. Under restrictive temperature, some microtubules are detached from the spindle pole bodies (SPBs), from which microtubules are nucleated and attached. DAPI staining of the DNA shows that 9.6% of mutant cells have the entire nucleus located into the bud cell. One of the γ-tubulin small complex (gTuSC, the minimal complex for microtubule nucleation) components, Spc97, seems to localize less onto the SPBs. All these data together indicates that phosphorylation on SXXX residue might regulate the nucleation activity of Tub4. Initial analysis indicates that Swe1 and Cdc28 might be involved in Tub4 phospho-regulation as some of the phospho-isofoms are Swe1 or Cdc28 dependent.

Interaction of [3H] Halichondrin B with Tubulin.
R. Bai¹, T. Nguyen², R. Gussio², E. Hamel³; ¹Toxicology and Pharmacology Branch, National Cancer Institute at Frederick, Frederick, MD, ²Information Technology Branch, National Cancer Institute at Frederick, Frederick, MD

Halichondrin B is a sponge-derived, complex natural product that binds in the vinca domain of tubulin and inhibits tubulin assembly. It noncompetitively inhibits the binding of both radiolabeled vinblastine and radiolabeled dolastatin 10 to tubulin. Although halichondrin B has excellent antitumor activity in vivo, scarcity of the natural product led to development of a truncated analog, NSC 707389 (eribulin) that is presently in late clinical trials. To gain greater insight into the interactions of halichondrin B with tubulin, we commissioned preparation of [3H] halichondrin B and have been studying its interactions with tubulin. Scatchard analysis indicated a single class of binding site, but the apparent Ka varied with the protein concentration used. Binding and dissociation reactions were nearly instantaneous, within the limits of the techniques used to study them. We examined inhibitory effects of 16 vinca domain compounds and found that only NSC 707389 and the antimitotic peptides dolastatin 10 and, to a lesser extent, hemiasterlin were strong inhibitors of halichondrin B binding to tubulin. NSC 707389 was a competitive inhibitor (Ki = 0.80 ± 0.3 μM) of halichondrin B binding, while dolastatin 10 was a noncompetitive inhibitor (Ki = 0.35 ± 0.2 μM). In an earlier modeling study, we found that halichondrin B could easily fit into the groove between adjacent αβ-tubulin dimers in the vinca site model, based on the structure of Gigant et al. (Nature 435: 519-522, 2005). This implied that halichondrin B would only bind to aggregates of tubulin larger than the 100 kDa αβ-dimer. However, gel filtration HPLC demonstrated binding of [3H] halichondrin B only to a 100 kDa species. Even when the column was equilibrated with 20 μM halichondrin B, there was no evidence for formation of tubulin species larger than 100 kDa. We have therefore revised our binding model for halichondrin B.

244/B191
Do the β Isotypes of Tubulin Protect Neuronal Cells against Reactive Oxygen Species? J. Guo, R. F. Luduena; Biochemistry, The University of Texas Health Science Center at San Antonio, San Antonio, TX

Microtubules in neurons are a critical component of the neuronal cytoskeleton. Some evidence suggests that the microtubule network of neurons can be impaired by oxidative stress. is it possible that β tubulin isotypes are involved in this? Reactive Oxygen Species (ROS) are major contributors to oxidative stress. Generation of ROS can be achieved in neuronal cells when NMDA receptors are activated by glutamate/glycine. Undifferentiated SK-N-SH neuroblastoma cells do not express the NMDA receptor, while retinoic acid-induced differentiated SK-N-SH cells do. Here we have shown that ROS were not generated by glutamate/glycine treatment of undifferentiated cells. Levels of β tubulin isotype expression and cell viability were not affected either. However, after glutamate/glycine was applied to differentiated SK-N-SH cells, ROS levels increased greatly, reaching a peak at 30 min, and then decreasing. The expression of both the βII and βIII tubulin isotypes decreased, reaching a minimum at 1 hour, then returning to normal by 24
hr. The expression of the βI isotype increased slightly in the first 2 hours, and then decreased. The mRNA levels of both βII and βIII tubulin increased in the first 2 hours, although they were lower at 30 min than was βI. Interestingly, cell viability was not affected by ROS. We also applied MK801, an NMDA receptor inhibitor, to the differentiated cells before glutamate/glycine treatment and found that ROS levels change only slightly. β isotype expression and cell viability were not affected either. These results suggest that β tubulin isotype levels can be affected directly by excessive ROS generation in the cells. Cells are viable regardless of ROS generation. However, when glutamate/glycine was applied to differentiated cells in which the β isotype levels had been lowered by siRNA knock-down, very different results were obtained. The viability of cells treated with siRNAs for βII and βIII, decreased greatly in 1 hour, later recovering. The effect was particularly large when βIII was knocked down. Our results suggest that βII and βIII, but especially βIII, play an important role in protecting neuronal cells from oxidative stress.

245/B192
TBCE and TBCB Share Molecular Recognition Mechanisms with +Tips.
R. Castaño1, 2, G. Carranza1, 2, M. Lopez1, 2, J. Villegas1, 2, J. Zabala1, 2, 1Biológía Molecular y de Anatomía y Biología Celular, Universidad de Cantabria, Santander, Spain, 2IFIMAV, Santander, Spain

Tubulin folding cofactors B and E are two CAP-gly containing proteins that participate in the folding and dimerization pathways, as well as the dissociation process of the tubulin heterodimer. This way, the TBCE-TBCB complex could behave as a quality control mechanism for alpha-tubulin monomers, being capable of selecting individual alpha-tubulin subunits for recycling or degradation. The presence of a UBL domain in both cofactors supports the fact that these proteins could participate in the removal from the cell of unsuitable tubulin monomers. TBCE and TBCB do also contain a CAP-Gly domain despite they have never been shown to localize on the tips of microtubules as other CAP-Gly containing proteins. We have investigated by means of biophysical (circular dicroism spectroscopy, dynamic light scattering and analytical centrifugation) and biochemical (native electrophoresis of purified proteins and the complexes formed) methods the molecular mechanism implicated in the association of TBCB with TBCE into the binary complex that efficiently recognizes and dissociates the tubulin heterodimer. We also show how that both, TBCE and TBCB localize on the vicinities of the mitotic spindle and that TBCB does indeed localize on the plus ends of mitotic microtubules.

Identification of New Tubulin Acetylation Modifying Enzymes by High-Throughput siRNA Screening.
M. Vuoriluoto1, 2, J. Rantala3, P. Kohonen3, O. P. Kallioniemi2,3,4, P. Saviranta3, M. J. Kallio1, 2, 3, 7Turku Centre for Biotechnology, Turku, Finland, 2Centre of Excellence for Translational Genom-Scale Biology, Academy of Finland, Finland, 3VTT Technical Research Centre of Finland, Medical Biotechnology, Turku, Finland, 4The Institute for Molecular Medicine Finland FIMM, University of Helsinki, Finland

One of the several types of post-translational protein modifications affecting the tubulins is the acetylation of alpha-tubulin at Lys40. The contribution of tubulin acetylation on dynamic instability of the microtubules, microtubule-dependent cellular processes, and anti-microtubule drug response are unclear. Similarly, the identity of enzyme(s) responsible for tubulin acetylation remains to be determined while a few tubulin deacetylating enzymes such as HDAC6 and Sirt2 have been described. In search for novel modulators of tubulin acetylation we performed a high-throughput siRNA screen utilising the Cell Spot Microarray (CSMA) technology. CSMA is based on a reverse transfection method, where individual gene silencing siRNAs are printed onto a microarray plate in a spot format. Tissue culture cells of interest are cultured on top of the individual siRNA spots and due to the specific matrix, they only adhere and grow onto the siRNA spots. Each cell island consists of 50-200 cells and up to 46000 individual gene silencing assays can be performed simultaneously allowing genome-wide analysis in a single assay plate. In our assay, the endpoint measurement was antibody-based detection of tubulin Lys40 acetylation. The
primary screen carried out using an epigenetic siRNA library consisting of 1328 siRNAs against known epigenetically active protein domains led to the identification of novel tubulin modifying genes. Validation of the hit genes and their functional characterisation is currently ongoing as well as extension of the study towards genome-wide siRNA screen. We expect the results of this study to provide new insights into the roles of tubulin acetylation in cancer biology and tumour chemosensitivity.

Structural Mechanisms Benzimidazole Interactions with β-Tubulin.
A. Y. Nyporko, A. I. Yemets, Y. B. Blume; Department of Genomics and Mol. Biotechnology, Institute of Food Biotechnology and Genomics, Kiev, Ukraine

Benzimidazoles are widely used as fungicides, herbicides and antihelminthic drugs due to their high affinity to tubulins of different origin. However, precise localization of benzimidazole binding site on tubulin molecular surface is still not described in details. For accurate prediction of benzimidazole binding site we used combination of several approaches: analysis of spatial distribution of tubulin mutations conferring benzimidazole resistance, analysis of benzimidazole structural peculiarities that are responsible for site recognition, reconstruction of spatial structure of fungal (Neurospora crassa and Mycosphaerella graminicola) and animal (Haemonchus contortus and Homo sapiens) β-tubulin complexes with albendazole (antihelminthic drug) and carbendazim (antifungal and antihelminthic drug) and further estimation of their stability via long-time (30 ns) molecular dynamics calculation. Accordingly to obtained data, β-tubulin benzimidazole binding site contains amino acids in positions 152, 156, 163-165, 167, 195-198, 200, 236, 250, 251 and 253. Ligands are buried into molecule enough deeply, what is typical for benzimidazole derivatives with affinity for other proteins. Conformation energy of studied ligands in binding sites are stable less than in free state. Energy downshift is within range from 48.6 kJ/mol for β-tubulin complex from M. graminicola with albendazole to 88.5 kJ/mol for tubulin complex from N. crassa with carbendazim. Average level of molecular oscillation for albendazole decreases from 2.5 Å to 0.7 Å. This value practically doesn’t change for carbendazim, but amplitudes of oscillation for both ligands diminish approximately 10 fold. Thus, described site can be considered as the most favorable for interaction between β-tubulin and benzimidazole molecules. This work is supported by cooperative STCU-NASU grant 4929 "Application of grid-resource for total analysis of β-tubulin spatial structure features causing a different sensitivity to benzimidazoles".

Beta Tubulin Class II Protein Increases with Low Dose Paclitaxel Treatment in MDA-MB-231 Breast Cancer Cells.
S. Lobert1, B. Jefferson1, B. Harwell1, R. Ladner1, J. J. Correia2; 1School of Nursing, University of Mississippi Medical Center, Jackson, MS, 2Department of Biochemistry, University of Mississippi Medical Center, Jackson, MS

Taxanes are commonly used in combination chemotherapy for solid tumors. These drugs bind to beta tubulin, stabilize microtubules in mitotic spindles and arrest cells in G2/M phase of the cell cycle. There are 8 genes that code for beta tubulins and the gene products are classified into seven isotype classes based upon their carboxyl terminal sequences. Unfortunately, the effectiveness of taxanes is reduced because some tumors are initially resistant or become resistant to taxanes after repeated cycles of chemotherapy. It is possible that changes in amounts of beta tubulin isotypes or microtubule interacting proteins (MIPs) could contribute to drug resistance. We investigated changes in tubulin isotypes and MIPs in response to paclitaxel in MDA-MB-231 breast cancer cells. We demonstrated previously that this cell line expresses primarily beta tubulin classes I, IV and V (Hiser et al., 2006, Cell Motil Cytoskel, 63:41-52). Using Western blotting and isotype-specific antibodies, we found that beta tubulin class II protein increases 2-3 fold after 16 hours treatment with 4 nM paclitaxel. Comparative real time PCR did not reveal a comparable change in mRNA for beta tubulin class II genes, TUBB2A or TUBB2B. Flow cytometry demonstrated that this increase in beta tubulin class II occurs prior to cell cycle...
synchronization and G2/M arrest. This result suggests that paclitaxel treatment leads to changes in either beta tubulin class II mRNA or protein stability. An increase in stathmin protein was also found over the same time period. Western blotting and comparative real time PCR did not show similar increases in tubulin isoform levels for tubulin isoform classes I, III, IV or V or MAP4.

How Does Nucleotide Content Regulate Microtubule Mechanics?
K. Taute, E. Florin; Center for Nonlinear Dynamics, University of Texas at Austin, Austin, TX

Various studies over the last decades have found that the stiffness of microtubules is a function of their length (Kurachi et al., 1995, Cell Motil. Cytoskeleton 30:221-228; Kis et al., 2002, PRL 89: 248101; Pampaloni et al., 2006, PNAS 103:10248 -10253). This length dependence has been successfully reproduced by mechanical models that take into account the molecular architecture of microtubules and allow for sliding of protofilaments relative to one another during bending (Heussinger et al., 2007, PRL 99:048101). In these models, the characteristics of the length dependence are determined by the bending stiffness of the protofilaments and the strength of protofilament interactions. Consequently, measurements of changes in microtubule mechanical properties, e.g. caused by microtubule binding proteins or other agents, can yield information on how the agent affects the molecular interactions of the tubulin dimers in the microtubule lattice. Based on high precision thermal fluctuation measurements on fluorescent tracer beads attached to grafted microtubules, we present results for the stiffness, relaxation times and friction parameters for microtubules polymerized from the slowly-hydrolyzable GTP analogue GMPCPP. In contrast to taxol-stabilized microtubules which show a pronounced length dependence of the stiffness that is attributed to weak protofilament interactions (Taute et al., 2008, PRL 100:028102), the stiffness of GMPCPP microtubules is constant in the measured length range of 4-25 µm. In agreement with structural data (Chang and Nogales, 2005, Nature 435:911-915), our results hence indicate that the coupling between protofilaments is much stronger in GMPCPP microtubules than in taxol-stabilized GDP microtubules, thereby supporting the notion that microtubule flexibility can be regulated by the nucleotide content of the polymer. Surprisingly however, the thermal fluctuation dynamics in the short length regime show evidence for internal friction contributions similar to those found for taxol microtubules.

Regulation of Tubulin-Membrane Interaction by Tubulin’s Carboxy-Terminal Tails.
D. L. Sackett; NICHD / NIH, Bethesda, MD

Microtubules and their subunit protein, the tubulin heterodimer, are components of the aqueous compartment of cells, and indeed aqueous solutions of tubulin at 50 mg/ml or greater are readily obtained. This is not surprising since tubulin is a highly negatively charged protein, largely due to the 10-15 residue long, glutamic acid-rich, unstructured carboxy-terminal tails (CTT) on both subunits. Nonetheless, tubulin has been reported as a component of purified membrane preparations for many years. Association of tubulin with membranes has included plasma membranes, intracellular membranes such as Golgi and mitochondrial outer membranes, and purified lipid membranes. The exact nature of the tubulin-membrane interaction has not been defined, nor has it been shown that all such interactions rely on the same underlying mechanism. In several cases, tubulin docking with lipid-embedded membrane proteins has been invoked. One such case is tubulin binding to the mitochondrial outer membrane. We have shown that tubulin binds to VDAC in the outer membrane through the CTT, with functional consequences for mitochondrial function. Thus tubulin’s CTT can promote membrane interaction by promoting binding to embedded membrane proteins. Tubulin has also been shown to bind to lipid membranes devoid of other proteins. We show by charge-shift electrophoresis and non-ionic detergent extraction that the presence of the CTT inhibits direct interaction of tubulin with amphiphiles. Thus, tubulin CTT can enhance or inhibit interaction with membranes, but these effects are mediated through two different molecular mechanisms.

**Growth-Arrest-Specific Protein 2 Arrests Cell Division by Disrupting Microtubule Dynamics.**

T. Zhang¹, C. A. Mandato¹,²; ¹Biology, McGill University, Montreal, QC, Canada, ²Anatomy and Cell Biology, McGill University, Montreal, QC, Canada

The growth-arrest-specific 2 (gas2) gene was initially identified from high levels of expression in murine fibroblasts under growth arrest conditions. It was also found that gas2 is down-regulated upon serum stimulation, which leads to re-entry into the cell cycle. It has been shown that the gas2 gene product-Gas2 protein, may interact with both F-actin and microtubules. In this study, full-length Gas2 protein was microinjected into *Xenopus laevis* embryos, and found to prevent subsequent cell divisions. Cryo-confocal microscopy analysis also suggested that Gas2 overlaps with microtubules. Electron microscopy further revealed that the purified full-length Gas2 can bundle microtubules. Furthermore, a cytokinesis analog contractile array assay showed that Gas2 co-localizes with double F-actin rings during the cell wound healing, which is a typical phenotype seen when the *Xenopus laevis* oocytes are treated with microtubule stabilization drug Taxol. Structure function analysis demonstrated that Gas2 can stabilize microtubules via its c-terminal Gas2 domain. Flow cytometry has shown that Gas2 DNA transfected HeLa cells have a significant increase in multiple nuclei cells in the culture, which suggests that over-expression of Gas2 can result in cytokinesis failure, and the cell cytokinesis failure is caused by the effect of Gas2 on microtubule dynamics.

**MAP1B Regulates Axon Formation by Promoting TIAM1 Association with Microtubules and Modulating RAC1/Cdc42/Rhoa Activities.**

C. Gonzalez-Billault¹, C. Montenegro-Venegas¹, E. Tortosa², J. Avila², A. Caceres³; ¹Cell and Molecular Biology, Universidad de Chile and Institute for Cell Dynamics and Biotechnology (ICDB), Santiago, Chile, ²Centro de Biologia Molecular Severo Ochoa and CIBERNED, Madrid, Spain, ³Instituto Mercedes y Martin Ferreyra, Cordoba, Argentina

Cultured neurons obtained from MAP1B-deficient mice have a delay in axon outgrowth and a reduced rate of elongation. We now show that MAP1B deficiency causes a significant decrease in Rac1 and cdc42 activity, along with an increase in Rho activity. MAP1B deficiency also prevents the binding of Tiam1, a guanosine nucleotide exchange (GEF) factor for Rac1, to microtubules. The decrease in Rac1/cdc42 activity is paralleled by decreased LIMK activity and reduced cofilin phosphorylation. The expression of a constitutive active form of Rac1 or of Tiam1 -a Rac1 GEF- rescue the axon growth defect of MAP1B-deficient neurons. Taken together, these observations, define a new and crucial function for MAP1B during neuronal polarization, which is required for an efficient crosstalk between microtubules and the actin cytoskeleton.

**MT Severing Activity Scales Spindle Length in Xenopus Egg Extract.**

R. Loughlin¹, J. Wilbur², F. McNally³, F. Nedelec⁴, R. Heald⁵; ¹Biophysics Graduate Group, University of California, Berkeley, Berkeley, CA, ²Molecular and Cellular Biology, University of California, Berkeley, Berkeley, CA, ³Molecular and Cellular Biology, University of California, Davis, Davis, CA, ⁴Cell Biology and Biophysics, European Molecular Biology Laboratory, Heidelberg, Germany

The *Xenopus laevis* metaphase spindle is a complex and dynamic steady state microtubule (MT) structure for which the physiological determinants of size and shape are poorly understood. To elucidate mechanisms of mitotic spindle assembly and scaling, we used a Brownian Dynamics numerical simulation to model a two-dimensional bipolar MT structure using a minimal set of protein components. Incorporating experimentally measured parameters, we found that focusing
of MT minus ends at spindle poles depended not only on motor-driven movements and minus end cross-linking, but also required depolymerization at the poles, and that altering this parameter changed spindle length. To test whether this mechanism contributes to the differential scaling of larger mitotic spindles in X. laevis compared to the smaller spindles in X. tropicalis egg extracts, we evaluated the stability of fluorescently-labeled, Taxol-stabilized MTs in extracts using a quantitative flow cell assay. We found that Katanin-dependent MT severing, but not Kinesin-13 dependent MT depolymerization, was significantly greater in X. tropicalis extracts. Although Katanin levels and pole localization were similar, extract-mixing experiments revealed that, like spindle length, severing activity was titratable and dose dependent in the two extracts. Katanin inhibition by antibody addition increased spindle length in both extracts and had a much more dramatic effect on the smaller X. tropicalis spindles, as kinetochore fibers (k-fibers) lengthened, causing centrosomes to fall off and disrupting pole structure. Introducing hyperstable k-fibers to numerical simulations reproduced this phenotype and predicted that spindle poles could withstand only small numbers of hyperstable k-fibers, which was confirmed by Katanin inhibition in spindles with reduced numbers of chromosomes. Thus, a combination of modeling and experimental approaches reveals mechanisms of spindle morphogenesis in Xenopus egg extracts.

K. H. Fisher1,2, F. Khan1, T. Duncan1, C. Deane2, J. G. Wakefield1; 1Zoology, University of Oxford, Oxford, United Kingdom, 2Statistics, University of Oxford, Oxford, United Kingdom

We recently used a MT co-sedimentation assay, combined with 1D and 2D PAGE and mass spectrometry, to identify 270 microtubule associated proteins (MAPs) from early Drosophila embryos. A bioinformatics analysis of this data set, based on binary protein interaction data, yielded a putative interaction network of MAPs. We have extended this data set to include Drosophila homologues of MAPs identified in other organisms, including plants, mouse and humans. The addition of homologues and interologs of MAPs leads to a relatively highly clustered network, 92% of which are fully connected. Network statistics indicate that the additional proteins added to the fly set are functionally relevant. This bioinformatics analysis identifies a complex network of putative interactions, which self organises into clades corresponding to known protein function, linked by key proteins. We have begun to assess the functional validity of our approach using sensitised RNA-interference in Drosophila S2 cells, in which centrosome-driven microtubule nucleation is knocked-down. A preliminary analysis of key candidate proteins suggests that at least some of these previously uncharacterised MAPs do, indeed, possess roles in MT organisation during mitosis. Together, our results reinforce the suggestion that a bioinformatics approach based on yeast two-hybrid data represents functionally relevant interactions, and identifies new MAPs whose roles in S2 cells are normally masked by the dominant role of centrosomes in microtubule nucleation.

Phosphoregulation of the Budding Yeast EB1 Homolog Bim1p by Aurora/Ipl1p.
T. Zimniak, K. Stengl, K. Mechtler, S. Westermann; Research Institute of Molecular Pathology (IMP), Vienna, Austria

EB1-like proteins are conserved regulators of microtubule dynamics in all eukaryotes. They target growing microtubule plus ends in Vivo and deliver associated factors to regulate the interactions of microtubules with cellular structures such as kinetochores or cortical attachment sites. Despite their widespread importance, molecular mechanisms regulating the activity of these proteins have largely remained elusive. Here we show that the budding yeast EB1 protein Bim1p is regulated by AuroraB/Ipl1p phosphorylation of its linker domain. Biochemical analysis has revealed that Bim1p directly associates with the Ipl1p kinase and, upon activation by Sli15p, becomes phosphorylated on a cluster of six sites in the flexible linker domain. Bim1 phosphorylation occurs during anaphase in vivo, and it is required for normal spindle elongation kinetics and an efficient
disassembly of the spindle midzone. Recombinant Bim1p phosphorylated with Ip1/Sli15 In Vitro or a mutant mimicking constitutive phosphorylation display a reduced affinity for taxol-stabilized microtubules. We have reconstituted the interaction between Bim1p and dynamic microtubules using total internal reflection fluorescence microscopy (TIRF) in vitro. Bim1p autonomously tracks growing microtubule plus ends and this activity requires the dimeric molecule. Our analysis indicates that the Bim1p linker domain is critical for MT binding, autonomous plus end tracking, and suggest a mechanism for the use and regulation of CH domains in an EB1 protein. Moreover, we are currently creating Ip1 mutants specifically affected in the interaction with Bim1p. These mutants allow us to investigate the role of Ip1 plus end targeting in vivo.

The Microtubule-Associated Rho Guanine Nucleotide Exchange Factor GEF-H1 Interacts with Exocyst and Regulates Vesicle Trafficking.
R. Pathak1,3, Y. Chang1,3, M. White2, G. M. Bokoch1,3; 1Immunology and Microbial Science, The Scripps Research Institute, La Jolla, CA, 2Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX, 3Cell Biology, The Scripps Research Institute, La Jolla, CA

The Rho-related small GTPases are involved in regulation of cell polarity and motility through their effects on the cytoskeleton, cell adhesion and membrane trafficking. They have been implicated in the regulation of both endocytic and exocytic membrane traffic by virtue of their capability to organize coordination between actin and microtubule cytoskeletons. Herein, we present evidence that GEF-H1, a Rho-specific nucleotide exchange factor that is regulated by its interaction with microtubules (MT) is involved in regulating vesicle trafficking. Depletion of GEF-H1 using siRNA leads to accumulation of large vesicles in the perinuclear region in Hela cells indicative of disruption in vesicular transport. GEF-H1 regulates membrane traffic by modulating Rho activity, since mutant deficient in catalyzing the nucleotide exchange was not able to rescue the knockdown phenotype. Expression of a dominant negative RhoA construct induces a similar block of vesicle transport. We determined that at least a sub-set of the accumulated vesicles in GEF-H1-depleted cells are recycling endosomes as they stained with Rab11, a small GTPase associated with the pericentriolar recycling compartment. Furthermore, GEF-H1-depleted cells show enhanced accumulation of labelled transferrin (Tfn) in punctate structures throughout the cytoplasm and at the cell periphery. We also observed a delay in recycling of labelled Tfn to the surface, indicating that GEF-H1 likely regulates the recycling of the transferrin receptors. Of particular interest, we find that GEF-H1 physically interacts with Sec5, Exo84 and Exo70, components of an evolutionarily conserved complex called the exocyst, known to be involved in tethering vesicles to the plasma membrane, further implicating GEF-H1 in vesicle transport. Furthermore localization of Exo70 and Sec6 to the plasma membrane is affected by GEF-H1 depletion indicating that latter might regulate vesicle trafficking by mediating the localization and/or function of the exocyst complex. Together these studies indicate that the Rho exchange factor GEF-H1 might be an ideal candidate for coordinating vesicular transport with regulation of the microtubule and/or actin cytoskeletons.

257/B204
Two Members of the ASE1/PRC/MAP65 Family Are Involved in MT Bundling and Cortical Array Organization in Arabidopsis.
J. R. Lucas, A. Bryant, S. L. Shaw; Biology, Indiana University, Bloomington, IN

Microtubules are organized into complex arrays that are required for critical cellular processes including cell division and morphogenesis. Bundled microtubules are important components of arrays. Ase1/PRC/MAP65 are microtubule bundling proteins predicted to play important roles in array organization. We investigated two of the nine MAP65 gene family members in Arabidopsis thaliana to define their specific roles in interphase microtubule bundling. In the plant cortical array, microtubule bundles form when the plus end of a treadmilling microtubule encounters another polymer and then changes growth trajectory to align parallel with the other microtubule. The probability of bundling is dependant upon the angle in which the two polymers interact. Live-cell observations of MAP65-1 and -2 fluorescent protein fusions indicate localization only to regions of
anti-parallel bundling within the cortical array. Double mutants (map65-1/map65-2) show growth defects relative to wildtype and single mutant plants suggesting that cortical array organization is impaired in these plants. Observations of microtubule behavior in the map65-1/map65-2 mutants suggest that MAP65-1 and -2 are important for both the initial bundling interaction and the maintenance of the bundle once formed.

Heterodimerization of Mammalian End Binding Proteins.
C. O. de Groot¹, I. Jelesarov², F. Damberger³, S. Bjelic², M. Schärer¹, I. Grigoriev⁴, R. M. Buey¹,
N. S. Bhavesh¹, K. Wüthrich⁵, G. Capitani¹, A. Akhmanova⁴, M. O. Steinmetz¹; ¹Structural Biology, Paul Scherrer Institute, Villigen, Switzerland, ²Biochemisches Institut, University of Zurich, Zurich, Switzerland, ³Institute of Molecular Biology and Biophysics, ETH, Zurich, Switzerland, ⁴Department of Cell Biology, Erasmus Medical Center, Rotterdam, Netherlands, ⁵Department of Molecular Biology and Skaggs Institute for Chemical Biology, The Scripps Research Institute, La Jolla, CA

Microtubule plus-end tracking proteins (+TIPs) are involved in many microtubule-based processes including regulation of chromosome segregation and maintenance of cell polarity. End binding (EB) proteins are highly conserved +TIPs that play a pivotal role in regulating microtubule plus ends and in organizing dynamic +TIP networks. Here we have analyzed in detail the dimerization properties of the three mammalian EB proteins, EB1, EB2 and EB3, using a combination of methods. Based on Förster resonance energy transfer we demonstrate that the C-terminal dimerization domains of EBs (EBc) which are targeted by numerous +TIP binding partners readily exchange their chains in solution and document that EB1c and EB3c preferentially form heterodimers. In contrast, EB2c does not participate significantly in any heterotypic complexes. Thermodynamic and kinetic experiments in combination with modeling and mutagenesis reveal that a structural property controls homo- versus heterodimer formation of EBc domains. Fluorescence and nuclear magnetic resonance studies in the presence of the CAP-Gly domains of either CLIP-170 or p150glued, or a fragment derived from APC show that chain exchange of EBs can be differentially controlled by +TIP binding partners. We extend our observations on the EBc domains to full length EB1 and EB3 and report that both proteins exchange their chains in solution and are capable of forming heterotypic complexes. Live cell imaging provides evidence that heterodimer formation between EB1 and EB3 but not between EB2 and EB3 is a mechanism occurring in cells. Together, our findings provide a molecular basis for understanding the dominant negative effect of C-terminal EB domains and expand our knowledge on the structural and functional properties of the remarkable family of EB proteins.

259/B206
Probing Interactions between CLIP-170, EB1, and Microtubules.
K. K. Gupta¹, M. V. Joyce², A. R. Slabbekoom¹, Z. Zhu¹, B. A. Paulson³, B. Boggess², H. V. Goodson¹; ¹Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, ²Mass Spectrometry and Proteomics Facility, University of Notre Dame, Notre Dame, IN, ³Biological Sciences, University of Notre Dame, Notre Dame, IN

CLIP-170 is a microtubule (MT) plus-end tracking protein (+TIP) that dynamically localizes to the MT plus end and regulates MT dynamics. The mechanisms of these activities remain unclear because the CLIP-170-MT interaction is poorly understood, and even less is known about how CLIP-170 and other +TIPs act together as a network. CLIP-170 binds to the acidic C-terminal tail of α-tubulin. However, the observation that CLIP-170 has two-CAP-Gly motifs and multiple serine-rich regions suggests that a single CLIP-170 molecule has multiple tubulin binding sites, and that these sites might bind to multiple parts of the tubulin dimer. Using a combination of chemical cross-linking and mass spectrometry, we find that CLIP-170 binds to both α- and β-tubulin, and that binding is not limited to the acidic C-terminal tails. We provide evidence that these additional binding sites include the H12 helices of both α- and β-tubulin and are significant for CLIP-170 activity. Previous work has shown that CLIP-170 binds to the +TIP EB1 via the EB1 C-terminus, which mimics the acidic C-terminal tail of tubulin. We find that CLIP-170 can utilize its
multiple tubulin binding sites to bind to EB1 and the MT simultaneously. These observations help
to explain how CLIP-170 can nucleate MTs and alter MT dynamics, and they contribute to
understanding the significance and properties of the +TIP network.

Death-Associated Protein Kinase Activates MARK2/Par-1 to Regulate Microtubule
Dynamics and Tau Toxicity.

P. Wu, Y. Huang, Y. Chen, C. Chien; 1Academia Sinica/Institute of
Biological Chemistry, Taipei, Taiwan, 2Institute of Molecular Biology, Academia Sinica, Taipei,
Taiwan, 3Institute of Molecular Medicine, Academia Sinica, Taipei, Taiwan

Death-associated protein kinase (DAPK) is a death-promoting, Ser/Thr kinase and is abundantly
expressed in neurons. DAPK has been linked to several modes of neuronal injury and implicated
in late-onset Alzheimer’s Disease (AD). In addition to its well-documented function in regulating
actin cytoskeletons, we report here that this kinase elicits an inhibitory role in microtubule (MT)
assembly. This effect of DAPK is mainly mediated by its activation of the microtubule affinity-
regulating kinase 2 (MARK2), which is known to phosphorylate tau and related microtubule-
associated proteins and thereby to cause MT destabilization. Intriguingly, the death domain of
DAPK, but not its catalytic activity, is both sufficient and required for MARK2 activation by
interacting with MARK2 spacer region, thereby relieving an autoinhibition mechanism of MARK2.
The DAPK-enhanced MARK2 activity to promote Tau phosphorylation at S262 (MARK2
consensus site) is observed in hippocampal neurons and, moreover, DAPK knockout mice have
reduced level of tau phosphorylation at this site. Using a Drosophila model for studying tau
toxicity, we show that DAPK acting through the Drosophila MARK2 homology Par-1 to trigger a
tau-mediated rough-eye phenotype. Furthermore, DAPK enhances tau toxicity through a S262-
dependent manner. Our findings reveal not only a new function of DAPK in regulating MT
dynamics but also a molecular link of DAPK to tau phosphorylation, an event associated with AD
pathology.

261/B208
The Doublecortin Family of Maps Stabilise Both Lateral and Longitudinal Contacts
between Tubulin Dimers.

F. Fourniol, M. Perderiset, C. V. Sindelar, B. Amigues, A. Bodey, M. Alonso, R. A. Cross,
F. Francis, A. Houdusse, C. Moores; 1Institute of Structural Molecular Biology, Birkbeck,
London, United Kingdom, 2CNRS UMR 144, Institut Curie, Paris, France, 3Marie Curie Research
Institute, The Chart, Oxted, United Kingdom, 4Brandeis University, Waltham, MA, 5INSERM
UMC UMR-S 839, Institut du Fer a Moulin, Paris, France

During brain development, immature neurons grow neurites and migrate to form the highly
ordered layers of the cortex. The doublecortin (DCX) family of microtubule-associated proteins
(MAPs) was found to be essential for this process. Single point mutations in DCX were found to
cause severe neuronal migration disorders in humans. Previous studies have opened the way to
an understanding of the relationship between the structure of DCX and its impact on microtubule
dynamics, the details of which are still being explored. DCX is a 40 kDa protein with a tandem of
11 kDa globular microtubule binding domains (called DC domains) and a C-terminal
Serine/Proline rich domain. Doublecortin-Like Kinase (DCLK) is a close homologue and has a 40
kDa N-terminal domain with 70% identity with DCX and a C-terminal 40 kDa kinase domain; its
function, however, remains unclear. Here we report biochemical evidence that DCL (DCX-Like,
splicing variant of DCLK lacking the kinase domain) nucleates and binds microtubules like DCX.
A previous study based on cryo-electron microscopy (cryoEM) and helical reconstruction showed
how a truncated construct of DCX stabilised the microtubule lattice by bridging adjacent
protofilaments with a DC domain, a unique mechanism among neuronal MAPs. Using cryoEM and
single particle algorithms we have generated reconstructions of 13-protofilament
microtubules co-polymerised in presence of full-length DCX. We show that a DC domain binds at
the interface between 4 tubulin heterodimers, in a way that apparently does not interfere with
kinesin binding, in good agreement with previous reports. Complementary biochemical
characterisation revealed tubulin C-terminal tails are not required for the DCX-tubulin interaction. These results provide insight into the complex interplay between DCX-like MAPs, tubulin and kinesin in neurons.

262/B209
Interactions between EB1 and Microtubules: Dramatic Effect of Affinity Tags and Evidence for Cooperative Behavior.
Z. Zhu1, K. K. Gupta1, A. R. Slabbeekoom1, B. A. Paulson1, E. Folker2, H. V. Goodson1; 1Biochemistry, University of Notre Dame, Notre Dame, IN, 2Department of Anatomy and Cell Biology, Columbia University, New York, NY

Plus end tracking proteins (+TIPs) are a unique group of microtubule binding proteins that dynamically track microtubule (MT) plus ends. EB1 is a highly conserved +TIP with a fundamental role in MT dynamics, but it remains poorly understood in part because reported EB1 activities have differed considerably. One reason for this inconsistency could be the variable presence of affinity tags used for EB1 purification. To address this question and establish the activity of native EB1, we have measured the MT binding and tubulin polymerization activities of untagged EB1 and EB1 fragments and compared them to those of his-tagged EB1 proteins. We found that N-terminal his-tags directly influence the interaction between EB1 and MTs, significantly increasing both affinity and activity, and that small amounts of his-tagged proteins act synergistically with larger amounts of untagged proteins. Moreover, the binding ratio between EB1 and tubulin can exceed 1:1, and EB1-MT binding curves do not fit simple binding models. These observations demonstrate that EB1 binding is not limited to the MT seam, and they suggest that EB1 binds cooperatively to MTs. Finally, we found that removal of tubulin C-terminal tails significantly reduces EB1 binding, indicating that EB1-tubulin interactions are mediated in part by the same tubulin acidic tails utilized by other MAPs. These binding relationships are important for helping to elucidate the complex of proteins at the MT tip.

263/B210
DTBCB: A New Drosophila Map Controlling MT Dynamics and Cell Polarity during Development.
A. Baffet1, B. Benoit1, V. Gourhand1, C. Heichette2, D. Chrétien2, A. Guichet1; 1Institut Jacques Monod. CNRS UMR7592, Paris, France, 2Université Rennes 1 / CNRS UMR6026, Rennes, France

The microtubule (MT) network is a core component of the cell cytoskeleton controlling fundamental processes as chromosomes segregation or polarized transport. These biological polymers are polarised with a stable, often anchored, minus end and a dynamic plus end. In the drosophila oocyte, the MT network is crucial to localise the polarity determinants that will generate both the antero-posterior and dorso-ventral axis of the adult fly. In order to identify genes required for the proper organisation of MTs in the oocyte, a genetic screen for polarity defects was previously carried out in the lab. We mapped one of the mutations identified to the uncharacterised CG11242 gene, which is the ortholog of the Tubulin Binding Cofactor B (TBCB) mammalian gene. Mammalian TBCB was reported In Vitro as being part of a chaperone complex required for αβ Tubulin heterodimer formation. We showed in S2 cells and fly embryos, that dTBCB is localised to the centrosome and along the MT network. We confirmed In Vitro by MT pull down that dTBCB could directly interact with MTs, showing that dTBCB is a microtubule-associated protein (MAP). We therefore analysed the microtubule network morphology in dTBCB mutant fly tissues. In the oocyte as well as in the surrounding epithelial cells, the mutation caused a very strong MT destabilisation, which correlated with severe polarity defects. In order to study the precise role of dTBCB association with the MTs independently of its α-Tubulin folding role, we incubated recombinant dTBCB with purified folded αβ Tubulin and measured the dynamic parameters of individual MTs. In this In Vitro assay, dTBCB enhances MT polymerisation speed as well as catastrophe rate, thereby making the MTs more dynamic. Hence dTBCB appears to function like some MT plus end tracking proteins such as EB1, to which we observed a direct binding with dTBCB. In summary, we propose that CG11242 codes for an ortholog of the
mammalian chaperone TBCB and identify a new function for this gene: dTBCB regulates MT dynamics In Vivo and In Vitro through a direct association with MTs, thereby controlling cell polarity during drosophila development.

Differences in Microtubule Attachment at the Yeast Spindle Pole Body.
Z. J. Bergman, X. Xia, C. Boone, T. Huffaker; 1Molecular Biology and Genetics, Cornell University, Ithaca, NY, 2Banting and Best Department of Medical Research, University of Toronto, Toronto, ON, Canada

Microtubules (MTs), dynamic structures involved in chromosome separation and spindle orientation, are anchored at the spindle pole body (SPB), the MT organizing center in yeast. The cytoplasmic MTs (cMTs) of budding yeast are responsible for the proper positioning and orientation of the mitotic spindle. A synthetic genetic array performed with a temperature-sensitive allele of Stu2, a MT associated protein thought to be involved with MT anchorage at the SPB, identified SHE1, a relatively uncharacterized gene. When SHE1 is deleted, cMTs detach from the SPB and track the periphery of the cell before depolymerizing. The detachment of cMTs in she1Δ mutants could stem from either a weakened connection at the SPB or an increase in pulling forces from MT motors. She1 has been shown to regulate the timing of the loading of dynactin components onto cMTs, which are required for dynein function. The motion of detached cMTs around the cortex of the cell is thought to be dynein dependent, as deletion of NIP100, a dynactin complex protein, rescues the detachment phenotype. SPB mutants that also detach cMTs have increased rates of cMT release when coupled with she1Δ, suggesting separate mechanisms. Additionally, attempts at finding any interactions with She1 at the SPB have all been negative. However, additional pulling forces cannot fully explain the detaching of cMTs because careful examination of the detachment phenotype in she1Δ asynchronous culture reveals that cMTs do not detach during anaphase when dynein is normally active. Arresting she1Δ cells in the mating phase increases the frequency of detachment. at this stage, as well as during G1, cMTs are anchored at the half-bridge of the SPB, as opposed to the outer plaque during mitosis. This has led us to the hypothesis that the MT anchoring complex at the half-bridge is weaker than that of the outer plaque and that part of She1’s function is to curb the pulling force of dynein during this part of the cell cycle. Cytoplasmic MTs can then remain attached and properly orient and position the nucleus for division.

Regulation of Bik1p.
R. Miller, S. D'Silva, H. Hoops; 1Biochemistry and Molecular Biology, Oklahoma State University, Stillwater, OK, 2Biochemistry and Biophysics, University of Rochester, Rochester, NY, 3Department of Biology, State University of New York, Geneseo, NY

Bik1p is the yeast homologue of the mammalian CLIP170 protein and is a member of the CAP-Gly protein family of microtubule binding proteins. Bik1p stabilizes microtubules and in its absence, microtubules are very short. In yeast two major pathways, the Kar9p and dynein pathways, determine accurate spindle positioning. These pathways carry out distinct functions for spindle positioning, with the Kar9p pathway orienting cytoplasmic microtubules and the dynein pathway pulling the spindle across the bud neck. In addition to playing a key role in the dynein pathway, Bik1p also interacts with Kar9p. However, the function of its interactions with the Kar9p pathway and how these interactions regulate the function of Bik1p are not completely understood. To better understand the mechanisms of interaction between the two spindle positioning pathways, a screen was carried out to identify bik1 mutants lacking the Kar9p-Bik1p interaction. This resulted in the identification of the Y61H mutant, which contains a tyrosine to histidine mutation at residue 61. This mutation results in weaker Kar9p-Bik1p and Kip2p-Bik1p interactions. Y61H displays short microtubules, and the fluorescent-tagged protein displays an altered localization. The protein encoded by Y61H is about 8 kD smaller than Bik1p indicating that this mutation affects the stability of the protein or prevents a post-translational modification.

LC8-Mediated Assembly Mechanism of Flagellar Complexes.

A. Gupta1, D. R. Diener2, P. Yang1; 1Wher Life Science, Marquette University, Milwaukee, WI, 2Yale University, New Haven, CT

The assembly of the axoneme inside cilia and flagella is an extraordinary undertaking. The components are synthesized in the cell body whereas assembly occurs at the tip of these slender organelles. In general, the components are first packaged into precursor complexes and then delivered to the flagellar tip to be converted into mature complexes, ultimately becoming part of the precise, elaborate axonemal nanomachine; however, the details of this process are poorly understood. To study this problem of assembly, we focus on two homodimeric molecules in Chlamydomonas radial spoke (RS) complex: RSP3 and LC8 that modulate various target proteins to promote assembly of various molecular complexes. RSs are absent in the axonemes of the RSP3 and LC8 mutants, yet curiously soluble precursor and mature RSs are present inside the flagella of LC8 mutants, suggesting a deficiency in RS docking. Interestingly, adjacent to the N-terminal axoneme-binding site of RSP3 are three conserved LC8-binding motifs aligned in tandem. We postulate that RSP3 is an LC8 target protein and their interaction is critical for RS assembly. To test this, wild type axonemes were treated with trypsin, digesting RSs into fragments. As revealed by 2-D native gel/SDS-PAGE and western blots, LC8 co-migrates with RSP3 N-terminal fragments when most of the other RSPs are not detectable. Likewise, the N-terminal fragment expressed in Chlamydomonas is assembled along with LC8 into axonemes even though the majority of RS proteins are absent. Importantly, while LC8 is present in mature RSs, it is absent from the precursor complex. These results suggest that LC8 dimers and RS precursors are delivered separately to the flagella and that the tip an array of LC8 binds to the RSP3 dimer to transform the precursor complex into a rigid stalk that docks to the outer doublets.

Role of EB1 and EB3 in Ciliary Assembly in Human Cells.

J. M. Schroder1, S. Geimer2, J. Larsen1, R. I. Thorsteinsson1, S. T. Christensen1, L. B. Pedersen1; 1Department of Biology, Section of Cell and Developmental Biology, University of Copenhagen, Copenhagen, Denmark, 2Biology/Electron Microscopy, University of Bayreuth, Bayreuth, Germany

We previously showed that the MT plus-end tracking protein EB1 is required for assembly of primary cilia in mouse fibroblasts (Schroeder et al. Curr. Biol. 2007), but the mechanism by which EB1 affects ciliogenesis remains unknown. In mammalian cells two additional members of the EB protein family (EB2 and EB3) are present, but their role in ciliogenesis has not previously been investigated. In order to gain further knowledge about the role of EB proteins in cilia formation we depleted EB1, EB2, or EB3 from Human Foreskin Fibroblast (hFF) and retinal pigment epithelial (RPE) cells using siRNA, and analyzed the effect of this depletion on primary cilia formation in growth-arrested cells using immunofluorescence microscopy (IFM). Consistent with our previous results we found that depletion of EB1 inhibits ciliogenesis by ca. 50% in growth-arrested cells. Furthermore, we found that depletion of EB3, but not EB2, had a similar inhibitory effect on cilia formation. These results were confirmed by IFM analysis of RPE cell lines stably expressing GFP-tagged full-length or truncated (dominant negative) EB1, 2, or 3. Preliminary transmission electron microscopy (TEM) analysis of serum-starved mock-transfected or EB1-depleted hFF cells showed that vesicles appear to accumulate in the vicinity of the basal body when EB1 is depleted. However, IFM analysis of EB1-, 2-, or 3-depleted cells using antibodies specific for the Golgi protein GMAP210 revealed no significant differences in the overall localization or organization of the Golgi as compared to mock-transfected cells. These results suggest that the defect in ciliogenesis resulting from depletion of EB1 or EB3 is not due to a general defect in the Golgi, but may result from a more specific defect in the trafficking of vesicles to the ciliary base.
We are currently addressing this issue further using TEM analysis as well as GST pull-down assays to identify binding partners of EB1 in the cilium Basal body.

Origin of the Cilium: Novel Approaches to Examine a Centriolar Evolution Hypothesis.
M. C. Alliegro¹, P. Satir²; ¹Bay Paul Center for Comparative Molecular Biology and Evolution, Marine Biological Laboratory, Woods Hole, MA, ²Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Recently, a new hypothesis was proposed regarding the evolution of the cilium from an enveloped RNA virus (Satir et al., 2007 Cell Motil. Cytoskeleton 64:906). The hypothesis predicts that there may be specific centriolar or basal body RNAs with sequences reminiscent of retroviruses, and/or that the nuclear genes for certain centriole-specific proteins would have viral origins. Four independent laboratories have reported the existence of centrosomal RNA (cnRNA). Methods for studying cnRNA are described. We analyzed evidence of relatedness of known full length cnRNAs to extant viral molecules. Out of 14 cn RNAs studied, 12 have similarity to entries in viral databases, all but one with E-values of ≤1e-4. Some centrosomal, and possibly uniquely centriolar, proteins also have protein relatives in viral databases that meet criteria accepted to indicate a relationship by descent. Nine general cytoskeleton proteins exhibited no significant similarity to viral proteins. The speculation that centrioles are invaders of RNA viral origin in the evolving eukaryotic cell is strengthened by these findings.

Remarkable Conservation of Non-Canonical Axoneme Structures from Parasites to Mammals.
E. M. Gluenz¹, H. R. Dawe¹,², J. L. Höög¹,³, M. K. Shaw¹, A. E. Smith¹, K. Gull¹; ¹Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom, ²School of Biosciences, University of Exeter, Exeter, United Kingdom, ³The Boulder Laboratory for 3D Electron Microscopy of Cells, University of Colorado, Boulder, CO

Cilia and flagella are generally classified into ‘9+2’ motile and ‘9+0’ immotile sensory cilia, but the true diversity of ciliary structures and functions across eukaryotes is becoming increasingly apparent. Promastigote forms of the Leishmania parasite utilize their 9+2 flagellum during their passage through the insect vector for locomotion, cell morphogenesis, attachment to insect vector epithelial cells and, most likely, sensory functions. The amastigote forms that infect macrophages of the mammalian host are often wrongly described as being ‘aflagellate’ despite the presence of a small flagellum that protrudes a short distance from the flagellar pocket. Why do amastigotes retain a short flagellum at all? Using electron microscopy and 3D electron tomography to analyse the structure of amastigote flagella at high resolution, we have uncovered a striking similarity between the microtubule axoneme structure of the Leishmania parasite infecting a macrophage and vertebrate sensory cilia. Both have nine microtubule doublets but in an unusual ‘collapsed’ symmetry. 3D reconstructions reveal that in both cases it is not a particular doublet that breaks the symmetry and moreover the initial collapse often involves two doublets. The tip of the Leishmania flagellum was frequently in intimate contact with the macrophage vacuole membrane, suggestive of a ‘parasitophorous synapse’. We propose that the amastigote flagellum acts as a sensory organelle with potentially important functions in the intracellular stage of the Leishmania life-cycle.

The Hydrolethalus Syndrome Protein HYLS-1 Links Core Centriole Structure to Cilia Formation.
A. Dammermann¹, H. Pemble¹, B. Mitchell², I. McLeod³, J. Yates³, C. Kintner², A. Desai¹, K. F. Oegema¹; ¹Ludwig Institute for Cancer Research, University of California, San Diego, La Jolla, CA, ²The Salk Institute for Biological Studies, La Jolla, CA, ³The Scripps Research Institute, La Jolla, CA
Centrioles perform two major functions in eukaryotic cells: 1) they recruit pericentriolar material proteins to form centrosomes that organize the cellular microtubule cytoskeleton, and 2) they template cilia, microtubule-based cellular projections with sensory and motile roles. Identifying the molecular mechanisms underlying the dual functionality of centrioles remains an important current challenge. Here we show that HYLS-1, a protein mutated in hydrolethalus syndrome, a perinatal lethal human developmental disorder, is a centriolar protein required for ciliogenesis. HYLS-1 is stably incorporated into centrioles during their assembly in a manner dependent on SAS-4, a core centriolar protein with which it directly interacts. Unlike SAS-4, HYLS-1 is dispensable for centriole duplication and centrosome function in cell division. Instead, HYLS-1 is specifically required for cilia formation in C. elegans and Xenopus. The hydrolethalus-associated missense mutation impairs HYLS-1 function in ciliogenesis, indicating that hydrolethalus syndrome is a severe ciliopathy. Our results further show that HYLS-1 does not contribute to the intraflagellar transport (IFT) -dependent extension of the ciliary axoneme, but is required for the earlier, IFT-independent, step of apical migration and/or anchoring of centrioles at the plasma membrane. Thus, HYLS-1 is the first core centriolar protein not involved in centriole assembly or centrosome function in cell division. Instead, incorporation of HYLS-1 confers on centrioles the capacity to initiate ciliogenesis.

EF Hand Mutations in a Tetrahymena Basal Body Protein, Cen1, Suggests a Possible Structure-Function Relationship.
T. Vonderfecht, M. Winey; Molecular, Cellular, and Developmental Biology, University of Colorado at Boulder, Boulder, CO

The basal body is a microtubule-based structure responsible for nucleating the cilium and anchoring it in place at the surface of the cell. Cilia are involved in a wide variety of important roles in metazoan cells, ranging from fluid flow to sensing the surrounding environment. A major question about the basal body is how are its molecular components involved in building, maintaining, and regulating the structure. A molecule that is conserved at basal bodies in many metazoans is a ~20kDa protein called centrin. Structurally, centrin consists of two independent domains tethered by a linker with each domain containing two EF hands, a Ca^{2+} binding motif. It has been shown that centrin is essential for proper basal body function; however, its molecular mechanisms and the specific role of its EF hands remains a mystery. We are using the ciliate protist Tetrahymena thermophila as a system to study basal bodies. Tetrahymena Cen1, which is closely related to the human Centrin2, is essential for the assembly and maintenance of basal bodies. We have mutated individual EF hands in Cen1 in order to gain a better understanding of its function. N-terminal EF hand mutations in Cen1 results in basal body orientation defects that occur only during the assembly of new basal bodies. Similar mutations to the EF hands of the C-terminal domain reduces the localization efficiency of Cen1, and these cells exhibit significant defects in basal body assembly and/or maintenance. Subsequent work shows that the C-terminal half of Cen1 is important for localization to basal bodies. These results raises the ideas that Ca^{2+} may be important for Cen1 function and that Cen1’s two domains have distinct functions, with the C-terminal domain being important for localization and the N-terminal domain regulating the protein’s function.

A Screen for Chlamydomonas Insertional Mutants with Altered Deflagellation-Induced Gene Expression.
J. M. Brown1, D. X. Quarless1,2, K. F. Lechtreck1, G. B. Witman1; 1Cell Biology, University of Massachusetts Medical School, Worcester, MA, 2Whitworth University, Spokane, WA

Deflagellation of Chlamydomonas results in rapid and coordinate induction of hundreds of genes. The resulting new protein synthesis is required for regeneration of full-length flagella. Although Chlamydomonas is the preeminent model organism for the study of flagellar structure and function, the proteins required for deflagellation-stimulated gene induction are unknown. Chlamydomonas is an ideal organism for genetic analysis of flagella-specific gene induction. It
can be transformed at high frequency with dominant selectable markers and the introduced DNA integrates throughout the genome, simultaneously disrupting and tagging genes at the sites of insertion. Following mutagenesis, haploid genetics allows straightforward identification of recessive mutations causing a phenotype of interest. We have developed a reporter strain, LC8GLuc4, in which expression of a codon-optimized *Gaussia princeps* luciferase (Shao and Bock, 2008, *Curr Genet*) is driven by the dynein light chain LC8 promoter. Deflagellation of LC8GLuc4 results in an increase in luciferase activity similar to increases in expression of genes encoding flagellar proteins. Induction is detectable using a standard luciferase assay within 15 minutes after deflagellation and peaks at ~10- to 20-fold by 60 minutes. The ease of the luciferase assay makes high-throughput screening for insertional mutants in the deflagellation-stimulated gene-induction pathway feasible. In a pilot screen, we mutagenized LC8GLuc4 with a fragment of pHyg3 (Berthold et al., 2002, *Protist*). Among the hygromycin-resistant transformants, we identified a strain that lacks flagella and exhibits constitutive luciferase upregulation. Importantly, most aflagellate strains generated in the reporter background do not constitutively upregulate luciferase activity, indicating that upregulation is not simply a response to lack of flagella. We are currently expanding this pilot screen to identify mutants unable to normally induce gene expression following deflagellation.

**Characterization of Putative Cilia Genes by High-Content Analysis.**

C. Lai, N. Gupta, X. Wen, S. J. Scales; Molecular Biology, Genentech, South San Francisco, CA

Cilia are microtubule-based structures that protrude from the surface of the cell and are involved in a number of essential signaling pathways, yet much is still not known about all of the proteins that regulate cilia structure and function. We have sought to characterize 41 putative cilia genes of unknown function previously identified by proteomics and sequence analysis. We measured the effect on cilia of siRNA knockdown of these genes using: 1) a microscopy-based assay in 3T3 cells, measuring cilia number, cilia length, and hedgehog-dependent transport of endogenous Gli3 to the cilia tip; 2) a microscopy-based assay in IMCD3 cells, measuring the hedgehog-independent transport of HTR6-GFP to the cilia shaft; and 3) a Gli-luciferase reporter assay in S12 (C3H10T1/2) cells, measuring hedgehog signaling. 31 of the genes resulted in interesting cilia phenotypes upon siRNA knockdown, divided into five phenotypic classes: including loss of cilia, shorter cilia, longer cilia, and normal cilia with cargo transport and/or signaling defects. We will summarize results of the three assays on all of the cilia candidate genes, as well as an in depth analysis of at least one validated hit.

**Functional Defects in Sperm from SPAG16L Disrupted Mice.**

K. A. Lesich1, Z. Zhang2, C. Kelsch1, K. Ponichter1, J. F. Strauss3, C. B. Lindemann1; 1Biological Sciences, Oakland University, Rochester, MI, 2Obstetrics and Gynecology, Virginia Commonwealth University, Richmond, VA, 3School of Medicine, Virginia Commonwealth University, Richmond, VA

Sperm from mice homozygous for a disrupted *Spag16L* gene (KO sperm), which encodes a central apparatus protein, were examined to assess their flagellar motor functions. The beat frequency, bend curvature and shear angle development of live sperm carrying the defect were compared to those of age- and strain-matched control sperm. Live KO sperm exhibited much less bending of the flagellum during the beat. Shear angle analysis showed that the amount of microtubule sliding in the R-bend direction of the beat was selectively restricted. This suggests that there is limited activation of the dyneins on one side of the axoneme in the live cells. The KO sperm were also demembranated with Triton X-100 and examined for their response to free Ca2+ and for their ability to undergo dynein-driven microtubule sliding. The flagellar curvature response to Ca2+ is significantly (p < 0.001) reduced in the KO sperm. The Ca2+ response requires the activation of the dyneins on outer doublets 1, 2, 3 and 4. These are the same dyneins required for R-bend formation. In axonemes prepared to disintegrate by microtubule sliding, we observed little or no extrusion of doublets 1 and 2, which is consistent with a reduced activity of their dyneins. In
addition, the passive flagella inhibited by sodium metavanadate to disable the dyneins were examined for mechanical abnormalities. We discovered that the midpiece region of the KO sperm is more rigid than that of wild-type sperm. The deficit we observed in motor function, together with the increased rigidity of the midpiece region can account for the motility characteristics of the SPAG16L disrupted sperm. The lack of a normal response to Ca$^{2+}$ would render these sperm incapable of hyperactivation, which might explain the infertility associated with this defect. Our findings implicate an important role for the central apparatus in Ca$^{2+}$-induced hyperactivation. Supported by N.S.F. grant MCB-0516181 (CBL) and N.I.H. grant HD037416 (JFS).

275/B222  
**Developmental Regulation of the Ciliary Proteome in Sea Urchin.**  

The sea urchin embryo has long been a model of choice for studying the formation and function of cilia. In most urchin species, ciliogenesis occurs on all cells just prior to embryo hatching and is regulated thereafter in a tissue-specific manner to generate cilia with different lengths and behaviors. Probing the genome of the purple sea urchin Strongylocentrotus purpuratus using the flagellar proteomes from human and Chlamydomonas, we studied how the urchin regulates tissue-specific differentiation of cilia in development. Genes representing all ciliary protein classes including the flagellar-associated proteins (FAPs) in the Chlamydomonas Flagellar Proteome, were identified in the S. purpuratus genome by reciprocal BLAST to generate a draft sea urchin ciliome. Analysis of S. purpuratus transcriptome data from sequential developmental stages revealed that the majority of putative ciliary genes exhibit four general temporal expression patterns: predominantly zygotic, zygote-blastular, and early blastular (prior to or during initial ciliogenesis), and larval (coinciding with formation of ciliary subtypes). Few putative ciliary genes exhibit peak expression during the gastrula stages. Some groups of genes whose products presumably function together, such as IFT genes, are expressed prior to or during ciliogenesis but have variable peak expression times. Most FAPs that show modulated expression exhibit a discrete peak at the onset of ciliogenesis in the early blastula. Gene Ontology suggests that ciliary proteins with general metabolic functions exhibit peak expression early in development while many ciliary proteins with more specialized functions exhibit peak expression only after organogenesis. Genes whose products are central to specific processes, such as kinesin-2 family members that drive anterograde IFT, are being targeted by antisense morpholino knockdown to test their roles inferred by expression pattern and Gene Ontology analysis. Producing a draft ciliary proteome in the sea urchin, with its readily available transcriptome data, has allowed us to study how the ciliogenic program can be modulated during development to generate cilia with tissue-specific morphologies, motilities, and functions.

276/B223  
**Chlamydomonas Kinesin 13, a Member of the Microtubule-Depolymerizing Family of Kinesins Functions Both in Flagellar Assembly and Disassembly.**  
T. Piao¹, L. Wang¹, M. Luo¹, Y. Guo¹, D. Li¹, P. Li¹, W. J. Snell², J. Pan¹; ¹Biological Sciences and Biotechnology, Tsinghua University, Beijing, China, ²Cell Biology, UT Southwestern Medical Center, Dallas, TX

Cilia and eukaryotic flagella are assembled and disassembled during cell cycle progression and upon environmental cues. Growth of the microtubule-based axoneme within the organelle requires assembly of microtubules at the tip of the flagellum, and axonemal disassembly depends on microtubule depolymerization at the tip. In *Chlamydomonas*, experimentally deflagellated cells immediately begin to regenerate new flagellar microtubules from tubulin precursor present in a pool in the cell body. Little is known about the molecular mechanisms that regulate microtubule dynamics during flagellar assembly and disassembly, nor is it known whether the cell body pool of tubulin is soluble or in the form of cell body microtubules. We have determined that CrKinesin13, a *Chlamydomonas* member of the kinesin13 family of microtubule depolymerizers, functions both during flagellar assembly and disassembly. Stimulation of a cell to assemble new
flagella triggers phosphorylation of CrKinesin13, whereas activation of flagellar shortening induces immediate transport of CrKinesin13 into the flagella from the cell body via intraflagellar transport (IFT). Cells depleted of CrKinesin13 by RNAi produce short flagella and are inhibited in flagellar shortening. Moreover, after deflagellation the CrKinesin13-depleted cells exhibit a 2 hr lag in regeneration, and assembly is blocked completely when protein synthesis is blocked. We propose that, in addition to its role during flagellar shortening to disassemble microtubules at the flagellar tip, CrKinesin13 functions in the cell body to mobilize tubulin from assembled microtubules for transport into the flagella. This work is partly supported by the National Natural Science Foundation of China (Grants 30671090, 30830057, and 30771084), National Institutes of Health (US) Grant GM25661, and the National Basic Research Program of China (Grant 2007CB914401).

Heterotrimeric Kinesin-2 Is Essential for the Assembly and Functioning of Adult Olfactory Cilia in Drosophila.
S. C. Jana, M. Girotra, K. Ray; Department of Biological Sciences, Tata Institute of Fundamental Research, Mumbai, India

Type-I sensory neurons in insects express cilia from the distal ends of their dendrites, which contain the machinery for stimulus reception and transduction. Although diverse in structures and functions, basic organizations are similar in all these cilia. They contain either an axoneme, or, a set of doublet microtubule bearing proximal segment; and a membranous distal region consisting of singlet microtubules and/or actin filaments. Cooperative and partly redundant anterograde transport by the homodimeric Osm3/Klf17 class of motors and the heterotrimeric kinesin-2 were shown to be essential for the assembly and maintenance of sensory cilia in worms and mammals. However, only kinesin-2 subunits were found necessary and sufficient to maintain the chordotonal cilium in Drosophila, bearing a 9+0 axoneme. All Drosophila olfactory neurons also express elaborate sensory cilia containing both the axoneme bearing inner, and singlet microtubule containing outer segments, but the mechanism underlying their assembly and maintenance were unclear. We found that all the kinesin-2 subunits are enriched in the olfactory cilia in adult Drosophila antennae. In addition, mutations in the kinesin-2 motor subunit gene Klp64D significantly reduced the odor receptions and enhanced reception thresholds for a variety of odors at the adult antenna. Ultrastructure analysis of multiple mutant alleles further showed that loss of KLP64D reduced membranous branches and microtubule localizations in the outer segments, whereas the loss of the accessory subunit DmKAP eliminated the entire cilia, indicating a complex and differential roles of kinesin-2 subunits in adult olfactory cilia.

The CSC Is Required for Complete Radial Spoke Assembly and Wild-Type Ciliary Motility.
E. Dymek, E. F. Smith; Biological Sciences, Dartmouth College, Hanover, NH

We previously identified a CaM and spoke associated complex (the CSC) and demonstrated a role for this complex in regulating dynein-driven microtubule sliding (Dymek and Smith, 2007). One CSC member, CaM-IP2, interacts with RSP3, an AKAP that links the spoke to the doublet microtubule. Based on this association, we hypothesized that interactions between CaM-IP2 and RSP3 play a role in spoke assembly and/or modulating motility. The CSC assembles onto the axoneme in the radial spokeless mutant pf14. Therefore, assembly of the CSC does not require the radial spokes. What is not known is, whether spoke assembly requires the CSC. No mutations have been identified that correspond to any of the three CSC components. Therefore, we used an artificial microRNA approach to reduce expression of CSC components (Zhao et al., 2008; Molner et al. 2009). Using constructs designed to silence expression of either CaM-IP2 or CaM-IP3, we obtained two mutants with reduced expression of these components. In both mutants, CaM-IP2 and -IP3 are lacking or severely reduced in isolated flagella, and immunoprecipitation with anti-CaM antibodies fails to precipitate any members of the CSC. Western blots of flagella using antibodies directed against radial spoke components suggest that a fraction of radial spokes failed to assemble in these mutants. Images of mutant axonemes using
thin section electron microscopy were consistent with results from western blots and revealed an unusual pattern of altered spoke assembly. In analyses of motility in these mutants we discovered that while swimming speed was reduced by 25-30% compared to wild-type, beat frequency was only slightly reduced. This reduction in beat frequency was not sufficient to account for the reduction in swimming speed. Upon closer inspection of flagellar beating by high speed video microscopy, we discovered that the flagella of these mutants often lost coordination, beating out of sync with one another. This lack of coordination resulted in frequent pauses rather than more constant trajectories. Our results strongly suggest that the CSC is associated with only a subset of radial spokes and that this association is required for complete spoke assembly and wild-type motility.

279/B226
**Calcium Induces Transcription/Translation-Independent Ciliogenesis.**
*S. Davis, P. Yang; Biological Sciences, Marquette University, Milwaukee, WI*

Cilia and flagella play critical roles in the development and function of vital organs. To elucidate the fundamental mechanisms controlling their generation, we take advantage of a usually aflagellate *Chlamydomonas* strain, *fla14*. This strain has defective cytoplasmic dynein motors and can only grow half-length flagella at best due to the absence of retrograde intraflagellar transport (Pazour et al. 1998). Flagella generate in 0.5 - 2 hours following suspension in distilled water or 10 mM HEPES buffer and exposure to light, a common practice to encourage flagella generation. Contrarily, aflagellate cells defective in axonemal complexes can generate flagella in 10 minutes after the suspension. Culture media can promote growth only when diluted at least four-fold. Addition of calcium is not required. The translation inhibitor cycloheximide has no effect on the process, while 10 mM KCl that depolarizes cells accelerates growth. In contrast, growth is inhibited by 50 μM EGTA, 10 mM NaCl, repeated suspensions, and Verapamil, an L-type voltage-gated calcium channel blocker. Furthermore, cells harvested from spent media cannot be induced to generate flagella. These results indicate that ciliogenesis is controlled by multiple pathways including calcium signaling. Hypo-osmolarity amplifies the light-induced depolarization, leading to the release and re-entry of calcium which signals flagellar generation downstream from transcription and translation.

**Structural Model of Microtubule Lateral Deformation Based on Studies of Multiple Types of Microtubules.**
*H. Sui1,2, K. H. Downing2; 1Division of Translational Medicine, Wadsworth Center, Albany, NY, 2Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA*

Microtubules are hollow cylinders formed by tubulin protofilaments. Microtubules are often exposed to mechanical stress, for example from motor-induced forces or passive bending under external forces. Rather than being rigid cylinders, microtubules are flexible and able to deform, which may be an essential property for them to tolerate environmental stress. Lateral deformation of microtubules has been identified in our cryo-tomography study of microtubule doublets, which are the major structure component of the axoneme. The molecular architecture of the doublet and the axoneme obtained by tomography has shed light on the mechanical properties of cilia/flagella. One structural feature revealed is that the microtubule in the intact doublet shows an oval shape in cross-section (Sui and Downing, Nature 2006). This distortion represents flexibility of the interprotofilament interactions in the microtubule and presumably results from mechanical stress that arises from binding of microtubule-associated proteins. It may also contribute to the anisotropic bending moment of doublets. Here we propose a structural model for lateral deformation based on studies of multiple types of microtubules. While most microtubules are found to contain 13 protofilaments, the interactions between adjacent protofilaments is sufficiently flexible to allow the number of protofilaments in a single microtubule to vary from 9 to 16. We used cryo-electron microscopy to study structures of microtubules composed of different numbers of protofilaments. Resultant density maps have reached a resolution sufficient to clearly reveal the tubulin secondary structure and enabled construction of pseudo-atomic models for multiple types of
microtubules. In these models, the structures of the protofilaments do not display any noticeable differences, other than that the angle between neighboring protofilaments changes with the number of protofilaments. Inter-protofilament interactions involve the M and H1-S2 loops. The loop-loop interactions offer structural flexibility and are therefore proposed to be the major contributor for the lateral deformation of the microtubule in our model.

Defining Functional Domains in PF6, a Component of the Central Apparatus C1a Projection and Required for Ciliary/Flagellar Motility.
D. J. Goduti, E. Smith; Department of Biological Sciences, Dartmouth College, Hanover, NH

The c1a projection of the flagellar central apparatus is critical for normal motility, as evidenced by Chlamydomonas pf6 mutants, which lack c1a and have twitchy flagella unable to generate productive movement. We have previously shown that PF6 forms a complex with C1a-86, C1a-34, C1a-32, C1a-18, and calmodulin (CaM); this entire complex fails to assemble in pf6 flagella (Wargo, et al., 2005). Based on this defect, PF6 (2301 amino acids) most likely serves as a scaffold or adaptor for complex assembly onto the C1 central tubule. Since no known mutants exist for other members of the PF6 complex, their specific contributions to motility are unknown. Presumably, CaM plays a role in calcium regulation of motility. As a first approach to generating mutants which fail to assemble specific members of the PF6 complex, as well as to define functional domains within PF6, we have created deletion constructs of PF6 and transformed these into pf6 mutants. Transformants expressing PF6 lacking either amino acids 68-752 or amino acids 854-1821 assemble truncated PF6 protein as well as all c1a projection components into their flagella. Motility is also restored to pf6 cells transformed with either construct. However, swimming velocity is decreased to one-half that of wild-type. This decrease is primarily due to a 50% reduction in beat frequency, although subtle waveform defects may also exist. These results suggest that the amino two-thirds of PF6 may interact with axonemal proteins other than PF6 complex components, and that these interactions are evidently critical for wild-type motility. In contrast, no motile cells are recovered when pf6 is transformed with a construct that produces PF6 lacking C-terminal amino acids 1459-2301. A smaller C-terminal deletion (1863-2230), which disrupts a basic domain and conserved ASH domain (Ponting, 2006) restores motility. Swimming velocity and beat frequency of these cells is slightly reduced compared to wild-type. Biochemical analyses indicate that the associations of C1a-86 and CaM with this smaller C-terminal deletion are unstable. These results indicate that the carboxyl one-third of PF6 is required for assembly onto C1 as well as for stable interaction with PF6 complex members.

3D Views of the Dynein Regulatory Complex by Cryo-Electron Tomography.
T. Heuser1, M. Raytchev1, J. Lin1, J. Krell1, M. E. Porter2, D. Nicastro1; 1Biology, Brandeis University, Waltham, MA, 2Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN

Cilia and flagella are highly conserved eukaryotic organelles with motile or sensory functions. In humans, many cell types assemble cilia, and they are crucial for the proper functioning of several organs. Ciliary defects are thus associated with a number of diseases, such as polycystic kidney disease or primary ciliary dyskinesia [1]. Most cilia share a common core-structure, the axoneme, which consists of nine doublet microtubules surrounding a central pair of singlet microtubules [2]. Motility is generated by the orchestrated activity of thousands of dynein motors that drive inter-doublet sliding. Structures that restrict sliding, such as the nexin-links that connect neighboring doublets, transform inter-doublet sliding into axonemal bending [3, 4]. The dynein regulatory complex (DRC) has a key role in controlling dynein activity and thus axonemal movement [5, 6]. Seven DRC components have been identified and characterized biochemically [5]. However, few details about the structural organization of the DRC are known. We analyzed rapidly frozen Chlamydomonas axonomes by cryo-electron tomography followed by image processing to gain new insights into the 3D structure and molecular organization of the DRC in situ. By correlating published biochemical data with our tomograms from the wildtype and five drc-mutant strains we

283/B230
A Conformational Switch for Outer Arm Dynein Motor Function.
R. S. Patel-King, S. King; Department of Molecular, Microbial and Structural Biology, University of Connecticut Health Center, Farmington, CT

Based on the experimental manipulation of mutant Chlamydomonas flagella lacking various axonemal substructures, Hayashibe et al (CMC 37, 232 [1997]) proposed the existence of two mechanosensory systems that respond to alterations in the mechanical state of the axoneme and allow for propagation of a flagellar bend along the axonemal length. One sensor appears to involve the central pair complex and impinges on the inner dynein arms, whereas a second distinct system was proposed to control outer arm function. The LC1 light chain within outer arm dynein associates with the motor domain of the gamma dynein heavy chain (HC), and crosslinking experiments, blot overlays and direct binding assays also indicate that it associates directly with tubulin. Based on both geometric constraints derived from the NMR structural ensemble (PDB 1M9L) and immunogold electron microscopy, LC1 appears to tether the HC motor unit to the A-tubule of the outer doublets. Thus, this dynein HC is bound to the same microtubule by both its N-terminal region and motor domain. We expressed mutant forms of LC1 (designed based on our structural data) in a wildtype background and found that they had dramatic dominant negative effects on cell swimming velocity but yielded only minor alterations in beat frequency. To further assess these observations, we determined the propulsive force generated under varying viscous load. We observed that these strains had a low force output similar to outer arm-less mutants under low viscous load but that this increased towards wildtype levels as load increased (and beat frequency decreased); this response essentially phenocopied the response observed for a mutant strain (oda2-t) lacking the gamma HC motor domain. Furthermore, high speed imaging revealed that the flagella of strains expressing mutant LC1 proteins almost always beat completely out-of-phase leading to a rolling forward motion. Furthermore, the flagella randomly stalled for a few msec at or near the power/recovery stroke transition point. We propose that the gamma HC/LC1/microtubule ternary complex acts as a conformational switch to control outer arm function.

DPY-30, a Versatile Docking Domain, Targets Structural and Signaling Modules for Integrated Control of Flagellar Beating.
R. Gopal, P. Yang; Biological Sciences, Marquette University, Milwaukee, WI

Numerous examples demonstrate that signal transduction pathways are localized to specific micro-compartments to ensure strict spatial or temporal regulation. A cardinal example is the targeting of cAMP-dependent Protein Kinase (PKA) via the RIIa domain in the regulatory subunit RII. Curiously, existing database contains nearly 400 molecules with either RIIa domain or a RIIa-like, DPY-30 domain. The additional sequences in these molecules are often irrelevant to PKA but rather related to nucleotide metabolism or calcium signaling. Particularly, many have short and inconspicuous sequences. Examples include DPY-30, a subunit in various chromosome modification complexes and mammalian homologues of two Chlamydomonas radial spoke proteins, RSP2, that is critical for the assembly of the spokehead module and RSP23, a nucleoside diphosphate kinase. To elucidate the role of DPY-30 domain, we focus on RSP2 and RSP23. Both contain calmodulin-binding domains, yet the putative calcium-sensing elements are absent in their homologues. We found that RSP2 mutants defective in calmodulin-binding are
normal in motility and phototaxis but display light-induced irregular trajectories, revealing a novel pathway that inhibits phototaxis amid conflicting light and barrier. On the other hand, RSP2 mutants lacking DPY-30 domain are paralyzed although all spoke proteins are assembled. Crucially, the polypeptide lacking DPY-30 domain and spokehead proteins dissociate after salt extraction. In contrast, the molecules containing the DPY-30 domain are always stable. These findings strongly suggest that the DPY-30 domain docks structural, enzymatic and calcium-sensing modules to a critical location in the radial spoke to integrate assembly and local nucleotide metabolism with a calcium/calmodulin-dependent signaling pathway special to phototrophic *Chlamydomonas*. This result reveals the extraordinary versatility of RIIa-like domains that localize various critical functional moieties, often in different combinations tailored to the unique needs of individual organisms.

**Outer Arm Dynein Is Required for Gliding Motility in Planaria.**
*P. Rompolas, R. S. Patel-King, S. King; Molecular, Microbial & Structural Biology, University of Connecticut Health Center, Farmington, CT*

Planarians are free living, non-parasitic flatworms and a model system for stem cell biology and regeneration. *Schmidtea mediterranea* is a species of planarian (Class: Tubellaria) with a well-defined monostratified ciliated epithelium. The current notion is that planarians, like other invertebrates (e.g. Mollusks), use their cilia for movement; however, the requirement of ciliary motility for planarian locomotion has not been tested directly. Planarian cilia are ubiquitously distributed on the ventral surface and are motile; beating at ~20 Hz using a highly asymmetric waveform. We studied the role of cilia in planarian physiology using RNAi in order to target conserved genes that are essential for cilia biogenesis (IFT88) as well as outer arm dynein assembly (IC1 and IC2) and regulation (LC1). We found that when the normal function of cilia was disrupted, the flatworms moved significantly more slowly than controls fed with an empty vector. More importantly, in the absence of normal ciliary function, planarians switched their mode of movement from a smooth gliding-type of locomotion to a crawl, which was powered by peristaltic muscle contractions. This behavior was observed regardless of whether the flatworms 1) completely failed to assemble cilia, 2) had normal length cilia lacking outer dynein arms, or 3) were merely missing a key regulatory component of the outer arm dynein complex. Our results suggest that planarian motility consists of two independent components; namely ciliary beating and muscular activity. In planarians normal cilia activity is required for gliding locomotion but not for movement in general. These observations also raise intriguing questions regarding the mechanism by which planarians are able to coordinate ciliary motility and muscular activity in order to control their movement.

**Identification and Characterization of the Major Tubulin Acetyltransferase.**
*N. Shida, M. Nachury; Department of Molecular and Cellular Physiology, Stanford University School of Medicine, Stanford, CA*

Since its discovery more than 25 years ago, the acetylation of alpha tubulin at lysine 40 has remained the marker of choice for stable microtubules in general and cilia and flagella in particular. Yet, the functional consequence of tubulin acetylation has remained a major unknown. While it is generally believed that acetylation is a mere consequence rather than a causative factor of microtubule stabilization, recent evidence have pointed to a role for microtubule acetylation in the regulation of neurogenesis. Still, a major obstacle in our progress towards a functional understanding of tubulin acetylation is that the tubulin acetyltransferase remains unidentified. Recently, we discovered that one of the BBSome subunits is required for tubulin acetylation in cells and we proposed that the BBSome may contact and activate the tubulin acetyltransferase. Here, we find that Arl6<sup>GTP</sup> affinity chromatography of retinal extracts recovers large quantities of the BBSome and trace amounts of an uncharacterized protein that we have named TACT1. Surprisingly, structure-based alignments reveal that TACT1 harbors cryptic homologies to the GNAT clade of acetyltransferases and genome mining shows that TACT1 is
universally conserved among ciliated organisms. Thus, we hypothesized that TACT1 may constitute the long sought tubulin acetyltransferase. Strikingly, bacterially expressed TACT1 efficiently transfers the radioactively labeled acetyl group from acetylCoA onto tubulin. Further analysis of the reaction product demonstrate that Lysine 40 is a major acceptor site for the TACT1 enzyme. Furthermore, TACT1 exhibits remarkable substrate specificity as it is unable to acetylate Histone H3/H4 in vitro. In vivo, overexpressing TACT1 is sufficient to induce massive tubulin acetylation in RPE, IMCD3, Hela and in particular in Ptk2 cells that entirely lack tubulin acetylation. at the same time, overexpression of a catalytically dead mutant of TACT1 does not result in any changes in acetylation levels in cells. Finally, depletion of TACT1 in RPE cells results in a significant decrease in tubulin acetylation. Thus we conclude that TACT1 is the major Tubulin AcetylTransferase in mammalian cells.

The Role of Microtubule Posttranslational Modifications in Cilia Formation and Function.
M. Bosch Grau1, M. Magiera1, A. Seixas1, M. Pequignot2, J. Corsi3, N. Spassky3, C. Janke1;
1Centre de Recherche de Biochimie Macromoléculaire, CNRS, Montpellier, France, 2Institut des Neurosciences de Montpellier, INSERM, Montpellier, France, 3Université Pierre et Marie Curie, Hôpital Pitié-Salpêtrière, INSERM, Paris, France

One of the most striking discoveries in the past decade is that a large number of a priori unrelated human diseases (including certain forms of polycystic disorders, cognitive defects, obesity and retinal degeneration) result from defects in the structure and function of a single cell organelle: the cilium. The cilium is a microtubule (MT)-based organelle that projects from the surface of most eukaryotic cells to perform two major biological roles, sensory transduction and cell motility, which explains why cilia-related disorders can affect diverse organ systems. The proper functioning of a cilium depends on a variety of MT-associated proteins (MAPs) and molecular motors that interact with its MT core structure, the axoneme. The essential question of how the specific interactions between MTs and their interacting proteins remains not completely understood. One common feature of ciliary MTs is that they are strongly modified by a range of posttranslational modifications, including glutamylation and glycylation. Since these modifications have been suggested to regulate the interactions between MTs and MAPs/motors, it is generally considered that they are important regulators of cilia assembly and function. However, the knowledge on the functions of tubulin glutamylation and glycylation is still restricted since the modifying enzymes have only recently been discovered. Both, tubulin glutamylases and glycylases are member of the Tubulin Tyrosine Ligase Like (TTLL) family. Each modifying enzyme has particular specificities, allowing for the generation of complex modification patterns. To address their potential role, we have first characterised the distribution of MT glutamylation and glycylation in axonemes of mouse ependymal cells and photoreceptors, as a model for motile and sensory cilia respectively. Next, to study the impact of MT modifications patterns on ciliary integrity and function, we have established a cell model for culturing ependymal cells. Our first results show that overexpression or suppression of certain MT modifying enzymes results in a reduced number of cilia, which suggests that glutamylation and glycylation may be essential for cilia assembly.

Essential Role of Tubulin Polyglutamylation in Asymmetric Cilia Bending and Beating.
K. Ikegami1, S. Sato2, K. Nakamura2, M. Setou1; 1Hamamatsu University School of Medicine, Hamamatsu, Japan, 2MITILS, Machida, Japan

Mammalian respiratory cilia generate unidirectional flow by beating asymmetrically. What is essential for the asymmetric beating as well as how the asymmetric beating is achieved are central questions in cell biology. Tubulin constructing ciliary or flagellar axoneme undergoes a unique post-translational modification, polyglutamylation. Polyglutamylation occurs on glutamate residues in the carboxy terminal of tubulin. Under the modification, a long peptide chain composed of multiple glutamate residues (>10 glutamates) are attached to gamma-carboxyl group of glutamate residue in the tubulin carboxy terminal. Physiological significance of tubulin
polyglutamylation in ciliary function is also poorly understood. We in this work examine whether tubulin polyglutamylation is required for the asymmetric ciliary beating. We generated a knockout mouse that lacked a polyglutamylation-performing enzyme, TTLL1, and investigated alterations in structure and motility of tracheal cilia of TTLL1-knockout mouse. Axonemes of tracheal cilia of TTLL1-knockout mice grossly lost polyglutamylated tubulins. Surprisingly, axonemes isolated from TTLL1-deficient mice were straighter compared to wild-type axonemes, which were well bent. Similar a result was obtained under the presence of low concentration of ATP, where axonemes became a relaxed state from a rigor state. This indicates that the axoneme bending observed in wild type occurs intrinsically in axoneme and that tubulin polyglutamylation is required for the axoneme-intrinsic bending. In parallel with this, the axoneme isolated from TTLL1-knockout mouse lost beating asymmetry, i.e. it was difficult to distinguish between effective and recovery strokes. The loss of beating asymmetry was also observed in cilia motility of TTLL1-knockout mouse trachea. In agreement with this finding, the mucociliary function is drastically reduced in TTLL1-knockout mice. Finally, TTLL1-knockout mice showed a severe respiratory phenotype; the mice frequently coughed and sneezed. In conclusion, tubulin polyglutamylation is essential for structural and functional asymmetry of respiratory cilia.

Tubulin Polyglutamylation Is Regulated by TTLL-4 Polyglutamylase through Ca²⁺-MAPK Signaling Pathway.
Y. Kimura, M. Setou; Department of Molecular Anatomy, Hamamatsu University School of Medicine, Hamamatsu, Japan

The primary cilium is a microtubule-based organelle that is significant for sensory signal transduction. Sensory channels and receptors are transported and condensed on the sensory cilia through intraflagellar transport (IFT). Polyglutamylation is a post-translational modification that adds multiple glutamates to specific glutamate residue within tubulins and is proposed to be important for several microtubule-related processes. Polyglutamylation is accomplished by TTLL family protein polyglutamylases, but their functions In Vivo and the regulatory mechanisms are not well characterized. In this study, we have tried genetical approach to elucidate these questions using C.elegans. Immunohistochemistry with the polyglutalylated tubulin-specific antibody revealed that the signals are only detected in the cilia of sensory neurons. C.elegans has six ttll genes—ttll-4, -5, -9, -11, -12 and -15. In the sensory neurons, TTLL-9 is distributed in a whole sensory neuron. On the other hand, TTLL-4 and TTLL-11 are complementarily localized in cilia and axons, respectively. Analyses for mutant strains for each gene have revealed that ttll-4 is the only gene that regulated polyglutamylation levels in sensory cilia. The ttll-4 mutant worms completely lost the polyglutamylation signals, whose sensory neurons show abnormal ciliary structure and also IFT defects. The ttll-4 mutants move normally but they show some sensory defects, such as chemotaxis for NaCl and nose-touch response, which is sensed by amphid sensory neurons. Finally, we analyzed the regulatory mechanism of ttll-4. Several mutant strains of Ca²⁺-MAPK pathway, most of which have chemosensory defects, show the reduction of polyglutamylation, suggesting that ttll-4 is regulated by conventional environmental signals. Notably, excess artificial signals such as vibration and heat-stress also affect the level of polyglutamylation. According to the experimental results above, we can conclude that TTLL-4 is a key polyglutamylase that controls IFT for the appropriate sensory transduction and is regulated by environmental signals through Ca²⁺-MAPK signaling pathway.

Engineered Allosteric Regulation of Kinases in Living Cells.
A. Karginov1, F. Ding2, N. V. Dokholyan2, K. Hahn1; 1Pharmacology, University of North Carolina, Chapel Hill, NC, 2Biochemistry and Biophysics, University of North Carolina at Chapel Hill, Chapel Hill, NC
Manipulation of protein activity in living cells is an extremely valuable tool, but for many specific proteins is not available or suffers from serious limitations. We describe here a new approach for selective allosteric regulation of a single domain within a multidomain protein, and demonstrate a broadly applicable method to activate kinases in living cells with high specificity and within minutes. A new small domain, named iFKBP, was developed for insertion in the middle of protein structures, where it acts as an allosteric switch responding to the small membrane-permeable molecule rapamycin. Introduction of iFKBP into a catalytic domain of focal adhesion kinase (FAK) enabled specific regulation of its kinase activity without affecting other properties of FAK. Using this new tool, we provide the first direct demonstration of FAK-mediated activation of Src in live cells. Furthermore, we show that that FAK stimulates formation of large dorsal protrusions via activation of Src, a new property for FAK, implying a mechanism for its involvement in tumorigenesis. Computational studies reveal a potential mechanism for iFKBP-mediated regulation and, together with generation of rapamycin-regulated Src, demonstrate general applicability of the method.

Genetically-Encoded, Reversible Photoactivation of Rac and Cdc42 in Living Cells Illuminating the Coordination of Rho GTPases in Cell Motility.
Y. Wu1,3, O. Lungu2,3, B. Kuhlman2,3, K. Hahn1,3; 1Department of Pharmacology, University of North Carolina, Chapel Hill, NC, 2Department of Biochemistry and Biophysics, University of North Carolina, Chapel Hill, NC, 3Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC

For many highly dynamic cell behaviors such as cell migration, signaling events occur transiently at specific locations, with subsecond and submicron precision. Study of such rapid dynamics has been hindered by our inability to manipulate protein activities with precise spatio-temporal control in living cells. Recently we engineered a genetically-encoded photoactivatable Rac1 (PA-Rac1) using a light-responsive LOV (light, oxygen or voltage) domain from an oat phototropin protein. A LOV domain fused to constitutively active Rac1 sterically blocked the active site of Rac1 until illumination at specific wavelengths induced a LOV conformational change, releasing inhibition. In living cells, PA-Rac1 enabled reversible and repeatable control of Rac1 activation at precise times and subcellular locations. This was used to specify the direction and extent of cell locomotion. Combining PA-Rac1 with a biosensor of RhoA activation demonstrated localized control of Rac-Rho inhibition. We have also extended the photoactivation technology to dominant negative Rac1, via a related design, to the structurally similar small GTPase Cdc42. These technical developments pave the way to study the coordination between different GTPases during cell migration.

Opposing Pathways Regulated by Rac1 and RhoC at the Leading Edge of MTLn3 Carcinoma Cells.
Y. Moshfegh1,2, J. Bravo-Cordero1,2, L. Hodgson1,2; 1Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, 2Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY

p21 Rho family of small GTPases are involved in cell motility and migration. Preliminary results have provided evidence that overexpression of RhoC in the MTLn3 breast carcinoma cell line downregulates Rac1, but not Cdc42. While similar antagonism has been reported between RhoA and Rac1, such a mechanism between RhoC and Rac1 has not been directly observed. To study the relationship between RhoC and Rac1 during cell protrusion, we developed a novel, genetically-encoded fluorescent Rac1 biosensor, based on a single-chain design. Our design maintains the correct C-terminal lipid modification of full-length Rac1, enabling proper interaction with upstream regulators, including GEFs, GAPs, and GDIs. Because of the parallel amino to carboxy terminal directionality of both the binding domain and the Rac1 molecule, we could not simply exchange the GTPase and binding domain from the previous-generation RhoA single-chain biosensor (Pertz, et. al. 2006 Nature). We constructed this new single-chain biosensor by
modifying the placement of the binding domain in relation to the first fluorescent protein, to achieve the proper orientation for optimal interaction between the GTPase and its binding domain. By using this design, we were able to maintain a 1:1 donor to acceptor FRET ratio, which is an improvement over the previously designed Rac1 biosensor based on a bi-molecular design. This design should be generalizable to most GTPase Binding-domain pair with a similar parallel orientation. We used this novel single-chain biosensor, together with a previously-developed single-chain RhoC biosensor to investigate further the balance between these two molecules in the control of cancer cell motility. These biosensors allow visualization of the spatial and temporal activation patterns of Rac1 and RhoC simultaneously in real time in breast carcinoma cells. This work shows the interactions and spatiotemporal dynamics of the Rho family GTPase proteins.

Screening of Compounds Modulating ARP2/3 Activity for Keratocyte Motility Effects Using a Cell Sheet Assay.
I. Cheng, K. Cooper, E. E. Hull; Biomedical Science Program, Midwestern University, Glendale, AZ

Fish keratocytes used in cell motility studies are typically cultured in explant cultures for 24 - 48 hours to form cell sheets which are then replated before use in cell motility assays. In order to form the initial cell sheet, the cells associated with the scale must initially adhere to the culture surface and then the keratocytes migrate from the scale to form a cell sheet. We have used keratocyte cell sheet assay to rapidly screen for motility effects of compounds affecting the activity of the ARP2/3 complex. The percentage of scales with cell sheets is used as a measure of cell adhesion. The area of the cell sheet can be used to assess cell migration and spreading. Preliminary data indicates that wiskostatin, a cell permeable inhibitor of WASP, significantly inhibits cell sheet growth at 1 uM concentration. Although more data needs to be gathered, there is an apparent increase in the percentage of scales with cell sheets and a possible dose-response when wiskostatin dose is increased. These data suggest that measurements on keratocyte cell sheets in explant cultures may provide a rapid screen to identify compounds that effect cell motility.

The Use of Laser Tweezers and the Mitochondrial Membrane Proton-Detecting Dye, DiOC(3), to Measure Sperm Motility.
T. J. Chen1, L. Z. Shi1, Q. Zhu1, C. Chandsawangbhuwana1, M. W. Berns1,2; 1Bioengineering, University of California, San Diego, La Jolla, CA, 2Beckman Laser Institute, University of California, Irvine, Irvine, CA

PURPOSE: The purpose of this study is to investigate how the mitochondrial membrane potential affects sperm motility using laser tweezers and the fluorescent probe, DiOC6(3) [Invitrogen dye D-273]. METHODS: A 1064 nm Nd:YVO4 continuous wave laser was used to trap motile sperm at a power of about 450 mW into a focused trap spot. Using customized tracking software, the curvilinear velocity (VCL) and the escape force (Pesc) from the laser tweezers were measured. Human sperm were labeled with the fluorescent dye DiOC6(3) as way to measure membrane potential in the sperm midpiece. The VCL was measured prior to, and after, sperm trapping. The fluorescence was measured before and during trapping. Fluorescence intensity of the DiOC6(3)-treated sperm were compared to untreated sperm. Controls were also performed to verify that the DiOC6(3), itself, does not affect sperm motility. Carbonyl cyanide m-chlorophenylhydrazone (CCCP) was used to inhibit mitochondrial respiraion as measured by a loss of DiOC6(3) fluorescence. RESULTS: The results demonstrate that DiOC6(3) has no effect on the VCL and Pesc of the sperm even though there was a marked reduction in dye fluorescence when the CCCP was applied. Non DiOC6(3)-treated sperm had a VCL of 79.3µm/sec (n = 72), while DiOC6(3)-treated sperm had an average of 84.5 µm/sec (n = 232). The statistical difference between the two groups was p = .294 using the Wilcoxon rank-sum test. CCCP + DiOC6(3) labeled sperm had a VCL of 83.3 µm/sec, which was not statistically different from either of the
previous two groups of sperm. DiOC6(3)-labeled sperm exhibited a fluorescence (pixel intensity) of 96.3, unlabeled sperm 80.0, and CCCP-DiOC6(3) treated sperm 79.85. The unlabeled and CCCP-DiOC6(3) sperm appear similar to the background intensity. Despite the statistically significant difference between the DiOC6(3) fluorescent sperm, CCCP-DiOC6(3) sperm, and non-DiOC6(3)-treated sperm, the motility parameters are statistically equal for all groups. These results suggest that the primary driving energy source for motility in human sperm is not from aerobic mitochondrial respiration. The results for dog and mice sperm will be compared to human sperm.

In Silico Reconstitution of Actin-Based Motility.

M. J. Dayel1, O. Akin2, M. Landeryou2, V. I. Risca4, A. Mogilner5, D. Mullins2; 1Miller Institute/MCB, UC Berkeley, Berkeley, CA, 2CMP, UCSF, San Francisco, CA, 3Mechanical Engineering, University College London, London, United Kingdom, 4Biophysics Graduate Group, UC Berkeley, Berkeley, CA, 5Departments of NPB and Mathematics, UC Davis, Davis, CA

Eukaryotic cells assemble viscoelastic networks of crosslinked actin filaments to control their shape, mechanical properties, and motility. One important class of actin network is nucleated by the Arp2/3 complex and drives both membrane protrusion at the leading edge of motile cells and intracellular motility of pathogens such as Listeria monocytogenes. These networks can be reconstituted in vitro from purified components to drive the motility of spherical micron-sized beads. An Elastic Gel Model has been successful in explaining how these networks break symmetry, but how they produce directed motile force has been less clear. We have combined numerical simulations with in vitro experiments to reconstitute the behavior of these motile actin networks in silico using an Accumulative Particle-Spring (APS) model that builds on the Elastic Gel Model, and demonstrates simple intuitive mechanisms for both symmetry breaking and sustained motility. The APS model explains observed transitions between smooth and pulsatile motion as well as subtle variations in network architecture caused by differences in geometry and conditions. Our findings also explain sideways symmetry breaking and motility of elongated beads and show that elastic recoil, though important for symmetry breaking and pulsatile motion, is not necessary for smooth directional motility. The APS model demonstrates how a small number of viscoelastic network parameters and construction rules suffice to recapture the complex behavior of motile actin networks. The fact that the model not only mirrors our in vitro observations, but also makes novel predictions that we confirm by experiment, suggests that the model captures much of the essence of actin-based motility in this system.

296/B243

Force Transmission from Actin Network to the Substrate in Migrating Cells.

M. F. Fournier1, R. Sauser1, D. Ambrosi2, J. Meister1, A. B. Verkhovsky1; 1Lab. of Cell Biophysics, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland, 2Dipartimento di Matematica, Politecnico di Milano, Milano, Italy

During cell migration, forces generated by actin cytoskeleton are transmitted through adhesion complexes to the substrate. To investigate the mechanism of force generation and transmission, we analyzed the relationship between the velocity of actin network and traction stress applied to the substrate using a simple model of persistently migrating fish epidermal keratocytes. Local forward stress at the back of the cell was largely proportional to the local actin velocity. Similar relationship between actin velocity and stress was observed at the sides of the cell, but the stress/velocity curve was steeper than at the back. In contrast, backward propulsive stress at the cell front exhibited significant velocity-independent component. These results suggested that the mechanisms of conversion of actin dynamics into the traction stress were different in different cell regions: back and sides of the cell were characterized by frictional slippage, while at the front actin network gripped to the substrate. Analysis of substrate stress and cell motion in the presence of inhibitors of actin/myosin system cytochalasin D and blebbistatin indicated that cell translocation could be driven by two different processes: actomyosin contraction, and actin assembly, the former associated with significantly larger traction stress than the latter.

**Turnover Dynamics of Diffuse Actin and Regulators at the Leading Edge.**  
M. B. Smith¹, N. Watanabe², D. Vavylonis¹; ¹Physics, Lehigh University, Bethlehem, PA, ²Pharmacology, Kyoto University Faculty of Medicine, Kyoto, Japan

The lamellipodium at the leading edge of motile cells is a dynamic structure consisting of a dense network of branched actin filaments. These actin filaments polymerize in a region close to the leading edge and undergo retrograde flow towards the main body of the cell. A large number of experimental techniques have been used to monitor the structural aspects of actin networks at the leading edge. However, the role of concentration gradients and local heterogeneity of soluble actin, actin oligomers, and actin regulators in the crowded filament network is little explored. We combined single molecule fluorescence microscopy with image analysis and modeling to quantify the role of diffuse actin species and their gradients in actin reorganization at the leading edge of motile cells. Actin, capping protein, and Arp 2/3 complex, were marked with fluorescent probes at low concentrations and imaged at high spatiotemporal resolution in XTC fibroblasts. Particle tracking was used to mark the appearance and disappearance of bright spots that correspond to proteins becoming associated to, or dissociated from, the actin network. Image correlation analysis was used to quantify the motion of proteins in the cytoplasm. We developed conditional image correlation methods to study local dynamics prior to assembly and immediately following disassembly. From these data we create a map of the lamellipodium showing the dynamics of lamellipodium proteins and their turnover. Bounds on the fraction of actin that leaves the filament network as oligomers was determined by measuring the distribution of diffusion coefficients which correspond to different oligomer lengths. We used numerical simulations to model these turnover dynamics and to simulate FRAP experiments. These results help resolve apparently disparities in measurements found through FRAP and single molecule speckle microscopy.

**Automated Detection and Characterization of Pseudopodial Behavior during Amoeboid Motility.**  
Y. Xiong¹, C. Kabacoff², P. N. Devreotes², D. Robinson², P. Iglesias¹; ¹Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD, ²Cell Biology, Johns Hopkins School of Medicine, Baltimore, MD

When distinguishing among strains of chemotaxing cells, it is common to compare aspects such as speed, chemotaxis index and persistence. However, amoeboid motion is a complex cellular process driven by highly-organized cytoskeletal dynamics involving alternating cycles of pseudopodial protrusions and retractions. A comparison of the pseudopodial dynamics may reveal subtle differences between some strains. Because of the highly variable stochastic fluctuations in the behavior of pseudopods, large data sets may be necessary, making manual detection, identification and quantification impractical. Here we present an automated method that automatically detects and characterizes pseudopodial behavior of cells. We illustrate the algorithm on movies of chemotactic *Dictyostelium* cells. The method uses skeletonization, a technique from morphological image processing to reduce a shape into a series of connected lines - the skeleton - which maintains prominent shape patterns similar to those perceived by human eyes. It involves a series of automatic algorithms including image segmentation, boundary smoothing, skeletonization and branch pruning, and takes into account the cell shape changes between successive frames to detect protrusion and retraction activities. In addition, the activities are clustered into different groups, each representing the protruding and retracting history of individual pseudopods. The algorithm tracks the state and angle dynamics for each pseudopod, and provides a number of characterizing quantities, such as the lifetime, splitting rate, state persistence, protrusion and retraction speeds, and angle changes. Additionally, more quantitative measurements can be acquired and analyzed according to the specific goals of study. No chemical markers are required for our method; however, the results can be correlated with other signals from the cell, such as fluorescent intensities, to facilitate the understanding of the relationships between motility and other cellular processes. In conclusion, the method provides a
powerful tool to investigate amoeboid motility by making it possible to capture the spatial and temporal dynamics as well as the stochastic features of the pseudopodial behavior.

**Actin Tyr-53 Mutants Inhibit Chemotactic Signaling in Dictyostelium.**
S. Shu, X. Liu, P. Kriebel, C. Parent, E. D. Korn; 1Laboratory of Cell Biology, NHLBI, NIH, Bethesda, MD, 2Laboratory of Cellular and Molecular Biology, NCI, NIH, Bethesda, MD

We recently published that phosphorylation of Tyr-53 of *Dictyostelium* actin, which occurs during development and when amoebae are subjected to stress, inhibits filament nucleation and elongation in vitro, and destabilizes filaments (PNAS 103:13694, 2006; PNAS 105:11748, 2008). To further study the function of Tyr-53 In Vivo and in vitro, we substituted Tyr-53 with Phe (Y/F), Ala (Y/A) or Glu (Y/E), fused a FLAG-tag at the N-terminus to facilitate purification, and expressed the mutant actins and FLAG-WT (Y/Y), as a control, in *Dictyostelium AX3* cells. The expressed actins accounted for about 25% of the total actin in cells. We found purified Y/Y and Y/F are very similar to WT actin but purified Y/A and Y/E polymerize more slowly, have a higher critical concentration, form abnormal, broken filaments, and have a higher Km for activation of myosin ATPase. In addition, co-polymers of 25% Y/A or Y/E and endogenous WT actin form shorter filaments than WT actin with a higher Km for activation of myosin. In Vivo studies showed that all expressed FLAG-actins co-localize with endogenous actin and that the mutant actins have no effect on growth in suspension, pinocytosis or phagocytosis. However, cells expressing Y/A or Y/E exhibit serious defects in chemotaxis, streaming and development. Cells expressing Y/A and Y/E have a 50% reduction in cAMP receptor number in both vegetative and developed cells, a 50% reduction in cAMP-induced ERK2 phosphorylation, a 75% reduction in cAMP-induced adenyl cyclase activation, and a 30-40% reduction in instant actin polymerization in response to cAMP. Our results suggest that the expression of Y53A and Y53E actin mutants affects actin structure and function In Vivo resulting in a global inhibition of cAMP-mediated signaling during *Dictyostelium* development.

**Elucidation of Signaling Mechanism during Folic Acid Mediated Chemotaxis.**
K. Srinivasan, A. Roberts, C. Elzie, L. Jiang, C. Janetopoulos; Biological Sciences, Vanderbilt University, Nashville, TN

*Dictyostelium discoideum* chemotax towards folic acid during vegetative growth and to cAMP during aggregation and development. A number of signaling molecules are activated downstream of the heterotrimeric G proteins during cAMP-mediated chemotaxis including the Ras small G proteins, the TORC2 complex, PKBs, and the enzymes PI3K and PTEN which regulate the phosphoinositides. Similar activation of Heterotrimeric G protein during folic acid chemotaxis has been reported, however, downstream signaling events have not been investigated and are not well understood. We have developed a robust chemotaxis protocol which allows us to use folic acid as a chemoattractant to investigate cellular responses. Even though Ras is implicated in cAMP chemotaxis, Ras C, Ras G and Ras CG null cells were found to be capable of chemotaxing towards folic acid. We are now investigating the activation of Ras, the localization of PI3K-GFP and the synthesis of PIP3 in wild-type and mutant cell lines upon uniform folic acid stimulation and during folic acid chemotaxis. These data suggest that similar downstream signaling and cytoskeletal proteins are activated in cAMP and folic acid-mediated chemotaxis.

**Hax1 Regulation of Neutrophil Chemotaxis.**
P. Cavnar, E. Bertheir, A. Huttenlocher; Medical Microbiology and Immunology, University of Wisconsin-Madison, Madison, WI

Severe congenital neutropenia (SCN) is a heterogeneous group of primary immunodeficiency disorders characterized by neutropenia and life threatening bacterial infections. SCN include inherited disorders caused by homozygous mutations in HS1 associated protein X-1 (HAX1).
Hax1 is an adapter protein that interacts with the Arp2/3 binding protein and hematopoietic cortactin homologue HS1. We have generated Hax1-deficient PLB-985 neutrophil-like cells using lentiviral shRNA. Here we show that Hax1-deficient PLB-985 neutrophil-like cells have impaired directed cell migration and demonstrate an elongated morphology consistent with a retraction defect. Using microfluidic chemotaxis chambers, we show that Hax1-deficient cells show reduced migration speeds in gradients of chemoattractants. Endogenous Hax1 showed localization to the uropod during random motility and targeted to the leading edge during directed migration. Preliminary data suggest that Hax1 depletion may affect the activity of Rho GTPases. These findings suggest that Hax1 mutations may contribute to congenital neutropenia by affecting neutrophil motility and trafficking.

**Gβγ Signaling Regulates Primordial Germ Cell Migration in Zebrafish.**
H. Xu1, S. Chen2, E. Raz3, F. Lin1; 1Anatomy & Cell Biology, The University of Iowa, Iowa City, IA, 2Department of Pharmacology, The University of Iowa, Iowa City, IA, 3Institute of Cell Biology, ZMBE, University of Münster, Münster, Germany

Primordial germ cell (PGC) migration in zebrafish serves as an excellent model for the study of long-distance cell migration within a complex and developing intact organism. It has been established that the chemokine SDF1a and its cognate G protein-coupled receptors, Cxcr4b and Cxcr7, constitute a signaling axis that is essential for proper PGC migration. However, how G proteins and their downstream effectors contribute to this process remains poorly understood. Here we show that signaling mediated by the G protein βγ subunits is required for the directionality of PGC migration in zebrafish. Embryos with PGC-specific overexpression of a Gβγ scavenger, Gαt or a dominant-negative form of Gγ2 that disrupts Gβγ function, exhibited ectopic PGC localization. Analysis of cell migration behaviors revealed that PGCs in embryos with compromised Gβγ function were unable to migrate directionally toward a chemoattractant, and that they migrated at reduced speed. Furthermore, confocal time-lapse imaging showed that compared to WT PGCs, which are polarized in the direction of migration and migrate actively to a source of chemoattractant, PGCs with disrupted Gβγ signaling failed to become polarized and extended “bleb”-like protrusions in multiple directions, which caused them to migrate in random directions. Finally, in the chemo-attractant experiment PGCs with disrupted Gβγ function failed to respond to the exogenous chemoattractant Sdf1. Collectively, our findings support a crucial role for Gβγ signaling in Sdf1a/Cxcr4b-regulated PGC migration. We are currently investigating the molecular mechanisms by which Gβγ signaling regulates PGC migration. Given that the signaling pathways involved in cell migration are highly conserved during embryogenesis, the immune response and cancer-cell metastasis, our studies in an animal model with a vertebrate body plan are likely to provide new insights into the regulation of cell movement in humans, both during normal development and in the context of disease.

**Cryo-Electron Microscopy and Single-Particle Analysis of MSP Filaments Derived from the Amoeboid Sperm of Ascaris suum.**
A. Malowney1, M. Stewart2, T. M. Roberts1; 1Biological Science, Florida State University, Tallahassee, FL, 2MRC Laboratory of Molecular Biology, Cambridge, United Kingdom

Locomotion of nematode sperm is remarkably similar to that of most other crawling cells but is powered by a system of filaments composed of major sperm protein (MSP) instead of the actin-myosin machinery typically associated with amoeboid motility. The MSP motility apparatus has been reconstituted in vitro, and individual MSP filaments can be generated by either of two methods: the addition of ethanol or other water-miscible alcohols to purified MSP (King et al. 1992. JCS 101:847) or by the addition of ATP to detergent-treated Ascaris sperm cytosol. Filaments obtained by both methods have been successfully vitrified and examined by cryo-electron microscopy, thereby enabling detailed structural comparison of filaments formed from purified protein to those assembled in the presence of the other components of the motility apparatus. Both preparation techniques utilize steps that remove unwanted components, namely
excess ethanol or other cytosolic proteins, which hinder vitrification and obscure filament structure. We sampled individual filaments along their lengths and generated three-dimensional reconstructions by single-particle analysis using the Spider software suite. Comparing the cryo-EM models, as well as comparisons with MSP filament models derived from helical diffraction of negative-stained filaments formed in ethanol or by x-ray crystallography (Bullock et al. 1998. NSB 5:184) suggest important differences between filaments formed under physiological and nonphysiological conditions. There are currently six *Ascaris* sperm proteins known to modulate MSP filament dynamics in sperm; these same proteins are absent from filaments prepared using purified MSP. Comparing MSP filament models with and without these accessory proteins allows us to map the binding sites of these accessory proteins and provides a greater understanding of how they effect MSP filament dynamics and influence motility. Supported by NIH Grant R37 GM29994 and by the American Heart Assoc.

**The Effect of Monothioglycerol in the Freezing Extender for Boar Sperm Cryopreservation.**

Cryopreservation and In Vitro fertilization (IVF) protocols are important in genetic studies and applications to transgenic animals. Various studies about boar sperm cryopreservation have been studied for a long time. Those were about the use of extenders, the choice of sugars, the cooling and warming rates. Furthermore our study focused on the integrity of genetic materials. The factors that influence the boar sperm are the dramatic changes in temperatures, osmotic and toxic stresses, and reactive oxygen species (ROS) generation. Among these factors, ROS generation is the main damage to DNA which is a principal genetic material and the most important for the practical applications. So we wondered whether ROS generation could be reduced. In previous study, monothioglycerol (MTG) was essential for the culture of embryo stem cells. Therefore we added MTG in the freezing extender based on lactose-egg yolk (LEY) with trehalose. For the assessment of the frozen-thawed sperm, we focused on DNA damage. First, we used a computer-aided sperm analysis system for overall conditions of sperm such as motility and viability. Then we performed the sperm chromatin structure assay for DNA integrity. And our result showed the existence of MTG in the freezing extender caused less damage to DNA in frozen-thawed boar sperm. We concluded that this reagent is due to the oxidation of lipids and proteins that participate in the fusion and subsequent penetration of the oocyte by sperm and the characteristic of MTG which is reactive with oxidizing agents would be helpful because ROS could reduce ROS generation which causes less damage to DNA in sperm.

**Evaluation of Antifreeze Protein (AFP) on Boar Sperm during Cryopreservation.**

D. Kwak, H. Choi, Y. Jeung, Y. Choi, S. Hong, S. Kim, B. Kim, J. Yang, D. Kim, Y. Hwang; Gachon University. Medicine & Science, Incheon, Korea, South

Research for optimal cryoprotectant of cryopreservation is very important and has been studied in the field of storing sperm in freezing at low-temperature. In these days, glycerol has been used for many studies. But, glycerol has cytotoxicity that induces changes in the lipid packing structure of the cell membrane. Otherwise, antifreeze proteins (AFPs) had been reported to protect cells in low temperature from cold shock damage. So, we applied AFPs to boar sperm cryopreservation and estimated AFPs as the optimal cryoprotectant to boar sperm in cryopreservation. The boar semen were centrifuged for 3 minutes at 2,400 g, 15 degree of Celsius and then separated to sperm from the semen by Hulsen solution. The sperms were diluted with the BF5 solution. BF5 diluent, an extender, mixed with glycerol and AFPs. Control group was the AFPs-free extender. Sperm was freezed by programmable freezer and stored in liquid N2. We measured sperm viability and intact acrosome status as parameters to evaluate the condition of boar sperm added AFP. To determine the status of the viable population of cells, a double staining technique (SYTO16 and PI) was used in fluorescence activated cell sorting (FACS). Also, intact acrosome
status was tested by using fluorescein isothiocyanate-conjugated peanut agglutinin (FITC-PNA). We observed sperm, stained FITC-PNA, using fluorescence microscopy. In these experiments, Sperm quality was enhanced by extender with glycerol containing AFPs, in comparison with that with glycerol only. It suggests that AFP have effect of increasing efficiency for sperm cryopreservation. This research fund was performed KOPRIS PE09070.

**Light Effects on Cell Adhesion and Motility in Diatoms.**  
S. A. Cohn, A. B. Nootens; Biological Sciences, DePaul University, Chicago, IL

Diatoms are single celled algae that move via musculagel-mediated contact and translocation with solid underling substrates. As such, diatom adhesion is directly associated with motile activity. Abiotic conditions that influence diatom adhesion and motility thereby have dramatic consequences for cells in environments such as streams where cell colonization requires proper attachment and movement onto available surface areas in the presence of local water flow. In order to test the effects of light on diatom adhesion in natural water flow settings, our lab has tested the ability of diatoms to remain adhered to solid glass or tumbled marble substrates in an artificial flume in which both light and water flow could be controlled. Using a water speed of about 10 cm/sec, cells were placed onto substrates and allowed to adhere in the presence of either dim (ca. 50 umol/m2/s) or bright (ca. 250 umol/m2/s) light, then measured for percentage of cell retention over 3 minutes. Ability of cells to be retained showed a strong relationship to both light exposure and type of substrate. on the marble substrate, *Pinnularia* cells exposed to bright light lost much of their ability to stay adhered (7.4 ± 0.9% remaining adhered compared to 37.6 ± 7.6% remaining adhered under dim light; P =.02), but showed no light-dependent loss of adhesion when incubated on the glass surface. In contrast, *Stauroneis* cells showed a weakly significant (P=.05) greater adhesion to glass (7.8 ± 1.3% remaining adhered on glass compared to 4.5 ± 0.7% on marble) that did not show significant light dependence, although the adhesion in the presence of blue light generally did result in more cells adhering than in either bright red light or dim natural light. By comparing the flume results with those from tests on cell motility responsiveness (which show *Pinnularia* more sensitive in the blue wavelengths and *Stauroneis* more sensitive in the blue and red) we can better determine the environemental conditions under which different diatoms can move and colonize onto surfaces most effectively. This work was supported by DePaul University Research Council, the DePaul College of Liberal Arts & Sciences, and equipment purchased through NSF Grant IBN-9982897.

**Zyxin Regulates Delamination of Migratory Cells during Embryonic Chick Tri-Geminal Placode Morphogenesis.**  
R. Sperry, R. Vellinga, R. Lassiter, M. Stark, M. D. Hansen; Physiology and Dev. Biology, Brigham Young University, Provo, UT

Self assembly of tissues and organs during embryogenesis is dependent on dynamic regulation of cell shape and cell-cell adhesion. Epithelial cells adhere through cadherin-based junctions, which are coupled to the actin cytoskeleton by actin regulatory and binding proteins. Epithelial cells retain the ability to revert to a non-adherent state, dismantling adherens junctions and becoming migratory, in the process of epithelial-mesenchymal transition (EMT). Live cell imaging of cultured MDCK cells expressing zyxin mutants, induced to undergo EMT by HGF treatment, demonstrate that the actin regulatory protein, zyxin, regulates EMT response by mediating linkage between dynamic contractile actin networks and the cell-cell junctional membrane. Constitutively active zyxin mutant expression results in a scattering phenotype in which cells become migratory but fail to fully disrupt cell-cell adhesions, resulting in a partial EMT response in which cells migrate while remaining cell-cell adherent. These effects suggest that zyxin may regulate the ability of migratory epithelial cells to detach during morphogenegetic rearrangements of embryonic development. To verify this idea, we characterize effects of mutant zyxin expression on trigeminal placode development in an embryonic chick model. During trigeminal placode development individual and small groups of cells delamate from the ectoderm, invade the
mesenchyme and coalesce to form the placode. Zyxin mutants were introduced into trigeminal placode precursor cells by electroporation and placode cells’ position during subsequent development monitored. Supporting our hypothesis that zyxin regulates coordination of migratory behavior between cells in cell-cell contact, we observe that electroporation with constitutively active zyxin results in trigeminal placode precursor cells remaining in the ectoderm, rather than invading into the mesoderm as observed in non-electroporated controls. A putative dominant negative zyxin mutant has no effect on placode cells’ delamination and invasion. Zyxin effects on placode morphogenesis recapitulate observed effects in cell culture, confirming zyxin’s role in the coordination of morphogenetic cell movements during embryogenesis.

**GRASP and IPCEF Promote ARF to Rac Signaling and Cell Migration by Coordinating the Association of ARNO/Cytohesin 2 with Dock180.**

D. T. White, K. M. McShea, M. A. Attar, L. C. Santy; Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA

ARFs are small GTPases that regulate vesicular trafficking, cell shape and movement. ARFs are subject to extensive regulation by a large number of accessory proteins. The many different accessory proteins are likely specialized to regulate ARF signaling during particular processes. ARNO/cytohesin 2 is an ARF-activating protein that promotes cell migration and cell shape changes. We report here that protein-protein interactions mediated by the coiled-coil domain of ARNO are required for ARNO induced motility. ARNO lacking the coiled-coil domain does not promote migration and does not induce ARF-dependent Rac activation. We find that the coiled-coil domain promotes the assembly of a multiprotein complex containing both ARNO and the Rac-activating protein Dock180. Knockdown of either GRASP/Tamalin or IPCEF, two proteins known to bind to the coiled-coil of ARNO, prevents the association of ARNO and Dock180 and prevents ARNO-induced Rac activation. These data suggest that scaffold proteins can regulate ARF dependent processes by biasing ARF signaling toward particular outputs.

**Atypical PKC Zeta Regulates Recruitment, Release and Activation of MMP-9 at Podosomes.**

H. Xiao1,2, X. Bai2, A. Kapus3, A. S. Mak4, M. Liu1,2; 1Department of Physiology, Faculty of Medicine, University of Toronto, Toronto, ON, Canada, 2Division of Cell and Molecular Biology, University Health Network Toronto General Research Institute, Toronto, ON, Canada, 3Keenan Research Centre, Li Ka Shing Knowledge Institute, St. Michael’s Hospital, Toronto, ON, Canada, 4Department of Biochemistry and Protein Function Discovery Program, Queen’s University, Kingston, ON, Canada

Podosomes are transient cell surface structures essential for degradation of extracellular matrix during cell migration and invasion. Protein kinase C (PKC) is involved in the regulation of podosome formation; however the roles of PKC isoforms in podosome formation and proteolytic function are largely unknown. Recently, we reported that phorbol-12, 13-dibutyrate (PDBu), a PKC activator, induced the formation of podosome-like structures in primary normal (non-cancerous) human bronchial epithelial cells. Here, we demonstrate that PDBu-induced podosome formation is mainly mediated through translocation of conventional PKCs, especially PKCα, from the cytosol to the podosomal plasma membranes. Interestingly, although blocking atypical PKCs did not affect podosome formation, it significantly reduced matrix degradation. Inhibition of atypical PKCζ reduced PDBu-induced matrix degradation at podosomes through less recruitment of MMP-9 to podosomes, and decreased local MMP-9 release and activation. Down-regulation of MMP-9 by siRNA and neutralization antibody also significantly reduced matrix degradation. PDBu-induced recruitment of PKCζ and MMP-9 to podosomes was blocked by novel PKCs inhibitor Rottlerin and PKCδ siRNA. In summary, our data suggest that although the redistribution of classical PKCα controls podosome formation and dynamics, it is the atypical PKCζ (which is recruited by novel PKCδ to podosomes) that locally control the proteolytic activity of podosomes.

Cdk5 Limits Src Activity by Targeting C-Src for Ubiquitin-Dependent Degradation.
F. Qiao, Q. Pan, C. Y. Gao, P. Zelenka; National Eye Institute, NIH, Rockville, MD

Purpose: Activity of the non-receptor tyrosine kinase, cSrc, is stringently controlled by inhibitory phosphorylation of a C-terminal tyrosine and by Cullin5-dependent ubiquitylation and degradation of the active form, Src(pY419). Recent studies from this laboratory have shown that inhibition of Cdk5 in spreading cells increases cSrc activity and prevents stress fiber contraction in a Src-dependent manner, demonstrating that Cdk5-dependent regulation of Src activity is physiologically relevant. The present study was undertaken to explore the mechanism underlying regulation of Src activity by Cdk5. Methods: Human lens epithelial cells (FHL124) were transfected with cDNA for the indicated fusion proteins. V5-tagged proteins were isolated by immunoprecipitation and immunoblotted for Src(pY419), V5, and ubiquitin. Src activity was measured as the ratio of Src(pY419)/total Src. Cdk5 activity was blocked by 15 microM olomoucine, Cdk5(D144N) (dominant negative), or siRNA oligonucleotides. Proteosomal degradation was inhibited with 50 microM Z-L3VS. Results: Inhibiting Cdk5 activity by three independent methods increased Src activity 50-70%. Suppressing Cullin5 expression increased Src activity 2 +/- 0.2 fold, and abolished the effect of Cdk5 inhibition. V5-tagged cSrc(S75A), which lacks a potential Cdk5 phosphorylation site, was 2-2.5 fold more active than the wild type protein when expressed in cells. Following inhibition of proteosomal degradation, incorporation of ubiquitin into Src(S75A) was approximately 77% of wild type Src. Since ubiquitylation rate is proportional to the concentration of active Src(pY419), the calculated rate of Src(S75A) ubiquitylation is approximately 40% that of wild type Src. Conclusions: Cdk5 limits Src activity by increasing the rate of ubiquitylation by Cullin5. This effect requires an intact phosphorylation site at Src(S75), a site known to be phosphorylated by Cdk5 in vitro.

Dynein (311 - 333)

311/B258
Morphogenesis of the Endoplasmic Reticulum (ER) and the ER-Golgi Intermediate Compartment (ERGIC): Requirement for Dynein-Dynactin, Lis1, and Spectrin, but Not for Membrane Proteins.
V. Muresan, Z. Muresan; Pharmacology and Physiology, UMDNJ - New Jersey Medical School, Newark, NJ

Models for the generation of membrane tube networks, such as those of the ER, implicate the morphogenic membrane proteins of the reticulon/Yop1p families. Yet, these models do not account for the participation of the microtubule cytoskeleton in the generation and maintenance of ER in vivo. Here, we report that, in neurons, the cytoplasmic dynein machinery, Lis1, spectrin, and the microtubules are essential for the structural integrity of the ER and ERGIC. We found that βIII spectrin and reticulon 4 (ret4), a resident protein of the reticular ER, localize to microtubule-tethered filamentous/vesicular structures; cold-induced depolymerization of microtubules leads to fragmentation and peripheral dispersion of ret4- and βIII spectrin-labeled structures, a response typical for the loss of activity of cytoplasmic dynein. Downregulation of βIII spectrin, a protein that recruits dynein-dynactin to membranes, or of Lis1, a regulator of cytoplasmic dynein activity, disperses the ret4 network and the ERGIC53-positive tubulo-vesicular structures. Thus, the maintenance of the reticular ER and ERGIC relies on their interaction with the microtubules. These results could be explained by the ability of dynein-dynactin to bind to acidic phospholipids within membranes via spectrin, and extension of the anchored tubes by moving along microtubules. In support of this hypothesis, with purified proteins, we show that a mixture of cytoplasmic dynein, microtubules, and liposomes containing acidic phospholipids generates elaborate networks of interconnected membrane tubes (with ER-characteristic ring closures and
three-way junctions), and freely moving tubulo-vesicular clusters, typical for the ERGIC. With this reconstituted system, we further show that the formation of tubes requires dynactin and spectrin, and is regulated by phospholipase D and small GTPases. Taken together, these results indicate that similar mechanisms underlie the generation and maintenance of ER-like tube networks and small tubular transport entities, by the action of soluble microtubule motors and anchoring proteins, which bind to phospholipids, not to membrane proteins. Funded by March of Dimes (1-FY04-240) and NIH (R01GM068596).

312/B259
The Role of Dynactin in Dynein-Based Intracellular Transport.
M. M. Kincaid, S. J. King; School of Biological Sciences, University of Missouri-Kansas City, Kansas City, MO

A diverse number of cellular functions require the cytoplasmic dynein and dynactin motor complex to generate force for movement. Cytoplasmic dynein is essential for organelle distribution and transport, mitotic functions, microtubule and neurofilament transport, and retrograde axonal transport. Long-range movements of retrograde cargo, ranging from microns to meters, are particularly important in the axonal processes of neurons. Dynein processivity, the ability to take multiple steps without dissociating from the microtubule, is enhanced by dynactin. Mutations in the cytoplasmic dynein and dynactin motor complex could result in severe neuronal disorders by altering axonal transport. The aberrant function of the motor complex has been implicated in a vast number of human diseases, suggesting that dynactin may be a useful target for treatment of neurodegenerative diseases and motor neuron diseases, such as amyotrophic lateral sclerosis, or ALS. We are employing several intracellular trafficking assays to examine the role of dynactin in dynein-based motility. Utilizing GFP-labeled cargoes and BODIPY-ceramide, we are analyzing the effects of alterations in dynactin on the motility of cargoes inside a variety of mammalian tissue culture cell lines.

Direct Observation of Dynein/Dynactin Complex Dynamics in MAP2c Induced Microtubule Bundle Motility.
A. Biesemann¹,², M. Krejczy², T. Mazel¹,², S. Halpain³, L. Dehmelt¹,²; ¹Systemic Cell Biology, Max-Planck-Institut für molekulare Physiologie, Dortmund, Germany, ²Chemical Biology, Technische Universität Dortmund, Dortmund, Germany, ³Division of Biology, Section of Neurobiology, University of California at San Diego, La Jolla, CA

In neuronal and non-neuronal cells, MAP2c decorated microtubule bundles are under the influence of a dynein-dependent pushing force. If such microtubule bundles are free to move, they are rapidly transported through the cell. at the cell periphery, such bundles can exert an outward force that is opposed to an actin mediated inward force. Changes in the balance of these forces can lead to the induction of new neurite-like cell protrusions. Here, we directly observed cortical dynein/dynactin complexes and motile microtubule bundles via wide-field and TIRF microscopy. Cortical dynein/dynactin complexes are preferentially associated with microtubule bundles that come in close proximity with the plasma membrane in the TIRF field. We find that at least two different dynein/dynactin populations exist, that are either stationary or associated with the minus ends of motile microtubule bundles. Our results support a model in which free dynein complexes are transported towards the microtubule bundle minus-end, while stationary, cortex associated complexes can push microtubules directionally with leading plus-ends, thereby focusing a dynein-mediated force to locally induce neurite-like cell protrusions.

Madmax-1 Organizes Dynein-Dependent Secretory Transport in Developing Neurons.
M. Schlager¹, I. Grigoriev¹, L. C. Kapitein¹, G. M. Burzynski¹, P. Wulf¹, N. Keijzer¹, E. de Graaff¹, M. Fukuda¹, I. T. Shepherd¹, A. Akhmanova², C. Hoogenraad¹; ¹Neuroscience, Erasmus MC,
Membrane and secretory trafficking are essential for proper neuronal development. However, the molecular mechanisms that organize secretory trafficking are poorly understood. Here, we identify Madmax-1 as an effector of the small GTPase Rab6 and key component of the molecular machinery that coordinates dynein-dependent secretory vesicle transport. We show that Madmax-1 has homology to Bicaudal-D (BICD) family proteins, interacts with the dynein/dynactin retrograde motor complex, organizes Rab6-positive secretory vesicle exocytosis and is required for neural development in zebrafish. In developing neurons, Madmax-1 expression strongly declines during early neurite outgrowth. Sustained expression of Madmax-1, as well as knockdown of Rab6 suppresses neuritogenesis. In contrast, sustained expression of BICD2 does not significantly affect neurite development. These results indicate an important developmental role for Madmax-1 as an organizer for dynein-dependent trafficking of Rab6-decorated secretory vesicles. The data uncover a new mechanism to achieve regulation and specificity in secretory trafficking and exocytosis during neuronal development.

Motor Coordination via Tug-Of-War Mechanism Drives Bidirectional Vesicle Transport.
J. L. Ross1, A. Hendricks2, E. Perlson3, H. W. Schroeder2, E. L. Holzbaur2; 1Department of Physics, University of Massachusetts Amherst, Amherst, MA, 2Department of Physiology/Pennsylvania Muscle Institute, University of Pennsylvania, School of Medicine, Philadelphia, PA

The microtubule motors kinesin and dynein function collectively to achieve long-range, bidirectional transport in the cell. While previous work suggests kinesin and dynein motors may be bound to cargos simultaneously, the mechanisms that regulate bidirectional motility are not well understood. Analysis of axonal transport in live cells reveals that multiple modes of transport may be observed concurrently. Cargos exhibit fast, unidirectional movement in both anterograde and retrograde directions, as well as saltatory, bidirectional movement and pausing. To characterize bidirectional transport in a simplified In Vitro system, we purified endogenous cargos from transgenic mice with neuronally expressed GFP-dynamitin. We isolated fluorescent vesicles ~90 nm in diameter that are enriched for markers of the axonal transport compartment. These purified axonal transport vesicles bind to and translocate along microtubules in an ATP-dependent manner. Quantitative photobleaching and western blot analysis indicate that 3-6 dynein motors and one kinesin-1 motor were stably bound to each vesicle. In Vitro vesicle motility is bidirectional, similar to the saltatory motility seen in cellular assays. High-resolution analysis using total internal reflection microscopy indicates that directional switches are correlated with off-axis movement, and are likely due to stochastic switching between vesicle-bound kinesin and dynein motors. Inhibitory antibodies to dynein modulate the net direction of transport, consistent with this hypothesis. We compared the predictions of a simple tug-of-war model to the observed trajectories, velocities, and directional motility of vesicles in vitro, and good agreement was found assuming 6 dynein motors and 1 kinesin motor are active. The inhibitory effects of antibodies were modeled as a reduced number of active dynein motors, and the simulated trajectories compare well with the observed experimental trajectories. Together, our observations and modeling results indicate that vesicles move robustly with a small complement of motors, and suggest an efficient regulatory scheme where small changes in the number of engaged motors manifest in large changes in the motility of the cargo.

Dynein Drives Autophagosome Motility in HeLa Cells.
S. Maday, E. L. Holzbaur; Department of Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA
Dynein, an essential microtubule-based motor for retrograde axonal transport, plays a central role in autophagy, a process by which defective cellular components are degraded by the lysosomal machinery. Dynein has been proposed to drive the transport of autophagosomes to the cell center, allowing for effective fusion with lysosomes and clearance of toxic cellular material (Köchl et al., 2006; Jahreiss et al., 2008; Kimura et al., 2008). Disruption of either dynein function or autophagy is sufficient to cause neurodegeneration marked by the accumulation of protein aggregates. We aim to understand the mechanisms that regulate autophagosome transport and how this process is misregulated in neurodegenerative diseases. To develop an assay to monitor autophagosome motility and localization, we transfected HeLa cells with GFP-LC3, a marker for autophagosomes. We found that treatment of HeLa cells with either nocodazole or vinblastine to depolymerize microtubules results in an accumulation of autophagosomes, as evidenced by an increase in GFP-LC3 puncta. Microtubule depolymerization also disrupted the predominant perinuclear localization of LC3, which became distributed throughout the cytoplasm. To examine dynein function in autophagosome localization, we overexpressed the coiled-coil region (CC1) of the p150Glued subunit of dynactin, an activator of dynein. CC1 blocks dynein-dynactin interactions and disrupts dynein-based motility. Overexpression of CC1 in HeLa cells dispersed autophagosomes to the cell periphery. This effect was enhanced by starvation in Earle's balanced salt solution in the presence of bafilomycin A1, an inhibitor of the vacuolar H+-ATPase. Live cell imaging of HeLa cells revealed much bidirectional movement of LC3 and retrograde transport events towards the perinuclear region were observed. These results, together with previous observations, indicate that dynein drives the transport of autophagosomes along the microtubule network in HeLa cells. These observations will serve as a foundation to dissect this process at a mechanistic level and to study how defects in this pathway may contribute to neurodegeneration by failing to eliminate toxic protein aggregates.

Mechanical Cues Induce Asymmetric Dynein Distributions Driving Large-Scale Movements in the Cell.

S. K. Vogel¹, N. Pavin²,³, N. Maghelli¹, F. Jülicher², I. M. Tolic-Norrelykke¹; ¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ²Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, ³Department of Physics, Faculty of Science, University of Zagreb, Zagreb, Croatia

Motor proteins, exerting force on microtubules, position nuclei, spindles, and other organelles in eukaryotic cells. Hence a central question is how a multitude of motor proteins and microtubules work together to produce large-scale movements of organelles in the cell. The vigorous nuclear oscillations during the meiotic prophase of the fission yeast Schizosaccharomyces pombe provide an excellent system to study organelle movements dependent on cytoplasmic dynein and microtubules. These oscillations span the whole cell and are crucial for proper chromosome pairing and recombination, yet the mechanism of the oscillations was unknown. We provide a mechanism of these oscillations based on collective behavior of dynein motors linking the cell cortex and dynamic microtubules that extend from the spindle pole body in opposite directions. By combining live cell imaging, laser ablation and quantifying the number of dynein motors with a theoretical description, we show that dynein dynamically redistributes in the cell in response to load forces, resulting in more dynein attached to the leading than to the trailing microtubules. The redistribution of motors introduces an asymmetry of motor forces pulling in opposite directions, leading to the generation of oscillations. Our work provides the first direct In Vivo observation of self-organized dynamic dynein distributions, which, due to the intrinsic motor properties, generate regular large-scale movements in the cell. We propose a novel mechanism for spatio-temporal pattern formation of motor proteins governed by mechanical cues that differs from conventional molecular signaling, as well as from self-organization based on a combination of biochemical reactions and diffusion.

LIS1 and Nude Allow Multiple Dynein Motors to Cooperate to Transport High Loads.

- 153 -
Cytoplasmic dynein is involved in a wide range of intracellular movements including fast vesicular transport and slow nuclear translocation. How one motor contributes to fast, low load movement as well as slow, high-load movement is unknown. We have found that two dynein regulatory factors, LIS1 and NudE, cooperate to convert dynein to a novel persistent force state under load (Mol Biol Cell 19 (suppl.), 1546). We found that NudE recruits LIS1 to dynein to form a triple complex, in which LIS1 binds the dynein motor domain in an ADP-VO4 transition state-specific manner. LIS1 enhanced the affinity of dynein for microtubules, but only under transition state conditions. In single molecule bead assays, LIS1 dramatically prolonged the interaction of dynein with microtubules under load, providing the first evidence for a role in dynein force regulation. We have since examined the effects of LIS1 and NudE on the dynein-microtubule interaction in further detail. To measure the resistance of dynein to detachment from microtubules directly, we used “superforce” analysis. Beads bearing single dynein molecules were subjected to sudden increases in laser trap strength to exceed the dynein stall force, and the time to detachment from microtubules was determined at high precision. LIS1 alone or in combination with NudE extended the detachment time by up to 5-fold. To test how LIS1 and NudE affect dynein force production under multi-motor conditions, we incubated beads with dynein at high concentration and monitored force production at 3.7 pN trap strength. Beads coated with ~2-3 dynein molecules showed an increased frequency of multi-motor events with addition of LIS1 and NudE, which also caused a dramatic increase in trap escape. In silico simulations confirm that the prolongation of individual dynein-microtubule interactions should result in enhanced force production by multiple motors. These results appear to explain the need for LIS1 and NudE in dynein-dependent, high-load intracellular movements, where multiple motor activity is critical. Structure-function analysis of the relative contributions of LIS1 and NudE to these aspects of dynein behavior is under way. Supp. by GM47434, HD40182, and GM070676.

*Construction of BiFC Fusions to Assay for In Vivo Interactions among Dynein HC, Pac1/LIS1, and Bik1/CLIP-170 at Microtubule Plus Ends.*

K. Plevock, S. M. Markus, W. Lee; Biology Department, University of Massachusetts, Amherst, MA

Pac1/LIS1 and Bik1/CLIP-170 are two key proteins required for the targeting of dynein to cytoplasmic microtubule plus ends in budding yeast. We have previously proposed a model whereby Pac1/LIS1 binds to the motor domain of the dynein heavy chain, Dyn1/HC, forming a complex that interacts with the +TIP protein Bik1/CLIP-170 at plus ends. Here, we utilized Bimolecular Fluorescence Complementation (BiFC) probes derived from Venus (VN, N-terminal 172 amino acids of Venus; VC, C-terminal 83 amino acids of Venus) to assay for protein-protein interactions among Pac1/LIS1, Bik1/CLIP-170 and Dyn1/HC. We observed that cells co-expressing Dyn1-VN with Pac1-VC or Bik1-VC exhibited fluorescent foci associated with microtubule plus ends, the cell cortex, and the spindle pole bodies (SPBs). Additionally, cells co-expressing Pac1-VC with Bik1-VN exhibited fluorescent foci associated with microtubule plus ends. As controls, strains expressing Dyn1/HC, Bik1/CLIP-170 or Pac1/LIS1 fused with either VN or VC exhibited no fluorescence signal above background. These data support the model that these three components associate in a complex at the plus end of microtubules.

*Pathway in Dynein Targeting to a Microtubule plus End: Differential Roles of Pac1/LIS1 and Bik1/CLIP170.*

S. M. Markus, J. Punch, K. Plevock, W. Lee; Biology Department, University of Massachusetts, Amherst, MA
In S. cerevisiae, targeting of dynein and dynactin complexes to the microtubule plus end is a pivotal step of the dynein pathway, which is required for the movement of the mitotic spindle into the bud neck during anaphase. A total of thirteen motor and regulatory components of the dynein pathway are targeted to the plus end. Knowing the copy number of each of these components at one microtubule plus end is necessary to understand the molecular architecture of the plus-end complex, and to elucidate the mechanisms underlying dynein function. We have counted, with molecular accuracy, the number of each component using quantitative fluorescence microscopy. Our measurements reveal novel subunit stoichiometry for the dynein and dynactin complexes. Additionally, using bimolecular fluorescence complementation (BiFC), we have demonstrated In Vivo interactions between dynein, Pac1/LIS1 and Bik1/CLIP170, and mapped an interaction pathway for dynein plus-end targeting. We found that a stoichiometric amount of Pac1/LIS1 and an excess of Bik1/CLIP170 link the dynein complex to the microtubule plus end via the motor domain of Dyn1/HC. Pac1/LIS1 and Dyn1/HC are dependent on each other and on Bik1/CLIP170 for plus-end targeting, whereas Bik1/CLIP170 is independent of either. Furthermore, overexpression of Pac1/LIS1 enhances Dyn1/HC targeting, and vice versa. These data suggest that dynein and Pac1/LIS1 assemble as a 1:1 pre-complex that then associates with Bik1/CLIP170, which we propose mediates direct interaction with the plus end. Our findings allow us to visualize the overall arrangement of a functional plus-end complex at a single microtubule plus end.

Interactions of the I1 Intermediate Chain Dyneins IC140 and IC138.
O. Aburime, J. Goss, T. W. Hendrickson; Biology, Morehouse College, Atlanta, GA

The dynein microtubule motors belong to class of ubiquitous and essential family of molecular motors that are involved in many vital biological processes such as left-right patterning during development, chromosome segregation, vesicular trafficking, and ciliary and flagellar motility. This work focuses on the role of axonemal dynein intermediate chains in targeting the I1 dynein complex to the microtubule doublet using *Chlamydomonas reinhardtii* as a model system. The I1 dynein complex is targeted and anchored to a unique position on the A-microtubule of the doublet yet the mechanism by which this happens has yet to be fully elucidated. Chemical cross-linking studies revealed that the inner arm dynein I1 intermediate chains IC138 and IC140 each independently form complexes of approximately 200 kDa and 300 kDa when treated with a zero-length cross-linker. We have determined that the smaller cross-linked product is a complex containing the I1 intermediate chain (IC140 or IC138) and tubulin. Furthermore, 200 kDa cross-linked complex is capable of forming in the presence of purified I1 (f-dynein) and taxol-stabilized microtubules only. These results indicate that not only can the dynein intermediate chains bind directly to the microtubule but no other non-I1 proteins are required to mediate that interaction.

B. R. Scipioni, D. C. Oh, T. A. Schroer; Biology, Johns Hopkins University, Baltimore, MD

Dynactin is a multi-subunit complex that links microtubule-based motors to the cargo they transport. Loss of some subunits (Arp1, Arp11 and p62) leads to loss of the entire dynactin complex and results in aberrant mitotic spindle formation and endomembrane mislocalization. However, the core dynactin structure is unperturbed in the absence of the p25 and p27 subunits, indicating that these proteins are not required for dynactin stability. Cross-linking of native dynactin reveals that p25 and p27 are closely associated with each other. These proteins are distal components of the “pointed end complex” which is involved in cargo specification. In addition to the dynactin-associated pool, cells contain free p25/p27 heterodimers that are not associated with other dynactin subunits. p25 and p27 are genetically related and are predicted to adopt a left-handed beta-helical fold. We have mapped the epitope recognized by the p27 monoclonal antibody, mAb 27A, to an alpha-helical loop that projects away from the beta helix. In fixed cells and cytosols, mAb 27A recognizes the free pool of p25/p27 heterodimers but not the dynactin-associated pool, suggesting that this surface loop is masked in native dynactin, most
likely by other subunits. We are undertaking cross-linking analysis of purified recombinant p25/p27 heterodimers in order to reveal the binding interface between these two proteins. This analysis may also provide information about the solvent-exposed surface. This work should provide important new information regarding the way in which p25 and p27 bind each other and will also provide new insights regarding possible mechanisms for dynactin and cargo-binding.

The Dynamitin N-Terminus: A Potential Link between the Two Structural Domains of Dynactin.
F. Cheong¹, A. Sarkeshik², J. Yates², T. A. Schroer¹; ¹Biology, Johns Hopkins University, Baltimore, MD, ²The Scripps Research Institute, La Jolla, CA

Dynactin, a multi-subunit complex, works with dynein and other motors in a wide range of subcellular activities. Its subunit dynamitin (p50) is essential to its structural integrity. Over-expression of dynamitin dissociates the dynactin subunit p150glued from the Arp1 minifilament in vivo and in vitro. This suggests that dynamitin links the dynactin shoulder-sidearm domain (p150, dynamitin and p24) to the Arp1 filament. The extreme N-terminus of dynamitin N-DM (AA 1-90) is sufficient to disrupt dynactin in vivo and in vitro, yielding the same phenotypes as full-length dynamitin. N-DM's ability to disrupt dynactin in cells is unexpected, since a slightly smaller recombinant fragment (AA 1-81) of the dynamitin N-terminus does not disrupt or bind stably to purified bovine dynactin. To identify proteins that can interact with N-DM, we performed tandem affinity purification and found that N-DM pulls down the subunits of the Arp1 filament (consisting of Arp1, CapZ, Arp11, p62, p27, p25 and actin) but not the shoulder-sidearm subunits. Similar results were obtained by immunoprecipitation of myc-tagged N-DM. An in vitro binding assay using purified dynactin has further shown that N-DM can bind the Arp1 filament directly, and that other cytosolic factors are not required. Analysis of lysates lacking the dynactin p27/p25 subunits reveals that these subunits are not required for N-DM binding to the Arp1 filament. CapZ does not bind N-DM in lysates lacking Arp1 and Arp11, suggesting that N-DM binds Arp1 directly. Over-expression of N-terminal fragments of dynamitin enhances the formation of Arp1 cables, suggesting that the dynamitin N-terminus stabilizes Arp1 polymers. Together, our findings suggest an interesting new model of dynactin structure.

J. Scherer¹, R. Vallee²; ¹Biological Sciences, Columbia University, New York, NY, ²Pathology and Cell Biology, Columbia University, New York, NY

Besides its physiological binding partners, cytoplasmic dynein can be recruited by pathogenic cargo, such as viruses for intracellular motility. Incoming adenovirus 5 (Ad5) is known to use dynein-mediated transport toward the nucleus after its escape from the endosome. Our lab has previously reported that this interaction involves the adenovirus capsid protein hexon (MBC, 2007, 18(suppl):1661). Biochemical, immunolocalization, and phenotypic analysis also indicated that the interaction with cytoplasmic dynein is direct and appears not to require the known adaptors ZW10, NudE, or dynactin. We now report that short-term exposure of adenovirus or purified hexon to decreasing pH strongly enhances the subsequent interaction with purified rat brain cytoplasmic dynein at neutral pH. Using pH-optimized binding conditions we find the dynein intermediate chain (IC) and light intermediate chain 1 (LIC1) expressed in Cos-7 cells interact with hexon, whereas LIC2 and the dynein light chains RP3, TcTex-1 and LC8 do not. Hexon-IC binding does not involve the N-terminal IC residues 1-125, the known binding site for the dynein regulator dynactin. These results indicate that the passage through the acidic lumen of the endosome primes the adenovirus capsid for dynein binding. Furthermore, the capsid interacts with multiple cytoplasmic dynein subunits and - in the case of IC binding - presumably at a novel site. This is consistent with our more general observation that adenovirus recruits cytoplasmic dynein directly through a mechanism that differs from that used by physiological forms of cargo. Supp. by NIH GM47434.

Dynein Unmasking: Spatial Regulation of Dynein Mediated by Intramolecular Associations.
S. M. Markus, W. Lee; Biology, University of Massachusetts Amherst, Amherst, MA

In *S. cerevisiae*, cortical dynein plays an integral role in positioning the mitotic spindle in the bud neck prior to anaphase. For dynein to associate with the cell cortex, it must be off-loaded from the plus-ends of astral microtubules emanating from the spindle pole body (SPB). While the mechanism preventing dynein from bypassing the off-loading process is unclear, we recently proposed a model whereby the N-terminal cortical association ‘tail’ domain of the heavy chain is masked by the C-terminal ‘motor’ domain until its association with plus-ends, thus precluding its ability to associate with the cortical receptor, Num1. To test whether the tail and motor domains are capable of associating *in vivo*, we attached bimolecular fluorescence complementation (BiFC) probes to the extreme termini of the dynein heavy chain (Dyn1/HC) and observed fluorescent foci associated with the SPB but not with plus-ends or the cell cortex, suggesting that this intramolecular association is spatially restricted. Into the junction between the tail and motor domains, we systematically inserted variable linker sequences to constitutively unmask Dyn1/HC. All mutants tested exhibited properties expected of a constitutively unmasked dynein motor; namely, an unregulated ability to associate with the cell cortex. This association depends on Num1, but occurs independently of Pac1/LIS1 and Bik1/CLIP-170, two proteins required for the cortical targeting of wild-type Dyn1/HC. Strikingly, when imaged using time-lapse fluorescence microscopy, we directly observed the unmasked dynein motor off-load from the plus-end to the cell cortex, lending support to the notion that unmasking is indeed a critical step in the process of delivery of cortical dynein. Taken together, our data support the notion that Dyn1/HC likely adopts a masked conformation at the SPB, is unmasked upon associating with plus-ends, which allows for the association of dynein with the cell cortex from where it mediates spindle orientation.

The Dynactin Subunits p27 and p25 Are Membrane-Targeting Factors.
T. Yeh, B. R. Scipioni, T. A. Schroer; Biology, Johns Hopkins University, Baltimore, MD

Dynactin is well known for its roles as a cargo adaptor and processivity enhancer for cytoplasmic dynein and kinesin-2. Although dynactin is essential for mitosis and endomembrane trafficking, it remains unclear how dynactin is targeted to its various cargoes. We have used RNAi to identify the dynactin subunits p27 and p25 as membrane targeting factors. p27 knockdown selectively depletes the p27/p25 heterodimer while leaving the rest of the dynactin molecule intact, unlike Arp11 or p150Glued knockdown which compromise dynactin complex integrity and/or motor binding. Cells lacking p27/p25 form normal spindles, in marked contrast to what is seen when other subunits are knocked down. However, we find that p27 and p25 are required for centripetal movement of recycling endosomes as well as the steady state localizations of early endosomes and the trans-Golgi network. The effects of p27/p25 knockdown are specific for these particular compartments, as late endosome motility is not impaired. Membrane-associated dynactin is reduced in p27 knockdown, consistent with the hypothesis that p27/p25 is required for dynactin recruitment to specific membrane compartments. We also unravel that p27/p25 play essential roles in completion of cytokinesis, as cells lacking these subunits show defective dynactin-mediated delivery of recycling endosomes toward the midbody bridge. Our results provide new insights into the mechanism by which dynactin binds membrane cargoes and further suggest that p27/25 may serve to regulate and/or discriminate dynactin functions.

Processive Movement by Mutant Cytoplasmic Dynein Heterodimers with an Inactive Head.
T. Shima, H. Higuchi, K. Sutoh; University of Tokyo, Tokyo, Japan
SUNDAY

Cytoplasmic dynein is a two-headed molecular motor, which takes hundreds steps along a microtubule (MT) without dissociation. To elucidate the mechanism of the processive motion, we expressed the heterodimeric dynein constructs, in which one head completely lost its ATP-binding activity due to the K-to-T mutation in the Walker a motif in its AAA1 module (P1T mutation). Our single-molecule motility assays showed that the heterodimeric dynein of the wild type and the P1T mutant (Wild/P1T) moved processively on MT with its velocity approximately 40% of that of the wild-type homodimer. Step size distribution for the Wild/P1T heterodimer was similar to that of the wild-type homodimer, suggesting that the Wild/P1T heterodimer also moves in hand-over-hand fashion. Because P1T mutant head in the heterodimer cannot dissociate from MT by itself, this processive motion suggests that the wild-type head pull the P1T head off from MT. Therefore, intramolecular tension between two heads is predicted to play an essential role in the processive movement of dynein. We then examined the effect of intramolecular tension through the tail domain linking the two heads. We inserted a Gly-rich flexible linker with 20 or 30 residues between the tail domain and the heterodimerizer to reduce the tension. Unexpectedly, the wild-type homodimer and the Wild/P1T heterodimer with the flexible linker moved processively; their run length and velocity were similar to those of the homo- and heterodimer without the flexible linker. These results suggest that the tension through the tail domain does not play a critical role in the processive motion. The direct interaction of the two AAA rings in the dynein heads may be responsible for sustaining alternative steps of the two heads on MT.

Dissection of Chlamydomonas Dynein-C by Using High-Speed AFM.
D. Yamamoto¹, A. Miyagi¹, K. Oiwa², T. Ando¹, H. Sakakibara²; ¹Department of Physics, Kanazawa University, Kanazawa, Japan, ²KARC, NICT, Kobe, Japan

The high-speed AFM is a powerful instrument; using it, we can observe nano-meter-scale conformational change of protein molecule directly in nearly real time (~10 f/sec). By the use of the high-speed AFM in tapping mode, we have observed molecular morphology and conformational change of dynein-c molecules which were placed on mica surface. In most cases, dynein-c molecules were disrupted after several seconds’ observation, probably due to damages by the probing. However, we noticed that observation of disruption process of dynein would provide new insights in the internal structure of dyneins. In this study, we determined the linker-located side of dynein head. When we observed “left view” of dynein-c (left view: the view from perpendicular to the AAA-ring plane in which the tail protrudes to below and projecting points of the tail and stalk are left hand of the head), sometimes the dynein head was peeled off from the mica surface but the tail remained. at the same time, a hook-shaped structure appeared where the head had been placed. The hook-shaped structure was closer to the mica surface (2-3 nm) than the head surface (5-12 nm) before the peeling. The one end of the hook linked to the tail and the other end linked to the peeled head. We suppose that the hook corresponds to the linker. on the contrary, when we observed right view of dynein-c, the linker was occasionally observed through opening of disrupted head. The linker was located at almost same height to the head surface before the disruption. These indicate that the linker is located on the foreside of the head when we look at the right view of dynein-c. on the other hand, there was a ridge on the head surface of the left view. Occasionally, the majority of the ridge was peeled but one end was still linked to the head at around the position of AAA6. The peeling didn’t affect the remaining structure of the head and the tail. The tapping force of probe is so small (~10pN) that the provability of peptide-bond severing should have been very low. Taken together, we suppose that the ridge was C-terminal region of dynein-c, which would be located on the head surface when we observed the left view.

The Role of p28C Dynein Light Chain in Ciliary Motility in Tetrahymena Thermophila.
A. Subramanian, A. Kabi, D. G. Pennock; Zoology, Miami University, Oxford, Ohio, Oxford, OH

Axonemal dyneins drives microtubule sliding leading to ciliary motility. Cilia contain multiple dynein isoforms, The dynein light chains (LC) are thought to regulate the assembly, organization
and activity of the one headed inner arms. The work in our laboratory focuses on the p28 class of
dynein LC. A single p28 protein is present in Chlamydomonas, and it associates with a subset of
one headed inner arm dynein heavy chains (Le Dizet and Piperno, 1995). The Tetrahymena
also expresses more genes that encode one headed inner arm heavy chains than
Chlamydomonas (18 in Tetrahymena compared to 8 in Chlamydomonas) (Wilkes, 2004). These
data raise the question: Why are there three different p28 proteins in Tetrahymena? We
hypothesize that each of the light chains in Tetrahymena associate with a distinct subset of one
headed inner arm dyneins. In order to test our hypothesis, we performed qRT-PCR experiments
to determine the relative expression levels of p28. p28B was expressed at the highest
abundance, p28C at an intermediate level, and p28A at a very low level. We have initiated our
studies by introducing mutations in the p28C gene by targeted gene knockout. Southern Blot
analysis confirmed the knockout was complete. LC-MS/MS analysis of dynein HC isolated from
p28C knockouts indicated that a single inner arm dynein HC, DYH11, was missing from p28C
mutants. This suggests that p28C is required for the assembly of DYH11-containing inner arm
dynein. The observation that only one dynein HC is missing from p28C knockouts supports our
hypothesis. Behavioral analyses of the p28C mutant indicate that there is a 58% reduction in
ciliary beat frequency and 56% reduction in swimming speed compared to wild-type cells. These
data suggest that p28C associated inner arms are required for normal ciliary beat frequency in
Tetrahymena. This result was surprising since mutations in p28 affect waveform but not beat
frequency in Chlamydomonas. We are currently mutating genes p28B and a to detect whether
other p28 associated HC function in establishing waveform. Supported by NIH R15GM059855-03
to DGP.

Analysis of Dynein Heavy Chain Mutations in Neurospora crassa.
S. Sivagurunathan1, D. S. Razafsky1, R. R. Schnittker2, M. Plamann2, S. J. King1; 1School of
Biological Sciences, Division of Molecular Biology and Biochemistry, University of Missouri-
Kansas city, Kansas city, MO, 2School of Biological Sciences, Division of Cell Biology and
Biophysics, University of Missouri - Kansas city, Kansas city, MO

Cytoplasmic dynein is a minus-end directed microtubule motor involved in a variety of cellular
functions. Dynein is a multi-subunit complex composed of heavy chain, intermediate chain, light
intermediate chain and light chain subunits. The heavy chain consists of an N-terminal
dimerization domain followed by six tandemly linked AAA modules that includes a microtubule
binding stalk between AAA4 and AAA5. Of the six AAA modules only AAA1-4 are thought to bind
ATP and AAA1 has been shown as the principal ATP hydrolysis site. The presence of multiple
ATP binding and hydrolysis sites adds to the complexity of dynein heavy chain structure and
poses the question of how conformational change is coordinated and regulated around the AAA
modules. In the current study we used Neurospora crassa as a model organism to study dynein
heavy chain structure-function relationships. We utilized a genetic screen to identify ropy (ro)
mutant strains that exhibit abnormal growth phenotypes that are caused by mutations in
components of the dynein/dynactin pathway. We further studied ropy (ro-1) mutant strains that
carried point mutations in the dynein heavy chain. We replaced the endogenous intermediate
chain with a fluorescently tagged intermediate chain and used this tool to localize dynein in WT
and ropy mutant strains. In the wild-type strain a bright dynein localization signal was observed at
the hyphal tips with comet-like structures in distal regions to the tip. In contrast, ropy mutant
strains exhibited altered dynein localization which includes linear tracks of dynein, loss of bright
hyphal tip localization and diffusive staining throughout hyphae.

Proteomic and Functional Analyses of Dyneins in Cilia.
A. Kabi, A. Subramanian, D. G. Pennock; Zoology, Miami University, Oxford, OH

Axonemal dyneins are molecular motors composed of heavy chains (HCs), intermediate and light
chains. HCs comprise of the motor domain and make up most of the mass of the dynein complex.
Previous studies identified eight inner arm dynein HC (DHC) in different ciliated and flagellated organisms. However, recent analyses of completed genomes of different species identified additional one-headed dynein HC genes in most of the organisms examined. An extreme example in this case is exhibited by Tetrahymena thermophila which has eighteen one-headed inner arm dynein HC genes. These findings lead to two broad questions: i) Are all predicted dyneins present in the axonemal proteome and are they all equally abundant? ii) Are all dyneins equally important for ciliary motility? To answer the first question, we analyzed axonemal DHCs in Tetrahymena thermophila by LC-MS/MS and detected fifteen one-headed DHCs. The LC-MS/MS data suggested that the HCs are present in different abundances. qRT-PCR studies also supported the fact that axonemal DHCs are expressed at different levels. These observations raise the question of whether dyneins present in different abundances play different role(s) in ciliary motility. To address that question, we knocked out two different inner arm dyneins -DYH15, the highest abundant one-headed inner arm dynein, and DYH18, present in very low abundance. Both mutants displayed a 15-25% reduction in swimming speed. Beat frequency and feeding behavior was affected in KO15, but not in KO18. Thus we can conclude that each dynein may be playing a unique role in ciliary motility. Interestingly, LC-MS/MS analyses of axonemes isolated from both the mutants revealed an increase in levels of three one-headed DHCs in KO15. No such compensation was observed in case of KO18. This raises the possibility that some dyneins are partially redundant.

Cell Migration I (334 – 364)

Integrin-Dependent Invasive Migration in 3D Collagen of Human Lung Adenocarcinoma Cells That Survived 10Gy Irradiation.
S. Ishihara1, M. Yadusa2, T. Mizutani2, K. Kawabata1, T. Nishioka3, H. Haga1; 1Division of Biological Sciences, Graduate School of Science, Hokkaido University, Sapporo, Japan, 2Department of Oral Pathobiology, Graduate School of Dental Medicine, Hokkaido University, Sapporo, Japan, 3Department of Radiology, Graduate School of Medicine, Hokkaido University, Sapporo, Japan

Radiotherapy is one of the effective therapies for various malignant tumors. However, the emergence of tolerant cells after irradiation remains problematic since the tolerant cells show high metastaticity and sometimes result in poor prognosis. Recent studies revealed that integrins play a key role in cancer cell migration and invasion. Especially, integrin-beta1 regulates cell invasion into three-dimensional collagen matrix by accumulating at the direction of cell movement. In this study, we show that tolerant cancer cells through irradiation indicate high invasive activity in 3D collagen gel and a manner of the migration is dependent on integrin-beta1. First, we established several sub-clones of human lung adenocarcinoma cells (A549 cells). Then, one of the clones named as A549P-3 was exposed to 10 Gy of X-rays. After 30 days, the surviving cells were harvested (referred to as A549P-3IR). Collagen gel overlay assay for A549P-3 and A549P-3IR was performed to observe their morphology and invasiveness. We found that most A549P-3 cells indicated round and stable morphology and low migration activity, whereas a considerable number of A549P-3IR showed spindle morphology and rapid changes in cell surface, alternating phases of elongation and retraction of protrusions, and significant increase in migration rate. Immunofluorescence staining showed integrin-beta1 accumulated at the head of elongated A549P-3IR surface but did not in A549P-3. Blocking integrin-beta1 activity using monoclonal antibody (AIIB2) inhibited A549P-3IR cell movement and altered the cell morphology into round shape. Knockdown of integrin-beta1 by RNAi also induced the same effects as AIIB2 did. These results indicate that the surviving A549 cells against irradiation acquire a sustained activity of integrin-beta1 and result in a highly invasive phenotype.

Visualizing Rac1, RhoA, and Cdc42 Activity during Cell Migration within Three-Dimensional Extracellular Matrix.
The study of cell migration In Vitro on two-dimensional (2D) rigid surfaces has provided significant insight into the mechanisms of cell movement. Polarized intracellular signaling directs protrusion at the leading edge, adhesion to the underlying substrate, and retraction at the trailing edge to orchestrate cell motility. On 2D substrates, the Rho family GTPases Rac1, Cdc42, and RhoA are active at the leading edge, coordinating protrusion and adhesion; a second pool of active RhoA at the rear of the cell promotes actomyosin contraction to retract the trailing edge. It is important to determine whether the same mechanisms also drive cell movement within the structurally complex, three-dimensional (3D) environment found in tissues. Cell-derived extracellular matrix (ECM) provides a structurally complex 3D model system that is accessible to live cell imaging. We have now constructed and validated fluorescence resonance energy transfer (FRET)-based probes to visualize the spatial and temporal activation of Rac1, Cdc42, and RhoA within living cells. The activation-dependent binding of the intermolecular probes is detected by imaging the sensitized emission of the acceptor in the presence of the donor. Visualizing these biosensors in primary fibroblasts migrating in 3D cell-derived ECM or on glass has revealed similar intracellular localization of RhoA signaling in both environments. In contrast, Rac1 and Cdc42 activity is no longer restricted to the leading edge of cells migrating in 3D cell-derived matrix. Instead, their activity is concentrated in clusters behind leading protrusions, along the side, and at the rear of the cell. Determining how these pathways are organized in cells migrating in 3D ECM will highlight the similarities and differences in the mechanisms driving migration in 2D versus 3D environments and aid in the development of new models of cell migration.
E. L. Baker, J. Srivastava, M. Zaman; Biomedical Engineering, University of Texas, Austin, TX, Biochemistry, University of Texas, Austin, TX, Biomedical Engineering, Boston University, Boston, MA

Recent years have seen a surge of interest in 3D systems as improved models for In Vivo cell migration. However, majority of these models are not only qualitative, they are also blind to the underlying signaling pathways that are well characterized in 2D systems. Additionally, neither the influence of matrix chemical, mechanical and structural properties nor the matrix regulation of cellular signals is understood in the context of 3D cell migration. This lack of knowledge has been a major obstacle in harnessing the full potential of 3D cell cultures. Using a combination of approaches, including bulk and microrheology, siRNA knockdown and high resolution imaging, we have answered three simple, yet critical questions in 3D cell migration. 1) How do key matrix properties such as structure, composition and mechanics independently and collectively influence matrix derived signaling during 3D cell migration? 2) How do these key matrix properties regulate cellular shape and mechanics and 3) How do these answers differ from 2D cell migration models. To answer these questions, we have quantified how the concentration of total and phospho-FAK depends on these matrix properties. We note that matrix mechanics plays a far more important role than matrix porosity or ligand density. Similarly, we have quantified that cell mechanics not only depends upon matrix structure and stiffness but also upon integrin activity. Above all, our results quantitatively suggest that cellular signaling, shape, mechanics and migration are far more sensitive to minor changes in matrix properties in 3D than they are in 2D. Small changes in mechanical properties of the matrix go virtually unnoticed in 2D but result in significant differences in migration and mechanics in 3D. Collectively, we find that cell motion as well as signals and mechanics underlying this motion depend on matrix properties in a complex and a non-linear way that is consistent with results of our mechano-chemical models.

Cellular Control of Glial Cell Chain Migration.
S. Berzsenyi, A. Giangrande; Institut de Génétique et de Biologie Moléculaire et Cellulaire, Illkirch, France

Collective cell migration is a common and fundamental phenomenon during development. The developing wing of the Drosophila provides an excellent model to investigate the mechanism of cell chain migration where a high number of cells migrate together in a head-to-tail arranged manner. Veins between the two epithelial layers of the wing contain sensory nerves and ensheathing glial cells. These latter migrate from the position where they are born to cover the axonal tracks thereby providing the appropriate niche for axonal metabolism and conductance. After introducing fluorescent markers to the glial cells, the movement of the glia is followed using confocal microscopy. The chain migration of the glia is unidirectional and starts at a narrow time window in development. With cell ablation technique it has been already shown that the first few cells in the chain, named pioneer cells, play a very important role in initiating and leading the migration. Upon elimination some or all of these first few cells, the migration of the chain is impaired (meaning delay in the completion of the migration or even complete stall). Now we would like to decipher the role and behaviour of these first cells in the chain. We carried out cell ablation experiments where we eliminated the glial cells in different numbers and in different combinations at the front of the chain. from these experiments we can conclude that the initiation of migration is not only dependent on the pioneer cells but also on the interconnection of these cells with the follower cells (i.e. with those that are behind the pioneers). The glial cells at the front of the chain require the vicinity of other cells: if we leave only a few cells intact in a cluster (i.e. less than 4-5 cells) by eliminating the neighbouring cells, the isolated cells are not able to move properly. The migration of the glial cells in a chain is a very complex phenomenon: while the first cells guide the rest of the chain towards the destination our recent findings indicate that these cells require the presence of the neighbouring cells. These findings may provide important information to the collective cell migration in cancer as well as in neurodegenerative diseases.

TNFα and TGFβ Expression in Zebrafish Keratocyte Explant Cultures.
T. M. McDonald, E. E. Hull, K. Cooper; Biomedical Sciences, Midwestern University, Phoenix, AZ

Fish keratocytes are a useful, widely-used system to study cell motility. Typically, these cells are grown in primary explant cultures for 1-2 days before replating for use in cell studies focusing on individually migrating cells. Although it is a routine part of the experimental system, little is known about the initial explant culture period and any changes in gene expression during this period might affect keratocyte motility. The human analog of fish keratocytes, human keratinocytes, have a complex pattern of differential expression of cytokines and MMPs during primary culture. Therefore, we asked if similar changes in cytokine levels could be seen in the zebrafish keratocyte system and if these changes affect fish keratocyte motility. Initial data suggests that TNFa mRNA expression increases approximately 6 fold during the first 24 hours in culture and then decreases to values comparable to initial levels at subsequent time-points. In conjunction with data suggesting that TGFb expression by zebrafish keratocytes varies over time during explant cultures, we suggest that keratocytes may modulate the expression of cytokines during explant culture in a manner similar to the primary human keratinocytes and that expression of these compounds promotes fish keratocyte motility.

Traction Force Mapping in Colliding Cells.
J. Lee, T. J. Morin; Molecular and Cell Biology, University of Connecticut, Storrs, CT

The movement of fish epithelial keratocytes and other “fan” shaped cell types is unusual because these cells move in a direction that is perpendicular to the cell’s long axis. In keratocytes this mode of movement is associated with the existence of relatively large, inward facing traction stresses at the lateral cell edges. Preliminary data showed that the direction of keratocyte movement on an elastic substratum can be altered by stretching it on either side of the cell. To investigate whether keratocytes can respond to the traction stress generated by neighboring cells, we performed low magnification time-lapse imaging of colliding cell pairs, on elastic and glass substrata, for periods of 1-2 hours. On both surfaces, cells displayed similar responses that were characteristic of different types of collision. In general, the result of cell collisions is determined by the location and extent to which protrusion is inhibited by cell contact. However, a substratum dependent difference in behavior of colliding cells was seen when the front of one cell approached the lateral edge of the other. In these cases cells would begin to re-align with each other prior to making contact, and continue to move in the same direction after collision. Traction force microscopy of cells undergoing front to side collisions showed that regions of increased traction stress develop in both cells at sites of the cell margin that are within ~10 um of each other. As the cells reorient, regions of increased traction stress redistribute as the point of contact changes. Typically, the cell generating weaker forces will re-align, and appear to follow in the “wake” of the cell generating higher traction stresses. We term this phenomenon “tractotaxis” and conclude that this may provide short-range guidance cues to moving cells in vivo.

A Critical Tension Abrogates Frictional Slip in Nascent Focal Adhesions.
Y. Aratyn, M. L. Gardel; Physics, Biophysical Dynamics, University of Chicago, Chicago, IL

In directed cell migration, myosin-II tension impinged on lamellipodial, nascent adhesions modifies focal adhesion composition, signaling and size. To delineate the biophysical changes in focal adhesions during this maturation process, we utilized high resolution confocal and traction force microscopy to measure cytoskeletal dynamics and traction stresses simultaneously. Myosin-II-mediated focal adhesion maturation was synchronized by treatment and removal of the pharmacological inhibitor of myosin-II ATPase activity, blebbistatin. Myosin-II reactivation results in the dramatic shear slip between nascent adhesions and extracellular matrix (ECM) that is accompanied by rapid increase in cellular traction. This ‘frictional slip’ is concurrent with a notable
decline in F-actin retrograde flow that reaches a steady state around the time the focal adhesion position is stabilized. Subsequently, focal adhesions undergo elongation and F-actin bundles become apparent. Different classes of focal adhesion proteins, including vinculin, paxillin, talin and alphavbeta3 integrin, exhibit consistent, correlated slipping motion, indicating the interface of slip occurs at the integrin-ECM interface. Surprisingly, the magnitude and duration of this slip depends sensitively on the elastic properties of the extracellular matrix, with the largest amount of slip occurring on very soft matrices. By varying the stiffness of the ECM, we found that the stabilization of focal adhesions occurs over a narrow range of tension. By characterizing the changes in relative shear rates between the F-actin, focal adhesion, and ECM interfaces, we estimate that the effective viscosity between the integrin-ECM interface increases by several orders of magnitude during the myosin-II driven engagement of focal adhesions. In contrast, the viscosity of the F-actin-focal adhesion interface changes by less than an order of magnitude. Thus, the initial stages of myosin-dependent focal adhesion maturation are characterized by rapid strengthening of the integrin-ECM bonds under enhanced load to immobilize focal adhesions at a critical stress.

Filamins Stabilize the Integrated Cytoskeleton.
C. D. Lynch, N. C. Gauthier, N. Biais, M. P. Sheetz; Biological Sciences, Columbia University, New York, NY

Cell motility is an essential, complex process that depends on a coherent cytoskeleton to physically coordinate the actions of numerous structural and signaling molecules. The cytoskeletal actin crosslinking protein, filamin (Fln), has been implicated in the support of three-dimensional cortical actin networks capable of both maintaining cellular integrity and withstanding large forces. However, the impact of simultaneous FlnA and FlnB loss on cell motility has not yet been elucidated. To this end, we used shRNA-mediated knockdown of FlnA in FlnB -/- mouse embryonic fibroblasts (MEFs) to produce severe depletion of Fln. In cell spreading on fibronectin-coated surfaces, Fln-depleted cells exhibited extensive ruffling of the cell edge, unstable adhesions, a condensed endoplasm, and transient traction forces on the substrate. Immunofluorescence confirmed defects in the stabilization of adhesion sites and actin stress fibers as well as defects in microtubule extension. Single-knockout FlnA -/- MEFs, but not FlnB -/- MEFs, also showed a significant defect in endoplasmic spreading, characterized by transient extension with abrupt retractions coupled with stress fiber breakage, identifying FlnA as the major player in the Fln-depleted phenotype. FlnA immunostaining and GFP-FlnA expression confirmed the localization of FlnA to regions surrounding the endoplasm. Our results implicate Flns in the stabilization of an integrated cytoskeleton and suggest that they also contribute to the spreading of the endoplasm.

Distinct Functions of Anterior and Posterior Regions in Directional Cell Migration.
W. Guo, Y. Wang; Biomedical Engineering, Carnegie Mellon Univ., Pittsburgh, PA

Cell migration has generally been described as a cycle of coordinated steps: extension of the leading edge, adhesion to matrix, contraction of the cytoplasm, and detachment of the tail. However, neither the coordination of these steps nor the mechanism for moving the cell body has been clearly elucidated. We have addressed these questions by forcing cultured fibroblasts to take a linear shape with clearly defined anterior and posterior regions. A simple micropatterning method using linear polyacrylamide as the blocking agent was developed to control the cell shape and directional migration. When plated on narrow tracks, 3T3 fibroblasts show periodic tail retractions similar to cells in 3-dimensional matrices. Inhibition of Myosin II totally suppresses cell retraction but has little impact on cell protrusion at the leading edge, the morphology of the anterior region, or the translocation of the nucleus. Using GFP-a-actinin as a marker for the actin cortex, we observed distinct patterns of movement in different regions: stationary or slow forward transport in the anterior region, contraction and compression in the region immediately posterior to the nucleus, and stretching at the tail. Our results suggest distinct mechanical activities in
anterior and posterior regions during cell migration. Translocation of the anterior region is independent of Myosin II, while retraction of the posterior regions is strongly Myosin II dependent. Forces of the anterior and posterior regions converge in the middle, which may be responsible for positioning and forward movement of the nucleus during cell migration.

The Effects of Force and Surface Stiffness on Breast Cancer Cell Migration.
L. Cassereau¹, J. I. Lopez², V. M. Weaver²,³,⁴, ¹Bioengineering, University of California at Berkeley, Berkeley, CA, ²Surgery and Center for Bioengineering and Tissue Regeneration, University of California at San Francisco, San Francisco, CA, ³Institute for Regeneration Medicine, University of California at San Francisco, San Francisco, CA, ⁴Bioengineering and Therapeutic Sciences, University of California at San Francisco, San Francisco, CA

The transition of the mammary epithelium to a metastatic state is an important event that drastically increases mortality during breast cancer progression. Metastatic progression depends on the ability of tumor cells to migrate to nearby blood vessels and lymphatics before they can successfully metastasize and colonize into other tissues. An understanding of how biomechanical and biochemical signals influence directional migration to these sites of tissue escape could help develop therapies to slow or halt metastasis. To understand how the mechanical properties of the tumor microenvironment may affect metastasis, cell motility was measured by tracking mammary epithelia cells over night on fibronectin conjugated polyacrylamide gels of stiffness ranging from 140 Pa to 60,000 Pa as well as tissue culture glass. Average cell velocity and total distance traveled both increased with surface stiffness with maximal values observed at 2700 followed by a slight decrease in migratory behavior. Additionally, cells have been seen to respond to a surface stiffness gradient with directional movement towards the stiffer portion of the gradient. Mammary epithelia cells were tracked for 15 hours on fibronectin or collagen conjugated gels of gradient stiffness but uniform ligand density. Cells migrating on fibronectin gels showed significant directionality in the direction of greater stiffness while cells on the collagen gels did not. This suggests alternate migratory mechanisms utilized by mammary tumor epithelium when responding to the mechanical stimuli depend on fibronectin binding but not collagen. Both of these data underlie the importance of micro-environmental mechanical properties in dictating the migratory behavior of the tumor epithelium.

Stem Cell Durotaxis: Implications for Trafficking to Rigid Fibrotic Scars.
M. Raab, D. E. Discher; Bioengineering, University of Pennsylvania, Philadelphia, PA

Scarring in the heart after a myocardial infarct, scarring in the skin after wounding, or scarring of the liver in cirrhosis - all lead to rigidification of tissue through extensive collagen crosslinking and can also lead to accumulation or ‘homing’ of adherent cells, including mesenchymal stem cells (MSCs). It is unknown how MSCs localize and, in particular, whether tissue rigidity plays a role. ‘Durotaxis’ is a term recently coined to describe the tendency in 2D culture for sparsely plated fibroblasts to crawl towards a stiff, collagen-coated gel made adjacent to a soft gel. Stiffness-induced motility would perhaps suggest cell homing to a stiff matrix, but clear evidence for accumulation of any cell type has been lacking. We cultured human MSCs on simple collagen-I coated gels with gradients in stiffness similar in magnitude to scars such as in the border zone of an infarcted heart. We first show that MSCs are indeed migratory with crawling speeds up to 1 micron/min. on stiffness gradients, we find that MSCs migrate toward the stiffer side of a substrate with definitive accumulation taking several days. Proliferation appears unaffected by stiffness in these systems, but to eliminate the potential for differential expansion, cell division was pharmacologically inhibited and durotaxis was once again documented. Consistent with past reports for cell spreading on homogeneous gels, the spread area of MSCs also increased along the stiffness gradient, which indicates that MSCs are not only responding to substrate stiffness but also tending to adhere more on stiff gels.
Amoeboid cell motility is a complicated process requiring the regulated activity and localization of many molecules and resulting in the cyclic repetition of a relatively small repertoire of shape changes. These changes are driven by the traction work produced by the cell, which can be estimated by measuring the forces and displacements exerted by the cells on their substrate during migration. We have developed and applied a novel implementation of Principal Component Analysis to identify and sort out the most important shape changes in terms of traction work produced by chemotaxing Dictyostelium cells. For this purpose, we acquired time-lapse recordings of cell shape and traction forces of Dictyostelium cells migrating on deformable substrates. Using wild-type cells as reference, we investigated the effect of altering Myosin II activity by studying Myosin II null cells and essential light chain null cells. Our results indicate that the spatio-temporal variation of the traction work produced by Dictyostelium cells can be described with a reduced number of modes. In fact, only four modes are needed to account for 65% of the traction work exerted by all cell lines studied. Furthermore, the first mode alone accounts for almost 50% of the traction work. Spatially, this mode consists of the attachment of the cell predominantly at two areas at front and back, contracting towards the center of the cell. The time evolution of this mode is approximately periodic and coincides with the time evolution of cell length. Each one of the remaining modes accounts for less that 10% of the traction work. Their temporal and spatial organization is less clear, suggesting that the cell performs a traction work cycle composed of a repetitive sequence of steps over which random fluctuations are imposed.

Human vascular endothelial cells (hVECs) serve as a critical barrier between the circulatory system and the rest of the body and participate in complex biological processes including blood transport, cell trafficking, and diapedesis. Failure of the vascular wall can result in serious and possibly life threatening complications. While vascular grafting using autologous and allogeneic material is routinely performed there remains a need for improved engineered vascular prosthetics. In the development of any solution, the influence of the three dimensional, nanoscale topography that exists In Vivo must be accounted for because of its influence upon cell behavior. To this end, we investigated the effects of biophysical cues on human umbilical vein endothelial cell migration. Previous studies have shown that native basement membranes that underlie the vascular endothelium possess feature sizes ranging from 400 - 4000nm. To simulate these features, polyurethane substrates containing either anisotropically patterned surfaces of parallel ridges and grooves or isotropically patterned surfaces with holes were produced that ranged in size from 400 - 4000nm in pitch (pitch = feature width + groove or hole width). Preliminary data demonstrate that migrating cells exhibit contact guidance on anisotropically patterned surfaces with the greatest rate of migration and distance travelled when cells were in contact with features of 1200nm or larger. Preliminary data suggest that on isotropically patterned surfaces the rate and distance traveled did not vary significantly from planar control surfaces. These data suggest that selected topographic features and size scales should be considered in the design parameters of vascular prosthetics.
Directed Cell Motility on 2-D Micron-Scale Patterns.
K. Kushiro, S. Chang, A. Asthagiri; California Institute of Technology, Pasadena, CA

Cell motility on 2-D surfaces has been extensively studied to unravel various cell-ECM interactions that affect cell migration. Recently, use of various micron-scale ECM patterns has shed light on the effects of geometrical constraint on cell survival and adhesion. However, limited work has been undertaken to study and manipulate cell motility using such patterns. Here we present various, micron-scale patterns based on asymmetric islands that can be used to control the directional bias and motility of epithelial cells. For example, we can program cells to move persistently in a counter-clockwise fashion around a path comprised of four asymmetric islands. We further demonstrate the ability to tune or alter these directional biases either by altering specific parameters of the micropattern or by altering intracellular signaling pathways by RNA interference. Finally, we apply these directional biases to partition cells between reservoirs connected by bridges composed of micron-scale patterns. Our findings provide new insights into how cells interpret micron-scale features and how such features may be used to direct cell motility over long length scales. These design principles provide a foundation for constructing “smart” devices for orchestrating multicellular organization, an essential building block for tissue engineering applications.

Mechanics in Neuronal Development.
K. Franze1,2, H. Svoboda2, P. Moshayedi1,3, A. Christ1, J. Fawcett3, J. A. Kas4, C. E. Holt2, J. Guck1; 1Physics Department, University of Cambridge, Cambridge, United Kingdom, 2Department of Physiology, Development and Neuroscience, University of Cambridge, Cambridge, United Kingdom, 3Brain Repair Center, University of Cambridge, Cambridge, United Kingdom, 4Physics Department, University of Leipzig, Leipzig, Germany

Nervous tissue consists of several different types of cells, blood vessels, and extracellular matrix. All these building blocks differ in their mechanical properties. Particularly during growth and migration, the local mechanical environment of neurons may thus change considerably. Here we show how neurons detect and avoid stiff substrates and how their mechano-responsiveness may be used to guide their axons along distinct pathways. In vitro, neurons continuously probe the mechanical properties of their environment. Growth cones visibly deformed substrates with a compliance commensurate with their own. To understand the growth cones’ sensing of stiff substrates, we investigated their precise temporal response to well-defined mechanical stresses. Externally applied mechanical stress exceeding the threshold of ~300pN/µm2 caused a calcium influx through mechanosensitive, stretch-activated ion channels in the growth cone membrane that triggered growth cone detachment and neurite retraction. Subsequently, neuronal processes re-extended, thereby enabling the exploration of alternative directions. To study the physiological consequences of this mechano-responsiveness, neurons were cultured on polyacrylamide gels of various compliances. Morphology, growth rate, and fasciculation of outgrowing retinal ganglion cell axons significantly depended on the mechanical properties of their substrate. On softer substrates, retinal ganglion cell axons fasciculated more and preferentially grew in a common direction, similar as in vivo, where these axons build the optic nerve. Hence, mechanics may be involved in neuronal development, leading axons together.

Strain Energy and Its Density Distribution around Invasive and Non-Invasive Carcinoma Cells in 3D Collagen Gels.
T. M. Koch1, S. Münster1, C. T. Mierke1, J. P. Butler2, B. Fabry1; 1Department of Physics, University of Erlangen-Nuremberg, Erlangen-Nuremberg, Germany, 2Physiology Program, Harvard School of Public Health, Boston, MA

Cell invasion through a dense 3D matrix is believed to depend on the ability of cells to generate traction forces. To quantify the role of cell tractions during invasion in a 3D reconstituted collagen
gel (shear modulus $G' = 118 \text{ Pa}$, 500 $\mu$m thickness, average mesh size 1.6 $\mu$m), we measured the
strain energy of highly invasive MDA-MB-231 breast carcinoma and A-125 lung carcinoma cells.
The results were compared to the strain energy generated by non-invasive MCF-7 breast
carcinoma and A-431 lung carcinoma cells. In all cases, cells locally contracted the gel. The
undeformed state of the gel was obtained after addition of the actin-disrupting drug cytochalasin-
D. Gel deformations were measured by tracking the 3D spatial positions of fluorescent beads (1
$\mu$m diameter) embedded in the gels. The bead positions served as nodes for a finite element
tessellation, from the local strain of each element and the known elasticity of the collagen, we
computed the local strain energy stored in the collagen gel surrounding the cell. As expected, the
strain energy of invasive breast carcinoma cells ($1.4 \pm 0.2 \text{ pJ}$, $n=34$) was significantly higher than
the strain energy of non-invasive breast carcinoma cells ($0.8 \pm 0.1 \text{ pJ}$, $n=28$). Surprisingly, the
strain energy of non-invasive lung carcinoma cells ($4.2 \pm 0.7 \text{ pJ}$, $n=31$) was similar to that of
invasive lung carcinoma cells ($3.5 \pm 0.4 \text{ pJ}$, $n=34$). Invasive cells, however, assumed an
elongated spindle-like morphology as opposed to the more spherical shape of non-invasive cells.
Accordingly, the distribution of strain energy density around invasive cells followed patterns of
increased complexity and anisotropy, quantified by its aspect ratio. These results suggest that not
only the magnitude of traction generation but also their directionality are important for carcinoma
cells invasion in 3D collagen gels.

**Tumor Cell Invasion through Enhanced Contractile Force Generation.**

C. T. Mierke$^1$, B. Frey$^2$, M. Fellner$^1$, M. Hermann$^2$, B. Fabry$^1$; $^1$Center for Medical Physics and
Technology, Biophysics Group, University of Erlangen-Nuremberg, Erlangen, Germany, $^2$Internal
Medicine, Clinical Immunology and Rheumatology, Erlangen, Germany

The process of metastasis formation causes malignant progression of tumors. An important step
during metastasis formation is the migration of tumor cells into the extracellular matrix. The
migration velocity depends on mechanical and biochemical signals such as
adhesion/deadhesion, matrix degradation, cellular stiffness or fluidity, transmission and
generation of contractile forces. Here, we tested whether $\alpha_5\beta_1$-expression influences cell
invasion into dense 3-D collagen fiber matrices. We isolated $\alpha_5\beta_1$-high and $\alpha_5\beta_1$-low expressing
sub cell lines from parental MDA-MB-231 breast cancer cells and found that higher $\alpha_5\beta_1$
expression significantly (3-fold) increased cell invasiveness. Knock-down of the $\alpha_5$ integrin
subunit in $\alpha_5$-high cells leads to decreased tumor cell invasion. Biomechanical measurements
using fourier transformed traction microscopy revealed that the $\alpha_5\beta_1$-high expressing cells
generated 5-fold larger contractile forces. In agreement with this finding, cell invasiveness was
reduced after addition of the myosin light chain kinase inhibitor ML-7 or the Myosin II inhibitor
blebbistatin in $\alpha_5\beta_1$-high cells, but not in $\alpha_5\beta_1$-low cells, suggesting that the $\alpha_5\beta_1$
inTEGRIN expression enhanced cell invasion into dense collagen matrices through enhanced transmission
and generation of contractile forces.

**Analysis of Live Cell Images to Determine Cell Population Migration Paramaters.**

C. Scelfo$^{1,3}$, B. Deasy$^{2,3,4}$; $^1$Department of Chemical Engineering, University of Pittsburgh,
Pittsburgh, PA, $^2$Departments of Orthopaedic Surgery and Bioengineering, University of
Pittsburgh, Pittsburgh, PA, $^3$Live Cell Imaging Lab, Children’s Hospital of Pittsburgh, Pittsburgh,
PA, $^4$McGowan Institute for Regenerative Medicine, Pittsburgh, PA

Stem cells are unique cells which have the potential to differentiate to multiple cellular lineages
[1], aiding in growth and regeneration of various tissues. Live Cell Imaging is a tool uniquely able
to define and capture stem cell activities, and monitor the behavior of a stem cell population in
culture, through numerous real-time measurements at the single cell level. This results in a
detailed behavioral phenotype of the stem cell population, which can be linked to In Vivo outcome
measures. However, collection of data is time intensive, and a hindrance to the analysis of large
sets of image data. This problem may be circumvented via an automated analysis system. The
quantitative data gained from LCI is a powerful way to characterize individual or populations of cells in a user specified environment. An analysis program, Image-Pro Plus, is currently used as the premier tool in obtaining numerous measurements of cellular behavior and growth characteristics. The time-lapsed image sequences [2] are imported into Image-Pro. from here, the software can separate cellular objects by color / contrast, and count individual objects. The resulting information may be exported by the user for further analysis. The calculated cellular parameters obtained here are routinely used in graphs to display the results, for comparison to values obtained in experimental methods. The opportunity to gather large amounts of data in a single experiment necessitates automation of the analysis process for feasibility. The actual number of measurements totals >12,000 per experiment when done manually. To achieve multiparametric analysis and data display in the form of graphs - the streamlining process becomes more complicated. Image-Pro allows for the implementation of Macros, or specified sets of instructions, in the form of code, to fine tune the computational process to the user’s needs. The more automated the overall process becomes, the easier it will be to gather and interpret the data, allowing for more experiments to be run or a more in depth look of each experiment may be obtained.

M. Adler¹, D. Fuller², W. Loomis³, R. A. Firtel², K. Takeda², A. Groisman¹; ¹physics, UCSD, La Jolla, CA, ²Biology, UCSD, La Jolla, CA

Chemotaxis, the chemically guided movement of cells, is important to many biological processes. Cells exhibit chemotaxis in response to external gradients of chemoattractants, which include soluble bio-molecules (such as cAMP for D. discoideum and Serine for E. coli) and dissolved gases (such as oxygen in bacterial aerotaxis). Chemotactic cells usually respond to temporal changes in the concentration of chemoattractant as well. We present three types of microfluidic devices for studies of different types and aspects of chemotaxis. Microfluidic devices of the first type generate linear and exponential concentration profiles of soluble factors with different slopes. Exponential profiles with the concentration of cAMP varying by 1.25%, 2.5%, 5%, 7.5%, and 10% over a distance of 10 μm (typical cell diameter) were used to study chemotaxis of D. discoideum.

We found that chemotactic response depends on both ambient concentration and steepness of cAMP gradient. A modification of the devices has a capability of switching between a stable exponential profile and zero chemoattractant in the test area in a time sequence mimicking the environment experienced by D. discoideum in a colony. Microfluidic devices of the second type expose adherent cells in a test area to a uniform concentration of attractant that can be changed it time in a broad range either step-wise, with ~0.5 s transition time, or in continuous linear time ramps, which can last between 10 and 800 sec. The devices were used in combination with fluorescence microscopy to test the molecular signaling responses of D. discoideum to step-wise temporal changes of cAMP concentration. The duration, latency, and magnitude of the responses was found to be dependent on the height of the steps. The microfluidic devices of the third type generate gradients of concentration of oxygen with a variety of shapes, including linear, exponential, and non-monotonic (wavy). As a proof of concept, the devices were applied to testing the response of B. subtilis to gradients of oxygen and cells were found to congregate at high oxygen concentrations.

Cell Shape and Speed Oscillation in Migrating HL60 Cells and Neutrophils.
T. Y. Tsai¹, J. E. Ferrell¹, J. Theriot²; ¹Chemical and Systems Biology, Stanford University, Palo Alto, CA, ²Biochemistry, Stanford University, Stanford, CA

It is frequently observed that migrating cells exhibit oscillations in shape and speed. Previous investigation in fish keratocytes has shown that fundamental modes of cell shape are closely correlated with global migration parameters, such as speed and persistence. In this study, we aim to study the oscillation of shape and speed in migrating neutrophils and HL60 cells, and the
correlations between them. We acquired time-lapse movie for over one hour with high temporal resolution on several migrating HL60 cells and neutrophils under a uniform field of chemoattractant. Cells were segmented frame-by-frame using automated image processing. Using principal component analysis of the obtained contour, we decomposed the variation of shape in migrating HL60 cells and neutrophils into few fundamental modes that are biologically meaningful. The first fundamental mode, representing elongation and roundedness, highly correlates with cell area and exhibits similar oscillatory pattern as cell speed and the protrusion-retraction cycle. The second fundamental mode resembles the turning phase of the cells. The two fundamental modes are observed in both HL60 cells and primary neutrophils, supporting the similarity of the two cell types. A more detailed analysis looking at temporal correlations of individual fundamental modes with global migration parameters (e.g., speed, angular velocity, acceleration, area speed) would help understand the mechanism of whole-cell integration during migration.

The Mechanics of Cell Turning in Epithelial Keratocytes.
G. Allen1, A. Mogilner4,5, J. Theriot1,2,3; 1Department of Biochemistry, Stanford University, Stanford, CA, 2Department of Microbiology and Immunology, Stanford University, Stanford, CA, 3Howard Hughes Medical Institute, Stanford, CA, 4Department of Neurobiology, Physiology and Behavior, UC Davis, Davis, CA, 5Department of Mathematics, UC Davis, Davis, CA

The motility of fish epithelial keratocytes is typically highly directionally persistent, compared to other motile cells such as neutrophils or fibroblasts; but even for keratocytes cell trajectories are never perfectly straight. An open question remains as to what asymmetries along the left-right axis of the direction of cell motility arise to produce long-range cell turning events, which would be necessary for directed cell motions. In this study cell trajectories were characterized to quantify the amount of turning over time periods ranging from 2 minutes to 6 hours. An average individual keratocyte was found to exhibit approximately ninety degrees of rotation in traversing an average distance of 50 um over a time of 5 minutes. Cells could enter persistent states with high mean angular speeds yet low variance, producing circular tracks that retraced themselves. The magnitude of turning is an ergodic parameter, as an individual cell can transition between highly and poorly path persistent states. Cell shape was correlated to the magnitude of turning on the population level, and individual shapes become asymmetric during turns. Pharmacological inhibition of actin-myosin contractility inhibited cell turning, and conversely activation of myosin activity increased cell turning. Cells turned less at higher ambient temperatures, but other perturbations of actin motility or signaling pathways had no effect on turning. Cells can be forced to turn toward the cathode of an applied electric field (1 to 10 V/cm). Induced turns took ~5 minutes to complete and over-steering with a characteristic length scale (~30 um) was observed. Cells in a coherent turning event have small radii of curvature (~30 um) that produce up to a five fold speed differential along the leading edge. To produce higher speeds along the outer edge of the cell increased actin polymerization must occur on the side of the cell opposite the direction of the turn. This is correlated with an asymmetry in aspect ratio, actin distribution and myosin localization suggesting an organizational mechanism to maintain a persistent asymmetric state.

Insights from Quantitative Cell Shape Analysis - Intermittent Protrusions and Internal Waves.
M. Driscoll1, R. Kopace1, T. Homan1, S. Freedman1, J. Fourkas1, C. Parent2, W. Losert1,2; 1University of Maryland, College Park, MD, 2Laboratory of Cellular and Molecular Biology, National Cancer Institute, NIH, Bethesda, MD

Dynamic cell shape is a highly visible manifestation of the interaction between the internal state of a cell and its external environment. We quantitatively analyzed the dynamic change in shape of migrating Dictyostelium discoideum, a model system for the study of cellular migration. Using a snake algorithm, we extracted each cell boundary as 400 equidistant boundary points. By tracking each boundary point from frame to frame, we determine how measures associated with
boundary points, such as the local velocity and curvature of the boundary, change in time. To visualize and interpret the dynamic changes in cell shape we used modified kymographs or space-time plots, where space is measured along the boundary of the cell and color corresponds to the measure being visualized. This analysis shows that protrusions are intermittent and the direction of protrusions alternates in a zig-zag pattern, while retractions are sustained and straight. By comparing the spatial auto-correlation of the local motion, we found that extensions are more localized than retractions. From space-time plots of the local curvature, we see that localized protrusions originate at the front of cells and travel towards the back at a constant and reproducible speed of order ten microns per minute. We hypothesize that these localized protrusions of the cell membrane correspond to internal waves of actin polymerization and depolymerization. The speed and frequency of localized protrusions appears to exhibit greater inter-cellular variability than any effect induced by a wide range of surface chemistries, specifically glass, acrylic resin, bovine serum albumin, and gold nanoparticles. Having no surface, however, does appear to alter localized protrusions. The speed of localized protrusions on a cell whose front is protruding off of a tall cliff is greater than the speed of localized protrusions on cells migrating on surfaces.

A. Gulyani1, D. Gremyachinskiy1, E. Vitriol1, K. Hahn1, L. M. Graves1, B. J. Dewar1, B. Kay2; 1Pharmacology, University of North Carolina, Chapel Hill, NC, 2Department of Biology, University of Illinois, Chicago, IL

Biosensors that report activation of native, unmodified proteins can help delineate complex cellular processes with minimal perturbation of normal behavior. However, sensors for endogenous proteins are rare, in part due to the absence of readily available binding reagents that are selective for the active form of the targeted molecule. To address this issue we combined high throughput screening of engineered state-specific binding elements with a fluorescence-based reporting system that turns these elements into biosensors. We have targeted Src family kinases (SFKs) since they are key signaling nodes that control numerous cellular functions, including migration and adhesion. Also, the multiple roles performed by Src kinases and their involvement in several signaling networks suggest spatio-temporally regulated pools of SFK activities. Phage display screening was used to generate fibronectin domain III (FN3) binders that selectively bind SH3 domains from Src family kinases. Pull down experiments demonstrated that an FN3 binds selectively to active Src kinases. Using merocyanine dyes developed in our lab for live cell imaging, we have converted this FN3 into a sensitive fluorescence-based biosensor for activation of Src family kinases. The new sensors reveals patterns of Src activation in migrating cells and in cells stimulated with growth factors. In migrating cells, a distinct band of Src activation was observed at the leading edge. This transient activation coincided with protrusion. We also observed precisely timed Src activation in linear and circular dorsal ruffles. In keeping with our overall aim of developing a generally applicable strategy of sensor design, we have generated multiple binders using HT screening and are developing biosensors specific to individual Src family kinases.

Fluorescence Fluctuation Analyses Reveal That FAK-Paxillin and A5 Integrin-Talin Form Complexes within Adhesions.
C. K. Choi1, A. Bachir2, J. Zareno1, M. Digman2, E. Gratton2, R. Horwitz1; 1Cell Biology, University of Virginia, Charlottesville, VA, 2Laboratory for Fluorescence Dynamics and Department of Biomedical Engineering, University of California, Irvine, CA

Transient, localized protein interactions are central to adhesion formation, turnover, and signaling during cell migration. In highly motile cells, initial contact with the extracellular matrix is established via nascent adhesions in the lamellipodium. These adhesions function as signaling hubs that regulate protrusion and adhesion and also serve as traction points for migration. Paxillin
and its putative binding partner FAK have emerged as critical regulators of migration. Using dual-color total internal reflection fluorescence (TIRF) and confocal imaging modalities, we measured the simultaneous fluctuations of paxillin and FAK fluorescence intensity and used cross-variance and cross-correlation techniques to detect their interactions and kinetics in living cells at high spatiotemporal resolution. The TIRF-based cross-variance analysis shows that paxillin and FAK reside and exchange as multimeric complexes in nascent adhesions. A phosphomimetic mutant of paxillin (Y31E, Y118E), which increases protrusion and adhesion assembly and turnover, significantly increases the complex size. In contrast, a non-phosphorylatable paxillin mutant (Y31F, 118F) that suppresses adhesion turnover reduces the paxillin aggregation nearly 2-fold. In addition, confocal-based cross-correlation analysis (ccRICS) showed only minimal levels of wild-type paxillin and FAK interactions in the cytosol; however, the phosphomimetic mutant forms robust, freely diffusing complexes. We also investigated the associations between talin and α5 integrin, two molecules thought to link the ECM to actin. We measured the differences between their rates of assembly using a high resolution derivative as well as cross variance analyses. Both analyses show that α5 integrin and talin reside in complexes in stable adhesions but enter adhesions independently. Taken together, our measurements demonstrate the feasibility of identifying and quantifying molecular complexes at high spatiotemporal resolution in adhesions in living cells. Moreover, our data reveal that two interacting pairs, paxillin-FAK and integrin-talin, appear to form complexes after they enter adhesions rather than entering as preassembled complexes.

Spatio-Temporal Dynamics of RhoG Activation during Cell Migration.
C. Welch1, T. Samson2, J. Wu1, K. Burridge2, K. Hahn1; 1Department of Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Department of Cell and Developmental Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Background: Cell morphodynamics are critically important in a variety of normal and pathological processes, including neuronal cell migration in development, leukocyte transendothelial migration (TEM), and cancer cell metastasis. The Rho family GTPases are a class of molecular switches that regulate the cell cytoskeleton and cell migration. RhoG is a highly conserved but less well understood member of this family and plays a role in cell migration. Given that RhoG has been found to indirectly activate Rac1, we hypothesize that RhoG activation is involved in the initiation of cell protrusion at least in part by influencing the spatio-temporal dynamics of Rac1 activity. Testing this hypothesis requires measurement of RhoG activation and inactivation kinetics in real time. Methods: to test our hypothesis, we developed a new activation biosensor for RhoG, together with our published biosensor for Rac1 and computational approaches that allow us to resolve the coordination of Rho GTPases with submicron and seconds resolution. Using these techniques, we were able to relate RhoG and Rac1 activation locally to cell morphological dynamics, enabling us to determine the relationships between them and their effects on cell migration. Additionally, we have begun using this methodology to study leukocyte migration in a model of TEM. Results and Conclusions: RhoG is activated at the cell edge synchronous with edge advancement, whereas Rac1 is activated 2 μm behind the cell edge with a delay of 40 s relative to initiation of protrusion. Upon knockdown of RhoG, Rac1 activation shifts from 2 μm to 6.5 μm from the leading edge. These results demonstrate distinct roles at the leading edge for these GTPases. We have also found that Rac1 is activated with tight spatial and temporal control downstream of ICAM-1 engagement in a model of leukocyte TEM. This work was supported by NIH grants GM57464, GM008719, F30HL094020, and HL080166.

Apocynin and Its Derivatives Disrupt the Signaling Pathway Leading to Metastasis of Cancer Cells.
S. Nag, T. Bradke, G. Plopper, J. M. Mora, J. Dordick; Rensselaer Polytechnic Institute, Troy, NY

Cancer cells are characterized by the rapid, uncontrollable division and spreading of cells in the body. A drug that would suppress this process would prove to be very useful in the field of cancer
cell biology. The objective of this study was to show that Apocynin (4-acetovanillone), an NADPH oxidase inhibitor, inhibits the migration of cancer cells and to illustrate a mechanism by which it functions through a series of activity assays, such as Rac and Cdc42. Apocynin was the monomer used to synthesize Trimer Hydroxylated Quinone (HQIII), a more potent derivative of Apocynin, by enzymatic synthesis using soybean peroxidase enzyme. MTT proliferation and migration assays in a previous study illustrated a decrease in breast cancer cell metastasis when cells were exposed to Apocynin or HQIII at varying concentrations; similar results are obtained here in prostate cancer cells (DU-145). Filter-based migration assays demonstrate that cells treated with concentrations of Apocynin starting at 250 μM result in decreased cell migration. The more potent HQIII decreased cell migration at concentrations as low as .01 μM. The same concentrations had no affect on cell proliferation in the prostate cancer cells based on a MTT assay. These results indicate that Apocynin and it's derivatives could be a powerful anti-migratory compound for the treatment of cancer.

Synthetic Triterpenoids Target Actin-Related Protein 3 (ARP-3) and Inhibit Cell Migration.
C. To1, J. Di Guglielmo1, M. B. Sporn2; 1Physiology and Pharmacology, University of Western Ontario, London, ON, Canada, 2Pharmacology and Toxicology, Dartmouth Medical School, Hanover, NH

Synthetic triterpenoids are anti-tumor agents that affect numerous cellular functions including apoptosis, growth inhibition, anti-inflammation and cytoprotection. Previously, an imidazolide derivative of 2-cyano-3, 12-dioxooleana-1, 9-dien-28-oic acid (CDDO-Im) was shown to inhibit cell polarity and migration (To et al., J. Biol. Chem., 2008, 283: 11700-11713). The present study investigates the mechanism(s) whereby the synthetic triterpenoids inhibit cell migration. Using two proteomic approaches, protein array and mass spectrometry, we identified that Actin-related protein 3 (Arp3) and actin are triterpenoid binding proteins. Arp3, a subunit of the Actin-related protein 2/3 (Arp2/3) complex, is involved in branched actin polymerization and the formation of lamellipodia; processes which lead to cell migration. In-vitro pull down assays confirmed Arp3 to be a direct target of synthetic triterpenoids and immunofluorescence studies revealed that upon triterpenoid treatment, the localization of Arp3 and actin at the leading edge was inhibited. In-vitro branched actin polymerization was also observed to be inhibited by triterpenoids in a dose-dependent manner. Taken together, our data suggests that synthetic triterpenoids target Arp3 and branched actin polymerization to inhibit cell migration.

Simultaneous Reconstitution of MSP-Based Protrusion and Retraction in the Amoeboid Sperm of Ascaris.
K. Shimabukuro1, N. Noda2, M. Stewart3, T. M. Roberts1; 1Florida State University, Tallahassee, FL, 2Marine Biological Laboratory, Woods Hole, MA, 3MRC, Laboratory of Molecular Biology, Cambridge, United Kingdom

Crawling movement in eukaryotic cells is produced by coordination of the force for protrusion of the leading edge and with that for retraction of the trailing cell body. In Ascaris sperm, protrusion and retraction are powered by a motility system comprised of major sperm protein (MSP) in place of the actin apparatus typically associated with cell migration. To explore the detailed mechanism of the MSP-based force production we developed an In Vitro motility system in which adjustment of the ATP concentration in cell-free sperm extracts resulted in the simultaneous reconstitution of protrusion and retraction in MSP filament meshworks called fibers. Under these conditions, polymerization of filaments immediately behind plasma membrane-derived vesicles to push the vesicle forward was accompanied by filament rearrangement and disassembly that pulled the rear of the fiber forward. This simultaneous assembly-disassembly resembled the dynamics of actin comet tails observed in Listeria and related In Vitro systems. Analysis of platinum replicas by EM showed a progressive loss of filament density from the front to the back of MSP comet tails. Interestingly, we also found that filaments in the retracting region of the tail exhibited alignment along the fiber axis that was not evident at the growing end of the tail. Thus, filament
orientation changes during fiber retraction. To explore this reorientation in real time we examined live MSP comet tails using a liquid crystal polarization microscope (LC-Polscope). We detected a chevron-like orientation of filaments at the newly assembled growing end of the comet tail that gradually converted to the axis-aligned pattern observed by EM as the comet tail disassembled and retracted. These data suggest that cell body retraction in *Ascaris* sperm is powered by the rearrangement and interaction of the subset of MSP filaments that survive depolymerization. Because no molecular motor proteins have been identified in the MSP motility apparatus the movement of filaments during MSP-based retraction appear to occur without the assistance of components analogous to myosin. Supported by NIH Grant R37 GM29994.

**Rapidly Locomoting Fish Epithelial Keratocytes Switch Among Three Adhesion-Dependent Migration Regimes.**

E. Barnhart\(^1\), G. Allen\(^2\), A. Mogilner\(^4\), J. Theriot\(^1\), \(^2\), \(^3\); \(^1\)Department of Biochemistry, Stanford University, Stanford, CA, \(^2\)Howard Hughes Medical Institute, Stanford University, Stanford, CA, \(^3\)Department of Microbiology and Immunology, Stanford University, Stanford, CA, \(^4\)Department of Mathematics, University of California Davis, Davis, CA

Keratocytes are fast-moving cells in which adhesion dynamics are tightly coupled to the actin polymerization motor that drives migration, resulting in highly coordinated cell movement. We have found that modifying the adhesive properties of the underlying substrate has a dramatic effect on keratocyte morphology. Cells plated on intermediate adhesion strength surfaces looked like stereotypical keratocytes, characterized by a broad, fan-shaped lamellipodium and persistent rates of protrusion and retraction. Cells plated on low adhesion strength surfaces were small and round with noisy protrusion and retraction rates, and cells on high adhesion strength surfaces were large and asymmetrical and, strikingly, exhibited traveling waves of protrusion. In addition, we imaged individual keratocytes as they crawled on micropatterned substrates, moving from regions of low to medium adhesion strength and from regions of medium to high adhesion strength. Individual cells were able to immediately transition among the adhesion-dependent behaviors observed in populations of cells, indicating that changes in adhesion strength of the underlying surface are sufficient to switch keratocytes between the three adhesion-dependent migration regimes. To elucidate the mechanisms by which adhesion strength determines cell behavior, we examined the size and distribution of adhesions and the organization and dynamics of the actin network in keratocytes migrating on substrates with different adhesion strengths. Our results suggest that on low adhesion strength surfaces, cell behavior is primarily dependent on the balance between adhesion forces and myosin contraction, and on high adhesion strength surfaces, cell behavior is primarily dependent on cycles of myosin-dependent maturation of adhesions, which periodically inhibit polymerization of the dendritic actin network at the leading edge, resulting in traveling waves of protrusion. on the whole, our results are consistent with a model in which keratocyte migratory behavior emerges from the self-organization of actin, adhesions, and myosin, and quantitative changes in either adhesion strength or myosin contraction switch keratocytes among migration regimes.

**Characterization of a Cell Invasion Assay for High Content Screening.**

K. I. Hulkower\(^1\), D. Onley\(^2\), P. Wylie\(^2\); \(^1\)Platypus Technologies LLC, Madison, WI, \(^2\)TTP LabTech Ltd., Herts, United Kingdom

The drug discovery process for novel anti-metastatic therapies depends upon robust screening assays that mimic 3-Dimensional tumor cell invasion through an extracellular matrix. We have utilized the 96-well Oris™ cell-based assay platform to perform 3-D invasion assays. Cells are seeded into wells coated with an extracellular matrix (ECM) such as basement membrane extract (BME) or type I collagen. These wells contain a silicone stopper that occludes cells from the well center and following cell attachment, the stoppers are removed to reveal a central exclusion zone that is void of cells. A second layer of ECM is overlaid onto the wells and cells are then permitted to invade into the exclusion zone. We have established the relative invasiveness of two widely
studied human cancer cell lines, HT-1080 fibrosarcoma and MDA-MB-231 breast carcinoma, using different concentrations of ECM overlays. Cells were fixed and stained with TRITC-phalloidin and DAPI followed by readout with the Acumen® eX3 high content microplate cytometry system. Results demonstrate that HT-1080 cells invade more aggressively than MDA-MB-231 cells into both BME and type I collagen gel overlays and that the amount of invasion for a given cell line is inversely proportional to the concentration of ECM used in the overlay. Additionally, use of the nuclear stain DAPI provides a more accurate quantitation of the number of invading cells compared to the F-actin stain. Our results suggest that 3-D invasion assays can be optimized for use with a variety of cancer cell lines by employing high content screening systems for data acquisition to generate Z’-factors suitable for compound screening.

**C. elegans** FOG-3 Can Affect Germline Proliferation, Differentiation and Survival.

J. Snow¹, M. Lee², P. L. Kroll-Conner², J. Kimble¹,²,³; ¹Program in Cellular and Molecular Biology, University of Wisconsin-Madison, Madison, WI, ²Howard Hughes Medical Institute, Madison, WI, ³Department of Biochemistry, University of Wisconsin-Madison, Madison, WI

FBF, FOG-1 and FOG-3 are key members of a regulatory network that controls germline fates in *Caenorhabditis elegans*.¹ FBF is a Puf RNA-binding protein, FOG-1 is a CPEB RNA binding protein, and FOG-3 is a Tob BTG homolog.¹ FBF regulates the expression of FOG-1 and likely FOG-3²; FOG-1 and FOG-3 are required for sperm fate specification and can influence germline proliferation,¹,² but less is known about how they drive those biological fates. This work focuses on our preliminary studies of FOG-3 and its control of germline fates. We first used genetic mosaics to confirm that FOG-3 controls the sperm/oocyte decision by acting within the germline tissue, as expected.¹ We next used a rescuing FLAG-tagged FOG-3 transgene to explore FOG-3 expression. FLAG-FOG-3 is seen in early meiotic germ cells destined to become spermatocytes, but it is no longer detectable in primary spermatocytes. That pattern is consistent with its role in sperm specification. FLAG-FOG-3 is primarily cytoplasmic, suggesting a post-transcriptional role. [In vertebrates, Tob BTG proteins have been implicated in both transcriptional and post-transcriptional controls.⁴] We are exploring FOG-3 dosage effects, in part because such effects were found for FOG-1.² Dosage effects are not seen in a wild-type background,⁵ but germlines in the progeny of *fbf(0); fog-3/+* animals can be spermatogenic, oogenic, deteriorated or tumorous. Our current experiments are focused on understanding how the dose of FOG-3 influences the network to produce these phenotypes. <P> <P>¹ Kimble J, Crittenden SL. **A Novel CRL4⁰DCAF1 E3 Ubiquitin Ligase Complex Is Critical for Ribosome Biogenesis and Nucleolar Morphology in C. elegans Germ Cells.**

M. M. Rahman¹, Y. Kim¹, R. Proenca², E. Hedgecock³, E. T. Kipreos¹,²; ¹Genetics, University of Georgia, Athens, GA, ²Cellular Biology, University of Georgia, Athens, GA, ³Biology, Johns Hopkins University, Baltimore, MD

Cullin4 RING finger ubiquitin ligase (CRL4) complex is a key regulator of DNA replication initiation. Inactivation of CRL4 function produces a fully penetrant germ cell growth defect in nematode *C. elegans* although there is no evidence of DNA re-replication usually observed in
somatic cells. Notably, nucleoli in the mutant germ cells exhibit an abnormal, globular morphology. We identified DCAF-1 (DDB1 and CUL4-associated factor) as the substrate recognition subunit for the CRL4 germline function. The dcaf-1 mutant animals develop slower than wild type, and become sterile adults. We noticed that ncl-2 mutants have a similar germ cell nucleolar morphology defect implying that they are the same gene as dcaf-1 and ncl-2 mutants fail to complement each other. Transmission electron microscopy reveals that mutant germ cells possess fewer ribosomes than wild type, suggesting a profound defect in ribosome biogenesis. Recently we observed that reducing the activity of FOG-1, a cytoplasmic polyadenylation element binding (CPEB) protein, rescues the dcaf-1 germ cell nucleolar defect. We are currently investigating the role of CPEB proteins in ribosome biogenesis in order to better understand the molecular mechanisms underlying this novel function of the CRL4 DCAF1 complex in germ cell growth.

Regulation of P Granule Integrity by the Phosphatase PP2A.
J. T. Wang, C. M. Gallo, G. Seydoux; Johns Hopkins School of Medicine/HHMI, Baltimore, MD

Germ granules are ribonucleoprotein complexes found uniquely in germ cells. The mechanisms that hold these complexes together are not known. In the C. elegans zygote, germ granules are partitioned to the germline through a series of asymmetric divisions that separate soma from germline. During each division, P granules are selectively disassembled in the area of the cytoplasm destined for the somatic daughter cell, and are maintained and grow in size specifically in the area of the cytoplasm destined for the germline daughter cell. To gain insights into this process, we performed an RNAi screen for regulators of P granule integrity and identified protein phosphatase 2A (PP2A). Inactivation of the PP2A regulatory subunit caused P granules to disassemble throughout the cytoplasm during mitosis. As a result, P granule proteins were segregated equally into both somatic and germline daughter cells. Surprisingly, however, after division, P granules reappeared only in the germline daughter. Consistent with symmetric inheritance of P granule components, the P granules grew smaller and fewer with each division, eventually becoming almost undetectable. The embryos, however, developed normally and experienced only a partial loss of fertility. We conclude that asymmetric segregation of P granules during mitosis depends on the phosphatase PP2A, and is only essential for maximal fertility.

Regulation of RNP Granule Assembly in Oocytes.
A. Alker1, M. Hanson1, C. Aguirre1, M. Jud1, E. Beshore2, J. Patterson1, A. Goike1, K. Bennett2, J. Schisa1; 1Biology, Central Michigan University, Mount Pleasant, MI, 2Molecular Microbiology and Immunology, University of Missouri, Columbia, MO

As C. elegans hermaphrodites age, sperm become depleted, ovulation arrests, and oocytes accumulate in the germline. Large ribonucleoprotein (RNP) granules form in arrested oocytes that include: P granule proteins, P body proteins, and stress granule proteins. Large RNP granules also assemble in non-arrested oocytes when worms are exposed to environmental stresses such as heat shock and anoxia (1). We hypothesize RNP granules function in arrested or stressed oocytes to maintain RNA stability or prevent precocious translation until fertilization or a stress-free environment resumes. The somatic branch of the major sperm protein pathway appears to regulate the subcellular changes of RNPs in arrested or stressed oocytes (1). Our current goal is to better define the pathways regulating the assembly of the different classes of proteins that aggregate into large RNP granules in oocytes. We have undertaken a functional RNAi screen to identify genes required for RNP assembly when ovulation is arrested and identified 31 genes including: putative RNA-binding proteins, proteins involved in ribosome biogenesis, and several ATP and GTP-binding proteins including the C. elegans homolog of Dicer, dcr-1. In a candidate gene approach we have identified GLH-1 as a regulator of MEX-3, PGL-1, and CGH-1 assembly into granules. We have determined that GLH-1 and DCR-1 are mutually dependent by Western analyses, and that DCR-1 localizes to large granules in oocytes. Interestingly, MEX-3 ectopically localizes to large granules in young, dcr-1 worms, suggesting DCR-1 negatively regulates granule
assembly in young worms. Complementary TEM studies are aimed at further characterizing the ultrastructure of germline RNP granules both in arrested oocytes and in immature germ cells when granules are associated with the nuclear envelope. Preliminary analyses reveal the presence of free membranes with nuclear pores in arrested oocytes that are similar in appearance to annulate lamellae and an enrichment of nuclear pores clustered on nuclear envelopes at the position of RNP granules. 1) Jud et al., 2008. Dev Biol 318: 38-51.

Polyadenylation of Stored Transcripts Mirrors Translational Patterns and Is Necessary for Proper Development during Spermatogenesis in Marsilea vestita.
T. Boothby, S. M. Wolniak; Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

The regulated translation of stored mRNA is an important mechanism that underlies rapid development in a variety of organisms. The processing of stored transcripts is central in controlling rates and extents of rapid morphogenesis. The transcriptionally-quiescent process of spermatogenesis in the water fern Marsilea vestita offers an opportunity to study the mechanisms of post-transcriptional regulation and its role in rapid gamete development. The spermatozooids of Marsilea develop in an endosporic gametophyte that arises from a single meiotic cell contained within a microspore. Development begins with hydration of the microspore, which is followed by 9 rapid mitotic divisions cycles that produce 7 sterile cells and 32 spermatids. Each spermatid undergoes de novo basal body formation, cytoskeletal assembly, nuclear remodeling, elongation and coiling, and finally ciliogenesis, to form a motile male gamete. Throughout the 11 h process, little if any transcription occurs; instead development relies on the translation of stored transcripts and the utilization of new and stored proteins in gamete formation. We are interested in the role of polyadenylation in regulating the translation of stored RNA during spermatogenesis in the gametophyte. RNAi silencing and antibody localization assays were performed on homologs of the Cytoplasmic Polyadenylation Specificity Factor (CPSF100) and Cytoplasmic Polyadenylation Polymerase (PAP), respectively. CPSF100 silencing resulted in perturbed development, with the most severe effects halting gamete formation around 2 hours. from 2 hours of development up through full maturation, dramatic PAP accumulation was seen in the cytoplasm of spermatogenous but not sterile cells. The polyadenylation of stored transcripts was also assayed. Transcripts encoding the developmentally important homologs of Centrin, Magonashi, and SERK, all appear to undergo different levels of polyadenylation over time and these patterns presage the apparent levels of translation of each mRNA. These findings indicate that polyadenylation plays a key role in controlling the translation of stored transcripts in the male gametophytes of Marsilea vestita. Supported by NSF grants MCB-0720486 and DBI-0842525 to SMW.

Characterization of Peroxiredoxin 3 Protein Expression in Drosophila melanogaster Testes.
M. Rivera1, J. Rollins2, T. M. Onorato1; 1Natural Sciences, LaGuardia Community College, Long Island City, NY, 2Natural Science, College of Mount Saint Vincent, Riverdale, NY

Peroxiredoxin 3 (Prx3) is a mitochondrial thioredoxin-dependent peroxidase that neutralizes excess peroxides, and helps protect against oxidative-stress-induced apoptosis. The gene DPX-5037 in Drosophila melanogaster encodes for a homolog of mammalian Prx3. DPX-5037 mRNA is expressed in all stages of Drosophila development. However, Prx3 protein expression in the Drosophila testes has not yet been established. We utilized immunofluorescence microscopy to examine the expression of Prx3 in the fly testis. Whole mounts and squashes were prepared from testes dissected from 0-3 day old flies. No signal was detected in control samples that were incubated without anti-Prx3 serum or heated anti-Prx3 serum. Signal was detected when samples were incubated with a 1:500 dilution of anti-Prx3 serum. Prx3 appears to be expressed in spermatogonia, spermatocytes, and round haploid spermatids. Prx3 signal is detected in the nebenkern as well as in the unfurling mitochondrial derivative. However, immunofluorescence did
not reveal any signal in the individualized sperm. Further studies using confocal microscopy will have to be performed to determine whether Prx3 is present in the tails of individualized sperm. In addition to establishing Prx3 protein expression in the adult fly testis, we also examined whether Prx3 is expressed in the larval testis. Whole mounts of testes dissected from wandering third instar larvae were prepared. Prx3 protein was detected in the larval testis. In summary, this study shows for the first time that the Prx3 protein is expressed in both larval and adult fly testes. Prx3 is expressed in the nebenkern and the unfurling mitochondrial derivatives. Further studies will be conducted to determine the role of Prx3 in Drosophila spermatogenesis.

Auxilin Is Required for Proper Plasma Membrane Formation during Drosophila Spermiogenesis.
H. C. Chang, X. Zhou; Biological Sciences, Purdue University, West Lafayette, IN

In Drosophila, clathrin-mediated transport has been implicated in spermiogenesis, during which the haploid spermatids undergo drastic cell shape change to become functional sperms. It has been long appreciated that this transformation of spermatids from ovoid cells to long string-like cells requires extensive membrane biosynthesis and remodeling, although the precise mechanism remains unclear. To further understand the role of clathrin in this process, we have analyzed the phenotypes of viable Drosophila auxilin (dAux) mutations. As auxilin is known to participate in clathrin-mediated transport at multiple steps, dAux mutant males are sterile and produce no mature sperms. This reproductive defect of dAux males could be restored by germ cell-specific expression of dAux, indicating that, for spermatogenesis, auxilin function is required cell autonomously in the germ cells. EM analysis showed that in dAux mutant, the plasma membrane surrounding spermatids was not formed properly, resulting in the subsequent defect in investment cone (IC) migration. To understand the role of clathrin in spermatid elongation, we placed a GFP-tagged clathrin under the control of a germ cell-specific promoter. Using this reagent, we showed that, in wild type, intensely clathrin-positive vesicular structures were seen around the cell periphery and in the vicinity of the Golgi. In contrast, clathrin appeared mostly associated with enlarged Golgi in dAux mutants. Based on these results, we propose that during spermatid differentiation, clathrin mediates the membrane transport from the Golgi to the cell surface. In the absence of clathrin function (e.g. in dAux mutants), these Golgi-derived clathrin-dependent vesicles become reduced and the formation of the plasma membrane is deficient. Our data suggest that clathrin functions in both the endocytic and the secretory pathways during Drosophila development.

Signaling Pathways in Activation of Water Strider Sperm Motility.
C. D. Thaler, H. Miyata, L. T. Haimo, R. A. Cardullo; Department of Biology, University of California, Riverside, Riverside, CA

Sperm are often maintained in a quiescent state and exhibit beating only upon activation by a signaling event. We are investigating the regulation of motility of sperm from the water strider Gerris remigis, which, like many insect species, produces extremely long sperm. The sperm flagellum of the water strider is ~2500 μm in length and can generate waveforms of varying amplitudes and frequencies. These sperm also exhibit a very unusual motility in which a region of the flagellum loops back upon itself and the two sections of the flagellum then rapidly twist around each other to form a tight helically coiled region. Sperm stored in the male seminal vesicles are normally immotile, but motility can be stimulated by addition of trypsin. We are investigating the signaling pathways that mediate activation of motility. The broad spectrum kinase inhibitor staurosporine completely blocked trypsin induced motility, and, conversely, the phosphatase inhibitor calyculin a was sufficient to activate motility. Sperm loaded with BAPTA-AM exhibited reduced levels of trypsin-induced motility, which was partially restored by the addition of A23187 and calcium. Incubation with A23187 and calcium alone partially activated immotile sperm, but to a lesser extent than calyculin A. These data suggest that a calcium sensitive component, potentially a kinase, mediates activation of motility. Preliminary results also suggest that several
sperm proteins are serine phosphorylated following trypsin activation. Trypsin has previously been suggested to activate sperm by degrading a glycoprotein matrix around the sperm, but treatment with PNGase F did not activate motility. Further, activation of motility by calyculin A alone suggests that degradation of a matrix is not required. Potentially, trypsin may activate a PAR2 type receptor on sperm to stimulate motility. Treatment of immotile sperm with thrombin, at levels of enzymatic activity equivalent to trypsin, did not activate motility, which is consistent with the behavior of the vertebrate PAR2 receptor. Characterization of this signaling cascade may reveal how sperm are maintained in a quiescent state until motility is activated.

The Motility Lifetime of *Xenopus laevis* Sperm Is Extended by Egg Jelly-Derived Factors.
N. Tholl1, S. Boyles1, E. McLaughlin1, A. Bieber2, D. Chandler1; 1School of Life Sciences, Arizona State University, Tempe, AZ, 2Department of Chemistry and Biochemistry, Arizona State University, Tempe, AZ

*Xenopus* sperm motility is initiated by the osmotic shock experienced when these cells are delivered from the testes into low salt pond water. Motility is brief, a number of minutes, and is required for the sperm to penetrate the jelly layers and fertilize the egg. In this study we use video and time-lapse microscopy to demonstrate that egg jelly contains substances that prolong the motility lifetime of these sperm. The number of motile sperm in F1 (low salt) buffer decreased exponentially with a half time of about 3 minutes when viewed under cover glass. Addition of 10% v/v “egg water” (a jelly extract) increased the number of motile sperm about 2-fold over controls at 20 seconds and about 4- to 10-fold over controls between 5 and 10 minutes after initiation of motility. Egg water did not increase the average forward velocity of the sperm and the effect of egg water on motility lifetime was reduced but not eliminated in the absence of calcium (<10^{-7} M). Bovine serum albumin (20 μg/ml) and glucose (1 mM) did not produce this effect suggesting that it is not due to non-specific proteins or an energy source. Purified allurin, a 21 kD jelly protein known to be a sperm chemoattractant, did not produce this effect, indicating that other components of egg water are responsible. Motility of *Xenopus laevis* sperm and their response to egg water appeared to be seasonal with lower motility and response being observed in winter as opposed to spring. This study was supported by the NSF.

Distribution of Cystatin Related Epididymal Spermatogenic (CRES) Protein in the Testis, Efferent Ducts and Epididymis and Alterations Associated with Its Absence in Cst8-/- Knockout Mice.
A. D. Parent1, G. A. Cornwall2, L. Y. Liu1, C. E. Smith3, L. Hermo1; 1Cell Biology, McGill University, Montreal, QC, Canada, 2Cell Biology and Biochemistry, Texas Tech University Health Sciences Center, Lubbock, TX, 3Stomatologie, Université de Montréal, Montreal, QC, Canada

CRES (Cst8) is a member of the cystatin superfamily of cysteine protease inhibitors. It differs from typical cystatins because it lacks consensus sites for cysteine protease inhibition and exhibits reproductive tract-specific expression. In the present study, we examined CRES expression within the testis, efferent ducts (EDs) and epididymis of normal mice by light microscope immunolocalization (LMI) following tissue fixation with zinc and by wide-field fluorescence imaging. Alterations to these tissues in Cst8-/- mice were also characterized by histomorphometry and electron microscopy (EM). In the testis of wildtype mice, CRES expression was restricted to the cytoplasm of elongating spermatids, while in the epididymis, principal cells showed intense supranuclear reactivity predominantly in the initial segment. The latter was suggestive of CRES secretion as also indicated by luminal reactions associated with sperm. In the cauda region, CRES appeared to be endocytosed by clear cells. In addition, distinct aggregates of CRES reactivity were noted in the epididymal lumen suggestive of its oligomerization. The presence of CRES mRNA by RT-PCR analysis in the EDs, along with the protein seen by LMI in the epithelium, suggests that the EDs synthesize CRES rather than endocytose it from the lumen. In older Cst8-/- mice, statistically significant reductions in tubular, epithelial and luminal profile areas of testis and epididymis were found compared to age-matched
wild type mice. Further analyses revealed significant differences by stages of the cycle in Cst8-/mice. In the EM, Cst8-/ mice showed vacuolated seminiferous epithelium, degenerating germ cells and premature release of germ cells into the epididymal lumen, which also contained abnormal sperm and the presence of large amorphous cocoon-like bodies. In addition, principal cells of the epididymis contained numerous large irregularly shaped lysosomes suggestive of lysosomal storage disease. These findings suggest that CRES is essential for testis and epididymal integrity and functions related to normal sperm maturation. (Supported by NIH HD56182 (GAC) and CIHR).

Characterization of Rex1 (zf42) Knockout Mice.
M. Lee¹, A. Lu², L. J. Gudas¹; ¹Pharmacology, Weill Cornell Medical College of Cornell University, New York, NY, ²inGenious Targeting Laboratory, Stony Brook, NY

The Rex1 (zf42) gene has been identified by its reduced expression in F9 teratocarcinoma cells after retinoic acid treatment and is now considered one of the several stem cell markers in a complicated transcriptional network. Although the Rex1 gene has been studied extensively for several years, most of these studies focused on either its expression pattern or its interaction with other stem cell markers by chromatin immunoprecipitation assay. However, the function of Rex1 has not yet been thoroughly investigated. To study the function of Rex1, we created Rex1 knockout mice by homologous recombination followed by a conditional knockout using the Lox/Cre system. The results showed that the Rex1 knockout mice were not embryonic lethal and the ratio of male and female pups followed the expected Mendelian inheritance. Both male and female knockout mice were fertile. However, the fertility of male knockout mice seemed to decrease with age. The testis, which is the only adult tissue that has been shown to express Rex1, showed phenotypes followed. We found many vacuoles in the seminiferous tubules of Rex1 knockout mice and disruption of the edge of the tubules. Testes size was smaller in knockout mice as compared to normal, and sperm count was also decreased in the knockout male mice. TUNEL assay showed increased apoptosis in Rex1 knockout testes compared to wild type. Staining for the cell proliferation marker, PCNA, indicated abnormal cell proliferation and immunohistochemistry with specific cell markers, including androgen receptor, p450 scc, and dazL also showed abnormalities in Rex1 knockout mice. From these data, we conclude that the major function of the Rex1 gene may play a role in the process of spermatogenesis and may somehow affect Leydig cell function.

The Blood-Epididymal Barrier Is Altered in Obstructive Azoospermic Patients.
E. Dube¹, J. Dufrènes¹, L. Hermo², P. Chan³, D. Cyr¹²; ¹INRS-Institut Armand-Frappier, Laval, QC, Canada, ²Anatomy and Cell Biology, McGill University, Montreal, QC, Canada, ³Urology, McGill University, Montreal, QC, Canada

Azoospermia, defined as the absence of spermatozoa in the ejaculate, is present in 10 to 15% of infertile men and can be due to an obstruction of the epididymis. The epididymis is responsible for post-testicular sperm maturation. This maturation is dependent upon the creation of a specific microenvironment in the epididymal lumen which is partly created by the blood-epididymis barrier. This barrier is formed by apical tight junctions (TJ) between adjacent principal and principal/clear cells that line the epididymal lumen. Although several tight junctional proteins, including occludin and a large number of claudins (CLDNs), have been identified in the human and rat epididymis, their role and regulation in male infertility are relatively unknown. Our objectives were to determine if the blood-epididymis barrier was altered in obstructive azoospermic patients. In different regions of the epididymis of obstructive azoospermic patients, we observed by real-time PCR an altered expression of CDH1, TJP1, and CLDN1, 4, 7 and 10 compared to the same region of the epididymis of fertile patients. These results were confirmed by immunohistochemistry for CDH1 and TJP1. UsingIHCE1 cells, which are novel cell lines derived from the caput epididymidis of an obstructive azoospermic patient, we noted lower expression levels of several genes encoding junctional proteins (CDH1, CDH2, CLDN1, 3, 4, 7 and 8) than cell lines derived
from a fertile (FHCE1) patient. In addition, IHCE1 cells were not able to form tight junctions, as determined by measuring the transepithelial resistance (TER) across the cells, in contrast to FHCE1 cells. Microarray analyses comparing gene expression in IHCE1 and FHCE1 cells revealed differential expression of several genes encoding other junctional proteins and regulators of cellular junctions, such as RAB13, CDC42 and SNAI2. These results suggest that disruption of adherens, tight and gap junctions could therefore be involved in obstructive azoospermia and that the regulation of human epididymal TJs depends on the activation of specific intracellular signalling pathways. Supported by CIHR, FRSQ, and Armand-Frappier Foundation.

Identification of Proteins Interacting with Adam7 in Sperm Membrane in Mice.
C. Han, C. Cho; Life Science, Gwangju Institute of Science and Technology, Gwangju, Korea, South

In mammals, sperm acquire motility and an ability to fertilize eggs in the epididymis. This maturation process involves the acquisition of particular proteins from the epididymis. One of such secretory proteins is a disintegrin and metalloprotease 7 (ADAM7) expressed specifically in the epididymis. ADAM7 belongs to a family of transmembrane proteins, sharing a conserved multidomain structure: an N-terminal signal sequence, pro-, metalloprotease, disintegrin, cysteine-rich, EGF-like, transmembrane and cytoplasmic domains. Previous studies have shown that ADAM7 residing in an intracellular compartment of epididymal cells is transferred to sperm and the level of ADAM7 on sperm is dependent on the expression of ADAM2 and ADAM3 with critical roles in fertilization. In the present study, we investigated a molecular mechanism underlying interaction between ADAM7 and sperm. Immunoprecipitation with sperm lysates was performed using an anti-ADAM7 antibody and the resulting precipitates were analyzed by mass spectrometry. The proteomic analysis revealed that ADAM7 forms complexes with calnexin (Canx), heat shock protein 5 (Hspa5, a.k.a. glucose-regulated protein, 78 kDa) and integral membrane protein 2B (Itm2B). The interaction of ADAM7 with these proteins was confirmed by immunoprecipitation-western blot analysis. We found that ADAM7-interacting Canx, Hspa5 and Itm2B are located on the sperm membrane and, partly, in a detergent-resistant region in the membrane. Thus, our results suggest that the ADAM7 transfer from the epididymis to sperm occurs at the specialized domain on the sperm surface and ADAM7 functions in the fertilization process through the formation of the chaperonic complex.

Meiotic Maturation Arrest Is Associated with Synaptic Disruptions in Human Zygotene-Pachytene Spermatocytes, Aberrant Sumoylation and Ubiquitylation.
K. Hwang1, P. W. Brown1, P. N. Schlegel1,2,3, P. L. Morris1,2,3; 1Center for Biomedical Research, Population Council, New York, NY, 2The Rockefeller University, New York, NY, 3Urology, Weill Cornell Medical College, New York, NY

Spermatogenesis is highly susceptible to errors that result in reduction or failure in sperm production. Little is understood regarding underlying causes for meiotic arrest (MA) in men, while experimental genetic models have offered some insights regarding abnormal gene and protein expression. Using proteins extracted from human testes with normal spermatogenesis, we demonstrated that small ubiquitin-related modifier (SUMO) interactions occur during meiosis and synapsis, including SUMOylation of the synaptonemal complex (SC). To investigate whether faulty meiotic protein modifications could participate in MA, we isolated spermatocytes from biopsy materials obtained for possible testicular sperm extraction (TESE) for ART. Spermatocytes were obtained from men with obstructive azoospermia but normal spermatogenesis and those with non-obstructive infertility and MA, documented by histopathology. Fluorescent in situ hybridization (FISH), immunodetection and high-resolution bioimaging were performed. In an individual with MA, spermatocytes arrested at the zygotene-pachytene transition, with few observed to be in “true pachytene”; spermatocytes displayed prolonged asynaptic regions with possible non-homologous pairing. To identify whether double strand breaks (DSBs) were
resolved through meiotic recombination, spermatocytes were labeled with MLH1. MLH1 normally appears as small foci on SC throughout pachytene. In the MA patient, although there were no typical pachytene, MLH1 was identified, but with diminished intensity and greatly reduced foci. Aberrant SUMO-1 association was seen in zygotene-like cells with synapsed regions of incompletely synapsed chromosomes; normally SUMO-1 localizes to SC structures only after complete synapses. In MA, all prophase spermatocytes showed significant nuclear ubiquitin (Ubq) localization. In contrast, no ubiquitin (Ubq) was observed in spermatocytes from control samples at any stage of meiotic prophase. We demonstrate spermatogenic arrest at meiosis associated with aberrant SUMO-1 and Ubq in zygotene-to-pachytene transition spermatocytes, findings suggestive of a possible pathogenic role of SUMO-1 and Ubq in at least some patients with infertility.

Molecular Basis of the Upregulation of Store-Operated Calcium Entry in Mammalian Maturing Oocytes.

E. Pozo-Guisado¹, C. Gómez-Fernández², I. Álvarez², F. Martín-Romero¹; ¹Biochemistry and Molecular Biology, University of Extremadura, Badajoz, Spain, ²Cell Biology, University of Extremadura, Badajoz, Spain

Calcium waves at fertilization trigger a number of cellular events that are required for the exit from metaphase II arrest and the resumption of the cell cycle in mammalian oocytes. We have suggested that store-operated calcium entry (SOCE) can be directly involved in Ca²⁺ signaling in mammalian oocytes at fertilization by regulating calcium influx. Upon ER depletion, the protein STIM1 which acts as Ca²⁺ sensor within the intraluminal space of this store, aggregates and activates a series of calcium channels at the plasma membrane, including ORAI1. However, the presence of ORAI proteins and its possible role on Ca²⁺ signaling has never been described in oocytes. On the other hand it is accepted that those mechanisms involved in the control of Ca²⁺ spikes are strictly optimized during meiotic maturation of oocyte, i.e. in the transition from immature germinal vesicle (GV) to mature oocyte (metaphase II or MII oocyte). After inducing meiotic maturation of mouse oocytes In Vitro we measured SOCE triggered by the treatment with 5 μM thapsigargin (TG) in Ca²⁺-free medium. We found that SOCE was absent in GV, whereas a minor SOCE was detected in GV breakdown stage (GVBD, prometaphase I). SOCE was found in intermediate levels in MI oocytes compared to the highest levels in MII oocytes. Although RT-PCR from total RNA using random primers showed similar levels of Stim1 transcripts in all stages of maturation, immunoblots revealed that STIM1 protein level is low in GV and that a sharp increase of expression occurs at the GVBD stage. Moreover, the relocalization of STIM1 triggered by the emptying of intracellular stores with TG, a marker of SOCE activation, was negligible in GV or GVBD, and limited in MI oocytes. Finally, we observed that Orai1 transcripts were present in all stages of maturation and that ORAI1 protein levels remained constant during this meiotic maturation. Taken together, our results suggest that STIM1 but not ORAI1 levels are limiting SOCE in immature oocytes and that the meiotic upregulation of STIM1 supports a fully response to ER depletion in MII oocytes. Supported by Junta de Extremadura (grant PDT08A027) and Ministerio de Ciencia e Innovación (grant BFU2008-00104).

STIM1 Relocalization in Mouse Oocytes at Fertilization Suggests an Early Involvement of Store-Operated Calcium Entry.

C. Gómez-Fernández¹, E. Pozo-Guisado², M. Gañán-Parra², M. Perianes¹, I. Álvarez¹, F. Martín-Romero²; ¹Cell Biology, School of Life Sciences. University of Extremadura, Badajoz, Spain, ²Biochemistry and Molecular Biology, School of Life Sciences. University of Extremadura, Badajoz, Spain

The transient and repetitive increases of the cytosolic free Ca²⁺ concentration are considered a crucial event in mammalian oocytes at fertilization. This signaling is essential for the exit from metaphase II arrest and the resumption of the cell cycle. This signaling is initiated by the sperm-specific phospholipase C (PLC) zeta with the production of inositol 1,4,5-trisphosphate, that binds
to its receptor at the endoplasmic reticulum (ER), leading to the release of Ca\textsuperscript{2+} from this intracellular store. In order to assess the contribution of store-operated calcium entry (SOCE) to this signaling we studied the localization of the protein STIM1 in oocytes under different experimental conditions. STIM1 has been described to recruit and activate store-operated calcium channels at the plasma membrane in other cell types. RT-PCR of total RNA isolated from oocytes, and immunoblot experiments show that STIM1 is expressed in mouse oocytes. Moreover, immunolocalization of the endogenous STIM1 demonstrate an ER-dependent distribution in clusters close to the plasma membrane in resting oocytes. Treatment of oocytes with 5 \( \mu \)M thapsigargin (TG) or 10 \( \mu \)M ionomycin leads to the rapid depletion of ER. In parallel, there is a significant redistribution of STIM1 over larger areas covering the periphery of the oocyte during this treatment, confirming that STIM1 senses calcium concentration within ER in oocytes. Since the pharmacological activation of endogenous PLC with \( m \)-3M3FBS induces a TG-like redistribution of STIM1 in the oocyte, we tested the hypothesis that SOCE could be involved in signaling at fertilization, a PLC-mediated process. We found that fertilization of oocytes leads to a significant and rapid relocalization of STIM1. In addition, short times of exposure of oocytes to sperm demonstrated that STIM1 relocalization is a very early event in fertilization, matching well with the first Ca\textsuperscript{2+} spike found at fertilization in mouse oocytes (i.e. 7-15 min after the exposure to sperm) suggesting that SOCE could be involved not only in the support of the long-lasting calcium waves, but also in the generation of the earliest calcium spikes. [Supported by Junta de Extremadura (grant PDT08A027) and MICINN (grant BFU2008-00104)].

Identification of 14-3-3 Protein Isoforms and Their Differential Subcellular Distribution in Mouse Oocytes and Eggs.
S. De, B. F. Villarreal, S. Vijayaraghavan, D. Kline; Department of Biological Sciences, Kent State University, Kent, OH

The 14-3-3 proteins are known regulators in important intracellular events including signal transduction, cell cycle control and embryonic development. 14-3-3 (also known as YWHA or tyrosine 3-monooxygenase/tryptophan 5-monooxygenase activation protein) plays a central role in mitosis in mammalian cells and meiosis in amphibians, but its role in mammalian meiosis has not been entirely defined. The mammalian isoforms of 14-3-3 are beta, eta, gamma, epsilon, tau/theta, zeta, and sigma (the official protein designation for 14-3-3 sigma is SFN). To begin an examination of the role of 14-3-3 in mammalian meiosis and oocyte maturation, we have determined which isoforms are present in oocytes and eggs and examined their subcellular distribution. 14-3-3 isoforms in protein extracts from oocytes and eggs were detected by Western blotting using isoform-specific antibodies. All isoforms were identified by Western blots of oocyte and egg proteins, except sigma. Immunofluorescence confocal microscopy confirmed the presence of all of the isoforms in both oocytes and eggs with characteristic differences in some of their intracellular localizations. For example, 14-3-3 epsilon is found throughout the oocyte with some cortical accumulation, while it is notably absent in the interior of the egg. On the other hand, 14-3-3 eta is diffusely dispersed in the oocyte and attains a uniform punctate distribution in the egg with marked accumulation in the region of the meiotic spindle apparatus. 14-3-3 tau, while distributed throughout oocytes and eggs, shows selective absence along the inner nuclear membrane of all oocytes examined. Some of the isoforms (beta, zeta and gamma) express prominent cortical accumulation in oocytes, but are uniformly dispersed within eggs. The identification and study of differential subcellular distribution of 14-3-3 isoforms in female germ cells will enable characterization of potential 14-3-3 isoform-specific interactions with other key proteins involved in meiosis and oocyte maturation. This will lead to a better understanding of the individual functional roles of the 14-3-3 protein isoforms in mammalian oogenesis.

Strain Difference in Luteinizing Hormone Receptor Protein Expression in Mouse Ovaries.
O. Suzuki, M. Koura, Y. Noguchi, K. Uchio-Yamada, J. Matsuda; Laboratory of Experimental Animal Models, National Institute of Biomedical Innovation, Ibaraki, Japan
Induction of superovulation by gonadotropin treatment is widely used in reproductive experiments. However, our previous study (Reprod. Fertil. Dev., 8:975-80, 1996) demonstrated that the differential response among various mouse strains to gonadotropins still poses a major problem for practical applications. To elucidate the mechanism underlying the strain difference in superovulation induction, we planned qualitative and quantitative comparisons of the gonadotropin receptors in various mouse strains. At the previous ASCB meeting, we reported no difference in cDNA sequences and mRNA expressions of luteinizing hormone receptors (LHR) among mouse strains. In this study, we quantitatively compared time-dependent ovarian LHR protein expressions between high (BDF1) and low (A/J) responder strains at superovulation induction in mice. Five IU of equine chorionic gonadotropin (eCG) were injected into 4-week-old females. Ovaries were collected from females, four females per time point, 48, 51, 54, 57, 60, and 63 h after eCG injection. Membrane protein fractions of each ovary were extracted using ReadyPrep sequential extraction kits (Bio-rad), separated by SDS-PAGE, and transferred onto PVDF membranes (Pall). Ovarian LHR and α-tubulin (loading control) proteins were detected by Western blotting using SNAP i.d. (Millipore) with anti-LHR (Santa Cruz) and anti-α-tubulin (Rockland) antibodies. The blots were visualized with HRP-conjugated secondary antibodies (Jackson ImmunoResearch) and chemiluminescence (GE). The relative band densities of the two molecules were measured in a linear range with CCD-captured images (LAS-3000, Fujifilm). The amounts of ovarian LHR in both strains showed a similar bi-phasic change, but the first peak in A/J was 3-hour earlier (54h) than that of BDF1 (57h). The LHR levels reduced slightly after the peak and then rose again 63h after eCG injection. These differential peak times of ovarian LHR protein expression suggest that the strain-dependent timing for hCG injection might be considered for better superovulation induction. This work was supported by a grant from the Ministry of Health, Labour and Welfare of Japan.

Ultrastructural Characterization of Porcine Oocytes.

R. C. Silva¹, S. N. Bão¹, C. Lucci², ¹Institute of Biological Sciences, University of Brasilia, Brasilia, Brazil, ²Faculty of Veterinary Medicine, University of Brasilia, Brasilia, Brazil

The knowledge of oocyte morphology is crucial to the development of reproductive biotechnologies associated to the female gamete, such as cryopreservation and In Vitro embryo production. The aim of the present work was to characterize the ultrastructure of pig oocytes in different developmental stages. Ovarian tissue and dissected antral follicles were processed for transmission electron microscopy, both routine and osmium-imidazole method (for lipid detection). Preantral follicles were classified as primordial follicles (one layer of flattened or flattened-cubical granulosa cells around the oocyte), primary follicles (one layer of cubical granulosa cells around the oocyte) and secondary follicles (two or more layers of cubical granulosa cells around the oocyte). Ultrastructurally preantral follicles presented an ellipsoid or spherical oocyte, with a homogeneous cytoplasm and oval nucleus. The most abundant organelles were round mitochondria, rough and smooth endoplasmic reticulum. At primordial follicle oocytes, lipid droplets had polarized localization. In primary follicle oocytes, lipids droplets were more dispersed in ooplasm. Junctions such as zones of occlusion and adhesion were present between oocyte and granulosa cells. Secondary follicles presented an oocyte with peripheral nucleus. Round mitochondria were organized as string of pearls. The zona pellucida was completely formed and some microvilli and granulosa cells projection ending in Gap junctions were seen through it. A lot of electron-lucent vesicles in ooplasm were observed. Along with round mitochondria and endoplasmic reticulum cisternae, antral follicle oocytes presented many electron-lucent vesicles all over the cytoplasm. When the osmium-imidazole method was preformed it revealed that most of the vesicles seen in secondary and antral follicles oocytes were lipid droplets. In conclusion, this work described the ultrastructure of pig preantral and antral follicles oocytes. Moreover, the use of osmium-imidazole showed that pig oocytes are rich in lipids and that lipid contents increases and changes in nature as the oocyte develops.
Lipid Activation of Src during Fertilization in *Xenopus laevis*.

B. J. Stith, R. Bates, S. Smith, C. Fees; Integrative Biology, University of Colorado Denver, Denver, CO

Based on fat blot, phosphatidic acid (PA) mass measurements and other data, our current model for Xenopus fertilization involves sperm activation of phospholipase D1b (PLD1b) which would increase PA, PA would then bind to and activate Src. As described in the work by K.-I. Sato, Src would then phosphorylate and activate phospholipase C which in turn would lead to the major event of fertilization: elevation of intracellular calcium. 1-Butanol (which inhibits PA production by PLD) or 2-Butanol (ineffective derivative) was incubated with Xenopus eggs for 90 minutes and, after insemination, Src activation was recorded (Western blot, Src tyrosine 418 phosphorylation). 2-Butanol (0.50%, 0.75%, 1.0%) treatment did not produce any decrease in the activation of Src at fertilization, while similar concentrations of 1-Butanol significantly reduced PP60Src. To quantify the rate of successful fertilization, videomicroscopy was used to measure the percent of cells undergoing gravitational rotation (GR). 1-Butanol (0.50, 0.75%) treated eggs did not undergo GR while 69% GR was recorded in 0.75% 2-Butanol treated eggs (untreated eggs: 100% GR). There was no change in total Src levels after butanol incubations (Western blot with a human Src antibody generated to the region of highest human and Xenopus Src homology). We also describe the release of intracellular calcium by addition of synthetic PA to Xenopus oocytes and report the I-V relationship for the calcium-activated chloride channels after PA addition.

Cell Polarity (385 – 408)

Bile Acids Regulate Bile Canaliculal Formation in Primary Hepatocytes.

D. Fu, Y. Wakabayashi, J. Lippincott-Schwartz, I. Arias; NICHD, National Institute of Health, Bethesda, MD

Bile acid synthesis and canaliculal formation are sparse in fetal hepatocytes, but increase significantly after birth. Based on these observations, we investigated the role of bile acids on canaliculal development using nondividing rat hepatocytes in collagen-sandwich cultures. Our previous study revealed association of canaliculal formation with activation of the LKB1-AMPK system. Methods: Immunofluorescent studies of tight junctions (occludin) and an apical ABC transporter (ABCB1) were used to characterize canaliculal formation. Phosphorylated/activated LKB1 and AMPK were quantified in Western blots. Results: Canaliculal formation revealed sequential morphologic patterns proceeding from a few small canaliculi (day 2) to an extensive branched network (day 6). Addition of taurocholate (25-200 μM), but not urso- or cheno-deoxycholate, on day 2 resulted in dose-dependent two-fold acceleration of canaliculal formation and activation of LKB1/AMPK. To understand the mechanism, pathways affected by taurocholate were studied. Inhibitors and/or activators of PI-3 kinase, CaMKK and FXR, which are activated by taurocholate, did not affect canaliculal formation. Since bile acids activate adenylyl cyclase and increase cAMP, we examined the role of adenylyl cyclase in taurocholate-induced canaliculal formation. Morphologic and LKB1-AMPK effects of taurocholate were reproduced by forskolin (100 μM), an adenylyl cyclase activator; prevented by adenylyl cyclase inhibitors (2’5’-dideoxyadenosine, 200 μM or MDL-12330A, 25 μM). Because taurocholate-induced canaliculal formation was cAMP-dependent, we studied two downstream cAMP-dependent pathways, PKA and Epac. Taurocholate-induced canaliculal formation was unaffected by PKA inhibition (14-22Amide, 500nM). In contrast, Epac activator (8-CPT-2’-O-Me-cAMP, 3 μM) produced the same effect as taurocholate on canaliculal formation and LKB1-AMPK activation. Inhibition of MEK, which is downstream of Epac, by PD98059 (100 μM) blocked taurocholate-induced canaliculal formation and activation of LKB1-AMPK. Conclusion: Taurocholate-induced canaliculal formation is mediated through adenylyl cyclase and cAMP, primarily through Epac downstream signaling, and is associated with LKB1-AMPK activation.

Rab11a and Myosin Vb Are Required for Canalicular Network Formation in Rat Hepatocytes.
Y. Wakabayashi, D. Fu, J. Lippincott-Schwartz, I. Arias; CBMP, NICHD, NIH, Bethesda, MD

The apical domain of polarized hepatocytes consists of an extensive canalicular network. Cytoskeletal elements, motor molecules and other components are proposed to participate in canalicular network formation; however, their specific functions are not known. Using collagen sandwich cultures of rat hepatocytes, we investigated the role of rab11a and myosin Vb, which are components of the apical recycling system, in canalicular formation. Freshly isolated rat hepatocytes were cultured on collagen-coated grass bottom dishes. After 24hr culture, cells were overlaid with collagen gel. One day after overlay with collagen gel, individual hepatocytes establish small circular canalliculi between adjacent cells. By day 3, canalliculi become tubular structures. Between days 3 and 6, tubular canalliculi fuse to form an extensive canalicular network. To study canalicular network formation, cells were infected with rab11aWT, rab11aS25N and myosin Vb tail adenoviral expression constructs at 24 hr after seeding. After 24hr expression of rab11aS25N and myosin Vb tail, individual canalliculi retained small circular morphology. at Day 6, infected cells fail to establish canalicular network. Expression of rab11aWT had no effect on the canalicular network formation. In exploring the basis for these effects, we monitored expression and distribution of endogenous canalicular membrane proteins, i.e. canalicular ABC transporters (ABCB1, ABCB11, ABCC2). Canalicular ABC transporters are minimally expressed at Day 1. The amount of canalicular ABC transporters progressively increased after collagen overlay. at Day 6, endogenous canalicular ABC transporters localize on rab11a-positive endosomes. Expression of rab11aS25N perturbed expression of canalicular ABC transporters. Live cell imaging revealed that rab11aS25N expression inhibited constitutive cycling of ABCB11-YFP. These results suggest that rab11a and myosin Vb play essential roles in canalicular network formation by regulating membrane traffic to canalicular domain.

Mathematical Model of Dual Mechanisms of Cdc42 Recycling in Yeast: Relationship of Internalization Rate and Morphology.
B. D. Slaughter1, A. Das1, J. W. Schwartz2, B. Rubinstein1, R. Li1,2; 1Stowers Institute for Medical Research, Kansas City, MO, 2Department of Molecular and Integrative Physiology, University of Kansas Medical Center, Kansas City, KS, 3Department of Neurobiology, Duke University, Durham, NC

Biological processes such as development, cell motility, and immune response depend on the maintenance of robust cell polarization. Cdc42, a conserved Rho-GTPase, is a master regulator of cell polarization. Previous studies in yeast have found that after initial polarity establishment, the individual molecules of Cdc42 are rapidly exchanged between the membrane and the cytosol. Despite these rapid dynamics, the site of Cdc42 accumulation is held constant to allow for polarized growth. Here, we provide evidence that, after initial symmetry breaking, Cdc42 is dynamically maintained at the polar cap by recycling between the membrane and intracellular regions by two independent mechanisms: actin-mediated transport / endocytosis and cytosolic recycling through the Rho-GDP dissociation inhibitor (GDI) Rdi1. However, the mechanism by which the spatial relationship of these dual recycling pathways is controlled is unclear. Here, we present the results of a study combining live cell fluorescence measurements with a detailed mathematical model to examine how dual recycling pathways of Cdc42 in yeast work together to shape the Cdc42 membrane distribution. We find that in order to recapitulate the steady-state distribution of WT Cdc42, the dual recycling pathways must employ overlapping delivery windows of similar size. Interestingly, we find that Rdi1-mediated tuning of a single dynamic parameter, internalization rate inside the delivery window, is sufficient to explain differences in the Cdc42 cap distribution between cells undergoing pheromone response and cycling cells progressing to bud emergence. These changes in Cdc42 cap distribution are correlated to the observed morphogenic differences under these conditions. We find that the mechanism of action of each recycling pathway relies on the ability of Cdc42 to cycle between nucleotide bound states, and
does not depend on the states themselves. In addition, we employed fluorescence cross-correlation spectroscopy (FCCS) in live yeast between Rd1 and Cdc42 and Cdc42 mutants to provide insight in cytosolic interactions that are involved in the mechanism of Rd1-based recycling.

The Exocyst and the Par-Cdc42 Complex Regulate Ciliogenesis.
B. Fogelgren\textsuperscript{1}, X. Zuo\textsuperscript{1}, S. Lin\textsuperscript{2}, R. Reichert\textsuperscript{3}, P. Bell\textsuperscript{3}, R. Burdine\textsuperscript{2}, J. Lipschutz\textsuperscript{1}; \textsuperscript{1}Medicine, University of Pennsylvania, Philadelphia, PA, \textsuperscript{2}Princeton, Princeton, NJ, \textsuperscript{3}Medical University of South Carolina, Charleston, SC

Our goal is to understand the role of the highly conserved eight protein exocyst complex in ciliogenesis and cystogenesis. Cysts are building blocks for epithelial organs such as the kidney, and defects in cyst formation lead to polycystic kidney disease (PKD). We previously showed that the exocyst localized, in renal cells, to the primary cilium, an organelle involved in flow sensing and PKD pathogenesis. We also showed that the exocyst was centrally involved in ciliogenesis. Most recently, we showed that exocyst protein Sec10 regulates primary ciliogenesis, with shRNA knockdown of Sec10 leading to decreased ciliogenesis and cystogenesis, and Sec10 overexpression leading to increased ciliogenesis and cystogenesis. In addition, the exocyst and Par3, which is also necessary for ciliogenesis, co-localized and co-immunoprecipitated (Zuo et al, 2009, Mol Biol Cell). Cdc42 is part of the Par complex, and we show here, using tetracycline repressible cell lines, that expression of dominant negative Cdc42 prevents ciliogenesis and leads to abnormal cystogenesis with inverted polarity. Interestingly, expression of constitutively active Cdc42 also decreases ciliogenesis (though only by 50%) and also leads to inverted cyst morphology. Similar to PKD cells, Fura 2-loaded Sec10 knockdown cells exhibited a reduced basal Ca\textsubscript{2+} concentration that did not respond to increases in apical flow, while cytosolic Ca\textsubscript{2+} concentration in the Sec10-overexpressing cells was higher and these cells exhibited Ca\textsubscript{2+} transients with increased apical flow. Again similar to PKD cells, the Sec10 knockdown cells were hyperproliferative. Finally, we show In Vivo correlation with injections of an antisense Sec10 morpholino in zebrafish. Sec10 morphants shared many phenotypes with pkd2 morphants, including: A curly-up tail, brain defects, and cystic dilation of the pronephric region. These data support a model in which the Par-Cdc42 complex localizes the exocyst to the primary cilium, and the exocyst then targets and docks vesicles carrying proteins necessary for ciliogenesis. When this does not occur, ciliogenesis and cystogenesis are defective.

Dynamin Participates in the Maintenance of Anterior-Posterior Polarity in the C. elegans Embryo.
J. Shivas\textsuperscript{1}, Y. Nakayama\textsuperscript{1,3}, J. Squirrell\textsuperscript{2}, D. Poole\textsuperscript{1}, A. Skop\textsuperscript{1}; \textsuperscript{1}Genetics, University of Wisconsin-Madison, Madison, WI, \textsuperscript{2}Laboratory of Optical and Computational Instrumentation, University of Wisconsin-Madison, Madison, WI, \textsuperscript{3}Molecular Cell Biology, Chiba University, Chiba, Japan

The PAR polarity factors and the actin cytoskeleton are crucial for generating cell diversity throughout development. Recent evidence from a genome-wide RNAi screen in C. elegans reveals that anterior polarity cues (PAR-6, PKC-3, PAR-3, and CDC-42) can also specifically regulate the endocytic machinery. Current models for the role of PAR proteins in polarity suggest that PAR-dependent membrane recycling is required to generate or possibly maintain a plasma membrane domain and boundary, yet the links between the PAR proteins, endocytic machinery and the actin cytoskeleton during development have not been identified. Dynamin is a large GTPase that plays key roles in both endocytosis and actin dynamics and therefore a possible factor that could connect these events to cell polarity pathways. Here, we show that C. elegans dynamin, DYN-1, is required to maintain the anterior polarity factors PAR-6, RHO-1 and CDC-42. Interestingly, DYN-1-GFP foci are enriched in the anterior cortex of the embryo where endocytosis primarily occurs. DYN-1 regulates anterior membrane and actin comet dynamics specifically during the polarity maintenance phase. Foci of actin closely associated with RAB-5 foci, suggesting a link between actin-based endocytosis in the one-celled embryo. Finally, PAR-6-
labeled foci are closely associated with DYN-1-GFP foci and with endosomal markers, suggesting that PAR-6 is endocytosed and possibly recycled back to the anterior cortex during maintenance phase. Our results demonstrate a dynamin-dependent mechanism for the spatial and temporal regulation of polarity, endocytosis and actin dynamics in the anterior of the embryo, contributing to the precise localization and maintenance of polarity factors within a dynamic plasma membrane. Currently, we are interested in further characterization of the links between membrane trafficking and anterior-posterior polarity in the embryo.

Cdc42 and Par Proteins Stabilize Dynamic Adherens Junctions through Interactions with Membrane Trafficking Proteins.
K. P. Harris, U. Tepass; Cell and Systems Biology, University of Toronto, Toronto, ON, Canada

Cdc42 and the Par complex are part of the intricate network of factors that establish and maintain epithelial cell polarity. Cdc42 binds to Par6 to promote the kinase activity of atypical protein kinase C (aPKC), which supports formation of the apical membrane. When Cdc42 function is compromised in Drosophila embryos, apical proteins are lost from the plasma membrane and instead accumulate in enlarged endosomes. Using the epithelium of the Drosophila embryonic neuroectoderm as a model, we found that this redistribution of apical membrane components is accompanied by loss of adherens junctions (AJs) during the ingression of neural progenitor cells, a process requiring extensive cell rearrangement. Our data support the hypothesis that the loss of AJs during cell rearrangement is a downstream consequence of the depletion of important polarity factors, such as Crumbs, from the apical membrane. Par complex mutants also accumulate apical markers in endosomes. Furthermore, Cdc42 mutant defects are rescued by expression of an activated form of aPKC. These results suggest that Cdc42 and Par proteins function in the trafficking of apical proteins, and that aPKC kinase activity is the key effector mechanism. Our current results indicate that Cdc42/Par interact genetically with genes encoding proteins involved in endocytosis and recycling, including components of the early endosome, ESCRT and retromer machinery. We will discuss our efforts to identify direct targets for aPKC phosphorylation amongst these trafficking proteins.

Theoretical and Experimental Study of Par Protein Polarization in the Early Caenorhabditis elegans Embryo.
A. T. Dawes1,2; E. M. Munro2; 1Mathematical and Statistical Sciences, University of Alberta, Edmonton, AB, Canada, 2Center for Cell Dynamics, University of Washington, Friday Harbor, WA

Par proteins establish complementary domains in the early Caenorhabditis elegans embryo, polarizing the cell. It has been demonstrated that Par proteins interact through mutual phosphorylation, and in Drosophila melanogaster, it has been shown that PAR-3 oligomerization is required for proper localization of the Par proteins. The objective of this study is to determine whether these known interactions between Par proteins can lead to stable maintenance of the Par domains in the early embryo. Theoretically, we develop a mathematical model consisting of coupled differential equations whose terms use first order, mass action kinetics to describe interactions between the Par proteins. We find that mutual phosphorylation alone is not sufficient for maintenance of Par protein domains in the early embryo. We demonstrate that PAR-3 oligomerization along with mutual phosphorylation is sufficient to maintain complementary domains. The model predicts a sudden loss of polarization as a result of Par protein depletion. We test this experimentally, using epifluorescent microscopy of live transgenic embryos expressing fluorescent proteins to observe the localization of Par proteins, and RNAi to modulate protein expression. We find that experimental tests are consistent with behaviors predicted by the mathematical model. The model can explain previous observations, such as the possible mechanism behind Par protein mislocalization when the PAR-3 oligomerization domain is impaired, and how polarization may be rescued when both anterior and posterior Par proteins are sequentially or simultaneously depleted. The model also predicts possible cues for the initiation of Par protein polarization in the early embryo.

**Generation of Asymmetry in the Cytoplasm by Par-1-Dependent Local Regulation of Protein Diffusion.**

_E. Griffin, G. Seydoux; Hopkins, Baltimore, MD_

The PAR polarity regulators promote cell polarity by creating distinct domains in the cortex and cytoplasm of cells. How PAR asymmetry at the cortex promotes protein asymmetry in the cytoplasm is not understood. Here we report that PAR-1 polarizes the distribution of the cytoplasmic RNA-binding protein MEX-5 by directly phosphorylating MEX-5 and locally increasing its diffusion rate. During polarization of the C. elegans zygote, PAR-1 becomes enriched on the posterior cortex. The cell fate determinant MEX-5 accumulates opposite PAR-1 in the anterior cytoplasm. Segregation of MEX-5 requires PAR-1, but the mechanisms involved were not known. Using a photoconvertible Dendra2 tag and live imaging, we have found that before polarization, MEX-5 diffuses quite slowly throughout the cytoplasm (~1um²/sec). During polarization, MEX-5 diffusion increases specifically in the posterior (to ~3um²/sec). As a result, MEX-5 levels increase in the anterior, where the diffusion rate remains slow. Similar observations were made by Tenlen et al., 2008 using FRAP analysis. What increases MEX-5 diffusion in the posterior? In vitro, PAR-1 phosphorylates MEX-5 directly on two residues: S548 and S404. We found that S404 is phosphorylated In Vivo and is absolutely essential for MEX-5 asymmetry. A MEX-5(S404A) mutant remains slow diffusing and uniformly distributed during polarization of the zygote. Loss of par-1 kinase activity also slows down MEX-5, whereas ectopic localization of PAR-1 increases MEX-5 mobility throughout the cytoplasm. Interestingly, mutations that change MEX-5’s affinity for mRNA In Vitro (Pagano et al, 2007) also increase MEX-5 mobility. Together these results suggest the following model: 1) MEX-5 mobility is slowed by a uniformly distributed RNA anchor or complex, 2) direct phosphorylation by PAR-1 releases MEX-5 locally in the posterior cytoplasm, 3) As MEX-5 diffuses away from PAR-1, de-phosphorylation traps MEX-5 dynamically in the anterior cytoplasm. Our observations provide a simple model for how a cortically-enriched kinase can localize proteins in the cytoplasm by local regulation of protein diffusion.

**Spatiotemporal Regulation of the Membrane Cortex in Cleavage Stage Sea Urchin Embryos.**

_H. F. McKay, L. M. Alford, D. Burgess; Biology, Boston College, Chestnut Hill, MA_

Previously, we have shown that the polarity proteins of the Par complex as well as the membrane raft marker ganglioside GM1 are localized to the free, apical surface of cleavage stage sea urchin embryos as early as the two cell stage. We investigated the spatial and temporal regulation of this polarity using Fluorescence Recovery After Photobleaching (FRAP) analysis and immunofluorescence in one, two, and four cell stage sea urchin embryos. GM1 was found to be mobile only during late anaphase in control embryos. Disruption of actin or microtubules via treatment with Cytochalasin D, Latrunculin B, or Nocodazole had little effect on GM1 mobility in the apical membrane. When Myosin II phosphorylation was inhibited by treatment with the myosin light chain kinase (MLCK) inhibitors ML-7 and ML-9, or the Rho-kinase (ROCK) inhibitor H1152, GM1 was found to be mobile regardless of the cell cycle stage, and this disruption was enhanced in dissociated blastomeres. Immunofluorescence analysis revealed changes in myosin distribution from being predominantly apical to near even distribution around the membrane cortex. When Myosin II phosphorylation was inhibited by treatment with the myosin light chain kinase (MLCK) inhibitors ML-7 and ML-9, or the Rho-kinase (ROCK) inhibitor H1152, GM1 was found to be mobile regardless of the cell cycle stage, and this disruption was enhanced in dissociated blastomeres. Immunofluorescence analysis revealed changes in myosin distribution from being predominantly apical to near even distribution around the membrane cortex. Upon dissociation of blastomeres. Inhibition of myosin phosphorylation by MLCK also affects the apical localization of the Par complex proteins Cdc42, Par-6, and atypical protein kinase C (aPKC) as seen by immunofluorescence. These studies suggest that myosin filaments are involved in the spatial regulation of the membrane cortex as well as its temporal control during anaphase in early sea urchin development.

**Dissecting the Role of Individual PDZ Domains in Bazooka/Par-3 Cortical Localization and Clustering in Drosophila.**
The scaffold protein Bazooka (Baz/PAR-3) functions in positioning adherens junctions (AJ)s in the developing Drosophila embryo. Baz contains three PDZ domains, which are protein-protein recognition modules known to organize multiprotein complexes. Recently we showed that Baz and AJ components form clusters independently, and that Baz clusters may act as molecular nets to aggregate AJ clusters at AJ assembly sites. However, the mechanism of how Baz clusters are localized, formed and maintained at the cortex is not understood. To determine the role of Baz's three PDZ domains in its cortical localization and clustering, we generated transgenic flies expressing Baz with no PDZ domains, with each domain alone and with each possible pair of domains. Each construct is tagged with GFP and located at the same chromosomal site. Using the UAS-GAL4 system, we expressed and analyzed them with 3-D live spinning disk microscopy with/without endogenous Baz in the lateral epidermis at dorsal closure. Endogenous Baz shows an overall decrease in cortical levels, preferentially along the A-P contact leading up to dorsal closure. At dorsal closure, removal of all PDZ domains lead to a more even cortical localization compared to full length Baz, but at comparable levels. Surprisingly, the addition of PDZ1 reduced cortical levels. In contrast, adding PDZ2 or PDZ3 elevated cortical levels above those of the full length construct. Remarkably, when PDZ1 is added back with either PDZ2 or PDZ3, normal cortical levels were restored. Taken together, these results suggest PDZ1 mediates the removal of Baz from the cortex. We find that elevated levels of Baz lead to greater clustering at the cortex. Moreover, the excess Baz in the absence of PDZ1 preferentially accumulated along A-P contacts.

We hypothesize that the correct localization of Baz relies on a balance between anchorage at the cortex and removal, with the former mediated by PDZ2 and PDZ3 and the latter mediated by PDZ1.

Selective Targeting of ER Exit Sites Supports Axon Development.
K. N. Fish1, M. Aridor2; 1Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, 2Cell Biology, University of Pittsburgh, Pittsburgh, PA

During neuron development, the biosynthetic needs of the axon initially outweigh those of dendrites. However, while a localized role for the early secretory pathway in dendrite development has been observed, such a role in axon growth remains undefined. We therefore studied the localization of Sar1, a small GTPase that controls ER export, during early stages of neuronal development that are characterized by selective and robust axon growth. At these early stages, Sar1 was selectively targeted to the axon where it gradually concentrated within varicosities in which additional proteins that function in the early secretory pathway were detected. Sar1 targeting to the axon followed axon specification and was dependent on localized actin instability. Changes in Sar1 expression levels at these early development stages modulated axon growth. Specifically, reduced expression of Sar1, which was initially only detectable in the axon, correlated with reduced axon growth, while over-expression of Sar1 supported the growth of longer axons. In support of the former finding, expression of dominant negative Sar1 inhibited axon growth. Thus, as observed in lower organisms, mammalian cells utilize temporal and spatial regulation of ERES to address developmental biosynthetic demands. Furthermore, axons, like dendrites, rely on ERES targeting and assembly for growth.

Noncanonical Frizzled Signaling Regulates Cell Polarity of Growth Plate Chondrocytes.
Y. Li, A. T. Dudley; Northwestern university, Evanston, IL

A central question in developmental biology is how morphologically distinct structures are generated from similar cell types. The skeleton provides a good model system to answer this question due to the highly diverse and complex morphological differences displayed by individual elements. Analysis of the cartilage growth plate by Dodds suggested that longitudinal growth of long bones might result from the specific arrangement of chondrocytes. In the proliferative zone,
chondrocytes become discoid and arrange in columns, like stacks of coins, which are parallel to the long axis of the cartilage. Although well-organized chondrocytes derive from a relatively unstructured pool of progenitor cells, it is not known whether this arrangement of cells is the result of a regulated process or is in response to physical constraints of the cartilage matrix. We test this model that cell columns in the growth plate cartilage form from a single progenitor cell by a process in which cells divide orthogonal to the stack then rearrange. Our work has uncovered a central role of noncanonical Frizzled dependent signaling in the regulation of chondrocyte polarity and morphogenesis in the growth plate cartilage.

Structural Analysis of the Interactions between PIP3-Binding Protein Centaurin A1 and the FHA Domain of Kinesin-3 Motor Protein Kif13b.
Y. Tong1, W. Tempel1, H. Wang1, L. Shen1, H. Park1,2; 1Structural Genomics Consortium, University of Toronto, Toronto, ON, Canada, 2Department of Pharmacology, University of Toronto, Toronto, ON, Canada

Phosphatidylinositol (3,4,5)-trisphosphate, PIP3, is an important second messenger for the differentiation and development of neuron axons. The PIP3-binding protein centaurin α1 (CENTA1) contains one ArfGAP domain and two pleckstrin homolog (PH) domains in tandem. The CENTA1 is involved in the transport of PIP3-containing vesicles by interacting with the forkhead associated (FHA) domain of KIF13B (KIF13B-FHA). We solved the structures of CENTA1 in complex with PIP3 and of CENTA1 in complex with the KIF13B-FHA. The KIF13B-FHA interacts mainly with the first PH domain of CENTA1 using a novel interface that does not include a phospho-threonine. We verified the specific interactions between CENTA1 and KIF13B-FHA using a GST-pull down assay and isothermal titration calorimetry. The PIP3-bound CENTA1 structure suggested the second PH domain of CENTA1 could bind phosphatidylinositol (3,4)-bisphosphate, Ptdlns(3,4)P2, as well as PIP3, as confirmed by a PIP-strip assay. The structural results presented here are the first three dimensional model of a kinesin cargo binding domain complexed with a cargo adaptor protein, and the interaction of CENTA1 with PtdIns(3,4)P2 proposes a new physiological function of CENTA1 that can transport PI(3,4)P2-containing vesicles.

Investigating the Role of Abnormal Spindle Protein Asp in Brain Development.
M. A. Rujano, G. Le Dez, R. Basto; UMR 144, Institut Curie, Paris, France

Drosophila melanogaster Abnormal Spindle Protein (Asp) was first identified by phenotypic characterization of a late larval-pupae lethal mutation that display defects in spindle morphology, mitosis and meiosis. The gene encodes a 220 KDa microtubule-associated protein that contains actin and calmodulin binding domains. Interestingly, the human homologue of Asp, ASPM (abnormal spindle-like microcephaly-associated), is one of the genes implicated in primary microcephaly, a congenital disorder characterized by reduced brain size, specially the cerebral cortex, with no other abnormalities either within or outside of the nervous system. In addition, the mouse homologue is known to be necessary for the symmetric divisions of neuroepithelial cells during brain development. Thus, Asp function likely resides in the regulation of the proliferation of neural progenitors during neurogenesis. We utilized the larval Drosophila brain as a model system to ascertain the role of Asp during neurogenesis. Analysis of the dynamics of the protein In Vivo showed that Asp displays a cell cycle-dependent localization. However, during mitosis, it specifically localizes to spindle microtubules and spindle poles. In the larval mutant brain, as expected, several mitotic abnormalities were observed. The dividing neural progenitor cells or neuroblasts of the central nervous system, fail to complete asymmetric cell division and are arrested in prometaphase-like state with highly condensed chromosomes. Mitotic spindles are unfocused and disorganized and cells exhibit aberrant centrosome numbers. Intriguingly, while all other structures are properly developed, asp mutant larvae display reduced brain size, with extensive lost of cells in the optic lobe and in the eye imaginal disc. Likewise, despite reduced head size and severely impaired eye morphology, asp pharate adults appear morphologically
normal. Altogether, our results suggest that Asp is a neurogenic gene with a major role in the regulation of neural stem cell proliferation and differentiation during brain development.

**Electrical Control of Cell Polarization in the Fission Yeast Schizosaccharomyces pombe.**
*N. Minc, F. Chang; Microbiology, Columbia University, NYC, NY*

Endogenous electric signals surround tissues and cells in all organisms and have been proposed to participate in directing cell polarity in processes such as development, wound healing and host invasion. The application of exogenous electric fields (EF) can direct cell polarization in almost all cell types tested, ranging from bacteria to neutrophils, yet the mechanism for such effects remain a mystery. Here, we introduce the fission yeast Schizosaccharomyces pombe as a model system to elucidate the mechanisms underlying this process. In the rod-shaped fission yeast cells, we show that an exogenous EF reorients cell growth in a direction orthogonal to the field, producing cells with a bent morphology. A candidate genetic screen identifies conserved factors involved in this process: an integral membrane proton ATPase pma1p, the small GTPase cdc42p, and the formin for3p. Interestingly, mutants in these genes still respond to the EF but orient in the wrong direction, towards the anode. We propose that the EF reorients cell polarization by locally modifying a cortical pH gradient set by pma1p, that participate in the regulation of cdc42p and for3p to direct actin assembly and cell growth. Thus, these studies begin to elucidate some of the first molecular insights for mechanisms in the electrical dimension of cell polarization.

**Genetic Control of Cell Width in Fission Yeast.**
*F. Kelly, P. Nurse; Rockefeller University, New York, NY*

Proper cell shape is essential to cell function, but the genetic control of the dimensions of a growth zone has been difficult to understand. The fission yeast Schizosaccharomyces pombe is a rod shaped cell that grows by linear extension at the cell tips, with nearly constant width throughout the cell cycle. This simple geometry makes it an ideal system to study the control of growth zone dimensions. We conducted a visual screen of morphology mutants, screening nearly 3000 viable, haploid fission yeast strains, each carrying a deletion of a single gene. We identified 11 genes that when deleted produce cells whose diameter is at least 10% greater than wild type, though the overall cell volume is unchanged. Six of these wide mutants are involved in the regulation of the small GTPase Cdc42, which is a conserved regulator of polarized growth throughout eukaryotes. To distinguish between defects in the maintenance of cell diameter and defects in cell size establishment we tested the ability of these mutants to repolarize after cell wall removal, which creates a completely round cell. All the wide mutants tested repolarized after cell wall removal, forming a new growth zone with a larger diameter. Genetic analyses showed that at least two different pathways are involved in specifying cell width. When a Cdc42 GAP and GEF were deleted, the effects on cell morphology were additive. We then showed that the GFP-tagged GEF was found at the growing cell tips, and the GAP at the cell sides. By expressing the GFP-tagged proteins in deletions we found that the GEF and GAP localized independently of one another. We hypothesize that these regulators may be acting to set up a zone of active growth at the cell tip and an area where growth is inhibited on the cell sides. This hypothesis will be tested by ectopic targeting of these regulatory proteins to cell sides and cell ends.

**The PAM-1 Aminopeptidase Regulates Centrosome Dynamics to Ensure Anterior-Posterior Polarity Establishment in the One-Cell C. elegans Embryo.**
*P. Greene, S. Marshall, L. Brady, S. Fortin, A. Cohen, R. Lyczak; Biology Dept., Ursinus College, Collegeville, PA*

In the one-cell *Caenorhabditis elegans* embryo, the anterior-posterior (A-P) axis is established when the sperm donated centrosome contacts the posterior cortex. While this contact appears to be essential for axis polarization (1), little is known about the mechanisms governing centrosome
positioning during this process. In a screen for mutants with defects in A-P axis establishment, we identified mutations in \textit{pam-1}, which encodes a puromycin sensitive aminopeptidase. These aminopeptidases have been identified across a large range of species, but little is known of their \textit{In Vivo} functions (2). Previously we showed that \textit{pam-1} mutants fail to polarize the A-P axis and have centrosome positioning defects (3). Here we tested the hypothesis that PAM-1’s role in polarity establishment is to ensure centrosome contact with the posterior cortex. To test this, we inactivated the microtubule motor dynein, DHC-1, and its regulator LIS-1 in an attempt to prevent centrosome movement from the cortex and restore anterior-posterior polarity. This was indeed what we observed. Centrosomes remained anchored to the posterior cortex in \textit{pam-1; dhc-1(RNAi)} and \textit{pam-1; lis-1(RNAi)} embryos. In wild-type embryos, pseudocleavage, posterior localization of P granules, and asymmetric cortical localization of the PAR proteins are signs of proper A-P polarity. These signs of polarity are absent in \textit{pam-1} mutants; but, when combined with \textit{dhc-1(RNAi)} or \textit{lis-1(RNAi)}, we observed normal pseudocleavage and localization of the P granules and PAR proteins. We conclude that DHC-1 and LIS-1 are required for the abnormal centrosome movements in \textit{pam-1} embryos. Additionally, we show that PAM-1’s role in axis polarization is to prevent premature movement of the centrosome from the posterior cortex, ensuring proper axis establishment in the embryo. Thus we have determined a key regulator of centrosome positioning in the one-cell \textit{C. elegans} embryo, that is necessary for polarity establishment. \textbf{Testing the Role of a Putative Arf GTPase-Activating Protein dASAP in Epithelial Cell Polarity in Drosophila.}

\textit{W. Shao, T. J. Harris; Cell and Systems Biology, University of Toronto, Toronto, ON, Canada}

Epithelial cells are polarized with different proteins positioned at their apical and basolateral domains. This is critical for epithelial development and physiology. Among apically localized proteins, Baz/Par3 protein is a key polarity regulator. However, how Baz interacts with other proteins to modulate cell polarity is largely elusive. Therefore, we performed a genetic modifier screen to identify novel Baz interacting genes. Consequently, we found a mutation in \textit{dASAP} (\textit{Drosophila ArfGAP with SH3 domain, Ankyrin Repeat and PH domain}) encoding a putative Arf GTPase-activating protein significantly enhanced the baz zygotic mutant cuticle phenotype. By live imaging of \textit{Baz::GFP} Trap line in the homozygous \textit{dASAP} mutant background, we found Baz::GFP levels were substantially reduced at dorsal closure of embryogenesis. Mammalian ASAP1 is an important regulator of Arf GTPase family which are involved in vesicle trafficking and several actin-based cellular structures. We started to analyze the subcellular localization of dASAP during embryogenesis by live imaging of GFP-tagged dASAP. at cellularization, dASAP appeared to be localized at microvilli and furrow canal of forming epithelial cells. from germband extension to dorsal closure, cortical dASAP became enriched apically, localizing to the apical circumference and the apical surface of epidermal cells and amnioserosal cells. We also documented the movement of dASAP-positive vesicle-like structures in epidermal cells. To see if dASAP colocalizes with polarity and cytoskeleton proteins, we immunostained GFP-tagged dASAP embryos at dorsal closure stage for Baz, Arm, aPKC, Crumbs, actin and tubulin. dASAP generally overlapped with all four apical proteins but local mutual exclusion was evident. Notably, dASAP had relatively high colocalization with actin at both the apical circumference and the apical surface. There were minimal colocalizations with microtubule. Thus, dASAP may regulate actin-based processes at apical domain. Since dASAP localizes to both the apical domain and to intracellular structures, we hypothesize that dASAP may regulate intracellular trafficking to or from the apical domain.

\textbf{Rab11 Is Important for Chitin Deposition during Drosophila Sensory Bristle Development.}

\textit{R. Nagaraj, P. Adler; Biology, University of Virginia, Charlottesville, VA}
Sensory bristles of *Drosophila melanogaster* are polarized single cell extensions whose shafts extend between 70µM (microchaetes) and 500µM (macrochaetes). Their polarized structure makes them useful model systems to study the role of cytoskeleton in cellular morphogenesis. Previous work to understand bristle growth has focused on analyzing how actin filaments are assembled and positioned to mediate shaft elongation. Little is known about the mechanisms that mediate membrane and protein transport to bring about their growth. Our studies identify an important role for dRab11 a small GTPase in bristle development. Knocking down Rab11 function using Rab11dsRNA results in short knob like structures. Mutants with reduced Rab11 function display short bristles with deformed tips. Rab11-GFP preferentially accumulates to the tip of growing bristles. This pattern is altered more in bristles with disrupted microtubules than in those with disrupted actin filaments suggesting an essential role for microtubules in the polarized transport of Rab11. Live imaging studies show that Rab11 knockdown bristles elongate, but at a slower rate than wild types. At a late stage in elongation, bristles start to bulge at various positions along the shaft. These deformities become severe over time and the bristle eventually collapses. This collapse is the cause of small bristle stubs seen in the adult. Bristles with disrupted Rab11 function show dramatic differences in their arrangement of chitin, a key component of the adult exoskeleton. Chitin formation is delayed in these bristles and chitin bundles fail to show the distinct arrangement seen in normal bristles. Our results indicate that Rab11 plays a key role in maintaining bristle stability by mediating formation and/or organization of the chitin exoskeleton.

Endocytosis Is Required for Apical Constriction during Xenopus Gastrulation.

*J. Lee, R. Harland; Molecular and Cell Biology, University of California Berkeley, Berkeley, CA*

Apical constriction is a type of cell shape change that drives epithelial invagination, a process key to morphogenetic events such as gastrulation, neurulation, and organogenesis. We have chosen bottle cells of the Xenopus gastrula, which bend the tissue at the blastopore lip, to study apical constriction. Previously, we showed that actomyosin contractility drives apical constriction in bottle cells; however, it remained unclear whether it does so alone or in concert with other processes. As apical constriction involves rapid membrane remodeling, we hypothesized that endocytosis may be required for apical constriction. We found endosomes exclusively in bottle cells, where some are transcytosed from the apical to the basolateral membrane. Moreover, disrupting endocytosis with dominant negative versions of Dynamin and Rab5 resulted in defective apical constriction. As inhibition of endocytosis did not completely prevent apical constriction, we hypothesized that endocytosis acts as a clearing mechanism during constriction: as the membrane constricts into microvilli, excess membrane is removed via endocytosis. Indeed, inhibition of endocytosis led to a significant and specific decrease in the constriction rate late in the process. Our results indicate that endocytosis is required for apical constriction and acts downstream of actomyosin contractility to decrease apical surface area. We propose that active membrane remodeling during apical constriction could be a general mechanism used by embryos to achieve efficient invagination during morphogenesis.

The Short Isoform of PDGF-A Is an Instructive Signal Regulating Directional Intercellular Migration of Pre-Chordal Mesodermal Cells during Gastrulation in *Xenopus*.

*E. W. Damm, R. Winklbauer; Dept. of Cell and Systems Biology, University of Toronto, Toronto, ON, Canada*

The movements of leading edge mesendoderm during gastrulation in *Xenopus* have been well characterized, however the movements of the pre-chordal mesoderm have not been investigated in detail. It is thought that cells within the deep layers of the pre-chordal mesoderm undergo intercellular migration, a poorly understood process in which cells use the surfaces of other cells as a substrate for migration. Using scanning electron microscopy, we show that deep pre-chordal mesodermal cells are unipolar and are oriented toward the ectodermal blastocoel roof (BCR). We also show through timelapse recordings of mesoderm-BCR explant combinations that pre-chordal
mesodermal cells migrate directionally toward the BCR in an intercellular fashion. Platelet derived growth factor (PDGF) ligands and receptors are known for their roles in mitogenesis, angiogenesis, cell death regulation, and directional cell migration. We show that disruption of PDGF-A function by microinjection of morpholino oligonucleotides or dominant negative constructs inhibits directional migration of deep pre-chordal mesodermal cells. This effect is reversible by expression of the wild-type short isoform of PDGF-A in the BCR. We also show, using mesoderm-endoderm explant combinations, that PDGF-A is sufficient to regulate directional intercellular migration of these cells. Altogether, our data suggest an instructive role for the short isoform of PDGF-A as a chemoattractant in the directional migration of pre-chordal mesodermal cells. This research contributes to a further understanding of the process of mesoderm migration during gastrulation in Xenopus as well as introducing an In Vivo model to further the understanding of intercellular migration.

**Polarity of Microtubule Cytoskeleton during Zebrafish Gastrulation.**

D. Sepich, L. Solnica-Krezel; Biological Sciences, Vanderbilt University, Nashville, TN

Vertebrate gastrulation includes convergence and extension (CE) movements that narrow and elongate the embryonic body. Multiple cell behaviors underlie these movements; some require Wnt/Planar Cell Polarity (Wnt/PCP) signaling. Cellular phenotypes dependent on Wnt/PCP signaling during gastrulation are typically interpreted as aspects of cell polarity; e.g. cells elongate, align and migrate, divide or intercalate perpendicular to the body axis. To investigate mechanisms of Wnt/PCP dependent polarity we are examining the microtubule cytoskeleton during zebrafish gastrulation. An early step in migration of cultured cells is often the alignment of the nucleus and microtubule organizing center (MTOC) toward the direction of migration. Recent work shows Wnt5a, and its effector Dishevelled, are required for MTOC reorientation in cultured cells (Schlessinger et al, 2007, Nomachi et al, 2009). Here we show the microtubule cytoskeleton is aligned in gastrula cells and this is dependent on some components of Wnt/PCP signaling. To assess polarity in live zebrafish embryos at late gastrulation, we collected confocal images of MTOC and nucleus labeled with Xcentrin-GFP, cell membrane with RFP. Cells were scored for orientation of the MTOC relative to the nucleus and the dorsal direction of migration. We found that cells of both lateral ectoderm and mesoderm have a polarized arrangement of the nucleus-MTOC-leading edge during late gastrulation. The orientation of the MTOC is randomized in embryos in which some Wnt/PCP signaling components are disrupted or at a younger stage when lateral mesoderm migration does not require Wnt/PCP. These results indicate Wnt/PCP signaling controls MTOC polarity during gastrulation movements. To understand function of the microtubule cytoskeleton during convergence and extension, we are disrupting microtubule dynamics at late gastrula stages, and examining tissue morphogenesis, and cell properties associated with Wnt/PCP. Notably Prickle and Dishevelled are asymmetrically localized by late gastrulation or early segmentation. We find that the maintenance of Prickle localization does not require dynamic microtubules.

Cell shape determination is a dynamical process modulated by input from genetic and signaling pathways. In order to understand cell morphology as a dynamical system it is critical to determine the degree of spatial inheritance, that is, the degree of influence of spatial organization within a mother cell on the organization of her daughter cells. Visual comparison of symmetry relations between daughters was used by Albrecht-Buehler to probe spatial inheritance in a series of papers published in the 1970's. His results, that sister cells are sometimes mirror images of each other, were interpreted as reflecting spatial inheritance during cell division. We have reinvestigated these claims using quantitative image analysis and several different shape-comparison algorithms to test the symmetry relations between sister cells. Applying these methods to fixed and live RPE-1 and NIH 3T3 cells, we obtained the following results: (A) sister cells are quantitatively more similar in shape than pairs of unrelated cells, (B) When sister cells show a significant degree of shape similarity, they tend to be related by mirror symmetry, (C) the shape similarity between sister cells is highest soon after division and decays on a time scale of several hours, (D) the set-theoretic union of the two sister cell shapes is related to the shape of the mother with a degree of similarity that decays as a function of time before and after division. We have also developed methodologies to compare similarity of internal actin stress fiber organization between sisters and to compare the migration trajectories of sister cells as they move away from the site of division.

PTK7 Proteolysis by MT1-MMP Regulates Embryogenesis and Cancer.
V. Golubkov, A. Chekanov, P. Cieplak, A. Aleshin, W. Zhu, P. D. Dong, A. Y. Strongin; Burnham Institute for Medical Research, La Jolla, CA

PTK7 (colon carcinoma kinase-4, CCK-4) and MT1-MMP (membrane type-1 matrix metalloproteinase, MMP-14) are membrane proteins that are essential for non-canonical Wnt signaling, planar cell polarity (PCP) and convergent extension (CE) during gastrulation. Increased expression of both PTK7 and MT1-MMP are associated with the progression of multiple types of cancers. Our proteomics studies on normal and cancer cells identified PTK7 as a cleavage target of MT1-MMP. We determined that MT1-MMP cleaves the PTK7 ectodomain at the PKP621-LI site and generates the PTK7 soluble form. It was shown by others that soluble PTK7 antagonizes the function of the membrane PTK7. To determine the significance of the MT1-MMP-dependent generation of soluble PTK7 on the organism level, we used the zebrafish vertebrate model system. Injection of the mRNA encoding the human soluble PTK7 as well as the transcriptional silencing of MT1-MMP and PTK7 with specific morpholino antisense oligonucleotides, all resulted in similar defects normally associated with aberrant PCP and CE. Our results suggest that the soluble human PTK7 can antagonize the function of the zebrafish membrane PTK7, and that both the membrane PTK7 expression and MT1-MMP activity are essential for the normal embryonic development. These findings suggest that the MT1-MMP proteolysis of PTK7 is tightly controlled during embryogenesis and both the excess and the lack of soluble PTK7 adversely affect embryogenesis. Further, our studies in cancer cells revealed that the levels of the membrane PTK7, which co-localizes with MT1-MMP at the cell-cell junctions, inversely correlated with cell invasion and MT1-MMP activity. In addition, we find that the levels of PTK7 in breast tumor tissue were lower and inversely correlated with the stage of tumor progression. We hypothesize that upregulation of both PTK7 and MT1-MMP would lead to increased soluble PTK7 and subsequent defects in non-canonical WNT signaling and planar cell polarity, which in turn would promote malignant transformation.

An Insulin-Mediated Stem Cell Response Controls Adaptive Intestinal Morphogenesis in the Adult Drosophila Midgut.
L. E. O'Brien, D. Bilder; Molecular and Cell Biology, University of California, Berkeley, CA
In adult animals, differentiated tissues must continually adapt to changing environmental and physiological demands. Remodeling of the vertebrate intestinal lining in response to fluctuating dietary loads is a prime example of such adaptation. However, the cellular mechanisms of such post-developmental morphogenesis are poorly understood. Using a new model of adult organ remodeling, we show that intestinal stem cells in the mature Drosophila midgut interpret an instructive nutrient signal to direct tissue growth toward the functionally appropriate state. Food ingestion causes an increase in intestinal size and cell number. This adaptive growth occurs via insulin-activated stem cell proliferation. Synthesis of insulin matches the kinetics of stem cell proliferation in fed and fasted conditions. Insulin receptor activation in stem cells stimulates both symmetric and asymmetric divisions, thereby elaborating the intestinal epithelium when food is abundant. Altogether, these data suggest that mature organs can respond to external cues for adaptive change by leveraging programs of stem cell renewal. We postulate that in the gut, the nutrient-triggered stem cell response enables organ morphogenesis to be tuned to functional need.

The Role of Insulin Signaling and Nutrition in the Regulation of Drosophila Male Germline Stem Cells.
T. M. Roth, C. Chiang, C. E. Roth, Y. M. Yamashita; Life Sciences Institute, Center for Stem Cell Biology, University of Michigan, Ann Arbor, MI

A steady supply of differentiated cells from adult stem cells is critical to maintain tissue homeostasis. Defective control of stem cell number either results in loss of stem cells leading to tissue degeneration, or excess proliferation of stem cells leading to tumorigenesis. The Drosophila male germline stem cell (GSC) provides an excellent model system to study stem cell behavior in the context of the stem cell niche. Their niche is located at the tip of the testis. GSCs attach to a cluster of somatic cells called the hub, which provides an essential ligand (Upd) for stem cell identity, and divide asymmetrically by orienting their mitotic spindle perpendicularly to the hub. Stereotypical positioning of centrosomes with respect to the hub sets up this spindle orientation; one centrosome (mother centrosome) always locates close to the hub-GSC junction, while the other centrosome (daughter centrosome) migrates to the opposite side of the GSC. Recently, we have shown that GSCs with misoriented centrosomes, where neither of the two centrosomes is juxtaposed to the hub-GSC junction, undergo cell cycle arrest until their centrosomes reorient, suggesting a novel cell cycle checkpoint to monitor correct centrosome positioning. Here we show that nutrition, through the insulin pathway, may have an effect on centrosome orientation in GSCs. Flies grown in poor nutrient conditions have significantly higher frequency of GSCs with misoriented centrosomes. This response appears to be mediated via the insulin signaling pathway, since expression of constitutively active insulin receptor in GSCs restores centrosome orientation even when cultured in poor nutrient conditions. We propose that the nutrients’ condition modulates GSC division rates by controlling centrosome orientation, which can regulate cell cycle progression via the centrosome orientation checkpoint.

Reserve Stem Cells of Asexually Reproducing Organisms.
A. I. Shukalyuk1,2, A. V. Akhmadieva2, Y. N. Alexandrova2, V. V. Isaeva2,3; 1Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada, 2Laboratory of Embryology, Institute of Marine Biology, Vladivostok, Russia, 3A. N. Severtsov Institute of Ecology and Evolution, Moscow, Russia

Asexual reproduction is a natural cloning of oozooid, with development of many genetically and morphologically identical blastozooids. In asexually reproducing animals, the lineage of reserve stem cells ensures both sexual and asexual reproduction, being predecessors of germline and all somatic cells. We studied morphological and functional organization of reserve SCs in five animal types: Porifera (Oscarella malakhovi), Cnidaria (Obelia longissima), Platyhelminthes (Girardia tigrina), Arthropoda (Pelagogasterella gracilis, Polycascus polygenea), Chordata (Botryllus tuberatus) and mouse ESC in vitro. Asexual reproduction without separation of blastozooids in
some rhizocephalans results in the emergence of colonial organization that is unique among crustaceans, all arthropods, and all Ecdysozoa. Blastogenesis and coloniality in the rhizocephalans involve a radical, evolutionary secondary rearrangement of the ancestral reproductive biology due to the transition to parasitic life. We found germinal bodies in all or most blastomeres in cleaving embryos of P. polygenea. Each body selectively expresses mRNA transcript of vasa-like gene. This data indicates a saltatory evolution from determined mosaic cleavage with preformation to regulative development with epigenesis. The morpho-functional organization of stem and gonial cells in the studied species shares common properties: A high nuclear/cytoplasmic ratio, a large nucleus with diffuse chromatin and a large nucleolus, basophilic cytoplasm including specific perinuclear germinal granules, the positive reactions revealing proliferating cell nuclear antigen and alkaline phosphatase activity. We observed electron-dense granular structures in mESCs similar to germinal granules in metazoan oogenic cells. Similar structures were found in reproductive cells of lower and higher plants. This similarity indicates a very conservative pattern of reproductive cells in Metazoa and Metaphyta. Thus, our data indicates evolutionary conservatism and common morpho-functional organization of germ cells from all studied multi-cellular animals and unlimited morphogenetic potential of reserve stem cell capable of both gametogenesis (and embryogenesis) and asexual reproduction (blastogenesis).

Notch Signaling Is Activated during Regeneration of the Airway Epithelium.
Y. Tang, J. Qian, W. Cardoso; Pulmonary Center, Boston University, Boston, MA

Objective: Notch signaling plays an important role in establishing the balance between ciliated and secretory cell fates in the developing airways. However little is known whether this mechanism is present during regeneration of the airway epithelium in adult life. The goal of the study is to identify the Notch pathway components in adult airways undergoing regeneration after naphthalene injury. Methods: Adult CD1 mice were injected intraperitoneally with naphthalene and airway epithelium desquamation and regeneration were investigated, including changes in morphology, expression of differentiation markers and Notch components. We used in situ hybridization and immunohistochemistry on lung tissue sections. Results: Overall expression of Notch components/expression was nearly undetectable in adult lungs. at 52 hr of naphthalene injury, when secretory cells were ablated in the airway, the Notch signaling effectors (Hes1, Hey1, Hey2 and HeyL) remained low in the remaining cells. However by 72 hr, when the regeneration process started, Notch1 and the ligand Jagged1, as well as Hes1 and Hey1 were up-regulated in the airway epithelium with distinct patterns. Expression of Hey2 and HeyL remained low at all time points. Interestingly, up-regulation of Notch1 and Hes1 correlated with increased expression of Scgb3a2 (secretoglobin, family 3A, member 2), an early secretory cell marker. Additionally, increased Notch1 and Hes1 expression was observed almost exclusively in cells negative for Foxj1 (forkhead box j1), an early ciliated cell marker. These suggest that activation of Notch signaling, likely by Notch1, may favor the acquisition of the secretory cell phenotype during the repopulation of the airway epithelium after injury. Conclusions: Thus Notch signal may be crucial for the balance of differentiated cell fates during airway regeneration, as it is in development.

Inscuteable Drives Asymmetric Cell Divisions in the Mouse Epidermis.
N. Poulson, T. Lecher; Department of Cell Biology, Duke University, Durham, NC

Asymmetric cell divisions (ACD) are used throughout development to promote different fates between two daughter cells. In the mouse epidermis ACD within the proliferative basal layer promote stratification and differentiation. Unlike invertebrate model systems for ACD, which undergo obligate asymmetric divisions, basal cells have the capacity to undergo both asymmetric and symmetric divisions. Thus, a basal cell must be able to direct the proper orientation of its mitotic spindle to achieve the correct type of division. We provide evidence on how and when this decision is made. To this end, we used two transgenic mouse lines that labeled either the centrosomes or spindle poles. By quantifying their localization throughout the cell cycle, we have determined that basal cells do not establish their axis of division until metaphase via spindle
rotation. This phenomenon has been verified in cultured keratinocytes expressing centrin-GFP. This differs from invertebrates that establish their spindle orientation prior to nuclear envelope breakdown via centrosome migration. Thus basal cells may have the ability to choose between dividing symmetrically or asymmetrically even after committing to mitosis. ACD's require the formation of an apical protein complex. Inscuteable is a component of the ACD machinery that is necessary and sufficient to drive some ACDs in Drosophila. We have generated mice that allow inducible expression of mInscuteable in the epidermis. Upon induction of mInscuteable, the protein localized normally to the apical cortex and increased the occurrence of ACDs. From this we conclude that Inscuteable is sufficient to induce ACD and therefore is likely a key regulatory element in the process of stratification. Further exploring these questions will give us insight into how the spindle orientation machinery functions to achieve proper alignment and how basal cells use asymmetric divisions to properly develop.

Homeostasis of Infrequently Dividing Hair Follicles Stem Cells by Symmetric Daughter-Cell-Fate Determination.
Y. V. Zhang, J. Cheong, N. Ciapurin, D. J. McDermitt, T. Tumbar; Molecular Biology and Genetics, Cornell University, Ithaca, NY

Regenerative tissues contain stem cells that self-renew and differentiate throughout life. In normal vertebrate tissue homeostasis, stem cells are predicted to rarely divide and adopt an asymmetric progeny-cell fate: one daughter remains a rarely dividing stem cell and the other becomes a rapidly dividing short-lived progenitor. In order to test such hypotheses, we employ In Vivo division tracking and stem cell fate lineage tracing, to examine the long-term dynamic behaviour of hair follicle stem cells in mouse skin. We provide strong In Vivo evidence at the single-cell resolution for the infrequent stem cell division model in this vertebrate system. We find that proliferation and differentiation of progenitor cells occur at different times and tissue locations than self-renewal of stem cells. Distinct fates of differentiation or self-renewal are assigned to individual stem cells in a temporal-spatial manner. We propose that large groups of tissue stem cells behave as populations, in which pool maintenance involves symmetric daughter-cell-fate decisions.

Regulation of Homeostasis of Hair Follicle Stem Cells by Bmp Signalling.
E. Kandyba, Y. Leung, K. Kobielak; Eli and Edythe Broad Center for Stem Cell and Regenerative Medicine, Department of Pathology, University of Southern California, Los Angeles, CA

During the hair cycle, the behaviour of slow-cycling, hair follicle stem cells (hf SCs) is tightly governed by an intricate balance of signalling pathways which converge to induce bouts of SC quiescence and activation, resulting in new hair formation. We have previously shown that bone morphogenetic protein (BMP) signalling is essential for hair follicle stem cells homeostasis, revealing ablation of the Bmpr1a gene resulted in the precocious activation of quiescent hf SCs and premature expansion of the SC niche (Kobielak et al., 2007). However, precisely how BMP signalling functions in hf SCs at the molecular level still remains to be elucidated. Since CD34 the only available marker for isolation of hf SCs was lost upon BMPR1A ablation to address this question we employed, a Keratin 15 (K15)-driven model to simultaneously label and specifically target BMPR1A ablation within the hf SCs during the second postnatal telogen. Using this approach we were able to isolate hf SCs marked by eYFP from control and BMPR1A knockout (KO) by fluorescence activated cell sorting (FACS) before morphological changes in hair cycle were indicated. Transcriptional profiling reveals that after ablation of BMP signaling in hf bulge, stem cells show downregulation of approximately 25% of common upregulated hf SCs signature genes (Greco et al., 2009 and Blanpain et al., 2004). at the same time they acquire molecular characteristic of hair germ as our data show that 30% of genes overlapped with previously characterized hair germ signature (Greco et al., 2009) Our findings suggest a model where balancing BMP signalling in hair follicle stem cells is important to maintain their homeostasis and
its inhibition could be important to switch them from their quiescence to activation towards hair germ.

FGF2 Maintains the Proliferation of Neural Precursors by Actively Suppressing the Cki p27Kip1 through Regulation of Cks1b Transcription.

A. J. Darr 2,3, T. Okamoto 2, M. Arenas-Valdes 2, Y. Wang 2, P. Tsoulfas 1,2,3; 1Neurosurgery, University of Miami Miller School of Medicine, Miami, FL, 2The Miami Project to Cure Paralysis, University of Miami Miller School of Medicine, Miami, FL, 3Neuroscience, University of Miami Miller School of Medicine, Miami, FL

Identifying the mechanisms that regulate the proliferation and differentiation of neural precursor cells (NPCs) is important for understanding CNS development in vertebrates. We hypothesize that during embryogenesis, NPCs in the ventricular zone (VZ) maintain their proliferation in response to growth factors by repressing the cell cycle inhibitor p27Kip1, in part, through the up-regulation of Cks1b and activation of the degradation complex SCFSkp2. We report that while p27Kip1 mRNA is detected in the VZ and in the mantle zone of the spinal cord and cortical plate of the cerebral cortex, p27Kip1 protein is mostly absent from the VZ throughout the neuraxis. We show that NPCs harvested from E14 rat cerebral cortex in the presence of FGF2 express high protein levels of Cks1b and undetectable levels of p27Kip1, while removal of FGF2 causes a sharp decrease in Cks1b and corresponding increase in p27Kip1. Furthermore, our RNA expression data shows that Cks1b mRNA is reduced in non-dividing NPCs but is present in proliferating progenitors, suggesting that Cks1b is being regulated at the transcriptional level. Analysis of the putative promoter of Cks1b revealed numerous conserved transcription factor consensus sites, including E2F and cell cycle-dependent element (CDE) cell cycle genes homology region (CHR) consensus sites. We used chromatin immunoprecipitation to identify which E2Fs occupy the Cks1b promoter under different conditions of mitogen stimulation. Our results show that the E2F4/p130 complex occupies the Cks1b promoter in quiescent NPCs while E2F1 binds the Cks1b promoter in proliferating NPCs. In a luciferase reporter assay, mutation of either the E2F or CDE/CHR consensus sites de-represses Cks1b promoter activity in NPCs in G0/G1, while mutation of both sites together delays induction of promoter activity. Finally, we used a gain-of-function approach using in ovo electroporation to address whether or not p27Kip1 has a moonlighting role in neuronal differentiation. We find that ectopic expression of p27Kip1 reduces the number of proliferating cells in the early spinal cord, diminishing its overall size and shape, but is insufficient to induce neuronal differentiation in spinal cord neural precursors.

Lens Development in the Zebra Fish Resembles the Mammal.

T. M. Greiling, S. M. Houck, M. Aose, J. I. Clark; Biological Structure, Univ of Washington, Seattle, WA

OBJECTIVE: The progressive stages of development from lens placode to optical element was studied in real time to test the hypothesis that the primary fibers in the embryonic zebra fish lens originate in the central placode and the epithelial cells originate in the periphery of the placode. METHODS: 2-photon live-embryo imaging was conducted on Q01zebrafish that express cyan fluorescent protein fused to a membrane-targeted sequence of zebra fish Gap43 (mCFP), driven by an EF1α promoter and a hexamer of the DF4 pax6 enhancer element. Each differentiating cell was outlined. Fertilized Q01 zebra fish eggs were injected at the 1-cell stage with a combination of two plasmids, EF1α::Gal4VP16 containing a Pax6 enhancer and UAS::td-tomato, for mosaic expression of fluorescent tomato red protein. RESULTS: Cells in the peripheral lens placode migrated to the anterior lens mass and differentiated into the lens epithelium. Cells in the central lens placode migrated to the posterior lens mass and differentiated into primary fiber cells. Anterior and posterior polarization of the zebra fish lens cell mass resembled the anterior and posterior polarization of the mammalian lens vesicle. TUNEL labeling demonstrated that apoptosis was not a primary mechanism for separation of the lens from the surface ectoderm and future cornea. BrdU incorporation revealed that proliferation was restricted to a lateral zone in the
lens epithelium similar to the mammal. Fiber cell differentiation began prior to separation of the lens mass from the surface ectoderm, as evidenced by cell elongation, exit from the cell cycle, and expression of Z1-1, a lens fiber cell marker. Protein analysis of zebrafish lens homogenates at selected ages from 4 days to 6 months post fertilization determined that the variation in protein content with age resembled that of mammals. CONCLUSION The results confirmed the hypothesis that a symmetric, refractile, transparent zebrafish lens was generated from a sheet of undifferentiated, embryonic, cranial epithelium using biological mechanisms that are similar to mammalian lens development. Supported by EY04542 from the NEI. Dedicated to the memory of Prof. DW Fawcett.

Sox2 and the Xenopus Homologue of Oct4 Maintain Neural Progenitors in Xenopus laevis.
T. C. Archer, E. S. Casey; Department of Biology, Georgetown University, Washington, DC

Since Sox1, Sox2 and Sox3, the three members of the SoxB1 subgroup, have similar expression patterns, protein structures and functions, it has been suggested that they have redundant roles during neural development. Here we show that Sox1, Sox2, Sox3, and Oct91, the Xenopus homologue of Oct4, have overlapping and distinct roles in inducing neural progenitor identity. In naïve ectoderm using ectodermal explant assays, Sox1, Sox2, Sox3 induce a unique array neural genes markers but only Sox1 is sufficient for neuronal differentiation. Sox2 and Sox3 function independently of each other, yet Sox1 induces expression of both Sox2 and Sox3. While Sox2 induces limited neural progenitor markers, Sox3 induces a broad profile of neural progenitor and pro-neural markers and this may be due to its unique induction of FGF8 expression. Sox3-VP16, the dominant activator form of Sox3, does induce neuronal markers and Sox2 expression, which indicates that Sox3 requires the presence of a co-factor for neuronal differentiation. Only a few co-factors of the Sox proteins have been identified and therefore their function in combination with a partner has not been tested in early development of the nervous system. In naïve ectoderm, Oct91 induce sox1-3 expression and induces neuronal differentiation. Overexpression of both Sox2 and Oct91 maintained neural progenitor markers while also inhibiting neuronal differentiation. However, the addition of Sox1 or Sox3 abolishes the ability of Oct91 to induce any neural markers even though epidermis formation was still repressed. Finally, transgenic embryos were generated using a bicistronic expression vector to determine if transient overexpression of the SoxB1s delays neuronal differentiation due to loss of the mRNA over time. Constitutively-active expression of Sox1 or Sox2 transgenic embryos represses neuronal differentiation indefinitely while also increasing cell proliferation. Constitutively-active Sox3 leads to cell death.

TXNIP Regulates Hematopoietic Stem Cell Quiescence and Mobilization.
S. Yoon¹, M. Jeong¹, Z. Piao¹, M. Kim¹, S. Lee¹, S. Yun¹, J. Chung¹, I. Choi²; ¹Cell therapy center, Korea Research Institute of Bioscience and Biotechnology, Daejeon, Korea, South, ²Department of Biological Science, Dong-A University, Busan, Korea, South

Hematopoietic stem cells (HSCs) are maintained in a quiescent state in bone marrow (BM) niches by intrinsic and extrinsic signals. However, the mechanism that coordinates the cell cycle regulation of HSCs and the interactions between HSCs and the niche remains unclear. Thioredoxin-interacting protein (TXNIP) is known as a critical regulator of a broad range of cellular functions, including maturation of natural killer cells, immune regulation, glucose and lipid metabolism, and regulation of the life span, aging, renal function, homeostasis, and hematopoiesis. Here, we investigated the role of TXNIP in hematopoietic stem cell quiescence and mobilization using Txnip⁻/⁻ mice. The expression of TXNIP measured by quantitative real-time RT-PCR was decreased during HSC activation. Flow cytometry analysis and reconstitution assay showed that the long-term reconstituting HSC population was decreased and exhausted, and its capacity to repopulate was rapidly lost in Txnip⁻/⁻ mice. These effects are associated with hyperactive Wnt signaling, an active cell cycle, and reduced p21 expression under conditions of stress. TXNIP deficiency reduced the CXCL12- and osteopontin-mediated interaction between HSCs and the BM, and impaired homing and retention in the osteoblastic niche, resulting in...
mobilized HSCs. Therefore, we propose that TXNIP is essential for maintaining HSC quiescence and the interaction between HSCs and the BM niche.

**Fever Like Temperature Increases and Accelerates Erythroid Differentiation through Normal Regulatory Circuitry.**

*K. F. Tounkara\(^1,2\), L. Boyer\(^1\), N. Pineault\(^1,2\), \(^1\)R&D, Hema-Quebec, Quebec City, QC, Canada, \(^2\)Biochemistry and Microbiology Department, Laval University, Quebec City, QC, Canada*

The differentiation of hematopoietic stem cells (HSC) along the erythroid lineage is regulated by the cytokine erythropoietin (EPO). Central within the erythroid differentiation program is the transcription factor GATA-1 which regulates a wide array of genes required for the development of red cells. The heat shock factor protein HSP70 was recently shown to have important role in erythropoiesis through the regulation of GATA-1. This led us to test whether mild hyperthermia (MH) such a fever (39°C), could impact the differentiation of HSCs into erythrocytes. Our hypothesis is that MH would promote erythroid differentiation due to increased GATA-1 activity due to increased HSP70 expression. Cord blood CD34+ cells were grown at 37 or 39°C in medium supplemented with EPO and SCF. Cultures maintained at 39°C experienced a profound acceleration in erythroid differentiation as evident by accelerated appearance of glycophorin a (GPA)+CD71+ cells (66±3 vs 43±14 at day 5, at 39 and 37°C, n=2), and increased expansion of GPA+ cells (72±11 vs 36±8 x10^3 GPA+ cells at day 14, at 39 and 37°C, respectively n=3). Next, we set out to identify the molecular mechanisms responsible for this. First, we investigated the impact of MH on signal transduction molecules known to regulate erythroid differentiation through the EPO receptor (anti-phosphos antibodies and intracellular cytometry); these analyses revealed that MH led to the activation of STAT5 (2.6±1.9 fold), Erk1/2 (1.5±0.26 fold) and AKT (1.5±0.1) (n=3). Activation of these molecules by MH was not strictly dependent on EPO and addition of inhibitors to these molecules severely impaired (35-100%) the effect of MH suggesting that the effects of MH were mediated in part through these effectors. Secondly, we found that MH led to a strong increase in the expression of HSP70 (2-5X), and increased phosphorylation of GATA-1 at serine 310. Consistent with this, a rapid increased in GATA-1 transcriptional activity was observed in luciferase assay (1.3±0.3 fold,n=3). These results demonstrate that fever like temperature can promote the differentiation of progenitor cells along the erythroid pathway through normal regulatory circuitry that are sensitive to heat shock responses.

**Hematopoietic Stem and Progenitor Cell Division and Dynamics Modulated by Non-Muscle Myosin II Inhibition.**

*J. Shin\(^1\), D. E. Discher\(^2\); \(^1\)Department of Pharmacology, Graduate Group in Pharmacological Sciences, University of Pennsylvania School of Medicine, Philadelphia, PA, \(^2\)Biophysical Engineering and Nanobiopolymers Laboratory, School of Engineering and Applied Science, University of Pennsylvania, Philadelphia, PA*

Investigation of mechanisms behind hematopoietic stem and progenitor cell (HSPC) division is of clinical importance, including identification of optimal ex vivo culture conditions for HSPC expansion. Contributions of cytoskeletal machinery to HSPC division and population dynamics remain largely uninvestigated. One important cytoskeletal component of cell division is non-muscle Myosin II (NMM II) which mediates furrow ingression during cytokinesis. In the present study, contributions of NMM II to HSPC division were evaluated under ex vivo culture conditions that were previously used to expand human CD34+ cell number in clinical studies. This is followed by pharmacological modulation of NMM II ATPase activity by (±)-blebbistatin, a selective NMM II inhibitor, combined with subpopulation analysis using flow cytometry with defined surface markers for HSPCs. Cell number of the primitive HSPC subpopulation, CD34+CD90+ (~20% of total at day 0 culture) was maintained for 4 days and then rapidly declined to nearly 0% on day 7. In contrast, cell numbers of less primitive subpopulations, CD34+CD90- and CD34-CD90-, were slowly increased over 4 days. Afterwards, the number of CD34+CD90- cells remained relatively
constant, while that of CD34^+CD90^- was dramatically increased on day 7. Cells were treated with different doses of blebbistatin on day 4, when active cell proliferation was taking place (~3 fold increase from day 0). High concentration (>25uM) of blebbistatin led to progressive cell death, while 12.5uM of the drug reduced the total viable cell number (1.5~2 fold compared to untreated), but overall increase in cell number (2 fold increase from 0hr treatment) in 60hr treatment. An initial experiment also raises a possibility that blebbistatin may lead to alterations in HSC population dynamics - 12.5uM blebbistatin treatment for 60hr led to 2 fold increase in CD34^+CD90^- fraction (42.3% vs 18.2% of total) compared to untreated controls. In conclusion, the present study raises a possibility that NMM II may contribute to HSC cell division and population dynamics. Dose-dependent effect of blebbistatin on HSC subpopulation, cell division and cycle kinetics is currently being investigated.

Hematopoietic Progenitor Cell Communication with the Niche Microenvironment Is Regulated by a Specialized Plasma Membrane Domain.
J. Gillette1, A. Larochelle2, A. Cantilena3, A. Cerf4, C. E. Dunbar2, J. Lippincott-Schwartz5; 1NICHD, Cell Biology and Metabolism Program, National Institutes of Health, Bethesda, MD, 2NHLBI, Hematology Branch, National Institutes of Health, Bethesda, MD

The spatial organization and dynamic movement of proteins and lipids in cell membranes is essential for regulating cell-signaling and cell communication events. within the bone marrow niche, cell communication between hematopoietic progenitor cells (HPCs) and niche cells provides critical cues for their proliferation and survival. Work from our laboratory identified a specialized plasma membrane domain on HPCs that serves as the contact site with osteoblasts, members of the marrow niche. Characterization of this domain using primary CD34+ cells and the KG1a cell line identified the enrichment of specific tetraspanin family proteins including CD81 and CD63, which are known to organize the plasma membrane into domains important for signaling. Using live cell imaging techniques, we observed the intercellular transfer of proteins and lipids from the HPC specialized domain to osteoblasts. Transferred material was internalized by the osteoblasts into SARA-positive, signaling endosomes, which resulted in the downregulation of Smad signaling and an increase in stromal-derived factor-1 production, a chemokine responsible for HPC homing. Next, we evaluated the functional significance of the specialized membrane domains for In Vivo homing of HPCs to the bone marrow microenvironment. Disruption of HPC membrane domains by cholesterol sequestration had no effect on cell viability, proliferation or colony forming capacity in vitro. However, we observed an over three-fold decrease in homing of HPCs with disrupted membrane domains to the bone marrow of NOD/SCID IL2r ^-/- mice as compared to mock-treated HPCs. Given the known homing/engraftment defect of actively cycling HPCs, we went on to compare membrane domains on quiescent and cycling CD34+ cells. When HPCs were stimulated with cytokines to enter the cell cycle, the polarized morphology and the tetraspanin-enriched domain became undetectable. These findings suggest the importance of tetraspanin-enriched HPC membrane domains for cell communication and homing within the marrow niche. Furthermore, the turnover of this tetraspanin-enriched domain during the cell cycle suggests an importance for this plasma membrane site in maintaining the primitive phenotype of HPCs.

423/B370
MT1-MMP in B Cell Development.
G. Jin, Z. Zhou; the University of Hong Kong, Hong Kong, China

The development of early stage B cells occurs in bone marrow before they are recruited to peripheral organs during immature B cell stage and then develop into mature B cells. In bone marrow, B cell precursors derive from hematopoietic stem cells (HSCs). They first commit into pro-pre-B cells, and then go through pro-B cell stage, pre-B cell stage and immature B cell stage. It is demonstrated that stromal cells play an important role in organizing the bone marrow niches in which B cells can develop in an ordering way before going into pre-B stage and then leave the stromal cells. During different stages, a serial of different microenvironment factors support the
process. MT1-MMP is a membrane-tethered matrix metalloproteinase which is first found on tumor cell surface. It is critical for bone formation and adipogenesis. Loss of MT1-MMP manifests severe defects in both bone formation and adipogenesis. Here we show that MT1-MMP is expressed in bone marrow derived stromal cells. Because bone marrow stromal cells are important components of bone marrow niches in supporting B cell development, we explored the role of MT1-MMP in bone marrow B cell development. We found that loss of MT1-MMP leads to abnormal reduced B cells population in bone marrow. However, MT1-MMP is not expressed by B cell itself. In addition, reconstitution of MT1-MMP deficient bone marrow cells into lethally irradiated wild type mice can rescue the defect of B cell development, which indicating that the defect is not cell autonomous but comes from a defect of bone marrow niches. Furthermore, co-culture experiment showed that In Vitro cultured wild type bone marrow stromal cells support B cell development better than the stromal cells from MT1-MMP deficient mice. In this way, we demonstrated that MT1-MMP regulates the properties of bone marrow stromal cells and consequently it contributes to the microenvironment in supporting normal B cell development.

Epigenetic Regulation of Sox9 during Chondrogenesis.

L. Lu, D. Chan, K. Cheah, M. Cheung; Biochemistry, The University of Hong Kong, Hong Kong, China, Centre for Reproduction, Development and Growth, The University of Hong Kong, Hong Kong, China

Cell-base therapy has been evolved as one of the most popular strategies to treat various bone and cartilage disorders. Comparing with pluripotent stem cells, unipotent patient specific cells with defined differentiation potential might be more applicable in regenerative medicine. Osteo-chondroprogenitor with dual skeletogenic potentials has been considered as the key for bone and cartilage regeneration. However, the underlying mechanism directing the formation and maintenance of osteo-chondroprogenitor remains elusive. Sox9, an SRY related high mobility group family of transcription factor, is a master regulator for chondrogenesis based. In developing mouse embryos, Sox9 expression is initiated in the core of the limb bud mesenchyme at E10.5. Genetic lineage tracing analyses showed that Sox9 expressing cells in the limb bud mesenchyme and its progeny are able to form cartilage and bone, suggesting that they are osteo-chondroprogenitors. These bipotent progenitor cells expressing Sox9 will undergo mesenchymal condensation, proliferation and subsequently differentiation into hypertrophic chondrocytes where Sox9 is downregulated. Understanding how Sox9 expression in the osteo-chondroprogenitor is regulated would provide insight of how the cells are formed and maintained. While the chondrogenic enhancer and upstream regulatory factors directing Sox9 expression remain to be identified, epigenetic has been evolved to be an important element controlling gene activation and silencing. Several In Vitro evidence suggest that Sox9 expression can be subjected to epigenetic regulation. Using bisulfite sequencing, we found that DNA methylation, which appears to be more tissue specific, is rarely detected within the Sox9 proximal promoter region both before and after osteo-chondroprogenitor formation. The data suggests that there could be other epigenetic modifications regulating Sox9 expression at early stages of chondrogenesis. This is the first In Vivo study of DNA methylation profiling on Sox9 in limb bud formation. Understanding the epigenetic profiling of Sox9 would benefit the mechanistic study leading to In Vitro generation of osteo-chondroprogenitors.

Identification of the Genes Involved in Signal Transduction during Myogenesis by Using LA-PCs.

N. Kawaguchi, R. Nakao, R. Matsuoka; IREIIMS, Tokyo Women’s Medical University, Tokyo, Japan

[Objective] Identification of the genes involved in myogenesis can facilitate the development of regenerative medicines. In our previous study, we established left atrium-derived pluripotent cells (LA-PCs). When these cells were cultured in Methocult GF-M5334 (a semi-solid methylcellulose medium) containing cytokines (IL-3, IL-6, and SCF) or grown to high confluence, they
differentiated into functional cardiac myocytes and/or skeletal muscle cells. The objective of this study was to identify the genes involved in myogenesis by using the LA-PCs and performing microarray analysis. We especially focused on the genes involved in signal transduction during myogenesis. [Method] We extracted total RNA from undifferentiated LA-PCs (UND/LA-PC) and fully differentiated LA-PCs (D/LA-PC). Microarray analysis was performed using an Agilent DNA chip containing the rat whole genome. The genes that exhibited more than 2-fold alteration (between UND/LA-PC and D/LA-PC) in expression were selected as candidate genes, and RT-PCR was performed to examine their expression levels. [Results] We observed that the following genes were up-regulated: troponin T1 slow skeletal; myogenin; MEF2C; troponin C. These genes were previously known to be associated with myogenesis. These findings suggested that our technique was efficient in identifying the genes involved in myogenesis. Therefore, using this technique, we further identified the other candidate genes associated with signal transduction. RT-PCR analysis showed that although the noggin gene was expressed in the undifferentiated cells, its expression was down-regulated during the course of myogenesis. In contrast, the expression of IGF-1 and the Wnt inhibitory factor-1(Wif-1) were up-regulated during myogenesis. These findings suggest that the IGF-1 and/or the Wnt signal pathways were involved in myocyte differentiation. [Conclusion] We successfully established the LA-PCs that showed myogenic differentiation. By comparison expression levels of UND/LA-PC with D/LA-PC, we could identify the genes involved in signal transduction during myogenesis.

The Role of Homeodomain Factor Barx2 in Muscle Development and Regeneration.

M. V. Barro¹, R. Meech², K. N. Gonzalez¹, C. Woolley¹, H. P. Makarenkova¹,², ¹Neurobiology, TSRI, San Diego, CA, ²Clinical Pharmacology, The Flinders University of South Australia, Bedford Park, SA, Australia, ³The Neurosciences Institute, San Diego, CA

Adult mammalian muscle regenerates upon injury by activation of undifferentiated myogenic precursor cells called satellite cells, which are normally quiescent and situated between the plasmalemma and the surrounding basal lamina of muscle fibers. Upon activation, satellite cells proliferate and divide asymmetrically, producing one daughter cell that proceeds to myogenic differentiation and another that becomes quiescent and replenishes the satellite cell pool. We are investigating the role of the homeodomain factor Barx2 in skeletal muscle development and regeneration. Barx2 is co-expressed with paired-box transcription factor Pax7 in progenitor cells of fetal and adult muscle and its expression is up-regulated after muscle injury. Mice lacking the Barx2 gene show muscle regeneration defects, reduced muscle growth, and reduced Pax7 expression, suggesting a role for Barx2 in satellite cell survival and/or self-renewal. Cultured Barx2-/- satellite cells are less proliferative and slower to differentiate than Barx2+/- cells, and also show reduced expression of myogenic factor MyoD and myogenin. These findings suggest that defects in muscle regeneration in Barx2 null mice may be caused by reduced activation and/or delayed differentiation of satellite cells. Moreover, interbreeding of Barx2 mutants with muscular dystrophy model mice (mdx) leads to striking dystrophic features. These are characterized by muscle degeneration and the appearance of fibrous infiltrates, mimicking the dystrophic phenotype observed in human patients. Together, our ongoing work suggests that Barx2 is a critical component of the muscle growth and repair machinery in mammals and that it controls myogenic commitment and differentiation.

Directing Human Pluripotent Stem Cells Toward the Skeletal Muscle Lineage.

T. Tran¹,²,³, C. Peterson¹,³, A. D. Pyle¹,³, ¹Microbiology Immunology and Molecular Genetics, UCLA, Los Angeles, CA, ²Department of Molecular, Cell and Developmental Biology, UCLA, Los Angeles, CA, ³Eli and Edythe Broad Center of Regenerative Medicine and Stem Cell Research, UCLA, Los Angeles, CA

Human embryonic stem cells (hESCs) and human induced pluripotent stem cells (hiPSCs) hold great promise as a potential source of cells for use in therapeutic medicine due to their ability to differentiate into cells from each germ layer and continuously self-renew. Despite this potential,
there remains great variation in both methodology and efficiency of generating mesodermal lineages from either hESCs or hiPSCs. Of particular difficulty has been the development of reliable protocols to efficiently differentiate skeletal muscle lineages. Although CD73+ mesenchymal cells have been obtained through sequential culturing and cell sorting methods, skeletal muscle cell yield was low and the protocol requires media for neuronal growth. Therefore we are currently establishing an alternative approach for directing differentiation of hESCs and hiPSCs toward the muscle lineage. To this end, when embryoid bodies (EB) derived from hESCs and hiPSCs were differentiated after 24 days, maximal enrichment for early stage or progenitor muscle markers was achieved compared to those differentiated up to 30 days. Subsequently, dissociated cells from EBs at each time point were sorted for either NCAM or M-Cadherin and expanded in standard culture conditions for promoting muscle cell growth. Both cell types were confirmed to express Pax3 via RT-PCR. Establishment of standard protocols for the reliable generation of muscle progenitor cells from PSCs will be important in future experiments for assaying the differentiation potential of Duchenne Muscular Dystrophy (DMD) patient-specific hiPSCs as well as for identifying the muscle cell type(s) needed for efficacious cell therapy.

Abnormal Development of Skeletal Muscle Stem Cells in a Mouse Model of Spinal Muscular Atrophy.
M. H. Bennett1, M. Cerletti2,3, A. Wagner4, A. Wagers2,3, L. L. Rubin1; 1Havard Stem Cell Institute, Harvard University, Cambridge, MA, 2Department of Stem Cell and Regenerative Biology, Harvard University, Cambridge, MA, 3Department of Pathology, Joslin Diabetes Center, Boston, MA

Spinal muscular atrophy (SMA) is the leading genetic cause of mortality in infants and toddlers. The disease is characterized by the degeneration of spinal cord motor neurons and muscular atrophy. SMA is caused by homozygous mutations in or deletion of the Survival Motor Neuron 1 (SMN1) gene, which results in low levels of SMN protein in all cells. Several lines of evidence suggest that muscle cells are themselves affected by the low levels of SMN and that they may indirectly contribute to poor motor neuron survival. Here we examined skeletal muscle precursor cells (SMPs), a subset of muscle satellite cells that are defined by their unique anatomical location beneath the basal lamina and adjacent to the muscle fiber plasma membrane. These cells play an essential role in muscle growth and repair. SMPs were isolated from skeletal muscle of postnatal day 2 SMA (Smn-/-; SMN2+/+) or wildtype (Smn+/+; SMN2+/+ or Smn+/-; SMN2+/+) animals using cell surface marker expression (Sherwood et al., Cell, 119 (2004), 543-554). We found similar numbers of SMPs in SMA and wildtype mice, at least at this stage of development. Further, at day 4 in vitro, the survival and proliferation of SMPs from SMA and wildtype mice were comparable. However, on day 4, SMPs from SMA animals appeared to have an accelerated differentiation, as revealed by the presence of more elongated cells and the premature expression of the muscle differentiation markers MyoD and Myosin Heavy Chain. These data suggest that early withdrawal of SMPs from the cell cycle may ultimately lead to a diminished number of these cells and, consequently, the reduced capacity for muscle growth, and potentially for muscle repair, observed in SMA.

429/B376
Differentiation of Adult Stem Cells Induces DNA Damage.
D. A. Barry1,3,4, E. Weiss2,3,4, J. B. Pollett2,3,4; 1Department of Obstetrics, Gynecology & Reproductive Sciences, University of Pittsburgh, Pittsburgh, PA, 2Department of Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, 3University of Pittsburgh Cancer Institute, Pittsburgh, PA, 4Stem Cell Research Center, Pittsburgh, PA

It is established that multiple signaling pathways cooperate to maintain stem cell identity and, therefore, dysregulation of the tight control of these pathways will likely lead to changes in cell homeostasis. These changes can result in aberrant behavior and potentially transformation. Our lab, as well as others, has reported the transformation of stem cells following their implantation for the purposes of tissue regeneration. Herein, we report a putative mechanism to explain this
phenomenon. Preliminary experiments using a DNA integration method that induces GFP expression have revealed that DNA integration events increase when stem cells are subjected to differentiation signals. When adult muscle-derived stem cells (MDSCs) were treated to undergo either myogenic or osteogenic differentiation, we found that 1% and 3.5% of MDSCs that underwent osteogenic and myogenic differentiation, respectively, had integrated the reporter plasmid (over controls) after 7 days of culture. The concept of differentiation-induced DNA damage is not new. It was reported over 20 years ago that differentiation induces DNA nicking and strand breaks in a variety of cell types. To further investigate this, we focused primarily on myogenic differentiation. When we used a more refined fluorescence-activated cell-sorting based technique to explore DNA nicking, we found that, within 24 hours of myogenic differentiation, 12% of the cells had DNA damage. This trend increased over time, with the amount of damage peaking at 56% at 96 hours. By day 7, however, the damage was completely repaired. Furthermore, though we observed significant amounts of DNA damage, we observed no decrease in cell number, and no increase in the amount of dead/apoptotic cells over our controls. This data, though preliminary, provides evidence of transient DNA damage due to the differentiation of adult stem cells, and can help explain the spontaneous transformation of stem cells when used for regenerative medicine.

Generations of Induced Pluripotent Stem Cells from Human Aortic Smooth Muscle Cells.
G. Shin, S. Song, J. Yi, W. Suh, T. Lee; CHA Univ., Seoul, Korea, South

Generations of induced pluripotent stem(iPS) cells have been intensively studied by a variety of reprogramming methods, but the molecular and functional properties of cells differentiated from iPS cells have not been well characterized. Here, we generated iPS cells from human aortic smooth muscle cells (HASMCs) by using lentiviral transduction of defined transcription factors. Established iPS cells were characterized to possess equivalent properties of human embryonic stem cells in terms of the cell surface markers, that is global mRNA and miRNA expression patterns, epigenetic status of OCT4, REX1, and NANOG promoters, and in vitro/In Vivo pluripotency. Our study reports, for the first time, the generation of iPS cells from HASMCs.

SPARC and BMP2 Induce Cardiomyogenesis in Clonal Cardiac Stem Cell Lines in an Nkx2.5 Dependent Manner.
T. Gottschamel1, J. Hoebaus1, A. Kuzmenkin2, J. Hescheler2, G. Weitzer1; 1Medical Biochemistry, Medical University of Vienna, Vienna, Austria, 2Neurophysiology, University of Cologne, Cologne, Germany

Somatic stem cells of the heart have been isolated in past years by several groups using different strategies. These cell populations had different morphology but in common that they differentiate only to cells residing in the heart and that they could not be maintained as clonal stable cell lines so far. We have isolated and cloned stable cardiac stem cell lines from murine hearts and demonstrated that they express at the same time stemness genes such as Oct4, Nanog, Sox2, and Tert1, and marker genes for primitive mesoderm and early cardioblasts, such as Brachyury, Mesp1, Desmin, Nkx2.5, and Isl1. They self-renew in a LIF dependent manner for at least 80 passages without loosing their potential to spontaneously differentiate to cardiomyocytes, smooth muscle cells and endothelial cells, both in mono-layers and in embryoid body-like aggregates. Cardiomyocytes develop to mature pacemaker cells and atrial and ventricular cardiomyocytes expressing Connexin 43. SPARC, a matricellular protein promoting early cardiomyogenesis induces Nkx2.5 expression in cardiovascular progenitor cells and together with BMP2 promotes cardiomyogenesis via activation of the Nkx2.5 gene. Our results indicate successful isolation and long-term culture of clonal cardiovascular progenitor cells within a micro-environment accurately recapitulating a minimal stem cell niche.

432/B379
Mitochondrial ROS Formation Inhibit Cardiomyocyte Differentiation.
Reactive oxygen species (ROS) from different sources have direct or indirect effect on cardiomyocyte development. To investigate the effect of ROS produced within the electron transport chain (ETC) on cardiomyogenesis, embryonic stem (ES) cells expressing GFP under control of the cardiac specific α-myosin heavy chain (α-MHC) promoter were differentiated. Inhibition of complex III of the ETC with antimycin A or myxothiazol selectively abolished cardiomyocyte differentiation without effects on mesodermal or endothelial cell formation. However, ROS scavengers were able to reduce mitochondrial ROS levels and restored cardiomyocyte differentiation. We therefore conclude that the selective inhibition of cardiomyocyte differentiation was not due to impaired aerobic ATP production but to increased mitochondrial ROS levels. Cardiomyocyte formation was also restored by addition of a calcium-ionophore, indicating involvement of Ca²⁺ signaling. Our data were further supported by the finding that mitochondrial ROS impair Ca²⁺-spiking in early embryonic cardiomyocytes. Immunohistochemical analyses in differentiating ES cells revealed that mitochondrial ROS did not inhibit the expression of early cardiac transcription factors Nkx2.5 and MEF2C. In summary, elevated mitochondrial, but not cytosolic ROS levels block cardiomyocyte differentiation by inhibiting nuclear localization of early cardiac transcription factors via a Ca²⁺-dependent pathway.

Cardiac Stem Cells Labeled with GFP Protein to Demonstrate Engraftment in Mouse Model as an Alternative Potential Cell Based Therapy for Cardiac Transplant Patients.

J. Sharma1, J. Wibbenmeyer2, L. Ugozzoli2, A. McCoy1, M. Collins1, S. Kaushal1, C. DiMaggio1, N. Taw1, M. Majdoub1, N. Liles1, G. Velazquez1, S. Sharma1, N. Amezcua1, K. DeSimone1, C. Sharma1, M. Sharma1; 1Stem Cell Biology, Celprogen, San Pedro, CA, 2Life Science, BioRad, Hercules, CA, 3Div Cardiac Thoracic Surgery, Northwestern University, Chicago, IL

Cardiovascular disease remains the leading cause of death worldwide. Acute ischaemic injury and chronic cardiomyopathies lead to permanent loss of cardiac tissue and ultimately heart failure. Current therapies aim largely to attenuate the pathological remodeling that occurs after injury and to reduce risk factors for cardiovascular disease. The current studies in animal models indicate that transplantation of cardiac stem cells has the potential to improve the function of ventricular muscle after ischaemic injury. The cardiac stem cell pool utilized in this study is cKit, KDR, Sca-1 (mice) Isl1 positive. The current experimental evidence suggests cardiac stem cells are able to engraft and differentiate into generation of new cardiac tissue. The predominant mechanisms of action of transplanted cardiac stem cells involve favorable physiological effects on injured myocardium. The adult heart possesses various pools of putative resident cardiac stem cells that can be isolated for therapy or manipulated In Vivo to improve the healing of cardiac muscle after injury as evident from this study. The genetic and protein profiles of the engrafted tissue when compared to the normal tissue were comparable. This study reveals the properties and potential utilization of cardiac stem cell populations for cardiac repair and regeneration.

434/B381
Human Fibroblast/Keratinocyte De-Differentiation into Human Cardiomyocytes in Tissue Culture.

J. Sharma1, S. Kaushal2, R. Punzalan1, C. DiMaggio1, N. Taw1, M. Majdoub1, N. Liles1, G. Velazquez1, S. Sharma1, C. Sharma1, N. Amezcua1, M. Sharma1; 1Stem Cell Biology, Celprogen, San Pedro, CA, 2Cardiac Thoracic Surgery, Northwestern University, Chicago, IL

Somatic Cell De-differentiation provides an emerging strategy to produce embryo-independent pluripotent stem cells from somatic tissue. Induced pluripotent stem cells (iPC) demonstrate aptitude for de novo cardiac differentiation, yet their potential for heart disease therapy has not been tested. In this study, human fibroblasts/keratinocytes were transduced utilizing non-viral mechanisms with human stemness factors OCT3/4, SOX2, and c-MYC converted into an embryonic stem cell-like phenotype and demonstrated by their ability to spontaneously assimilate
into preimplantation host morula via diploid aggregation, unique to pluripotent cells. The iPCs were differentiated into normal heart tissue. The genetic and protein profiles of the differentiated cardiac patterning were comparable to normal human cardiac tissue. Human Fibroblasts / Keratinocytes De-differentiation with human stemness factors may provide an alternative potential to repair acute myocardial infarction, or in the understanding of novel drug discovery potential for heart disease.

**Focal Adhesion (435 – 447)**

Proteomic Analysis of Myosin II-Mediated Focal Adhesion Maturation Reveals a Role for β-PIX in Relaxation-Mediated Rac1 Activation.

J. Kuo1, X. Han2, J. Yates2, C. M. Waterman1; 1Cell Biology and Physiology Center, NHLBI/NIH, Bethesda, MD, 2Cell Biology, Scripps Research Institute, La Jolla, CA

Focal adhesions (FA) are plasma-membrane associated macromolecular assemblies that serve to physically connect cells to, as well as transduce signals to and from, the surrounding extracellular matrix (ECM). FA play a crucial role in the control of tissue structure and morphogenesis as well as cell motility. It is well established that FA undergo a tension-induced "maturation" process in which their size increases. Indeed, high cellular tension induced by Myosin II activity promotes FA growth and maturation, while reduced cellular tension promotes formation of small, immature FA. The protein compositional changes that accompany maturation of FA are thought to be critical to modulating signals transduced from the ECM that regulate cell growth and differentiation. To determine how FA protein composition changes during FA maturation, we developed a systematic method to isolate FA from human fibroblasts in native morphology, identify their protein composition by Mud-pit LC-MS proteomics, and validate the presence of specific proteins in FA by a series of stringent criteria. We performed this method to determine how FA-associated proteins respond to Myosin II activity to form FA structure by comparing the proteomimic profile of FA in the presence and absence of the Myosin II inhibitor blebbistatin. The results indicate that Myosin II activity promotes increased recruitment of a diversity of proteins in FA. Although Myosin II inhibition induces loss of many proteins from FA, a small subset of proteins actually increased in immature FA of blebbistatin-treated cells. Indeed, we found increased recruitment of β-PIX, a Rac1 GEF, to FA in blebbistatin-treated cells. We thus determine the role of β-Pix in Rac1 activation and lamellipodial protrusion that are induced by Myosin II inhibition. We found that overexpression of β-PIX increased the population of immature FA. In addition, when endogenous β-PIX was knocked-down, Rac1 activity induced by blebbistatin treatment was blocked, and the duration of FA maturation became shorter. These findings suggest that the β-PIX in FA is inhibited by Myosin II activity, and serves as a negative regulator of FA maturation to modulate Myosin II-driven FA maturation process.

Cellular Junctions Are Dynamic and Undergo a Constant Change during the Development of the Drosophila.

U. S. Tulu1, M. C. Beckerle2, D. Kiehart1; 1Biology Department, Duke University, Durham, NC, 2Department of Biology, University of Utah, Salt Lake City, UT

During development, cells migrate and change shape to form functional tissues and organs. To investigate cellular junctions in tissue movements and mechanics, we used GFP-fusions to follow zyxin, α-actinin, F-actin and zip/MyoII in Drosophila embryos. Zyxin-GFP outlined the cell membranes within amnioserosa and lateral epidermis and localized as puncta between junctions of 3 or more cells in the lateral epidermis. At the onset of dorsal closure, zyxin starts to accumulate in foci (larger, more intense puncta) at cell-cell junctions at the leading edge of the lateral epidermis, forming a beads-on-a-string pattern. Accumulation of zyxin coincides with the establishment of tension in the actin rich cable or purse string. Foci of zyxin-GFP or GFP-α-actinin can disappear, fuse or divide, suggesting that focal adhesions are dynamic and regulated.
during closure. After zippering forms a seam at each canthus, the purse string, and foci of zyxin and α-actinin disappear. This suggests that focal adhesions participate in dorsal closure but not in the mature epithelium, where we infer that cell-cell junctions predominate. Zyxin and α-actinin also localize where filopodia, extending from opposite sides of the leading edge during the zippering process, interact. Time-lapsed videos suggest that this occurs only in between the cells that are fated to zip together. In the myospheroid mutants, that lack zygotic βPS-integrin expression, zyxin still localized in foci along the purse string albeit with slight differences. Injection of latranculin-A disrupted zyxin foci. In embryos mutant for zip/MyoII, beads-on-a-string localization of zyxin is perturbed, suggesting a dependence on the tension along the purse string. When leading edge cells are ablated from the tissue using laser microsurgery, zyxin-GFP localizes to foci along the secondary purse string formed during the recovery. These data show that cell junctions undergo dynamic changes during development, indicate that junctions are closely associated with purse string, and that they respond to the tension developed in cells/tissues. Grant support: GM33830 to DPK and GM50877 to MCB

Role of Tyrosine Phosphorylated Caveolin-1 in Caveolae Formation and Focal Adhesion Dynamics.
S. S. Strugnell1, B. Joshi1, C. Boscher1, C. Ferguson2, R. G. Parton2, I. R. Nabi1; 1Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada, 2Institute for Molecular Bioscience, University of Queensland, Brisbane, QLD, Australia

Caveolin-1 (Cav1) is a major substrate of Src kinase, resulting in phosphorylation of Cav1 on tyrosine 14 (pY14Cav1). A phosphospecific antibody that localized pY14Cav1 to focal adhesions was subsequently found to crossreact with phospho-paxillin, questioning the focal adhesion distribution of pY14Cav1 (Hill et al, Traffic 8: 1695-1705, 2007). Metastatic MDA-435 tumor cells express limited endogenous Cav1 and few caveolae. To study pY14Cav1 distribution, we generated stable MDA-435 cell lines expressing RFP-tagged wild-type, phosphomimetic Y14DCav1, positively-charged Y14RCav1 and dominant-negative Y14FCav1 mutants. MDA-435 tumor cells stably transfected with either Y14D or Y14RCav1-mRFP showed a significant increase in caveolae formation with the latter having a pronounced effect on caveolae number, size and cluster formation. By TIRF microscopy wild-type Cav1-mRFP and Y14DCav1 did not colocalize with focal adhesion markers but were localized immediately behind the focal adhesion relative to the cell periphery. Y14FCav1-mRFP was not found in proximity to focal adhesions and Y14RCav1-mRFP clusters were further removed from focal adhesions compared to wild-type Cav1, implicating Y14 phosphorylation in the proximity of Cav1 clusters to focal adhesions. In both wild-type and Y14DCav1-mRFP stable MDA-435 cell lines, focal adhesions showed enhanced turnover relative to nontransfected or Y14FCav1 and Y14RCav1 transfected cell lines. Both Y14DCav1 and Y14RCav1 stable lines showed increased cell spreading with the Y14RCav1 stable line selectively presenting increased actin stress fibers. The similar effect of Y14 replacement by negatively charged aspartate (D) and positively charged arginine (R) amino acids on caveolae formation but not focal adhesion turnover suggests that tyrosine phosphorylation impacts on Cav1 function via both conformational and adaptor based mechanisms. The ability of wild type and phosphomimetic Cav1 to impact focal adhesion turnover in the absence of Cav1 recruitment to focal adhesions argues that tyrosine phosphorylated Cav1 indirectly regulates focal adhesion signaling and dynamics. Supported by CIHR grant MOP-43938.

Cdk5 (Y15) Phosphorylation Is Required for Src Activation and Localization at Focal Adhesions.
Q. Pan, C. Y. Gao, A. Parthasarathy, P. Zelenka; NIH, Bethesda, MD

Purpose: We have recently shown that an intact phosphorylation site at Cdk5(Y15) is required for stress fiber assembly in spreading cells. The present study examines the possible role of Cdk5(Y15) in FA assembly. Methods: Human corneal limbal epithelial cells (HCLE) were plated on fibronectin and examined after 60min. Endogenous Cdk5 was suppressed by stable or
transient transfection with siRNA. GFP-tagged Cdk5, Cdk5(K33T), Cdk5(Y15F) were expressed by transfection; 15 microM olomoucine was used for pharmacological inhibition of Cdk5. Expression, localization, and protein-protein interactions of focal adhesion proteins were detected by immunofluorescence, immunoprecipitation, and immunoblotting. Subcellular fractions were isolated by differential detergent solubility. Results: Cdk5, Cdk5 (pY15), and p35 co-localized with vinculin and other focal adhesion (FA) proteins at FAs. Suppressing Cdk5 expression with siRNA prevented the increase in Src(pY416) normally associated with focal adhesion formation, blocked binding of Src to FAK, prevented Src-dependent phosphorylation of FAK(Y576) and paxillin(Y118), and reduced formation of vinculin-containing FAs (75.1%, p<0.05). Src levels in a detergent-insoluble cytoskeletal fraction were also decreased (39 %, p< 0.05), indicating that focal adhesions failed to link to the cytoskeleton. Although siCdk5 reduced focal adhesion formation, it did not block FAK(Y397) autophosphorylation or affect adhesion to fibronectin at 4oC, demonstrating that integrin engagement was not affected. Cdk5(Y15F) and Cdk5(T33K), Cdk5 mutants that can not be phosphorylated on Y15, mimicked the effects of Cdk5 siRNA on Src activation and focal adhesion formation. In contrast, olomoucine, which blocks Cdk5 activity without affecting Y15 phosphorylation, did not block Src activation or reduce focal adhesion formation, indicating that Cdk5 activity is not required. Conclusions: Expression of Cdk5 with an intact phosphorylation site at Y15 is required for Src activation and recruitment to focal adhesions in spreading cells. This function of Cdk5 is independent of its kinase activity.

Regulation of Focal Adhesion Dynamics by Calpain Cleavage of FAK.

K. T. Chan¹,²,³, D. A. Bennin²,³, A. Huttenlocher²,³; ¹Molecular and Cellular Pharmacology, University of Wisconsin-Madison, Madison, WI, ²Medical Microbiology and Immunology, University of Wisconsin-Madison, Madison, WI, ³Pediatrics, University of Wisconsin-Madison, Madison, WI

Cell migration requires the coordinated and dynamic regulation of integrin-mediated adhesions. Previous studies in our laboratory have demonstrated that the limited proteolysis of talin1 by the calcium-dependent protease calpain 2 plays a critical role in focal adhesion disassembly in fibroblasts. We, and others, have identified another calpain substrate—the focal adhesion kinase (FAK)—which has also been shown to be a key component in the modulation of focal adhesion turnover. Using time-lapse video microscopy, we have examined the adhesion dynamics of GFP-talin1 in FAK-deficient cells. Quantification of adhesion assembly and disassembly rates demonstrates that FAK is required for the regulation of talin dynamics. However, the mechanisms by which FAK affects the adhesion dynamics of talin are not well understood. To begin to address this, we have mapped the calpain cleavage site of FAK and have generated a mutant form of FAK that is resistant to calpain proteolysis. Expression of wild-type but not calpain-resistant FAK restores focal adhesion dynamics in FAK-deficient cells. Current work is focused on elucidating how calpain cleavage of FAK contributes to the regulation of adhesion dynamics and cell migration.

The Analysis of Force Dependent Zyxin Dynamics Using a Miniature Force Sensor.

T. Nguyen, S. Yamada; Biomedical Engineering, University of California, Davis, Davis, CA

Cell migration requires generation and transmission of actin-myosin contractile force to the extracellular matrix via adhesive contacts. The assembly, disassembly, and size of focal adhesion plaques have been shown to alter traction force exerted by migrating cells. However, the mechanisms by which adhesive complexes regulate the transmission of traction force remain unclear. at focal adhesion sites, actin bundles also rapidly polymerize, which suggests that highly dynamic protein interactions and rapid actin assembly may be tightly coupled to the regulation of traction force at adhesive contacts. The focal adhesion protein zyxin recruits Ena/VASP proteins to promote actin polymerization, therefore, zyxin may be a key regulator of traction force. Using an elastic micro-pillar substrate and epithelial cells stably expressing GFP-tagged zyxin, we found the intensity of zyxin-GFP closely followed increasing and decreasing forces measured by
individual force-sensing pillars. Treatment with Rho kinase inhibitor Y27632 resulted in dissipation of zyxin-GFP from adhesion sites and reduction in traction force, suggesting that activated Myosin II is required for the zyxin localization. Surprisingly, the suppression of zyxin by siRNA resulted in faster single cell migration, but did not affect cell sheet migration in wound healing assays. This may be due to the presence of cell-cell adhesion, but further studies are needed to tease out the effect of zyxin siRNA on cell-cell adhesion. Because of its ability to accumulate at force-bearing adhesion sites and effect on single cell migration, zyxin plays a critical role in the regulation of traction force.

Vinculin Stabilizes Nascent Adhesions and Establishes the Lamellipodium-Lamella Border in Migrating Cells.

I. Thievessen1, S. Berlemont2, A. E. Zemljic-Harpf3, R. S. Ross3, C. M. Waterman1; 1Laboratory for Cell and Tissue Morphodynamics, Cell Biology and Physiology Center, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, MD, 2Laboratory for Computational Cell Biology, Department of Cell Biology, Harvard Medical School, Boston, MA, 3Department of Medicine, Division of Cardiology VA Healthcare San Diego, UCSD School of Medicine, San Diego, CA

The actin cytoskeleton at the leading edge of migrating cells consists of two actin networks, the lamellipodium (LP), characterized by fast polymerization-driven retrograde actin flow and the lamella (LM) with slow Myosin II (myoII) mediated actin flow. The engagement of LP actin to the ECM via nascent integrin-mediated focal adhesions (FA) establishes the flow velocity gradient between LP and LM. Nascent adhesions then elongate and mature via myoII LM actin flow. How integrins are connected to the retrograde actin flow is not known. Using primary murine embryonic fibroblasts (MEF) with cre-mediated excision of the vinculin gene (Vcl), we sought to test the hypothesis that vinculin mediates the coupling of actin retrograde flow to the ECM in FA. Single Vcl-/- MEF migrated faster than control (Vclfl/fl) MEF and displayed impaired anisotropic spreading. To determine if LP/LM organization was affected by loss of vinculin, we analyzed distributions of phospho-myosin light chain (pMLC), cortactin, and paxillin. This revealed a shift in pMLC distribution towards the cell edge, reduced LP paxillin intensity, and broadening of the cortactin band at the leading edge, suggesting a loss of delineation between the LP and LM. To test this, we performed spinning disc confocal (SDC) microscopy of MEF containing fluorescent paxillin and actin. This revealed a reduction in the rate of formation of short-lived, diffraction limited FA in the LP of Vcl-/- MEF, indicating an impaired stabilization of nascent LP FA. Kymograph analyses of high resolution DIC and quantitative fluorescent speckle SDC microscopy of actin indicate the lack of two distinct velocity zones of retrograde f-actin flow near the leading edge and an increased retrograde flow velocity in the LM region of Vcl-/- MEF. We suggest that vinculin stabilizes nascent FA by coupling to lamellipodial actin flow, thus establishing the flow velocity gradient between LP and LM and promoting the maturation of nascent adhesions. This implicates vinculin as an essential component linking the dynamic actin cytoskeleton to the ECM during cell migration.

Analysis of Traction Stress Variation across Single Focal Adhesions.

S. V. Plotnikov1, B. Sabass2,3, U. S. Schwarz2, C. M. Waterman1; 1Laboratory of Cell and Tissue Morphodynamics, National Heart, Lung and Blood Institute, Bethesda, MD, 2University of Heidelberg, Heidelberg, Germany, 3Institute for Theoretical Physics, University of Stuttgart, Stuttgart, Germany

The ability of eukaryotic cells to generate force and to sense the mechanical properties of the extracellular matrix (ECM) underlies many biological processes, such as cell migration, proliferation and differentiation. This is achieved in part by integrin-mediated focal adhesions (FA), protein assemblies that couple contractile actomyosin bundles to the plasma membrane and transmit force generated by the cytoskeleton to the ECM. It has been demonstrated recently that protein composition and/or post-translational modification state can vary across an individual
FA. However, whether this translates to variation in physiological properties and/or function for sub-FA domains is not known. We used dynamic high-resolution traction force microscopy (Sabass et al., 2008) in migrating fibroblasts to analyze the distribution of traction stresses on the ECM along single FA and to correlate it with the organization of specific proteins within FA. We identified two distinctive patterns of traction stress in single FA at protruding cells edges: for the majority of FAs, the region of maximum stress was located at the geometrical center of the FA and colocalized with maximal paxillin-eGFP intensity. For a subset of FA the traction peak was skewed significantly toward their distal edges (cell periphery). Translocation of the traction force maximum from the FA center towards its distal edge occurred abruptly and did not depend on the functional state (growing, stationary, sliding or disassembling) of FA. We then tested the hypothesis that variation in force transmission across a FA is directly coupled to differences in biochemical composition across an individual FA. We found that expression of paxillin mutants that perturb the gradient of paxillin phosphorylation across FA significantly reduced the traction and constrained the traction distribution to the center of FA. However, the latter effect could be rescued by decreasing myosin contractility. These results suggest that the magnitude of traction stress is modulated by local changes in phosphorylation state of paxillin while traction oscillation along the FA is purely a stochastic process mediated by balance between cellular contraction and ECM stiffness.

Mechanical Regulation of Focal Adhesions with Spatial Constraints.
J. Stricker1, Y. Aratyn2,1, K. Addae-Mensah3, B. Sabass4, U. S. Schwarz4, M. L. Gardel1,2; 1Physics, University of Chicago, Chicago, IL, 2Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, 3Biomedical Engineering, Columbia University, New York, NY, 4BIOQUANT, Heidelberg University, Heidelberg, Germany

The regulation of cellular traction stresses impinged on the extracellular matrix is essential in cell adhesion and migration as well as remodeling of the extracellular matrix. Adherent cells engage with the surrounding extracellular matrix (ECM) through dynamic protein assemblies termed focal adhesions. The size of the focal adhesion plaque can be intimately linked to changes in intracellular or extracellular tension. Newly formed adhesion clusters near the leading edge of cells are quite small (<1 \( \mu \)m\(^2\)) and generate very little stress on the ECM. If tension is applied, these plaques increase in area and, subsequently, the force impinged on the extracellular matrix increases. Because of the co-dependency of these two parameters, it is unknown whether increased focal adhesion size is required for the generation of large cellular traction stresses. We utilized microcontact printing to spatially control the distribution of ECM ligands to constrain focal adhesion area while simultaneously measuring cellular traction stresses impinged on the ECM using high resolution traction force microscopy. U2OS osteosarcoma cells and NIH 3T3 fibroblasts successfully spread on an array of 1 \( \mu \)m fibronectin circles (1 \( \mu \)m in diameter) with an approximate edge to edge spacing of 2 \( \mu \)m. Focal adhesions localize to the micropatterned spots of fibronectin and are constrained to 1 \( \mu \)m\(^2\) in area, approximately 35% of the size typically observed on unpatterned substrates. The focal adhesion proteins vinculin and zyxin, which are known to localize to focal adhesions at the end of their growth cycle, localize to constrained focal adhesions. The median traction stress exerted at these focal adhesions is typically 66 Pa, similar to control cells. However, the large variance of traction stress observed demonstrate that focal adhesions of similar size do not exert identical stress. Application of external force to constrained focal adhesions indicate a diminished rupture stress, as compared to unconstrained adhesions. Thus, the mechanical behavior of constrained focal adhesions retains some characteristic of unconstrained adhesions, but appear less responsive to changes in their external environment.

Cell Geometry Regulates Traction Force Generation.
A. Rape, Y. Wang; Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

Over the past decade, it has become increasingly clear that mechanical forces regulate many critical aspects of cellular functions from proliferation, differentiation, motility, to tissue formation.
Cells can respond to not only active forces exerted on them but also the resistance to forces they exert on the environment, termed traction forces. Although traction forces are known to be affected by cell geometry, the underlying principles governing geometric control of traction forces remain unknown. The purpose of this study was to determine these principles. A novel technique was first developed to generate high quality adhesion patterns on polyacrylamide hydrogels. This technique involves printing activated adhesion proteins onto a glass coverslip in a defined pattern, which is then transferred to the gel during polymerization. Combining patterned hydrogels with traction force microscopy then allows the measurement of traction forces as a function of cell area and shape. Our results suggest that traction forces of NIH 3T3 cells are regulated primarily by the distance from the center of the cell to the periphery. Forces are concentrated at distal areas and correlated positively with the distance from the cell center. This relationship remains intact until the cell takes an exceedingly elongated shape, where traction forces appear to become limited by reduction in focal adhesion size. These results demonstrate the dependence of cell traction force generation on cell shape, in a manner similar to the dependence of tension on the shape of a spread liquid drop. Resistance to these forces may in turn stimulate mechanotransduction responses that regulate a wide range of cell functions.

The Role of Mechanical Force in Regulation of Focal Adhesion Complex Proteins in Developing Kidney.
H. Ham1, J. Tsai1, Y. Wang2, Y. Wang3, M. Tang1; 1Department of Physiology, National Cheng Kung University, Tainan, Taiwan, 2Center for Bone and Joint Research, National Cheng Kung University, Tainan, Taiwan, 3Orthopedic Research Center, Kaohsiung Medical University, Kaohsiung, Taiwan

Mechanical force has been shown to affect the expression of focal adhesion complex proteins such as focal adhesion kinase (FAK). Our previous studies have found that focal adhesion kinase (FAK) was degraded gradually in late embryonic rat kidney development and rapidly diminished after birth, yet the regulating mechanism was unclear. We hypothesized that degradation of FAK in the developing kidney is caused by urine shear flow mediated by primary cilium of epithelium. This triggers elevation of intracellular calcium concentration and activates calpain that further cleaves FAK. Immunohistochemistry staining showed that cilia formation was found in kidney tubules at embryonic day 19.5 and later during development, which matched our initial observation in FAK degradation in embryonic kidney. In order to mimic urine flow in the kidney, we applied luminal shear flow (4 dyne/cm²) to MDCK subline 3B5 cells. We observed degradation of focal adhesion complex proteins and degraded fragments of α-spectrin at 145 and 120 kD within 30 min. These results were similar as in the developing kidney, suggesting possible activation of calpain and caspase-3. on the other hand, bidirectional and rotational stress produced by placing cultured cells on a rotator or shaker at 20 rpm resulted in downregulation of FAK in time dependent manner. Immunofluorescence studies showed that as fluid shear stress increased (2, 4, 6 dyne/cm²), FAK translocated from cell periphery to cytosol. The final localization of FAK was similar to that of developing kidney. This study provided a possible mechanism on how mechanical force regulates focal adhesion complex proteins during kidney development.

The Regulatory Role of Clusterin Expression in the Intracellular Metastatic Signaling of Prostate Cancer Cells.
A. Zardan1, A. Zoubeidi1,2, M. E. Cox1,2, M. Gleave1,2; 1Experimental Medicine, University of British Columbia, Vancouver, BC, Canada, 2Urologic Sciences, University of British Columbia, Vancouver, BC, Canada

Acquisition of migratory capacity of prostate cancer cells is an essential event for metastatic disease progression; however, the molecular mechanism underlying acquisition of a metastatic capacity remains unresolved. Clusterin (CLU) is a secreted chaperone protein, over-expressed in many cancers that has been previously reported as up-regulated during Castration Resistant
progression of prostate cancer (CRPC). We used an antibody array to identify changes in protein expression and phosphorylation of PC3 prostate cancer cells in which CLU expression was suppressed by siRNA knockdown. We observed that CLU siRNA knockdown leads to decreased focal adhesion kinase (FAK) phosphorylation as well as its downstream targets. FAK is a member of a family of non-receptor protein-tyrosine kinases that acts as a key regulator of cell migration and whose expression level correlates with CRPC progression. Validating the antibody array results, we confirmed that CLU siRNA knockdown decreases FAK phosphorylation in PC3 cells without affecting total FAK levels by immunoblot analysis. We have gone on to show that CLU siRNA treatment suppresses serum- and VEGF-inducing FAK phosphorylation, and attenuates PC-3 cell migration and invasion capacity in wound healing and matrigel invasion assays. All together, these observations implicate CLU as an important regulator of cell motility and FAK activation in PC3 cells.

Structure, Function, and Evolution of Cell Adhesion Proteins.
R. O. McCann, A. J. Lowrey, A. C. Ellyson, J. V. Ilieva; Basic Medical Sciences, Mercer University School of Medicine, Macon, GA

Phylogenomic analyses have revealed that choanoflagellates are a sister group to the Metazoa. Although choanoflagellates are predominantly unicellular, the genome of Monosiga brevicollis contains genes for proteins that are essential for cell adhesion. These include cadherins and several other cytoskeletal proteins associated with adherens junctions. M. brevicollis also contains a single gene for the large, modular protein talin, which is essential for the assembly of focal adhesion complexes in animal cells. Talin is also required for cell adhesion and cell differentiation in the amoebozoan Dictyostelium discoideum. The presence of talin in amoebozoans, choanoflagellates, and metazoans (including Trichoplax adhaerens) indicates that talin was present in the last common ancestor of the unikonts (amoebozoans, animals, choanoflagellates, and fungi). Talin is not present in fungi, but the essential, conserved C-terminal THATCH (I/LWEQ) domain that mediates F-actin binding and subcellular targeting in talin is present in the fungal cytoskeletal protein Sla2p/End4p. As part of an effort to understand the structure, function, and evolution of multicomponent assemblies required for cell adhesion, we have begun the study of talin and its physiological partner vinculin from M. brevicollis. The structure and regulation of the conserved C-terminus of M. brevicollis talin is similar to that of vertebrate talins. M. brevicollis vinculin shares several conserved features with animal vinculin, but the intrasteric regulation of vinculin is likely to be different in M. brevicollis. We anticipate that comparison of choanoflagellate adhesion proteins with those from metazoans will improve our understanding the evolution of these modular proteins as components of multiprotein assemblies and identify critical factors in the origins of multicellularity in animals.

Organization and Regulation of the Extracellular Matrix (448 – 465)

448/B395

Cellular Contractility Modulation of Extracellular Matrix Assembly, Composition and Growth Factor Activation in Human Mesenchymal Stem Cells.
R. Tenney, D. E. Discher; University of Pennsylvania, Philadelphia, PA

Mesenchymal stem cells (MSC) may hold great therapeutic promise, but like most other cells, MSC possess a contractile cytoskeleton which they constantly employ in shaping and responding to their microenvironment. MSC secrete a wide variety of extracellular matrix (ECM) proteins, from major structural proteins such as collagens and fibronectin to small, growth factor-binding proteoglycans. As ECM composition continues to emerge as a major cue in the regulation of biological processes, the extent to which MSC secretory patterns might coordinate cell growth and differentiation is important to understand. Furthermore, the TGF-beta family of growth factors are known to bind ECM and regulate differentiation. By manipulating the stiffness of cell culture substrates and thus the contractile engagement of MSC cytoskeleton, we find within hours that
marked differences in morphology as well as focal adhesion formation are evident. MSC assembly of Fibronectin (FN) is increased from ~5h up to 2 weeks when cells are plated on stiff substrates. One implication of such early-onset matrix assembly differences is the modulation of TGF-beta growth factor activation by MSC, and our data indeed indicates that the level of active TGF-beta protein is higher in MSC cultured on stiffer substrates. Ongoing work aims to specifically determine how FN dynamics correlates with TGF-beta activity and also to correlate broader ECM roles in MSC lineage choices.

449/B396
Signal Transduction Mediates the Remodeling of the Stem Cell Microenvironment.
K. Henderson1, C. C. Bilgin2, B. Yener2, G. Plopper1; 1Biology, Rensselaer, Troy, NY, 2Computer Science, Rensselaer, Troy, NY

The field of stem cell biology has immense potential but there is a lack of understanding about the relationship between changes in stem cell behavior and remodeling of the stem cell niche which prevents the realization of that potential. Identifying signal transduction pathways that activate the remodeling of collagen will help provide the information necessary to close some of the information gaps in stem cell biology. To address this problem, we monitored stem cell gene expression levels along with differential collagen gel compaction rates in changing three dimensional environments and we used three dimensional image analysis to provide additional spatial information. There is a correlation between signal pathway activities and collagen remodeling reflected in the level of gel compaction and collagen fiber organization. This relationship is also reflected by internal reorganization of the actin cytoskeleton. These results suggest that specific protein activation states and actin filament arrangement impacts the organization of collagen in three dimensions.

450/B397
Behavior of Cells on Tissue-Like Collagen Matrices.
T. Zaitseva1, G. Martin2, L. Terrasio6, N. Tyhovych6, P. Loomer4, T. Desai3, L. Peng3, L. Joubert5, M. Paukshto1; 1CollEngin, Inc, Sunnyvale, CA, 2NIH, Bethesda, MD, 3Physiology, UCSF, San Francisco, CA, 4Periodontology, UCSF, San Francisco, CA, 5Cell Sciences Imaging Facility, Stanford University, Stanford, CA, 6College of Dentistry, NYU, New-York, NY

Using a novel computer controlled process, we have prepared sheets of collagen from soluble collagen which have skin-like, tendon-like, or an aligned braided structure on glass and plastic substrates. The process provides uniform structures over large area as confirmed by AFM, SEM, laser diffraction, and polarized microscopy. In some experiments, parallel microgrooves have been created during the deposition process while preserving fibril structure. Various cell types when plated on these matrices preferentially align and migrate along the fibrils or along the crimped ridges depending on the geometrical parameters of the surface nanostructure, including fibroblasts, stem cells (induced pluripotent, adipose-derived and bone marrow-derived), cortical nerves, periodontal ligament fibroblasts and osteosarcoma cells. Over the course of a few days myoblasts fuse to form aligned myofibrils. Cells cultured on collagen scaffolds were monitored by light microscopy and analyzed for patterns of protein and gene expression by immunofluorescent staining and qPCR. Primary corneal keratocytes align along fibrils and show gene expression more characteristic of a differentiated phenotype vs. phenotype observed in wounded cornea, suggesting that this collagen scaffold may improve the quality of the corneal wound repair. In addition, supplementing collagen scaffolds with a variety of growth factors (attached via glycosaminoglycans) induces faster cell migration and show a potential for a more controllable cell growth system in vitro.

451/B398
Coupled and Integrated Spatiotemporal Responses of Fibronectin to Mechanical Stimulation.
R. L. Steward1, C. Cheng3, P. R. LeDuc2; 1Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA, 2Mechanical and Biomedical Engineering, and Biological Sciences, Carnegie
The extracellular matrix (ECM) is a critical cellular component for a variety of reasons including its structural support. Fibronectin (FN) is an ECM protein that is secreted by cells as a soluble dimer and assembled into insoluble multimeric fibrils at the cell surface. This extracellular component has been linked to wound healing, cell adhesion, blood coagulation, cell differentiation and migration, maintenance of the cellular cytoskeleton, and tumor metastasis. In addition FN is also highly elastic and constantly subjected to cell-generated forces. We believe that there is an intricate coupled feedback system between the ECM and mechanical stimulation. Also, since cells alter their extracellular environment through FN modulation and secretion, we investigated spatiotemporal alterations of the extracellular environment by cells in response to applied mechanical stimulation. In this study we used a custom fabricated device to expose single cells to equibiaxial strain and fluid shear stress for a period of up to 24 hours. We used immunofluorescence to examine the effects mechanical stimulation had on intracellular and extracellular FN patterns. After mechanical stimulation immunofluorescence images revealed an increase of extracellular FN matrix fibrils relative to unstimulated cells. Intracellular FN patterns were also observed to localize around the cell periphery in response to mechanical stress. The coupled stimulation and feedback from cells in terms of ECM and mechanical stimulation were probed to understand the intricate balance in mechanobiology. We believe that these results will be of great significance to the field of matrix biology and have implications into various ECM related fields such as wound healing and cell adhesion.

Fibronectin (FN) is an essential component of the extracellular matrix (ECM) and is assembled into a fibrillar matrix by many cell types. This large multi-domain protein harbors binding sites for cell adhesion receptors, ECM components, and FN itself. FN fibril assembly is initiated by integrin receptor binding to the III 9-10 domain, while fibril deposition depends on FN binding to the III 1-2 domain. We have examined the feasibility of directing FN assembly by using surface chemistry to conjugate these domains, individually or together, to synthetic polymers. Bacterial expression was used to prepare GST fusion proteins containing III 1-2, III 9-10, or III 1-2-III 9-10 expressed as a single polypeptide. We also prepared GST-III 1-2 Mut-III 9-10, which contains mutations that disrupt a salt bridge between III 1 and III 2 and enhances FN binding activity (Karuri et al. (2009) J. Biol. Chem. 284, 3445-52). A modular approach was used to covalently link domains to a surface metallic complex of zirconium and carbamate groups on polyurethane through phosphonic acid and chloroformate cross-linkers. Surface chemistry was evaluated at each step by contact angle measurements, and ELISA results confirmed that equivalent amounts of FN domains were coupled to the surfaces. Little cell attachment was observed on III 1-2 alone. Interestingly, while surfaces with III 9-10 supported cell attachment, the inclusion of the III 1-2 domain, either as a mixture or a fusion with III 9-10, significantly increased FN fibril assembly. Moreover, surfaces conjugated with III 1-2 Mut-III 9-10 supported more fibril assembly than III 1-2-III 9-10. These data suggest cooperation between surface-attached III 9-10 and III 1-2. III 9-10 supports cell adhesion, while III 1-2 appears to provide tethering sites for cell-associated FN which facilitates conformational changes during fibril assembly. Thus attachment of these domains creates a bioactive surface for matrix assembly and suggests a new avenue for directing FN matrix assembly on biomaterials.

Fibronectin elasticity does not involve unfolding of type III domains.
C. Lemmon, T. Ohashi, H. P. Erickson; Duke University Medical Center, Durham, NC
Fibronectin (FN) fibrils are elastic and can be stretched by cells to four times their resting length. The origin of this elasticity has been debated: some posit that the elasticity is mediated by unfolding of the 15 tandem Type III repeats, each of which has a similar, 7-beta-strand structure. Others believe that the elasticity is a function of a transition from a compact quaternary conformation to an extended conformation of the entire dimer. Here we investigate the folded state of the Type III domains within fibronectin fibrils by labeling free cysteines in assembled fibrils with a thiol reactive fluorescent probe. In this protocol, buried cysteines are not labeled by the probe, while exposed cysteines are. NIH3T3 cells were plated onto glass coverslips and allowed to form fibrils for 24 hours, after which time the fibrils were labeled with the thiol reactive probe. Initial results showed that neither of the native free cysteines (buried within domain III-7 and domain III-15) were exposed in assembling fibrils. Subsequently, 15 recombinant FNs were engineered such that each contained only a single, buried free cysteine within a Type III domain. Results show that only a small subset of these recombinant FNs could be labeled with the thiol-reactive probe. This indicates that most Type III domains remain folded during fibronectin fibril assembly. Furthermore, the few domains that were labeled during fibril growth are consistent with previous work that has shown that these domains spontaneously unfold in solution, independent of applied force. Since the observed 4-fold extension of fibronectin fibrils would require complete unfolding of all 15 domains, this data suggests that this cannot be the primary mechanism of fibronectin elasticity.

454/B401
A Proteomics Study of Molecular Interactions That Lead to the Establishment and Stabilization of a Mature Fibronectin Matrix.
S. A. Williams1, B. H. Friedman1, N. W. Karuri2, J. Schwarzbauer1; 1Molecular Biology, Princeton University, Princeton, NJ, 2Biological Sciences, New York City College of Technology, City University of New York, Brooklyn, NY

Fibronectin fibrillogenesis is a complex, multi-step process that involves the conversion of soluble, compact fibronectin into an insoluble fibrillar matrix. The formation, extension, and augmentation of fibronectin fibrils represent essential steps in the establishment of a mature matrix that is biochemically characterized by its insolubility in the detergent deoxycholate (DOC). These fibrils are formed by various intermolecular fibronectin-fibronectin interactions involving specific domains within fibronectin. Although several fibronectin self-binding sites have been identified, the domains responsible for matrix maturation are largely unknown. In this study we used mass spectrometry (MS) in a “bottom-up” strategy to identify regions of fibronectin that are involved in the establishment and stabilization of the mature matrix. Extended proteolysis of fibronectin matrices from NIH3T3 fibroblasts yielded multiple protease-resistant fibril fragments that were insoluble in DOC. Proteomic analyses identified three non-overlapping domains, each composed of type III modules, that were common to most of the DOC-insoluble fibril fragments analyzed by MS. Interestingly, none of the fragments contained the III1-2 domain of fibronectin which is known to be required for matrix maturation. The molecular weights of the proteolytic fragments ranged between 10 kDa and 50 kDa and were substantially less than the predicted size of a contiguous fragment bearing all three domains (142.5 kDa). Preliminary binding studies indicate that two of these domains contain fibronectin self-interacting sites. Based on these results, we propose that these domains are involved in fibronectin-fibronectin intermolecular interactions required for DOC-insolubility and matrix fibril stability.

A Cellular Reporter for Type I Collagen Transcription Allows Optimization of Bioartificial Tissue Engineered Arteries.
J. S. Weinbaum1, Z. H. Syedain2, L. A. Meier1, R. T. Tranquillo1,2; 1Biomedical Engineering, University of Minnesota, Minneapolis, MN, 2Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN
Objective: Optimizing collagen content of tissue-engineered arteries

Methods: Primary neonatal rat vascular smooth muscle cells (vSMC) were stably transfected with a plasmid containing the human COL1A1 promoter upstream of the luc2 gene. Three-dimensional fibrin-based tissue constructs were then fabricated in adherent disc and mandrel-mounted tubular geometries. Constructs were incubated for varying times in experimental media or in a bioreactor to apply cyclic distension and were assayed noninvasively for luminescence periodically. This luciferase strategy predicts changes in both collagen transcription and deposition (Weinbaum JS, Qi J, Tranquillo RT, Tissue Eng. Part C, 2009).

Results: Decreasing the concentration of the fibrinolytic inhibitor ε-ACA to 4 mM (from the 8 mM standard concentration) increased the collagen transcription rate in the disc constructs by 25±4% while raising the concentration to 16 mM lowered transcription by 37±4%. Inhibition of ERK signaling by the addition of 5 and 10 μM PD98059 lowered the transcription rate by 44±6% and 67±2%, respectively. Reduction of TGF-β from 1 to 0 ng/ml also led to a decrease in the transcription rate by 63±9%. In tubular constructs, TGF-β also showed potency, increasing the collagen transcription rate an average of 3.7±1.2 fold. Cyclic distension of the tubular constructs along with TGF-β supplementation increased the collagen transcription rate by 4.4±1.6 fold. Conclusions: vSMC engineered to report type I collagen promoter activity compact and remodel fibrin gel into tissue constructs and respond to extracellular and intracellular stimuli with easily monitored collagen transcription rates. These results suggest that a combination of minimal fibrinolytic inhibition, TGF-β supplementation, amplification of ERK signal, and mechanical conditioning may lead to improved vSMC-based tissue-engineered arteries; ideally, this approach will enable culture optimization leading to a bioartificial artery with sufficient mechanical strength to withstand pulsatile blood flow.

TGF-β3 Regulates Fibrosis in a 3D Self-Assembled Corneal Matrix Model.
D. Karamichos1,2, A. E. Hutcheon 1,2, J. D. Zieske 1,2; 1Schepens Eye Research Institute, Boston, MA, 2Department of Ophthalmology, Harvard Medical School, Boston, MA

Objective: Corneal injury/wounding, leads to death in cells adjacent to the wound, and stimulates cells distal to the wound to differentiate into fibroblast and/or myofibroblast phenotypes that orchestrate proliferation, cell migration and matrix remodeling. Scar formation is a common output of these injuries; however, the regulatory factors controlling the matrix remodeling are not well understood. Methods: TGF-β is known to modulate collagen synthesis and cause tissue fibrosis. We have developed an In Vitro 3D self-assembled model using human corneal fibroblasts in order to investigate the effect of three different TGF-β isoforms over time. Constructs were stimulated with stable Vitamin C (VitC) derivative and TGF-β1, -β2, and -β3 (T1, T2 and T3) at 0.1ng/ml concentration for 4 and 8 weeks. Results were analyzed using immunofluorescence and electron microscopy. Results: All TGF-β isoforms stimulated an increase in construct thickness by at least 3 fold, compared to controls (no TGF-β). High amounts of collagen III were shown for both T1 and T2 where T3 showed no expression. When smooth muscle actin (SMA) was localized, numerous cells were SMA-positive in T1, T2 and the controls. However, T3 had far fewer SMA-positive cells. Cells in T1, T2 and T3 expressed EDA-Fn at 4 weeks. No EDA-Fn was observed at 8 weeks. The presence of low numbers of myofibroblasts in T3 was confirmed by TEM results, suggesting a non-fibrotic TGF-β isoform. Finally, collagen fibril diameters were similar to In Vivo with T3; whereas, they were smaller in control, T1 and T2. Conclusions: Overall, our data demonstrates that T3 stimulates the deposition of a self-assembled matrix to the same level as T1 or T2, however, the response is significantly different than T1 or T2 in that, no expression of specific fibrotic markers was observed.

TGF-β Leads to Diminished Collagen Deposition via Decreased Perk during Long-Term Cyclic Stretching of Engineered Connective Tissue.
R. Tranquillo1,2, Z. H. Syedain2,1; 1Biomedical Engineering, University of Minnesota, Minneapolis, MN, 2Chemical Engineering & Materials Science, University of Minnesota, Minneapolis, MN
Objective: Optimize growth conditions for engineered tissue. Methods: Tubular constructs (TC) were formed by entrapment of neonatal human dermal fibroblasts in fibrin gel cast around a mandrel. TC were incubated in HG-DMEM supplemented with 10% FBS, +/- 1 ng/ml TGF-β, 2 μg/ml insulin and 50 μg/ml ascorbic acid. After 2 wk static incubation, TC were subjected to cyclic distention (CD) for 3 or 5 wk then tested for ultimate tensile stress (UTS) and modulus (E), cell (via DNA), collagen (via hydroxyproline), and total protein contents. Results: At 2 wk, +TGF-β yielded a 101% higher collagen density but no difference in UTS/modulus compared to -TGF. at 5 and 7 wk, -TGF-β yielded higher UTS/modulus and collagen density (also better organized by picrosirius red staining), but lower elastin density compared to +TGF-β. Western blots at 5 and 7 wk showed increased p-ERK for -TGF-β, correlating with higher collagen density. Western blots for αSMA and SMAD2/3 revealed 16x and 10x higher levels for +TGF-β. CD experiments for 5 wk were conducted -TGF-β to improve tensile properties (UTS = 1.4±0.3 MPa, E = 2.5±0.6 MPa), then +TGF-β for 2 wk to increase elastin density (0.19±0.1 mg/mL). Conclusions: While TGF-β can enhance elastin production, it is detrimental to collagen deposition during CD, attributable to inhibition of p-ERK. However, TGF-β following CD can yield both physiological UTS and modulus and substantial elastin content.

SHG Imaging of Collagen Reorganization during Cervical Remodeling.
M. L. Akins¹, K. Luby-Phelps², M. Mahendroo¹; ¹Obstetrics and Gynecology, UT Southwestern Medical Center, Dallas, TX, ²Cell Biology, UT Southwestern Medical Center, Dallas, TX

The ability of the cervix to dilate during labor is the culmination of a series of extracellular matrix remodeling events that begin early in pregnancy. The processes underlying cervical remodeling are still not clearly understood. In this study we quantitatively assess the changes of collagen structure via second harmonic generation (SHG) imaging of murine cervix during cervical remodeling. Cervices were collected from pregnant mice on day 6, 12, 15, and 18 of the 19-day mouse gestation, frozen in OCT medium and sectioned at 50um. Regions of the stroma near the cervical os were excited at 900nm and SHG signal was detected at 450nm, using a Zeiss LSM 510 NLO confocal microscope. Images collected in both the forward and backward directions were analyzed and quantified for changes in collagen fiber diameter, porosity (space between fibers), overall intensity and forward to backward intensity ratio (F/B), using ImageJ. Visual inspection of the images revealed substantial changes in collagen morphology throughout gestation. Early in pregnancy, fiber bundles appeared relatively short, narrow and straight, progressing to large, highly "crimped" fiber bundles by day 18. The amount of open space between fibers appeared to increase and was maximal at the end of pregnancy. The overall mean intensity of SHG signal increased quantitatively throughout gestation in both directions up to day 15. on day 18 the intensity in the backward direction decreased, resulting in an increased F/B ratio. This suggests increased randomness in the collagen and/or changes in the scattering properties of the extracellular matrix as a whole by day 18, both of which can lead to decreases in backward SHG. Fiber diameter progressively increased 30-40% from early to late pregnancy. Pores between collagen fibers increased in diameter by 40-70% and in spacing by 30-50%. However, the number of pores decreased by 50% resulting in no net change in fractional area. The dramatic collagen reorganization revealed by these studies may account for changes in tissue mechanics and loss of tensile strength during cervical remodeling.

The Association of Endurance Training with Heteropterys aphrodisiaca Results More Resistent Tendons to Support High Loads from Intense Exercises.
J. C. Monteiro¹, M. L. Gomes¹, T. C. Tomiosso², W. R. Nakagaki¹, M. M. Sbervelheri¹, D. L. Ferrucci², E. R. Pimentel¹, M. H. Dolder¹; ¹Departamento Anatomia, Biologia Celular e Fisiologia, Universidade Estadual de Campinas, Campinas, Brazil, ²Departamento de Bioquímica, Universidade Estadual de Campinas, Campinas, Brazil
Popular Brazilian medicine uses *Heteropterys aphrodisiaca* infusion as a tonic or stimulant, for the treatment of nervous debility and breakdown and for muscle and bone weakness. The present study investigated the effects of *H. aphrodisiaca* infusion on the tendon properties under endurance training. Forty-eight male rats were divided into four groups (n = 12): CS- control sedentary, HS- *H. aphrodisiaca* sedentary, CT-control trained, HT- *H. aphrodisiaca* trained. The training protocol consisted in running on a motorized treadmill, 5 times a week, with weekly increase in treadmill velocity and duration, consisting in 3 weeks of adaptation and 8 weeks of training. Control groups received water while the HS and HT groups received *H. aphrodisiaca* infusion (dose: 35 mg/animal/day) by gavage during 8 weeks of training or sedentary period. Achilles tendons were frozen for biochemical and biomechanical analysis or preserved in Karnovsky's fixative, then processed for histomorphological analysis by conventional and polarized light microscopy. Biomechanical analysis showed significant increase in maximum stress and modulus of elasticity of the tendons of the HT animals. The metalloproteinase-2 activity was reduced in the HT group. The compression region of tendons of HT animals had a stronger and more intense metachromasy, which suggests increase in glycosaminoglycan (GAG) concentration in this region of the tendon, although the GAG levels were statistically similar among the four groups. The most intense birefringence was observed in the tendon of HT animals, which may indicate a higher organizational level of collagen bundles. The quantification analysis of hydroxyproline in the different groups showed a higher content in the HT group. Our results suggest that the association of endurance training with *H. aphrodisiaca* resulted in more resistant tendons to support high loads from intense muscle contraction. This association stimulated tendon remodeling, promoting higher collagen content and probably increased cross-links. Despite the clear anabolic effects of *H. aphrodisiaca* and the endurance exercise association, no side effects were observed, such as those found for synthetic anabolic androgenic steroids.

**Periostin Knockout Mice Show a Reduction in Collagen Production, Wound Contraction and TGF Beta 1 Response in Experimentally Induced Dermal Wounds.**

C. Elliott¹, L. Boeters-Jackson¹, W. Wen¹, A. Leask¹, S. J. Conway², D. W. Hamilton¹; ¹Oral Biology, University of Western Ontario, London, ON, Canada, ²Herman B Wells Center for Pediatric Research, Indiana University, Indianapolis, IN

Periostin is a recently identified member of the matricellular proteins family, proteins identified by their ability to mediate interactions between cells and the extracellular matrix (ECM). The recently developed periostin knockout mouse shows serious alterations in the structure of the extracellular matrix (ECM) in skin, where decreased collagen fibre diameter is evident. Evidence Periostin may be important for the dermal wound repair, but over-expression of periostin is associated with keloid and hypertrophic scarring, conditions caused by excessive extracellular matrix production and prolonged survival of smooth muscle actin-rich myofibroblasts. We have previously shown that periostin is expressed in granulation tissue formed after excisional wound repair, where it is associated with myofibroblasts. The aim of this investigation was to examine dermal wound repair in periostin knockout mice. An excisional cutaneous punch biopsy model was employed with C57BL/6 wild-type (WT) and sex matched littermate periostin knockout mice. Repair was assessed In Vivo at 3, 7 and 11 days post-wounding through immunohistochemistry (IHC), and calculation of wound area. In periostin knockout mice, a delay in wound area reduction starting at day 3 was observed, increasing through to day 7 in comparison with WT mice. Analysis of collagen using Masson's trichrome staining revealed a reduction of collagen in periostin knockout mice in the granulation tissue at day 7 in the periostin knockout mice, which was quantified using hydroxyproline assays (p<0.05). In Vitro culture of periostin knockout and wild-type dermal fibroblasts demonstrated that cells from periostin knockouts showed reduced mRNA levels of collagen, SMA and connective tissue growth factor in response to transforming growth factor (TGF) beta 1. Furthermore, the cells were unable to contract collagen gels in comparison with wild-type cells (p<0.01). We conclude that periostin mediates dermal fibroblast response to TGF beta 1 and plays a central role in dermal wound repair.
POMGnT1 Deficiency Affects Assembly of the Basement Membrane.
P. Zhang, Y. Yang, H. Hu; Department of Neuroscience and Physiology, SUNY Upstate Medical University, Syracuse, NY

The pial basement membrane (PBM) is a thin sheet of extracellular matrix (ECM) formed between the glia limitans and the meninges. Formation of PBM is regulated by cellular receptors of ECM such as α-dystroglycan and integrins. α-dystroglycan is a heavily glycosylated protein that binds to laminin of the basement membrane. It is modified by several glycosyltransferases, which when mutated causes congenital muscular dystrophies (CMDs) with type II lissencephaly. One of the glycosyltransferases is POMGnT1, protein O-mannose N-acetylgalcosaminyltransferase 1. Analysis of POMGnT1 knockout revealed that breaches in the PBM is the key initial event that results in neuronal overmigration, leading to type II lissencephaly. The mechanisms of PBM breaching are poorly understood. We hypothesized that assembly of pial BM is reduced in rate. To test this hypothesis, we analyzed assembly of extracellular matrix on neural stem cells (NSCs) isolated from POMGnT1 knockout mice. Laminin or Matrigel were added to cultured neural spheres. ECM aggregation on neural spheres was detected by immunofluorescence staining against major components of the basement membrane. When incubated with Matrigel, the ECM aggregates were composed of all four major components of the basement membrane. Overall ECM aggregation was reduced on POMGnT1 knockout neural spheres when compared to the wildtype. Further analysis showed that aggregation on POMGnT1 null neural spheres had reduced rate as revealed by slower growth in size of aggregates compared to the wildtype. These results indicated that basement membrane assembles with a significantly reduced rate in POMGnT1 deficiency. Reduced rate in assembly of the basement membrane may be unable to meet the demand of a rapidly enlarging cortical surface area, thus resulting in breaches.

Autocrine TGF-β1 Activation Mediates Confluence-Dependent Transcriptional Expression of Laminin-332 in MDCK Epithelial Cells.
J. V. Moyano, P. Gonzalez-Greciano, M. M. Buschmann, K. S. Matlin; Department of Surgery (Section of Research), Committees on Cell Physiology and Molecular Medicine, The University of Chicago, Chicago, IL

Laminin-332 (LN332) is a heterotrimeric protein (α3β3γ2) of the basement membrane and its abnormal expression has been correlated with numerous pathologies. In the kidney, LN332 is of particular importance because is transiently upregulated during epithelial regeneration after ischemia. However, the molecular signals that drive this transient expression are unknown. In Madin-Darby Canine Kidney (MDCK) epithelial cells, a cell culture model of the renal epithelium, LN332 is expressed only under subconfluent conditions when the cells lack completely intact cell-cell contacts and apical-basal polarity, and is turned off after reaching confluency. Expression of the α3 subunit, which likely controls secretion of the other LN332 subunits, is transcriptionally regulated, with high levels of mRNA in subconfluent cells and almost none in confluent cells. It has been reported that the promoter of the gene for α3 contains, among others, a TGF-β response element. Addition of exogenous active TGF-β1 to confluent MDCK monolayers is sufficient to induce transcription of the laminin α3 gene and LN332 protein expression via TGF-β type I receptor (TR1). Expression of LN332 in MDCK cells is likely an autocrine response because MDCK cells constitutively secrete endogenous latent TGF-β1, but only activate it under subconfluent conditions. TGF-β1 activation (but not secretion) is dependent on the αvβ3 integrin because a function-blocking anti-αvβ3 integrin antibody prevents TGF-β1 activation and reduces LN332 expression, suggesting an activation mechanism dependent on mechanical tension. In fully confluent and polarized cells, latent TGF-β1 is mainly secrete apically, while the TR1 and αvβ3 integrins are localized to the (baso)lateral domain, physically separating the ligand from the activation machinery and its receptor under conditions when there is no LN332 expression. Disruption of cell-cell contacts in such cultures is enough to stimulate LN332 expression, possibly mimicking the physiological response that occurs following injury to the renal epithelium.
Altogether, our data suggests a novel mechanism for LN332 transitory regulation in kidney epithelial cells following injuries that disrupt epithelial continuity.

Intracellular Polarity Protein Par-1 Regulates Extracellular Laminin Assembly by Regulating the Dystroglycan Complex.
A. Suzuki, K. Yamashita, Y. Amano, M. Masuda-Hirata, S. Ohno; Department of Molecular Biology, Yokohama City University Graduate School of Medicine, Yokohama, Japan

Cell polarity depends on extrinsic spatial cues and intrinsic polarity proteins including PAR-aPKC proteins. In mammalian epithelial cells, cell-cell contacts provide spatial cues that activate the aPKC-PAR-3-PAR-6 complex to establish the landmark of the initial cellular asymmetry. PAR-1, a downstream target of the aPKC-PAR-3-PAR-6 complex, mediates further development of the apical and basolateral membrane domains. However, the relationships between the PAR-aPKC proteins and other extrinsic spatial cues provided by the extracellular matrix (ECM) remain unclear. Here, we show that PAR-1 is required for the assembly of extracellular laminin on the basal surface of mammalian cultured epithelial cell line, MDCK cells. PAR-1 is also indispensable for the basolateral localization of the dystroglycan (DG) complex, one of the laminin receptors essential for basement membrane formation, suggesting that PAR-1b affects extracellular laminin assembly by regulating this receptor complex. Consistently, loss of PAR-1 impairs the formation of a functional DG complex containing normally glycosylated alpha-DG and the spectrin-like actin-binding protein, utrophin. Furthermore, PAR-1 physically interacts with the DG complex through direct binding to the spectrin-like repeats of utrophin, and an alanine mutation of PAR-1-mediated phosphorylation sites on utrophin reduced the interaction between utrophin and dystroglycan. These results reveal the presence of a novel inside-out pathway in which an intracellular polarity protein regulates the ECM organization required for epithelial cell polarity and tissue morphogenesis.

Circulating Fibrillin Fragments as Biomarkers for Marfan Syndrome.
E. Carlson¹, N. L. Charbonneau¹, D. R. Keene¹, L. Y. Sakai¹²; ¹Shriners Hospitals for Children, Portland, OR, ²Biochemistry and Molecular Biology, Oregon Health and Science University, Portland, OR

The Marfan Syndrome (MFS) is caused by mutations in the gene for fibrillin-1 (FBN1), the major component of microfibrils in the elastic matrix. The major manifestation of MFS is aortic aneurysm and dissection or rupture. Using a new Fbn1 mutant mouse model of MFS called GT-8 (a conditional eGFP-tagged knock-in truncation), we found that heterozygous GT-8 aorta showed increasing fragmentation of the elastic lamellae, beginning at 2 months of age, followed by aneurysm and dissection. Because the mutant fibrillin-1 is tagged with eGFP, we could determine—for the first time—that mutant fibrillin-1 is assembled into microfibrils in both the heterozygous and homozygous mutant mice. Studies of GT-8 mice demonstrated that the presence of mutant fibrillin-1 targets the microfibrils for proteolysis. Therefore, we hypothesized that microfibril fragmentation is a major mechanism of disease pathogenesis in MFS. To test this hypothesis, we developed a panel of sensitive sandwich ELISAs, utilizing monoclonal antibodies with defined epitopes, to quantitate circulating fragments of fibrillin-1 and fibrillin-2. Samples were collected from MFS (n=48) and control (n=25) volunteers. The results showed that in MFS samples the concentrations of the fibrillin-1 fragments, 15-201 and 15-26, were decreased compared to controls (p<0.0008). By contrast, circulating 72-143, a fibrillin-2 fragment, was increased in MFS relative to controls (p=0.04). To test whether this profile was specific to MFS, plasma samples from individuals with scleroderma as well as individuals with other forms of aortic aneurysm were assayed. Fibrillin-1 and fibrillin-2 concentrations were both decreased in scleroderma and were similar to the MFS signature in other individuals with aortic aneurysm. Strikingly, the relevant fragments that showed statistical significance (p<0.05) in MFS were different from those in the aneurysm samples. These results suggest that different proteases are
involved in the pathogenesis of MFS and other forms of aortic aneurysm. Defining these proteases may provide new targets for therapies.

**Cytoplasmic Tails Delay Oligomerization of ZP2 and ZP3 Prior to Secretion and Formation of the Extracellular Zona Pellucida Surrounding Mouse Eggs.**

*M. Jimenez-Movilla, J. Dean; LCDB, NIDDK, Bethesda, MD*

The mouse zona pellucida (ZP1, ZP2, ZP3) forms an insoluble matrix surrounding ovulated eggs that is essential for fertilization and early development. Each component has a signal peptide, a conserved ‘zona’ domain, a C-terminal transmembrane domain and a short cytoplasmic tail. Only ZP2 and ZP3 are required to form a zona matrix, but little is known about the interaction of these two proteins necessary to assemble the extracellular zona pellucida. Objective: Here we adapt a fluorescent-based protein fragment complementation assay (BiFC) to detect ZP2-ZP3 interactions in the secretory pathway. Results: The N-terminal fragment (aa 1-156) of Venus was fused to ZP2 either just after the signal peptide (ZP2-NVenus) or just after the ‘zona’ domain (ZP2-CVenus). The C-terminal fragment of Venus (aa 157-239) was fused just after of the signal peptide of ZP3 (ZP3-NVenus). In addition, intact Venus and mCherry were fused just after the signal peptide of ZP2 and ZP3, respectively. To investigate the potential role of the highly conserved C-terminal tails, stop codons were introduced either just before or just after the transmembrane domain. ZP2/ZP3 proteins with the intact fluorescent and with the Venus fragments were co-expressed in mammalian cells and growing oocytes. The BiFC assay did not detect ZP2/ZP3 interactions within cells, but complementation was observed in secreted proteins with ZP2-NVenus (but not ZP2-CVenus) and ZP3-NVenus. However, each truncated zona protein (lacking a C-terminal tail by itself or in conjunction with the transmembrane domain) co-localized with the other and Venus complementation was detected inside cells. These studies were extended by microinjecting expression plasmids into growing oocytes and complementation was detected on the inner aspect of the zona matrix with ZP2-NVenus and ZP3-CVenus. More significantly, the BiFC assay did not detected ZP2/ZP3 interactions inside the oocyte unless they lacked their C-terminal cytoplasmic tails. Conclusions: Taken together, these data indicate that individually conserved C-terminal tails ensure that ZP2 and ZP3 traffic independently in the oocytes and that the two zona proteins interact via N-terminal domains only after they are secreted.

**Cell-Cell Interactions (466 – 490)**

**466/B413**

**Tracking CEACAM Dynamics and Interactions by Live Cell HOMO-FRET Microscopy.**

*J. Oreopoulos1,4, H. S. Lee3, S. D. Gray-Owen3, C. M. Yip1,2,4, 1Inst. of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada, 2Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, ON, Canada, 3Molecular Genetics, University of Toronto, Toronto, ON, Canada, 4Terrence Donnelly Centre for Cellular and Biomolecular Research, University of Toronto, Toronto, ON, Canada*

The interactions between cells is critically important to a vast array of biological phenomena and events, ranging from cellular apoptosis to cancer and tumour development. The carcinoembryonic antigen-related cellular adhesion molecules (CEACAMs) represent a subset of the immunoglobulin superfamily involved in homophilic and heterophilic intercellular binding interactions that affect the control of cellular growth and differentiation. While CEA (CEACAM5) has been used as a marker for colon cancer progression for decades, inappropriate expression of CEACAM1 and CEACAM6 also leads to cellular transformation and tumourigenesis. While these effects are mediated by intercellular signals transduced by these receptors, the molecular basis for the interactions that govern intercellular binding and mediate CEACAM signaling are not known. In order to understand the biology of CEACAMs, we need to elucidate their distribution, expression and association with other proteins on the cell surface. These challenges represent...
the greatest impediments to the development of strategies that target CEACAMs for anti-tumour or other therapies. Using a combination of traditional molecular, biochemical and cellular analyses with our recently developed platform of functional molecular scale imaging based on the convergence of optical and scanning probe microscopies (SPM), coupled with single-molecule optical imaging and spectroscopy, we are examining whether CEACAM-dependent control of cellular growth and differentiation depends upon interactions that affect CEACAM orientation, structure and oligomerization state at the cell surface. Through a combination of live cell confocal and TIRF-based homo-FRET fluorescence anisotropy imaging, we have been able to calculate spatial maps of homo-FRET intensity that reflects differences in the monomer-dimer equilibrium at the cell surface as well as track CEACAM transport. Extensions of these approaches for tracking cell-cell interactions and the effect of small molecule and peptide-modulation of CEACAM equilibrium will be presented.

SIRP-Alpha-CD47 System Functions as an Emergency Signal in Renal Glomerulus.
H. Kurihara; Juntendo University, Tokyo, Japan

Renal glomerulus consists with glomerular endothelial cells, podocytes and mesangial cells. Those cells cooperate with each other for the glomerular filtration. However, the intercellular signaling molecules among those cells have not so far been clarified. Perfusion of kidney with protamine sulfate (PS) induces foot process fusion and tyrosine phosphorylation of slit diaphragm molecules (ZO-1, nephrin and NEPH-1), suggesting that tyrosine phosphorylation is an indicator of the early event on the morphological changes in podocyte. Although src kinase is involved in this event, the molecules working for dephosphorylation are not fully determined. We found that SIRP-alpha is exclusively located in podocytes. SIRP-alpha is a type I transmembrane glycoprotein, which has three immunoglobulin-like domain in the extracellular region and two SH2 binding motif in the cytoplasm. This molecule functions as a scaffold to many proteins, especially SHP2-tyrosine phosphatase to the plasma membrane. SIRP-alpha is concentrated at the slit diaphragm region of podocyte. SIRP-alpha is heavily tyrosine-phosphorylated under the normal condition. on the other hand, PS-perfusion induced a dramatic decrease of tyrosine phosphorylation of SIRP-alpha. CD47, a ligand for SIRP-alpha, is also located in glomerulus, but its distribution is distinct from that of SIRP-alpha. CD47 is located along the plasma membrane of both mesangial and glomerular endothelial cells, but not podocytes. It is known that the cytoplasmic domain of SIPR-alpha is dephosphorylated, when CD47 is bound to the extracellular domain of SIRP-alpha. In normal glomerulus, mesangial cells can not attach directly to podocytes. However, when mesangial cells are injured by Thy1.1 monoclonal antibody injection, the phosphorylation of SIRP-alpha is dramatically decreased. The complex of SIRP-alpha and CD47 are incorporated in podocytes after mesangiolysis. The data suggest that SIRP-alpha-CD47 system plays a role in the cell-cell communication in diseased glomerulus.

Membrane Signaling Proteins That Interact in Cis and Trans: Functional Implications of Competition.
P. Rodriguez, R. Tsai, D. E. Discher; Chemical Engineering, University of Pennsylvania, Philadelphia, PA

A large number of membrane proteins possess extracellular domains that interact with other membrane proteins and that also send important signals into cells, but it is also possible that such proteins interact in cis on the same cell in addition to trans, raising important questions of cis-vs-trans differences in signaling. Many cells express not only the ubiquitous 'Marker of Self' protein CD47 but also some level of its counter-receptor SIRPa (CD172), and we show that CD47-SIRPa interactions occur not only in trans in cell-cell adhesion, but also in cis, modulating downstream signals. With human macrophages in sparse culture, SIRPa is a phagocytosis inhibition receptor upon binding CD47 in trans (Tsai & Discher, JCB 2008), but SIRPa exhibits a a basal level of phospho-activations, which suggested that CD47 (which is expressed on macrophages) might also interact in cis. Activation is clearly increased with CD47-SIRPa interactions in trans, which
inhibits phagocytosis of any CD47-displaying target, whereas knockdown of CD47 on macrophages decreases the basal signaling, increases binding of soluble CD47, and enhances phagocytosis of opsonized targets above wild-type. With a series of knockdowns, the effective Kd for binding in trans is shown to depend linearly on cis CD47 on the macrophage, consistent with the simplest mathematical modeling for cis-vs-trans competition. Additionally, CHO cells engineered to express CD47-GFP bind more soluble SIRPα than CHO cells displaying both CD47 and SIRPα, although high affinity antibodies can out-compete cis interactions. Cis interactions might be unavoidable with this system and others studied (eg. MHC receptors, and Notch-Delta), but it is also possible that by lowering the threshold at which activation exceeds inhibition, cis interactions optimize discrimination in trans.

469/B416
Polymorphisms in Human SIRPα Effect in CD47 Interactions Leading to Incompatibility with Homologous Cells.
K. Hsu, D. E. Discher, R. Tsai; CBE, University of Pennsylvania, Philadelphia, PA

CD47 (Integrin-Associated Protein) is a ubiquitous transmembrane protein that has been described to be a ‘marker of self.’ One of the determining interactions in phagocytic clearance of foreign cells has been demonstrated to be between CD47 and the transmembrane protein signal-regulatory protein alpha (SIRPα), which are present in professional phagocytes, including macrophages. CD47-SIRPα has been demonstrated to be species-specific leading to the phosphorylation of SIRPα. As a result, macrophages are able to distinguish between foreign and self cells. However, a high number of SIRPα polymorphisms exist in humans, which may have implications in homologous cell compatibility. In order to further characterize these polymorphisms, we used a CHO cell expression system to explore the binding affinities with the ligand CD47. Our results revealed that a subset of SIRPα showed a weaker binding to CD47, resulting in decreased SIRPα phosphorylation. The reduction in phosphorylation found in this subset of SIRPα polymorphisms may have an impact on stem cell therapies.

470/B417
IL-1RA Released by Corneal Epithelial Cells Induces Down-Regulation of MMP-2 in Cocultured Corneal Fibroblasts.
J. Ko, R. Yanai, T. Nishida; Ophthalmology, Yamaguchi University Graduate School of Medicine, Yamaguchi Ube, Japan

The epithelial-mesenchymal interactions may play an important role in maintenance of corneal structure and function. And, cytokine-mediated signaling may thus occur either unidirectionally, from epithelial cells to fibroblasts or from fibroblasts to epithelial cells, or bidirectionally. We previously showed that corneal epithelial cells regulate the expression of N-cadherin and gap junction protein (Cx43) in corneal fibroblasts with the use of our coculture system. In this study, we investigate the physiological relevance of interactions between corneal epithelial cells and fibroblasts through the expression of metalloproteinases (MMPs) in epithelial-mesenchymal interaction in the cornea. The amounts of MMP-2 mRNA and protein in corneal fibroblasts were decreased by the presence of corneal epithelial cells. Corneal epithelial cells had no effect on the expression of the other metalloproteinases (MMPs) 1 in corneal fibroblasts. Furthermore, the amount of IL-1 receptor antagonist (IL-1RA) was increased by coculture in corneal epithelial cells number dependent manner. And depletion of IL-1RA in corneal epithelial cells by RNA interference largely abolished the effect of these cells on MMP-2 expression in fibroblasts. The down-regulation of MMP-2 expression in corneal fibroblasts by corneal epithelial cells was blocked by inhibitors of signaling by the mitogen-activated protein kinases ERK (PD98059), but not p38 MAPK (SB203580). Therefore, the presence of corneal epithelial cells down-regulated expression of MMP-2 in corneal fibroblasts, suggesting that corneal epithelial cells are important for maintenance of homeostasis for stable conditions mediated communication with corneal fibroblasts.
Desmosome Assembly and Maintenance in Migrating Cells.
J. K. Wahl, B. Roberts, A. Pashaj; Oral Biology, UNMC College of Dentistry, Lincoln, NE

Desmosomes are prominent cell-cell adhesive junctions that anchor the intermediate filament cytoskeleton systems between adjacent cells in a tissue and provide the tissue the ability to withstand mechanical stress. The transmembrane core of the desmosome is comprised of cadherin family members, desmoglein and desmocollin. The cytoplasmic domain of the desmosomal cadherins associate with a number of desmosomal plaque proteins and in turn recruit the intermediate filament cytoskeleton to sites of cell-cell adhesion. The desmosomal plaque is comprised of two armadillo family members, plakoglobin and plakophilin and the plakin protein, desmoplakin. Cell-cell adhesion in a tissue is a dynamic process allowing individual cells the ability to change their location relative to neighboring cells. Tumor cells often display increased motility, lose adhesion to their neighbors and invade the surrounding stroma. In this study we examined the dynamics of desmosome assembly and junction localization in migrating oral SCC cell lines. In order to image desmosomes in live cells, desmosomal components (desmocollin 2a and plakophilin-3) were fused to GFP and stably expressed in UM-SCC-1 cells. Scratch assays were used to promote cell migration and desmosome assembly and maintenance was characterized. We observed initiation of new desmosome assembly near the leading edge of migrating cells and during cell migration the new desmosomal plaques are transported in a retrograde fashion. In addition, desmosomal plaques appear to accumulate some distance from the leading edge where their migration is decreased. Pre-treatment of the cells with drugs to disassemble the actin cytoskeleton altered the morphology of the cells however desmosome trafficking was unaffected. These studies begin to examine the complex process of coordination of desmosomal cell adhesion structures in migrating cells.

Relavance of Antifeeze Protein and Connexin43 during Hypothermal Preservation.

Antifreeze proteins (AFPs) enable organisms to survive under freezing or sub-freezing conditions. Antifreeze protein inhibits the ice nucleation by adsorbing to the surfaces of ice nuclei. This leads to an increase of the ice nucleation barrier. These days, it has been used at many aspects which maintaining frozen food, cryopreservation of stem cell, blood, tissue and breed preservation of endangered animal. Cell-Cell Interaction is also important for multicellular organisms to survive. for example, It regulate cell attachment, metabolite migration, embryonic development and differentiation. Connexin43 is one of Cell-Cell Interaction constitution and most abundantly expressed in different cell types. We suggest that viability of cell is related with change of Connexin43. Antifreeze protein purified from antarctic yeast using his-tagged protein purification. Cell viability was analyzed on 4 centigrade by WST-8 assay after to cells added some protectants those are sugars, as antioxidant and energy source, UW solution and DMSO. Cell morphology was observed by fluorescein microscope in 600nm. In the final part of study, alteration of Connexin43 expression was identified by western blotting. As a result, Cell viability was increased on each cell. Also, those were visual different morphology between the control and samples added antifreeze protein. Alteration of Connexin43 expression demonstrates that cell-cell interaction affect to viability. This research fund was performed KOPRI PE09070.

Endogenous Forces Exerted at E-Cadherin-Based Cell-Cell Contacts.
V. Maruthamuthu, M. L. Gardel; Institute for Biophysical Dynamics, University of Chicago, Chicago, IL

Cadherins are the primary mediators of calcium-dependent cell-cell adhesion in all vertebrates and serve as the mechanical link between adjacent cells. However, an understanding of the regulation of forces sustained at cell-cell contacts mediated by cadherin is largely unknown. To
measure the forces exerted at E-cadherin interfaces in MDCK cells, we use high resolution traction force microscopy and confocal microscopy to image GFP-E-cadherin or GFP-vinculin, a marker of focal adhesions. Cells plated on matrices coated with collagen exert traction stresses via focal adhesions. In isolated cells, the traction stresses exerted on the underlying matrix are balanced across the cell. However, traction stresses measured in the underlying substrate are not balanced in cells interacting with a neighboring cell through a cadherin-based adhesion. The force imbalance, which reflects the force exerted at the cell-cell contact, is typically between 5-10 nN and directed away from the plane of the cell-cell contact. Calcium-switch measurements suggest that this force is distributed unevenly at the plane of cell-cell contact. These quantitative results of forces at cadherin-based contacts have important implications for the mechanical integrity of tissues and mechanotransduction at cell-cell contacts.

Spatiotemporal Regulation of Epithelial Growth by the Quantitative Crosstalk between Cell-Cell Contact and EGF.
J. Kim1, K. Kushiro2, A. Asthagiri2; 1Engineering and Applied Science, California Institute of Technology, Pasadena, CA, 2Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, CA

Contact inhibition plays a key role in regulating the growth of epithelial tissue. While the mechanism of cadherin-mediated mechanisms of contact-inhibition is emerging, its quantitative aspects are still poorly understood. In particular, how cells quantitatively reconcile the opposing effects of cell-cell contact and soluble growth factors to make a “net decision” on cell cycle commitment remains unclear. Here, using quantitative analysis of single cells within multicellular clusters, we have demonstrated that contact is not a “master switch” that overrides epidermal growth factor (EGF). The mere presence of neighboring cells does not shut down epithelial cell proliferation. Rather, cell-cell contact inhibits proliferation only when the amount of soluble growth factor recedes below a critical threshold level. Furthermore, using micropatterned surfaces and molecular genetics approach, to modulate the amount of cell-cell interactions, we have demonstrated that this tipping point at which contact-inhibition is triggered is tunable, thereby providing means to manipulate the spatial dynamics of epithelial growth. This new quantitative model of contact-inhibition has direct implications for how tissue size may be determined and deregulated during development and tumor formation, respectively, and provides design principles for engineering epithelial tissue growth in applications such as tissue engineering.

The Molecular Mechanisms on the Anti-Inflammatory Property of Thrombomodulin Lectin-Like Domain.
W. Lin, G. Shi, H. Wu; Biochemistry and Molecular Biology, National Cheng Kung University, Tainan, Taiwan

Thrombomodulin (TM) is a type I transmembrane protein that exerts anti-coagulation and anti-inflammation. Previous studies show that the N-terminal lectin-like domain of TM (TM domain 1, TMD1) regulates inflammatory responses in models of sepsis, arthritis or ischemia. However, the mechanisms are still unclear. Our previous studies found that Lewis-y (Le-y) was a specific carbohydrate ligand that interacted with TMD1. Le-y belongs to one of the blood group antigens and recent studies show that the expression of Le-y correlates to malignancy and inflammation. Leukocyte recruitment is a complicated process in inflammation and carbohydrates play an important role in mediating cell rolling and adhesion. Therefore, we hypothesize that TMD1 reduces inflammation by regulating cell adhesion via interacting with Le-y. Our results showed that Le-y was expressed in various kinds of human endothelial cells and the expression level was upregulated upon tumor necrosis factor α (TNFα) stimulation. We generated FITC-conjugated recombinant TMD1 (rTMD1) protein to interact with human umbilical vein endothelial cells (HUVECs) and found that rTMD1 bound to HUVECs and the binding was increased under TNFα stimulation but decreased in the presence of Le-y carbohydrate. Next, we found that the adhesion of THP-1 monocytic cells to TNFα-activated HUVECs was inhibited by rTMD1 in static state and
shear flow condition (0.5 dyne/cm²). This inhibitory effect was blocked by preincubation of rTMD1 with Leα carbohydrate. We utilized TM knock-down THP-1 monocytic cells to investigate the function of TM on monocytes adhesion and the result showed that the adhesion was reduced upon TM knock-down. Our present results suggested that TM on monocytes may involve in leukocyte recruitment through binding to the carbohydrate ligand, Leα, on endothelial cells and these findings may explain the possible reason that TMD1 suppresses inflammatory events.

The Role of the GEF Trio in ICAM-1-Mediated Leukocyte Transendothelial Migration.
J. D. van Buul, J. van Rijssel, F. van Alphen, J. Geissler, P. L. Hordijk; Molecular Cell Biology, Sanquin Research at University of Amsterdam, Amsterdam, Netherlands

During inflammation, leukocytes transmigrate across the endothelium towards the site of injury. This process of extravasation requires integrin-mediated adhesion to endothelial adhesion receptors such as ICAM-1. Upon binding and clustering of ICAM-1, the small GTPases RhoA and Rac1 become activated, which induce endothelial cell shape changes to allow passage of transmigrating leukocytes. In addition, we demonstrated that another Rho family GTPase, RhoG, becomes activated after ICAM-1 engagement, controlling the cytoskeletal remodelling that are triggered downstream of ICAM-1 engagement. However, the signals leading to the activation of these small GTPases remain largely unclear. The guanine nucleotide exchange factor (GEF) Trio is able to activate RhoG, Rac1 and RhoA. We show here that Trio is expressed in endothelial cells and localized to F-actin stress fibers and cell borders. Moreover, the inflammatory stimuli TNFα, IL1β and LPS but not INFγ increase the mRNA and protein expression of Trio (~ 3-fold) in endothelial cells, but not in epithelial cells. A GFP-fusion protein of full-length Trio expressed in HeLa cells co-localized with ICAM-1-mCherry in lateral and apical membrane ruffles and is recruited to sites of ICAM-1 engagement. In addition, we show that full-length Trio is able to interact with a peptide encoding the intracellular tail of ICAM-1. Finally, using a GST-tagged nucleotide-free mutant of RhoG (G15A), we demonstrate that ICAM-1 clustering activates endogenous Trio in endothelial cells. Current studies are focussed on the role of endothelial Trio in the adhesion to and migration across the endothelium of leukocytes. Thus, ICAM-1-mediated activation the GEF Trio may a key event in ICAM-1-mediated endothelial signalling through a set of Rho-like GTPases, which is critical for the engagement of ICAM-1 as well as for efficient leukocyte transendothelial migration.

Dynamics of Rac1 GTPase Activity at De Novo Cell Adhesions.
K. Kitt, W. Nelson; Biology, Stanford University, Stanford, CA

The formation of cell-cell contacts involves the spatiotemporal regulation of protein complexes, including the trafficking and engagement of cadherins and reorganization of the actin cytoskeleton by Rho GTPases. Previous work identified the role of E-cadherin engagement in establishing localized zones of Rac and Rho GTPase activities during initial cell-cell contact. How initial cell-cell adhesion creates waves of Rac1 activation and inactivation as cell contacts expand remains unknown. In this study, we examined the immediate effects of cell engagement on Rac1 activity levels. Although published biochemical studies have implicated E-cadherin in the local activation of Rac1 at initial cell-cell contacts, our preliminary studies demonstrate that Rac1 activity upon cell-cell contact does not depend solely on E-cadherin engagement. We show that when cells make contact with their neighbors in a 3-D cell aggregate, the initiation of E-cadherin engagement results in a very rapid decrease in Rac1 activity. However, when cells spread in 2-D on a collagen surface make contact with neighboring cells, we find that there is a transient increase in Rac1 activity followed by a rapid decrease in Rac1 activity. These data suggest that cadherins and integrins cooperate to regulate Rac1 activity during initial cell-cell adhesion, and that the waves of Rac1 localization and activity observed in live cells depends on multiple proteins and signaling pathways. Future work aims to decipher the guanine nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs) involved in regulating Rac1 activity during
immediate cell-cell adhesion, and the signaling pathways involved in the spatiotemporal regulation of these protein complexes at cell-cell contacts.

Roles of Cdc42 in Yeast Cell Fusion.

C. Ydenberg, M. Rose; Dept. of Molecular Biology, Princeton University, Princeton, NJ

Haploid yeast cells mate to produce a diploid zygote. Mating entails cell fusion, requiring the localized breakdown of the intervening cell walls and fusion of the plasma membranes. Proteins required for efficient cell fusion include Rvs161p, an amphiphysin, and its binding partner, Fus2p. Fus2p contains a Dbl homology (DH) domain, suggesting that it acts as a GTP-exchange factor for a Rho-GTPase in yeast, and the DH domain is necessary for fusion. Three lines of evidence identified Cdc42p as the best candidate for the Rho protein regulated by Fus2p. First, high copy expression of BEM1, encoding a scaffolding protein for Cdc42p, suppressed a fus2 mutant. Second, a previous high-throughput 2-hybrid screen reported an interaction between them. Third, Cdc42p is the only Rho protein in yeast known to be required for mating, although previous work suggested that it is required for actin organization and polarization. To identify a specific role for Cdc42p in cell fusion, separate from actin polarization, we screened a collection of alanine-scanning cdc42 mutants. Two alleles were identified, cdc42-137 and cdc42-138, due to their reduced mating with fus1 fus2 mutants, but not wild-type cells. Microscopy showed that both mutations alone caused cell fusion defects. The defects were not due to reduced pheromone-dependent signaling, because a STE20-ACR1B mutation, which isolates Cdc42p from the pheromone response pathway, did not abrogate the effect of cdc42-138. In contrast to other cdc42 alleles, the cdc42-138 defect was not a secondary consequence of inefficient polarization; cdc42-138 cells formed shmoos with polarized actin (and other proteins required for cell fusion) as efficiently as wild-type. By electron microscopy, the morphology of cdc42-138 zygotes was virtually identical to fus2 and rvs161 zygotes. Finally, double mutant analysis demonstrated that fus2 and cdc42-138 act in the same pathway. Thus, Cdc42p has several roles in yeast cell fusion, regulating both actin polarization and pheromone signaling, as well as acting together with Fus2p late in the pathway. A function for Cdc42p is consistent with a conserved role for the Rho/Rac family of G-proteins in eukaryotic cell fusion.

Spatial and Mechanical Aspects of EphA2 Signaling.

R. Petit; Chemistry, University of California Berkeley, Berkeley, CA

The EphA2 receptor tyrosine kinase regulates intercellular adhesion and motility via interactions with its activating ligand ephrin-A1, expressed on the surface of apposing cells. Abnormal EphA2 levels are an established biomarker of tumorigenicity in neoplastic tissue, and increasing its expression in noninvasive cells has been shown to confer malignancy. However, the precise relationship between EphA2 activity and the pathological program of increased motility and decreased adhesion that characterizes invasive behavior in individual cells remains unclear. Here, we reconstitute the native intercellular signaling geometry using a hybrid junction between live human breast cancer cells expressing EphA2 and a supported membrane functionalized with ephrin-A1. After cells contact the membrane for 1 hour, we observe spatial reorganization of EphA2-ephrin-A1 complexes on multiple lengthscales as well as changes in cortical F-actin organization and recruitment of membrane metalloprotease ADAM10. Mechanical restriction of EphA2-ephrinA1 complex movement alters the cellular response to ephrin-A1. Here we find that abolishing actomyosin contractility with ROCK-inhibiting drugs prevents largescale EphA2 reorganization in a similar way. Both biochemical and mechanical methods of preventing EphA2 reorganization lead to the same result: we no longer observe either F-actin reorganization nor the recruitment of ADAM10 to EphA2 clusters. To further probe the radial polarization phenomenon, we have investigated a panel of membrane-associated effector proteins with functions associated with motility and membrane targeting to determine how they are affected by polarization. With these observations, we hope to elucidate the link between EphA2 and the irregularities in cytoskeletal morphology and cell behavior that accompany tumor invasion.

Role of Spatial Organization in Receptor Function: Eph-Ephrin Signaling in Breast Cancer.

P. Nair1, K. Salaita1,2, R. M. Neve2, J. W. Gray2,3, J. T. Groves1,2, D. Das1; 1Chemistry, University of California, Berkeley, Berkeley, CA, 2Lawrence Berkeley National Laboratory, Berkeley, CA, 3University of California San Francisco, San Francisco, CA

Activation of the EphA2 receptor tyrosine kinase by its natively membrane-bound ligand, ephrin-A1, plays an important role in breast cancer biology. In Vivo receptor-ligand binding is followed by EphA2-ephrin A1 complex formation, activation of the receptor, and ultimately receptor endocytosis and degradation. These events are all recapitulated when EphA2-expressing human breast cancer cells are cultured on a supported lipid bilayer presenting laterally mobile, membrane-tethered ephrin-A1. However ligand-induced receptor clustering and activity is altered when the ligand is presented in solution or bound to solid surfaces. Real-time fluorescence imaging, immunostaining, and protein expression analyses all show that membrane-presented ligand induces a global receptor spatial reorganization phenotype. Moreover, this phenotype correlates with disease characteristics and is linked to the expression of a subset of proteomic and genomic cancer biomarkers. Using nanopatterned substrates to impose geometrically defined barriers to lateral mobility, it is possible to restrict and guide the assembly of these patterns in living cells. We refer to this technique as a spatial mutation. This mechanically-induced EphA2 reorganization alters the cellular response to ephrin-A1 as observed by changes in cytoskeleton morphology and recruitment of the protease ADAM10. Our results indicate that mechanical restriction of EphA2 pattern formation can alter the outcome of its signaling pathway, which may also have consequences for certain aspects of cancer metastasis.

Basigin Gene Products Form a Novel Adhesion System between Photoreceptors and Müller Glia in the Vertebrate Neural Retina.

J. D. Ochrieter, J. Selfridge, D. McGarrell, K. Mince, A. McCormack; Biology, University of North Florida, Jacksonville, FL

In the neural retina, photoreceptor neurons and Müller glia are in intimate contact with one another. It is now known that Basigin gene products, members of the immunoglobulin superfamily, form a novel adhesion system that is crucial for photoreceptor function. Mice in which Basigin gene products have been deleted are blind from birth since photoreceptor neurons have limited responses to light in those animals. There are two Basigin gene products expressed in the neural retina. Basigin is found on the surface of Müller cells, whereas Basigin-2 is found on the surface of photoreceptors. The two polypeptides are identical in amino acid sequence, with an additional 116 amino acids in Basigin-2 that form an immunoglobulin loop at the amino (N)-terminus of the molecule. The purpose of this study was to characterize the interaction between Basigin gene products of the neural retina. Binding assays were performed using an ELISA protocol in which endogenous mouse Basigin, from both retina and kidney, was probed with recombinant Basigin-2-specific loop. The Basigin-2 loop was then truncated via molecular mechanisms to determine the amino acids used to bind Basigin. A BLAST search was also employed to identify proteins homologous to the Basigin-2-specific amino acid sequence. Basigin-2 does bind Basigin via its N-terminal immunoglobulin loop. Assays using Basigin from mouse kidney confirmed that the interaction is heterophilic, as Basigin-2 is not expressed in that tissue. The affinity of the interaction is rather weak, with a KD of approximately 2 microM. Amino acids within the N-half of the Basigin-2 loop bind to Basigin. This region has high amino acid sequence identity (66%) to L1 neural cell adhesion molecule, a known binding partner for Basigin in brain. It is thought that the Basigin gene products associate in the vertebrate retina as part of a monocarboxylate shuttle complex in which monocarboxylates (lactate, pyruvate) are transported from Müller cells to photoreceptors to fuel oxidative phosphorylation in the neurons. Absence of this complex likely leads to reduced energy output in photoreceptor neurons and is thought to be the molecular mechanism underlying blindness in Basigin null mice.
A Central Role of Radial Glial Stem Cells in Orchestrating Neural as Well as Vascular Development in the Cerebral Cortex.

Z. Huang1, H. Kwon1, S. Ma1, H. Johng1, K. Zang2, E. A. Grove3, L. F. Reichardt2; 1Neurology & Anatomy, Univ. of Wisconsin Madison, Madison, WI, 2Physiology, University of California San Francisco, San Francisco, CA, 3Neurobiology, University of Chicago, Chicago, IL

Cerebral corticogenesis involves the production, migration, and differentiation of multiple neural and non-neural cell lineages born inside and outside the cortex. Radial glia are well known for their roles in regulating the production and migration of neurons born in the cortical ventricular zone. Here we show that radial glia guide the migration and localization of Cajal-Reztius (CR) cells born outside the cortex as well as regulate the process of cortical vascular development. To determine the role of radial glia in CR cell migration, we took advantage of a β1 integrin conditional mutation to perturb cortical radial glial scaffold. We found that this resulted in the displacement of CR cells from the cortical marginal zone into deeper layers. The displacements closely correlated with local retraction of radial glial endfeet from the pia. They also took place before basement membrane defects and did not result from cell autonomous requirement for β1 integrin. Further, perturbation of radial glial scaffold by interfering with cell division resulted in a similar phenotype of local radial glial loss and CR cell displacement. These results thus reveal a crucial role of radial glia in coordinating the integration of CR cells from their extracortical origins into the cortex. To determine the role of radial glia in cortical vascular development, we employed an orc3 conditional allele to block radial glial division. We found that radial glial depletion resulted in defective blood vessel formation and cerebral hemorrhage at perinatal stages. Cortical blood vessels developed normally at early stages but stopped growing and regressed following radial glial depletion. Increased endothelial cell death was observed in the mutant cortex, concomitant with defective signaling in several pathways key to brain angiogenesis. These results thus identify a novel role of radial glia in coordinating cortical angiogenesis. Together, our results suggest that radial glia, through coordinating multiple neural and non-neural processes of cortical development, play a central role in orchestrating the program of corticogenesis.

Na,K-ATPase ß-Subunit Mediated Cell-Cell Adhesion Is Necessary for Epithelial Lumen Formation in Mammalian Cells.

S. P. Barwe1, S. A. Rajasekaran1, L. J. Inge2, A. Skay2, R. McSpadden1, A. K. Rajasekaran1; 1Nemours Center for Childhood Cancer Research, Nemours/Alfred I. duPont Hospital for Children, Wilmington, DE, 2Pathology and Laboratory Medicine, University of California, Los Angeles, Los Angeles, CA

Na,K-ATPase is a hetero-oligomer of an α- and a β-subunit. The α-subunit (Na,K-α) has the catalytic function of transporting two potassium ions into and three sodium ions out of the cell. The Na,K-ATPase ß-subunit (Na,K-ß) is involved in the regulation of the ion transport activity. We have shown that the Na,K-ß1 isoform has cell-cell adhesion function and is localized to the apical junctional complex in polarized epithelial cells. In cancer Na,K-ß1 expression is reduced and replenishing this protein in carcinoma cells induced epithelial polarity. However, the mechanism by which Na,K-ß1 induces epithelial polarity is not understood. We recently identified two distinct conserved motifs on the Na,K-ß1 transmembrane domain that mediate protein-protein interactions: A glycine zipper motif involved in the homo-oligomerization of Na,K-ß1 and a heptad repeat that is involved in the hetero-oligomeric interaction of Na,K-ß1 with Na,K-α. Point mutations in the heptad repeat motif reduced Na,K-ß1 binding to Na,K-α and Na,K-ATPase activity. The Na,K-ß1 transmembrane domain homo-oligomerizes in biological membranes and mutation of the glycine zipper motif affected oligomerization and cell-cell adhesion function (Barwe et al., J. Mol. Biol., 365; 706-14; 2007). Recent studies in Drosophila showed that Na,K-ATPase is involved in epithelial polarity and forms a complex with a novel group of polarity proteins,Yurt, Coracle, and Neurexin IV (Laprise et al., Nature, 459; 1141-5; 2009). MDCK cells when grown in collagen form cysts with a lumen and have been used as a model to identify mechanisms involved in the formation of apical and basolateral domains during epithelial polarization. We now provide
evidence that RNAi mediated knockdown of Na,K-β1 prevents the lumen formation in MDCK cysts. This phenotype could be rescued with wildtype Na,K-β1 and heptad repeat mutants but not with glycine zipper mutants that abrogate the Na,K-β1 mediated cell-cell adhesion function. These studies demonstrate that the Na,K-β1 cell-cell adhesion is necessary for epithelial lumen formation in mammalian cells.

484/B431

**Inhibition of Bicc1 Impairs Tubulomorphogenesis of Cultured Imcd Cells by Disrupting E-Cadherin-Based Cell-Cell Adhesion.**

P. Lian¹, Y. Fu¹, I. Kim², A. Li¹, D. Liang², G. Wu¹,²; ¹Chinese Academy of Medical Science, Beijing, China, ²Vanderbilt University, Nashville, TN

Bicaudal-C (Bic-C) gene was originally discovered in Drosophila melanogaster. The gene product Bic-C is assumed to serve as an RNA-binding molecule. Loss of mouse Bic-C homologue (Bicc1) results in phenotypes mimicking human hereditary polycystic kidney disease (PKD). To characterize the unknown cellular function of Bicc1 in mammalian system, we established Bicc1-silenced cell lines from mouse inner medullary collecting ducts (IMCD) by short hairpin RNA (shRNA). 95% of Bicc1-silenced IMCD cells failed to establish tubulogenesis, compared to less than 10% of wildtype. To determine what contribute to this defect, we systematically examined characteristics of Bicc1-silenced IMCD cells. The junctional staining of E-cadherin was markedly indistinguishable and more cytosolic. The cortical actin distribution, cytoskeleton organization and cell shape was abnormal, and stress fibers were thick and abundant. Treated with apoptosis inducer ionomycine, more than 25% of Bicc1-silenced IMCD cells underwent programmed cell death, much higher than wild-type and control cells (5-10%). However, the proliferation rate of Bicc1-silenced IMCD cells was lower than wild-type and control cells, suggesting Bicc1 might exert a “gain of function” regulation during tubulogenesis. In addition, we also examined the ciliogenesis of different cell lines. Approximately 83% of wildtype and control IMCD cells showed ciliary staining, while less than 20% of Bicc1-silenced IMCD cells were stained. To determine the subcellular localization of Biccl, we co-stained IMCD cells with anti-Biccl polyclonal antibody and anti-acetylated α-tubulin antibody. We found that Biccl predominantly displays a cytosol distribution. Hela cells were transiently co-transfected with expression constructs of Biccl and Argonaute—a protein localized to P-bodies, the result showed that Biccl colocalized with Argonaute, which indicated that Biccl may serve as a P-body associated protein. The observations of aberrant cellular behaviors in Bicc1-silenced IMCD cells revealed functions of Biccl in renal epithelial cells and may benefit an insight into the pathogenesis of PKD.

**Identification of a Cell Adhesion Molecule LagB as the Heterophilic Receptor of LagC in Dictyostelium Discoideum.**

G. Chen, X. Xu, R. Piao, C. Siu; Banting and Best Department of Medical Research and Department of Biochemistry, University of Toronto, Toronto, ON, Canada

Dictyostelium discoideum grows as unicellular amoeboid cells which aggregate into a multicellular organism upon starvation. Multicellularity is maintained by the expression of several cell adhesion systems. The cell adhesion molecule LagC/gp150 accumulates rapidly in the early mound stage and plays crucial roles in the regulation of cell differentiation and cell sorting in the post-aggregation stages. LagC/gp150 is known to mediate cell-cell adhesion via heterophilic interaction with a membrane protein in a Ca2+/Mg2+-independent manner. Using recombinant His6-LagC to probe far western blots, we have identified a 130 kDa ConA-binding plasma membrane protein as the LagC heterophilic receptor. Results from LC/MS/MS mass spectrometry indicate that the 130 kDa glycoprotein is the product of the lagB gene. Interestingly, both lagB and lagC genes are located adjacent to each other in the opposite direction on chromosome 3. They share the same promoter and display similar expression profiles. Recombinant proteins of LagC and LagB can pull down their respective endogenous binding partner from cell lysate derived from post-aggregation stage cells but not vegetative cells. Binding of recombinant His6-LagB to live cells followed by anti-His antibody leads to the co-clustering of His6-LagB and LagC
on the cell membrane, demonstrating trans interactions between these two proteins. Cells constitutively expressing LagB and LagC can aggregate together during vegetative growth. Additionally, antibodies raised against LagB inhibit EDTA-resistant cell-cell adhesion in the post-aggregation stages. Development is impaired when cells are incubated with the anti-LagB antibody, resulting in a substantial reduction in fruiting body formation and spore yield. Our results suggest that LagB and LagC interactions are critical for Dictyostelium morphogenesis and spore cell differentiation in the post-aggregation stages of development. (Supported by Canadian Institutes of Health Research)

Trans-Interactions between the IPT/TIG Domain of Two Cell Surface Glycoproteins Mediate Stage-Specific Cell-Cell Adhesion during Dictyostelium Development.

X. Xu, G. Chen, J. Wang, R. Piao, E. Huang, C. Siu; Banting and Best Department of Medical Research and Department of Biochemistry, University of Toronto, Toronto, ON, Canada

IPT/TIG domains are found in cell surface receptors such as Met and Ron as well as intracellular transcription factors involved in DNA binding. Membrane proteins of the IPT/TIG domain subfamily share several functional features including cell dissociation, motility, and invasive activities. What are the functions of these IPT/TIG domains? Our studies have led to the identification of a pair of IPT/TIG-containing membrane glycoproteins, LagB and LagC, which interact heterophilically to mediate cell-cell adhesion in the post-aggregation stage of Dictyostelium development. LagB contains one IPT/TIG domain while LagC contains two IPT/TIG domains. Binding studies using various recombinant protein fragments have led to the identification of the LagC IPT/TIG-2 domain as the binding site for LagB. Peptide competition studies have further mapped the site to the sequence between Ile-336 and Val-360. Using recombinant fragments of LagB to probe far western blots, we have localized the heterophilic binding site of LagB to the C-terminal one-third of the extracellular region of LagB. Since this region also contains an IPT/TIG domain, a His-tagged protein containing the LagB IPT/TIG domain was used to probe far western blots. Significantly, the data show that the LagB IPT/TIG domain binds with the IPT/TIG-2 domain of LagC. Peptides corresponding to the LagC TIG-2 domain inhibit this interaction. These peptides also inhibit cell adhesion in cell-to-cell binding assays. Taken together, our results show for the first time that interactions between the IPT/TIG domains of two different membrane glycoproteins mediate stage-specific adhesion among cells during development. (Supported by Canadian Institutes of Health Research)

Role of DdCAD-1-Mediated Cell Adhesion in Dictyostelium Pattern Formation.

S. Sriskanthadevan, Y. Zhu, C. Siu; Banting and Best Department of Medical Research and Department of Biochemistry, University of Toronto, Toronto, ON, Canada

DdCAD-1 is a Ca^{2+}-dependent cell adhesion molecule encoded by the cadA gene, which is expressed by the social amoeba Dictyostelium discoideum at the onset of development and present throughout development. The NMR solution structure of DdCAD-1 reveals two domains with β-sandwich architecture. DdCAD-1 is synthesized as a soluble protein and then transported to the plasma membrane through an unconventional transport pathway via contractile vacuoles. To investigate the biological roles of DdCAD-1, DdCAD-1-GFP was expressed in cadA-null cells. Both temporal and spatial regulation of DdCAD-1 expression became evident. At the slug migration and early culmination stages, cells in the anterior region contained higher levels of DdCAD-1. In order to test whether cells expressing higher levels of DdCAD-1 would sort to the anterior region, chimera experiments were performed by mixing DdCAD-1-GFP expressing cells and cadA-null cells. DdCAD-1-GFP expressing cells sorted out from the null cells and became localized to the anterior region. Notably, at the final stage of the development cadA-null cells were able to form viable spores and behaved like cheaters. Quantitative analysis of spores in these chimera structures indicated that cadA gene acted as a single gene green beard similar to the csA gene in Dictyostelium, which also codes for a homophilic cell adhesion molecule. Further analysis showed that DdCAD-1-GFP was present in cell-cell contacts among cells in the anterior
region but not in the posterior region. Cells expressing mutant DdCAD-1 that failed to reach the cell surface also exhibited defects in cell sorting and behaved like cadA-null cells in chimeras. Taken together, these observations suggest that differential cell adhesiveness contributed by DdCAD-1 in the post-aggregation stages of development is responsible for the cell sorting phenomenon, which underlie the mechanism of green beard behaviour of the cadA gene. Quantitative Evaluation of Characterized Alpha and Beta Glycosidase Effects on Sea Urchin Embryo Cellular Interactions.
B. Idoni¹, H. Ghazarian¹, S. Metzenberg¹, V. Hutchins-Carroll¹,², E. J. Carroll², S. B. Oppenheimer¹; ¹Department of Biology, California State University Northridge, Northridge, CA, ²Department of Chemistry and Biochemistry, California State University Northridge, Northridge, CA

Using the NIH designated sea urchin embryo model, we are studying the molecular basis of a set of cellular interactions that have interested investigators for over a century, archenteron organization/elongation/attachment to the blastocoel roof. Here we evaluate the effects of four commercially available glycosidases: alpha and beta amylase and alpha and beta glucosidase, that we independently characterized, on embryo development. In quantitative dose-response experiments we show an I-50 of 10-30 units/ml, in artificial seawater or low calcium artificial seawater, of beta amylase and alpha glucosidase in inhibiting archenteron organization/elongation/attachment to the blastocoel roof in living 48 hr Lytechinus pictus gastrula embryos using a microplate assay that allows quantitative assessment of embryo morphological characteristics. All concentrations tested (up to 5000 units/ml) of alpha amylase and beta glucosidase had no significant effects on archenteron morphology. All experiments involved assessing 3600-5600 embryos in at least 144 replicate wells for each enzyme. The differences in archenteron morphology compared with controls were significant to p values of less than 0.05, while any differences observed with the ineffective enzymes had p values of greater than 0.05, using two-tailed t-tests. All enzymes used were tested for their activity on known substrates, and found to be active, and specific unit activities were established. Product inhibition studies suggested that the effective enzymes acted by their specific glycosidase activities and polyacrylamide gel electrophoresis suggested that there was no detectible protease activity in the enzyme samples. The results suggest that glycans are involved in these cellular interactions and we propose possible conformations of these glycans (Supported by NIH NIGMS SCORE (S0648680), MARC, RISE, the Joseph Drown Foundation and the Sidney Stern Memorial Trust).

Cell Differentiation and Colony Formation in the Choanoflagellate Proterospongia sp.
M. J. Dayel¹, S. Fairclough¹, S. Nichols¹, K. McDonald¹, N. King¹; ¹MCB, UC Berkeley, Berkeley, CA, ²Electron Microscopy Lab, UC Berkeley, Berkeley, CA

Choanoflagellates, the closest known relatives of animals, promise to help reveal the origins of animal cell-cell interactions and cell differentiation. Here we examine Proterospongia sp., a choanoflagellate that transitions between single-celled and colonial forms under laboratory conditions. We show that Proterospongia undergoes cell differentiation during the transition from substrate-attached cells to free-swimming colonies, marked by a glycosylation change at the plasma membrane that is revealed by specific labeling with the lectin wheat germ agglutinin (WGA). Unlike substrate-attached cells, differentiated cells in the water column remain attached to each other following cell division, with fine cytoplasmic bridges that connect the cell bodies to form chains. Addition of Algoriphagus bacteria to Proterospongia cultures results in the development of colonies with a rosette morphology, in which cells attached by cytoplasmic bridges are arranged spherically around, and extend filopodia into, a central core. Substrate-attached cells secrete goblet-shaped thecae that hold the cell body in a cup at the apex of a fine stalk. We find that cultures fed on Algoriphagus bacteria have thecae with reduced stalk length, revealing a potential trade-off between theca formation and colony development. Future studies
of theca morphogenesis and cell attachment within colonies promise to illuminate the potential adaptive significance of colony formation, and the molecular mechanisms of cell-cell interactions in choanoflagellates.

**Bioastronautics: The Effect of Microgravity on Human Stem Cells.**

*E. Blaber¹,², H. Marcal¹,²,³, J. Foster¹, B. P. Burns¹,²; ¹School of Biotechnology and Biomolecular Sciences, University of New South Wales, Sydney, NSW, Australia, ²Australian Centre for Astrobiology, University of New South Wales, Sydney, NSW, Australia, ³Graduate School of Biomedical Engineering, University of New South Wales, Sydney, NSW, Australia*

A new field called bioastronautics has emerged in life sciences to ensure the health and safety of humans during space travel by addressing medical issues encountered, such as the absence of gravity. The aim of the present study was to employ a global approach to examine the effect of microgravity on stem cells. This was achieved using a NASA rotating-wall vessel bioreactor to simulate microgravity. The effect of microgravity was analysed on an embryonic stem cell line by utilising two-dimensional gel electrophoresis and Fourier Transform Mass Spectrometry to generate a comparative expression profile and to isolate and identify proteins of cells grown under microgravity. In addition, microarrays were used to generate a comparative genomic expression profile which was compared to proteomic analyses. Scanning Electron Microscopy (SEM) was also used to examine morphological adaptations to microgravity. Results demonstrated that 75% of proteins identified in the conditioned media from cells grown in microgravity were not found in control samples. Proteomic analysis demonstrated alterations in the expression of key proteins from cells grown under microgravity. As the functional unit of a cell are proteins, this suggests that microgravity has a significant impact on cell function. Similar trends were also observed at the genomic level whereby results showed considerable modifications to the genomic expression profile. SEM revealed that cells grown under microgravity exhibited an altered extracellular matrix that is thought to be due to growth under microgravity conditions. This is the first study conducted that has investigated the effect of microgravity on this embryonic stem cell line using both a proteomic and a genomic approach, demonstrating a significant alteration in human cell function as a result of growth in microgravity. This research is critical to space science and cell biology due to its vast potential to decipher the effect of microgravity on humans at a cellular level as well as regeneration of tissues in the human body and to use these alterations to solve ground based medical problems.

**Overexpression of Claudin-3 in a Breast Cancer Cell Line.**

*R. A. Sheller, M. E. Cuevas, M. C. Todd; Biology, Southwestern University, Georgetown, TX*

Claudin-3, one of the 24 identified members of the claudin family, is an integral membrane protein that helps form vertebrate tight junctions (TJs). The claudin proteins interact with other TJ proteins to determine cell polarity and specific ion diffusion through the paracellular pathway. Recently, several investigations have suggested that claudin proteins might be involved in cell signaling pathways. In this study, we showed that the breast cancer cell line MCF-7 markedly overexpresses claudin-3 protein, but can form TJs with a relatively high transepithelial resistance (TER). We used small-interference RNA (siRNA) to suppress claudin-3 protein expression to that of near normal levels in the MCF-7 cells over a period of 7 days. We observed a decrease in growth rate and TER in these transfected cells (normal claudin-3 levels) compared to nontransfected MCF-7 cells (high claudin-3 levels). Using MCF-7 cells that express high claudin levels, we have shown that the claudin-3 protein is readily detected in all cell fractions, the cytosolic, membranous, nuclear, and cytoskeletal fractions. We are currently investigating the cellular localization of claudin-3 protein in MCF-7 cells transfected with claudin-3 siRNA. The unusual localization of an integral membrane protein may further indicate a role for claudin
proteins in cell signaling pathways. The cellular localization of the claudin-3 protein and functional consequences may shed light upon the deregulation of TJ function in

**Structural and Functional Aspects of Claudins Forming Tight Junctions in the Brain.**
I. Blasig; FMP, Berlin, Germany

The structure of claudin-1, -2, -3, -5, and -12 expressed at the tight junction (TJ) in the brain is unknown. Claudin-5 tightens the cleft between endothelial cells forming the blood-brain barrier, and prevents paracellular permeation of small molecules. Claudin-2 forms paracellular cation pores between epithelial cells of the blood-cerebrospinal fluid barrier. The cerebral function of the other claudins remains unknown. To clarify the molecular interaction mechanism we investigated the oligomerization and strand formation of claudins using single amino acid exchanges. Mutants of claudin-5 and other claudins transfected into TJ-free cells demonstrated that the second extracellular loop (ECL2) is involved in the strand formation via trans-interaction (between opposing cells), but not via polymerization along the plasma membrane of one cell (cis-interaction). Combining the results of mutagenesis, live-cell imaging, electron microscopy, tightness studies and molecular modelling led to an antiparallel homodimer model of the ECL2. This may explain how two claudins hold onto each other and constrict the paracellular space. The interface includes an aromatic binding core and hydrophilic residues. On the basis of our data, we establish a novel molecular concept for TJ formation considering homo- and heterologous claudin-claudin interactions.

**Inhibition of Cell Migration by Claudin-7 Is Mediated through p42/44 MAPK Signaling Pathway.**
Z. Lu¹, H. Hong², Q. Lu¹, Y. Chen¹; ¹Anatomy and Cell Biology, East Carolina University, Greenville, NC, ²Department of Pathology and Laboratory Medicine, East Carolina University, Greenville, NC

Lung cancer is the leading cause of cancer deaths worldwide and responsible for 1.3 million deaths annually with a very poor overall 5-year survival rate. Recently, we found that claudin-7, a tight junction integral membrane protein, was either down-regulated or its distribution was disrupted in human lung cancer. Using tissue microarray (TMA) analysis, we showed that claudin-7 was distributed to cell-cell junction in normal lung epithelia, whereas its localization in lung cancer epithelia was either discontinuous, disperse in cytoplasm, or it was completely absent in many areas. To investigate claudin-7 function in lung cancer cells, we transfected claudin-7 cDNA into NCI-H1299, a human lung carcinoma cell line that has no detectable claudin-7 expression. Cells transfected with vector alone were used as a negative control. Our results showed that without any treatment, claudin-7 expression did not affect the expression level of p42/44 MAPK (ERK1/2) and cell migration using wound-healing assay and imaging analysis. However, when treated with hepatocyte growth factor (HGF) that activates p42/44 MAPK pathway, claudin-7 expressing cells showed a decreased response to HGF in that they were less motile and formed less foot processes compared to the cells transfected with vector alone. In addition, western blot analyses revealed that cells expressing claudin-7 decreased the upregulation of phospho-ERK1/2 expression upon HGF treatment in a time-dependent fashion. Cell migration and expression of phospho-ERK1/2 were completely inhibited by MEK1 inhibitor, PD98059. Taken together, our results indicate that claudin-7 inhibits cell migration through p42/44 MAPK signaling pathway in NCI-H1299 human lung cancer cells.

**Hormone Ouabain Modulates the Tight Junction.**
M. I. Larre¹, A. Lazaro¹, R. G. Contreras¹, O. Medina², M. S. Balda⁴, K. Matter⁴, C. E. Flores¹, A. Ponce¹, D. Flores-Benítez⁷, R. Rincon-Heredia¹, M. Cereijido¹; ¹Physiology, Cinvestav, Mexico City, Mexico, ²Molecular Biomedicine, Cinvestav, México, Mexico, ³Pharmacology, Cinestav, México, Mexico, ⁴Pharmacology, UCL Institute of Ophthamology, London, United Kingdom
Given that toxic levels of ouabain (more than 300 nM) disrupt several types of cell contacts, such as tight junctions (TJ), gap and adhesion to neighbors and substrate, in a previous work we suggested that the physiological role of ouabain may consist in the modulation of cell adhesion. Exploring further this possibility we now demonstrate that, at concentrations as low as 10 nM, ouabain does not detach the cells, triggers apoptosis, or abolishes the barrier function of the TJ, which are typical phenomena observed at toxic levels. Nevertheless it enhances the degree of sealing of the TJ, and specifically decreases the unidirectional flux of 3 kDa Dextran through the paracellular permeation route. These effects correlate with modifications of the amount of expression and pattern of distribution of claudins -1, -2, -3, -4 and -8 but not of occludin. Changes of a given type of claudin follow its own kinetics, which is not observed with the other claudin species tested. We focus on claudin-1 to further study signals and mechanisms, and find that ouabain enhances cln-1 expression by increasing its transcription, and the amounts of its mRNA. These responses are orchestrated by a complex cascade of signals triggered by ouabain and includes c-Src and the ERK1/2 complex. In summary, this work supports the view that hormone ouabain modulates cell-cell contacts in a highly specific way.

495/B442

**Ral GTPases Differentially Regulate Tight Junction Assembly and Function.**

C. Hazelett, C. Yeaman; Anatomy & Cell Biology, University of Iowa, Iowa City, IA

Tight junctions (TJs) serve an essential barrier function in epithelial and endothelial cells that is crucial to human health, but a detailed mechanistic understanding of how TJs form is lacking. TJ proteins must assemble at the junction between apical and lateral membrane domains to function as a permeability barrier, but factors responsible for targeting transport vesicles to developing TJs have not been identified. The Exocyst, under control of Ral GTPases, is known to regulate basolateral trafficking. Here, we have investigated the role of Ral GTPases in TJ assembly. During establishment of TJs in MDCK cells, trans-epithelial resistance (TER) displays a brief overshoot 4-5 times steady state levels. While this observation is well documented in the literature, its molecular basis is unknown. Silencing expression of either RalA or RalB drastically affects TJ formation and composition, although the direct consequences of each knockdown are radically different. Knockdown of RalA results in loss of the TER overshoot, while knockdown of RalB greatly exaggerates the overshoot. In both cases, TER reaches steady state levels comparable to control cells within 24 hours. TER profiles observed in knockdown cells are restored to normal upon expression of hairpin resistant RalA or RalB isoforms. Furthermore, data indicates that RalA exerts its effects on TJ formation through interactions with the Exocyst. Cells expressing inducible RalA mutants incapable of binding Sec5 or Exo84 do not display a TER overshoot. We postulate that differences in TER overshoot result from different rates of trafficking or exocytosis of TJ proteins. Consistent with this idea, composition of developing TJs is altered in Ral knockdown cells; incorporation of certain claudins into insoluble TJ complexes is either increased or decreased relative to control cells. Our working model is that RalA facilitates trafficking of TJ constituents to the plasma membrane, where RalB then ensures correct spatio-temporal fusion of transport vesicles and/or incorporation of these components into developing TJs. Future work will increase our understanding of how these GTPases, in collaboration with the Exocyst, contribute to TJ formation.

**NFκB Inhibitors Disrupt Alveolar Epithelial Tight Junctions.**

C. Ward1, L. Cunningham Mitchell1, A. Stecenko3, M. Koval1,2; 1Pulmonary Medicine, Emory University, Atlanta, GA, 2Cell Biology, Emory University, Atlanta, GA, 3Pediatrics, Emory University, Atlanta, GA

Tight junctions are required for the air/liquid barrier function of pulmonary alveolar epithelial cells. Tight junctions consist of several classes of transmembrane and scaffold proteins, including claudins, occludin, junction adhesion molecules (JAMs), zonula occludens (ZO)-1 and ZO-2 which act in concert to maintain a selective paracellular permeability barrier. We used inhibitors of
the NFκB signaling pathway to determine whether this transcription factor has a role in regulating alveolar epithelial tight junctions. Primary rat type II alveolar epithelial cells were isolated and cultured on Transwell permeable supports coated with collagen for five days to generate a model type I cell monolayer. Model type I cells formed a tight barrier as measured by transepithelial resistance (TER) values in the range of 500-700 Ohm x cm². Treatment of the monolayers overnight with either Bay-11 or BMS-345541 resulted in a dose-dependent decrease in TER at concentrations that did not affect cell viability. By immunoblot, there was little effect on the total amount of cell-associated claudin-4, -5, -7, -18, occludin, JAM-A, ZO-1 or ZO-2. However, the localization of these proteins at the plasma membrane was disrupted as assessed by immunofluorescence microscopy. There were several areas of cell-cell contact which lacked tight junctions and there appeared to be an increase in intracellular vesicles containing tight junction proteins in cells treated with either NFκB inhibitor. This suggests that one or more factors downstream of NFκB are required for assembly and/or stability of alveolar epithelial tight junctions.

The Subcellular Localization of ZO-2 Is Regulated by the Cell Cycle and PKCε Phosphorylation.
L. Gonzalez-Mariscal, R. Tapia, D. Chamorro, L. Alarcon, S. Islas, A. Ponce; Physiology, Biophysics and Neuroscience, Cinvestav, Mexico City, Mexico

ZO-2 is a dual localization protein that in confluent monolayers localizes at tight junctions while in sparse cultures is also conspicuously present at the nucleus. Here we have explored if the subcellular localization of ZO-2 changes during the cell cycle and analyzed the destiny of newly synthesized ZO-2. To analyze the presence of ZO-2 at different stages of the cell cycle we arrested the cells at G0 by serum deprivation, at late G1 with mimosine and at the start of mitosis with nocodazole. Fluorescence observation of ZO-2 and Facs analysis reveal that ZO-2 enters the nucleus at a late stage of G1 and leaves the nucleus during mitosis. We also observe that in sparse cultures a significant amount of newly synthesized ZO-2 goes into the nucleus and is later relocated to the plasma membrane. Departure of ZO-2 from the nucleus is regulated by nuclear exportation signals (NES). Ser369 located within NES-1 is a putative protein kinase C (PKC) phosphorylation site. Therefore we tested the effect of PKC inhibition and stimulation on the nuclear export of ZO-2. Our results indicate that the departure of ZO-2 from the nucleus is regulated by phosphorylation at Ser369 by novel PKCε.

Bacterial Quorum Sensing Effects on Epithelial Cell Structure and Protein Expression.
V. V. Borutinskaite¹, K. E. Magnusson², E. Vikstrom¹; ¹Division of Medical Microbiology, Department of Clinical and Experimental Medicine, Linkoping University, Linkoping, Sweden, ²Department of Developmental Biology, Institute of Biochemistry, Vilnius, Lithuania

The intestinal epithelium forms a selective permeability barrier between the lumen and the submucosa. It is maintained via complexes of cytoplasmic and transmembrane proteins composing the tight junctions (TJ) and the adherens junctions (AJ) connected to the cell cytoskeleton. The epithelial integrity can be regulated by a number of agents, including microorganisms, toxins, immune cells, cytokines, and growth factors. We have been recently shown that the Pseudomonas aeruginosa quorum sensing signaling molecule 3O-C12-HSL disrupts the barrier integrity in human epithelial Caco-2 cells and causes changes in expression and post-translational modifications of both TJ and AJ proteins. In the present study, we identified new proteins that can be important for the structure of junctions in human epithelial Caco-2 cells after treatment with P.aeruginosa 3O-C12-HSL. Using immunoprecipitation and MALDI-TOF-MS analysis, we found that the junction proteins ZO-1 and ZO-3 formed an association with alpha-actinin 4, villin, HSP90, calpain and actin in 3O-C12-HSL-treated Caco-2 cells. Another junction protein, JAM bound to Gap junction alpha-1 protein, actin, tropomyosin and myosin after administration of 3O-C12-HSL. In parallel, we showed that E-cadherin and beta-catenin were immunoprecipitated in association with myosin, actin, tropomyosin, Ca2+ binding protein,
connexin and lamin A/C. All of these proteins are important in cell proliferation and cell-cell communication, and our findings suggest that their disruption by P. aeruginosa 3O-C12-HSL quorum sensing signaling might lead to bacterial invasion and apoptosis.

499/B446
Dynamic Regulation of Septate Junction Formation during Morphogenesis.
K. Oshima, R. Fehon; Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

A key function of epithelial cells is to isolate internal and external environments by forming a tight seal between cells. This function is provided by the tight junction (TJ) in vertebrate epithelia, while in invertebrates it is provided by the septate junction (SJ). Epithelial polarity is essential for formation of both structures, but the molecular mechanisms that establish these barriers are still largely unknown. In this study we examined the dynamic behavior of four GFP-tagged SJ components (ATPa, Nrv2, Nrg and NrxIV) using fluorescence recovery after photobleaching (FRAP). Our results indicate that the SJ is an exceptionally stable and immobile structure, showing recovery times much slower than the adherens junction component E-Cadherin. In contrast Dlg, a component of the basolateral polarity complex that colocalizes with the SJ, turned over more rapidly than SJ proteins, suggesting that it is not in the same protein complex as other SJ components. Previous electron microscope analyses have shown that electron dense SJ structures initially appear at stage 14. Preceding this, SJ proteins started to be immobilized at the apico-lateral region immediately after completion of germ band retraction. To further dissect the molecular interactions within the SJ, we analyzed the stability of GFP-tagged SJ proteins in the background of mutations in other SJ genes. GFP-SJ proteins mislocalized and became more mobile in nrv2, atpα, cor, nrxIV, nrg, mega, and sinu mutants, suggesting that all of the encoded proteins form an interdependent multi-protein complex. In contrast Gli was necessary for localization of the SJ proteins but dispensable for their stability. In addition, SJ components accumulated in endocytic compartments in some mutant backgrounds, suggesting that endocytosis may play an important role in SJ formation or maintenance. Taken together these data suggest a model for SJ assembly in which a stable ‘core SJ complex’, including ATPα, Nrv2, Cor, NrxIV, Nrg, Mega and Sinu, is formed just after germ band retraction, possibly in association with membrane trafficking, and then sorted to the correct membrane domain and assembled as a highly-organized stable structure through the function of Gli.

Nuclear Architecture (500 – 511)

Nopp140 Gene Deletion in Drosophila Melanogaster.
F. He, P. DiMario; Biological Sciences, Louisiana State University, Baton Rouge, LA

Nopp140 is a nucleolar protein with multiple roles in ribosome biogenesis. Previous work in our lab (Cui and DiMario, 2007, Mol. Biol. Cell 18: 2179-2191) showed that a ≥50% reduction in Nopp140 mRNA, resulted in late larval lethality, while a 30% reduction resulted in Minute-like phenotypes that included delayed development, deformed adult wings, legs, and tergites, and occasionally missing or reduced thoracic bristles. To further characterize Nopp140 in Drosophila, we used the FLP-FRT recombination technique (Parks et al., 2004, Nat. Genet. 36: 288-292) to delete the Nopp140 gene. Genomic PCR, RT-PCR, and immuno-fluorescence microscopy all showed the loss of Nopp140 gene expression. Compared to the parental transposon-bearing embryos used for deletion recombination, Nopp140−/− embryos had similar hatching rates, but the resulting larvae died in the second instar stage after surviving for 8 days. Nucleoli were apparent by phase-contrast microscopy in Nopp140−/− cells with no apparent morphological defects, but the nucleolar rRNA methyl-transferase, fibrillarin, had a greater distribution in the nucleoplasm in Nopp140−/− cells than in control cells, suggesting that the loss of Nopp140 disrupted nucleolar function. Transmission electron microscopy showed that Nopp140−/− larvae had reduced cytoplasmic ribosomes, but contained excess nuclear virus-like copia particles, autophagosome-
like cytoplasmic structures, and many electron dense ~40 nm particles that we hope to show are RNP stress granules. Overall, our study suggests that Nopp140 is not required for morphological integrity of nucleolus, but that is necessary for proper nucleolar function, and that its deletion causes cell stress leading to larval growth arrest and eventual lethality.

501/B448
Net1-Mediated RhoA Signaling in the Nucleus Is Involved in the DNA Damage Response.
A. D. Dubash1, M. Srougi1,2, E. Boulter1, C. Guilluy1, K. Burridge1,2, R. Garcia-Mata1; 1Cell and Developmental Biology, UNC-Chapel Hill, Chapel Hill, NC, 2Lineberger Comprehensive Cancer Center, UNC-Chapel Hill, Chapel Hill, NC

Rho-GTPases are a family of proteins that control a wide range of different processes inside the cell, including cell survival, proliferation, gene expression, migration and death. Rho-GTPase activity is regulated by guanine nucleotide exchange factors (GEFs, which activate GTPases) and GTPase activating proteins (GAPs, which inactivate GTPases). Rho proteins reside mainly in the cytosol and are targeted to the plasma membrane (PM) upon activation. Accordingly, most GEFs and GAPs reside in the cytosol or PM of cells. However, some GEFs for the GTPase RhoA (like Net1 and Ect2) are localized to the nucleus of cells where they are assumed to exist as an inactive reservoir. Here, we show that the majority of nuclear-localized Net1 is in an active form and can induce nuclear RhoA activation upon overexpression. Furthermore, when cell are exposed to ionizing radiation (IR), which has been previously shown to activate total cellular RhoA activity, the activity of the nuclear pool of both RhoA and Net1 increases significantly, while cytosolic RhoA activity is not affected. This IR-mediated RhoA activation is inhibited by silencing Net1 expression, which causes a reduction in the amount of nuclear-localized RhoA, and a proportional decrease in nuclear RhoA activation. These results demonstrate for the first time a role RhoA and its exchange factor Net1 within the nucleus of the cell and suggest they may function in the DNA damage response.

502/B449
Fibroblast Growth Factor - 2 (FGF-2) Is a Regulator of Nuclear Body Structure.
A. Bruns1, J. van Bergeijk1, C. Lorbeer1, A. Nölle1,2, J. Jungnickel1, C. Grothe1,2, P. Claus1,2; 1Neuroanatomy, OE 4140, Hannover Medical School, 30625 Hannover, Germany, 2Center for Systems Neuroscience Hannover, Hannover, Germany

Nuclear bodies are distinct subnuclear structures. The survival of motoneuron (SMN) gene, which is mutated in patients with the neurodegenerative disease spinal muscular atrophy (SMA), is a marker protein for one class of nuclear bodies denoted nuclear gems. SMN has also been found in Cajal bodies, which colocalize with nuclear gems in many cell types. Interestingly, SMA patients display a reduced number of nuclear gems. Little is known about the regulation of nuclear body formation and stabilization. We have previously shown that a nuclear isoform of the fibroblast growth factor FGF-2 [FGF-2(23)] binds directly to SMN. In this study, we analyzed the consequences of FGF-2(23) binding to SMN with regard to nuclear body formation. on a molecular level, we could show that FGF-2(23) competed with Gemin2 - a component of the SMN complex, which is necessary for nuclear gem stabilization - for binding to SMN. on a cellular level, FGF-2(23) decreased the number of SMN-positive nuclear bodies. Knock-down of Gemin2 by siRNA caused destabilization of SMN-positive nuclear bodies. The same effect could be observed In Vivo in motoneurons of FGF-2 transgenic mice compared to their wild-type littermates. In addition, we analyzed the nuclear FGF-2(23) complex. The competition of FGF-2(23) and Gemin2 for binding to SMN is reflected on a cellular and In Vivo system level by a negative regulative function of FGF-2 in nuclear body formation. This study is the first demonstration of a new functional role of a growth factor in regulating structural entities of the nucleus. Treatment with Farnesyltransferase Inhibitors Causes Donut-Shaped Nuclei Due to a Defect in Centrosome Separation.

V. Verstraeten¹,², L. Peckham¹, M. Olive³, B. Capell⁴, F. S. Collins⁴, E. G. Nabel³, J. Lammerding¹; ¹Department of Medicine, Brigham and Women’s Hospital/Harvard Medical School, Cambridge, MA, ²Department of Dermatology, University Hospital Maastricht, Maastricht, Netherlands, ³Cardiovascular Branch, National Heart, Lung, and Blood Institute; National Institutes of Health, Bethesda, MD, ⁴National Human Genome Research Institute; National Institutes of Health, Bethesda, MD

Farnesyltransferase inhibitors (FTIs) were initially developed as anticancer drugs targeting Ras oncogenes and are now also used to treat patients with Progeria. Anecdotal observations suggest that FTIs cause donut-shaped nuclei. Objective: to identify the mechanisms underlying “donut-formation” and the effects of this nuclear abnormality on cell function. Methods: Donut-formation was monitored by time-lapse microscopy of primary human skin fibroblasts or HeLa cells expressing GFP-tagged lamin a and HEp2 laryngeal cancer cells co-expressing GFP-tagged histone-3 and mcherry-β-tubulin. Photo-conversion of Dendra-tagged histone-4 was used to evaluate the effect of donut-nuclei on proliferation. Results: FTI-treatment caused donut-shaped nuclei in 5-30% of skin fibroblasts, HeLa and HEp2 cells. Importantly, donut-nuclei were found in gut, skin, and blood vessel tissue sections of FTI-treated mice. Time-lapse imaging revealed that donut-shaped nuclei arose upon mitosis; blocking mitosis eliminated donut-formation. Strikingly, 70% of donut-nuclei were found in binucleated cells. Further analysis suggested a defect in centrosome separation as the primary cause. at interphase, 95% of these binucleated cells had a single centrosome-cluster located in between both nuclei. In mid-anaphase, however, multiple centrosomes could be seen close to or in the evolving donut-hole. A thick bundle of microtubules interconnected the holes of developing donut-shaped nuclei. In 35% of FTI-treated cells, centrosomes were located in between both daughter nuclei, i.e. facing the equatorial plane, in late anaphase. Overall, the distance between the centrosomes was smaller in FTI-treated cells, both at metaphase and anaphase. Although the donut-shape did not affect the rate of division, 60% of them divided abnormally; 95% of binucleated fibroblasts did not divide over a 4-day period. Furthermore, FTI-treatment increased the number of aneuploidic cells. Conclusions: FTI-treatment interferes with centrosome separation at mitosis and thereby, causes donut-nuclei and binucleation. The resulting proliferation defect could contribute to the anticancer effect of FTI, though warrants caution for its use in the treatment of Progeria.

---

Lamins are intermediate filament (IF) proteins specialized to form two-dimensional networks at the inner nuclear membrane (INM) as impressively represented in the giant cell nuclei of Xenopus oocytes. The establishment of such regular and extended lamin fiber systems as well as their degree of connectivity may be extensively regulated by factors within the INM, such as emerin and lamin B receptor (LBR), along with interactions that occur specifically in somatic cells, i.e. association with components of interphase chromatin such as histones and the barrier-to-autointegration factor (BAF). Recently, mutations in lamin a have been demonstrated to cause a bewildering number of different human diseases that may in part result from structural changes of the nuclear envelope but may also affect the specific association with distinct signaling molecules and transcription factors. In addition, it has been hypothesized that a widespread nucleoplasmic
A-type lamin system may functionally organize nuclear architecture. We have now established conditions to assemble recombinant lamin a filaments in a dilution-type fashion similar to the one successfully previously utilized for cytoplasmic IF proteins. Thereby we are able to analyze the assembly properties of wildtype versus mutated lamin A. Hence, by diluting the soluble, dimeric lamin complexes into buffers of appropriate composition, we are able to pilot their assembly process into different structural pathways. In addition, by restricting the spatial parameters to a near two-dimensional situation, we are able to enhance different assembly modes in a directed fashion. Moreover, we can influence the networking interactions of fiber-type structures by the addition of reactive fragments of several INM proteins. Here we worked out conditions that sharply distinguish wildtype lamin a from the progeroid mutant lamin E145K.

Dynamics of Telomere Clustering in Yeast.
N. Hoze¹, A. Taddei², D. Holcman¹; ¹Biology and Mathematics, Ecole Normale Superieure, Paris, France, ²Biology, Curie, Paris, France

For yet unclear reasons, telomeres form small but dynamical clusters. We study here the clustering of 32 independent telomeres modeled as Brownian object moving inside the restricted cellular domain. When the average number of telomere clusters is 5, we find that the dissociation constant of a telomere packet, regardless of its size in 3D is around 20s. By comparing several different models, we suggest that in a cluster, telomeres should all be attached to a unique docking zone that we characterize. Finally, we study the dynamics of two independent telomeres and show that at equilibrium, when the mean number of clusters is constant: two individual telomeres are highly dynamic and we obtain the intermittent law of switching between clusters. We conclude that telomere clustering is a highly dynamical process in Yeast Cerevisiae and we suggest similar results for Plasmodium falciparum telomeres.

Accurate, Efficient and Reproducible Electrophoretic Determination of the Mammalian Nuclear Matrix Proteome and Nucleic Acid Composition Using a Phastsystem.
X. G. Aranda¹, G. Pacheco-Rodriguez ², R. Alvarez-Gonzalez¹; ¹Graduate School of Biomedical Sciences, UNT Health Science Center at Fort Worth, Fort Worth, TX, ²Translational Medicine Branch, National Heart Lung and Blood Institute/NIH, Bethesda, MD

Nucleic acid metabolism is biochemically compartmentalized to the nucleus and it is necessary to define the proteome of the different macromolecular structures within this organelle. for that reason, a reproducible and efficient characterization of specific sub-nuclear structures is required. We have isolated the nuclear matrix (NM) fraction from rat liver nuclei by sequential centrifugation steps at 13,000 X rpm, staggered between an endogenous nuclease enzymatic treatment for 2 hours at 37 °C, followed by high salt (2.0 M NaCl) and non-ionic detergent extractions (0.1% Triton X-100) to eliminate the bulk of chromosomal DNA/RNA, chromatin histone proteins and the double lipid bilayer of the nuclear envelope, respectively. The integrity of intact rat liver nuclei, the NM, and the nuclear envelope structures was confirmed by electron microscopy. Upon demonstration of the high level of purity of these nuclear structures, we proceeded to run the NM extract on a 20% polyacrylamide gel, under SDS-denaturing electrophoretic conditions, using the phastsystem in less than 2 hours. We reproducibly observed the absence of histone proteins and the abundant presence of the characteristic NM protein lamins by Coomassie Blue staining in the region of 60-70 kD. By contrast, when we stained an identical gel with silver, following electrophoretic separation using a Tris-Borate-EDTA buffer, we observed the presence of significant amounts of NM associated nucleic acids, e.g., DNA, RNA, and more importantly protein-free ADP-ribose polymers. While ADP-ribose polymers are found in significantly lower concentrations than DNA and RNA (3-4 orders of magnitude lower concentration) in the NM, ADP-ribose chains could be purified by affinity chromatography on a boronate resin prior to electrophoresis on the phastsystem (Alvarez-Gonzalez, et al., 1983). As a result, we significantly improved the electrophoretic resolution to a highly efficient and reproducible detection of the
ADP-ribose polymer content associated with the NM fraction, after chemical release from NM proteins, under the mild alkaline pH conditions required for chromatographic purification.

The Role of Nup358 in Nuclear Import of the Tumor Suppressor DBC-1.
S. Waelde, R. Kehlenbach; Department of Biochemistry I, Center for Molecular Biosciences, Goettingen, Germany

Nucleocytoplasmic transport occurs through nuclear pore complexes (NPC) and is mediated by soluble transport receptors. Some nucleoporins, components of the NPC, have been suggested to function as initial or terminal binding sites for transport complexes. The 358 kDa nucleoporin Nup358/RanBP2 is a major component of the cytoplasmic filaments of the NPC. Earlier findings had suggested that Nup358 is dispensable for nuclear protein import. We could demonstrate, however, that depletion of Nup358 by RNA-interference leads to a reduced import rate for the importin α/β- as well as the transportin-dependent protein transport. Among others, we identified the tumor supressor DBC-1 (Deleted in Breast Cancer 1) as a protein, whose nuclear localization depends on Nup358. It is transported into the nucleus in an importin α/β-dependent manner. A putative coiled-coil region in DBC-1 appears to be required for its Nup358-dependent import. Furthermore, different regions within Nup358, which might be involved in DBC-1-import, are analyzed. Full-length Nup358 as well as C-terminal deletion mutants, expressed from RNAi-insensitive mRNAs, are able to rescue the observed import defects in cells depleted of endogenous Nup358. Together, our results point to an important role of Nup358 as a general docking site for specific incoming transport complexes.

A Relationship between Yeast Nuclear Morphology, Large Structural Nucleoporins, and the Sun Domain Protein MPS3.
K. Witkin1, O. Cohen-Fix1, S. Jaspersen2; 1The Laboratory of Molecular and Cellular Biology, NIDDK, NIH, Bethesda, MD, 2Stowers Institute for Medical Research, Kansas City, MO

Nuclear architecture regulates essential functions of the nucleus. Yet little is known about the genes that control nuclear structure or the mechanisms by which they affect nuclear function. In order to explore the relationship between nuclear structure and function in budding yeast, we are using both high-throughput and candidate approaches to study mutants with abnormal nuclear morphology. Cells carrying a deletion of the non-essential SPO7 gene misregulate phospholipid biosynthesis and exhibit expansion of the endoplasmic reticulum and nuclear envelope, causing aberrant nuclear morphology. In order to identify aspects of nuclear function that are compromised in this mutant, we have used a combination of approaches to identify genes whose disruption confers synthetic lethality with the spo7Δ allele. Temperature-sensitive alleles of the essential SUN domain gene MPS3 exhibited synthetic lethality and changes in nuclear morphology in combination with the spo7Δ allele. The Mps3 protein resides at the spindle pole body (SPB) and around the nuclear periphery, and MPS3 has been implicated in SPB duplication as well as various aspects of nuclear architecture. Using a high-copy suppressor screen, we have identified genes that rescue the synthetic lethality between spo7Δ and mps3 alleles, including two genes encoding large structural nucleoporins. Our data suggest that these nucleoporins act in a dominant negative manner to rescue a defect in MPS3 function. Ongoing studies aim to determine the biological basis of the synthetic lethality between SPO7 and MPS3, and to elucidate the relationship between these large structural nucleoporins and MPS3 function.

DNA Zip Codes: An Ancient Mechanism for Gene Targeting to the Nuclear Periphery.
S. Ahmed1, D. Brickner1, W. Light1, M. McDonough2, I. Cajigas1, T. Volpe2, J. Brickner1; 1Northwestern University, Evanston, IL, 2Feinberg School of Medicine, Northwestern University, Chicago, IL
Many highly expressed genes are dynamically recruited to the nuclear periphery upon transcriptional activation in Saccharomyces cerevisiae. We have identified two Gene Recruitment Sequences (GRSs) from the promoter of the INO1 gene that target the gene to the nuclear periphery upon activation. The GRSs function as DNA zip codes; they are sufficient to target a nucleoplasmic locus to the nuclear periphery through interaction with the nuclear pore complex. Full transcriptional activation of INO1 requires GRS-mediated targeting of the promoter to the nuclear periphery. Finally, a GRS functions as a DNA zip code in Schizosaccharomyces pombe as well, suggesting that this mechanism of targeting to the nuclear periphery is conserved over at least one billion years of evolution.

Phosphorylation of Nup1 by Cdk Regulates the Localization of Active Genes to the Nuclear Periphery through the Cell Cycle.

D. G. Brickner, J. Brickner; BMBCB, Northwestern University, Evanston, IL

Upon activation, a number of inducible genes in yeast are targeted to the nuclear periphery and physically interact with the nuclear pore complex. Using a quantitative chromatin localization assay, we find that the peripheral localization of the active INO1 and GAL1 genes is regulated through the cell cycle. Both genes localized at the nuclear periphery during G1, became nucleoplasmic during S-phase and returned to the nuclear periphery during G2/M. Relocalization of these genes to the nucleoplasm during S-phase required the initiation of DNA replication. The loss of peripheral localization required the cyclin dependent kinase inhibitor (CKI) Sic1 and could be induced during G1 by activation of the CKI Far1. These observations suggested that phosphorylation of a substrate by cyclin-dependent kinase (Cdk) promotes peripheral localization. Indeed, we found that two Cdk phosphorylation sites in Nup1 and the Cdc28 kinase were required for peripheral targeting of active INO1 and GAL1. Furthermore, introduction of aspartic acid residues in place of either of these two sites in Nup1 bypassed the requirement for Cdc28 and resulted in targeting of INO1 and GAL1 to the nuclear periphery during S-phase. Thus, cyclic phosphorylation of a nuclear pore component by cyclin dependent kinase coordinates gene localization and transcriptional activity with DNA replication.

Cysteine Reactivity as a Probe of the Nuclear Proteome: An In Situ Measurement of the Tolerance of Lamin A/C to Stress.

A range of diseases and syndromes can be traced to mutations to the gene *lmna*, which codes for the nuclear intermediate filament proteins, Lamin A and Lamin C. Emery Dreifuss Muscular Dystrophy is the consequence of a single amino acid substitution (R453W) to the c-terminal immunoglobulin-like (Ig) domain of the Lamin A/C proteins. Solution studies of the isolated domain have suggested that the disease mechanism could result from partial unfolding of the Ig domain at physiological temperatures. In order to make corresponding measurements of thermal stability within structurally intact nuclei, we introduce a novel assay in which the fold-state of a protein is probed by measuring the extent and kinetics of cysteine labeling. The lone cysteine within the Ig domain reacts slowly in a covalent reaction with the fluorescent dye bromobimane (mBBr) under native conditions, but this reaction is accelerated beyond Arrhenius behaviour as the protein unfolds and the cysteine residue is exposed at elevated temperature. By using LC/MS/MS to quantify the extent of labelling, we are able to extend this methodology to profile the response to thermal stress of a large number of nuclear proteins in parallel.

Ribonucleoproteins (512 – 526)

Poly(ADP-ribose) Is Required for Stress Granule Integrity and Regulates microRNA Activity.
A. K. Leung1, S. Vyas1, 2, P. A. Sharp1, 2, P. Chang1, 2; 1Koch Institute, MIT, Cambridge, MA, 2Department of Biology, MIT, Cambridge, MA

Cells respond to external stress via reprogramming of gene expression. One way to cope with stress, such as heat shock, oxidative stress, ischemia or viral infection, is to assemble large multiprotein complexes called Stress Granules (SGs). SGs contain stalled translation initiation complexes, poly(A)+ mRNAs, and their associated proteins, such as G3BP1, TIA1, and the microRNA(miRNA)-binding protein Ago2 which I previously identified as a component. SGs are thought to regulate the stability and translation potential of mRNAs, but the mechanism of SG function and the regulation of SG assembly are largely unknown. Here I will present that Poly(ADP-ribose) (pADPr) - a large, branched, negatively charged polymer - localizes to SG and is required for SG integrity. Moreover, I identify 5 specific pADPr polymerases (PARPs) and 2 pADPr glycohydrolase (PARG) isoforms as SG components - the first identification of multiple enzymes regulating pADPr function in one specific cellular activity. I will discuss how Poly(ADP-ribose) (pADPr) acts as a scaffold of SGs and its implication in assembly and disassembly of this organelle. All known de novo nucleators of SG assembly, including Ago2, G3BP1 and TIA1, are directly modified by pADPr and such modification increases upon stress. I will also present data on how this modification modulates one form of the post-transcriptional gene regulation - miRNA activity - in normal and stressed conditions. These results further expand the role of pADPr in responding to DNA damage in the nucleus and extend its function to the cytoplasm in modulating post-transcriptional gene regulation. The understanding of the cytoplasmic role will likely impact the current treatment in cancer, ischemia and inflammation diseases using PARP inhibitors, which are actively developed by pharmaceutical companies.

Map Kinase Signaling Regulates mRNA Export during Cellular Stress.
E. J. Tran, S. R. Carmody, S. R. Wente; Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

Gene expression in eukaryotes requires transcription, messenger RNA (mRNA) processing and nuclear mRNA export prior to translation. Transport of mature mRNAs occurs through nuclear pore complexes embedded in the nuclear envelope. It is well established that heat shock and other cellular stresses result in alteration of mRNA export, however the precise mechanism for transcript-specific regulation of transport is unknown. Using the budding yeast S. cerevisiae as a model system, we analyzed a panel of mRNA export factors for changes in cellular localization upon heat shock. Strikingly, we found that the mRNA-binding protein Nab2 forms nuclear foci upon heat shock. Foci formation was dependent on the NPC-associated protein gene MLP1. We also found that Nab2 was phosphorylated after shifting cells to heat shock. Interestingly, phosphorylation was independent of nuclear foci formation, suggesting that these processes reflect distinct cellular roles. By screening through the S. cerevisiae null collection, we identified a MAP kinase pathway responsible for the phosphorylation. In Vitro kinase assays showed that the MAP kinase directly phosphorylated recombinant Nab2. To determine the Nab2 phosphorylation sites, Nab2-TAP was isolated from heat shocked cells and mass spectrometry was conducted. Two specific sites were defined and confirmed by mutagenesis. Using yeast genetics, we are currently analyzing the requirements for phosphorylation in Nab2 foci formation and differential mRNA export. Overall, because Nab2 functions in both polyadenylation and mRNA export, we speculate that alteration of Nab2 promotes retention of non-heat shock transcripts potentially by altering mRNA 3’ end processing and/or export. This represents a novel mechanism for regulating mRNA binding proteins during differential mRNA export. Supported by NIH R01 GM051219 to S. R. W.

RNA Interference and Plant-Fungal Symbiosis- Characterization of Argonaute Genes from Laccaria bicolor.
RNA interference (RNAi) is a conserved group of regulatory mechanisms in which small regulatory RNA molecules serve as guides for protein complexes to suppress expression of targeted gene sequences. Argonaute is one of the key proteins in RNAi and is the catalytic cleaving component of the RNA induced silencing complex. Argonaute and other RNAi components have been found to have a role in fungal gene silencing, known as quelling, and is similar to RNAi in animals. The biogenesis of small regulatory RNAs involved in RNAi in fungi have yet to be identified. Using ectomycorrhizal symbiotic fungus *Laccaria bicolor* (*L. bicolor*) as a model, my objective is to identify the genes for biogenesis of small regulatory RNAs and determine their role in gene regulation. I have cloned and sequenced full length cDNAs of all three hypothetical Argonaute genes from *L. bicolor* during early interaction phase of symbiosis. via quantitative PCR analysis, I have also confirmed their interaction-specific high expression which suggests a possible regulatory role for Argonautes in symbiosis. Biochemical characterization of recombinant *L. bicolor* Argonaute proteins was determined through In Vitro RNA cleavage assays. Complementation of a *Schizosaccharomyces pombe* Argonaute mutant was attempted to establish the functional role of *L. bicolor* Argonaute genes. Our results strongly suggest RNAi machinery are likely involved in the production of small regulatory RNAs involved in symbiosis formation. This data will enable us in the future to elucidate the critical biological role played by RNAi machinery in *L. bicolor* and also its role in formation of symbiosis.

**Non-Coding ncRNA-Protein Interaction Networks, a “Rosetta Stone” to Decipher the Epigenetic Code and Algorithm.**

J. H. Wissler; Arcons Institute for Applied Research & Didactics, Postfach 1327, D-61231 Bad Nauheim, Germany

OBJECTIVE: From the same genotype, the genome orchestrates genetic [Mendelian] and epigenetic [non-Mendelian] information into different organized or mess-chaotic [tumor] phenotype variations. By genetic complimentary and triplet codes, transcription and translation of DNA genes into proteins matter only ~2% of transcriptional output. Functions of residual ~98% transcriptional RNA output of cells activated by extrinsic [environmental] factors were investigated on structural codes for episcription [greek: “overscription”]. METHODS: Ann.N.Y.Acad.Sci.1022:163-184,2004; 1137:316-342,2008. RESULTS: Functional edited, modified, redox- and metalloregulated small hairpin ncRNA [<200n] as bioaptamers in RNP complexes were isolated from epigenetic remodeling variation models directed to proteinaceous gene expression and regulation rather than genomic DNA sequence changes. Some are not complimentary to protein-coding DNA sequences. They may address defined homologous helix-nucleating domains shared in epigenetic regulator proteins entangled in tolerated growth, vascularization, metabolic syndromes, cancer and epigenetic and genetic information indexing of the epigenome. at variance to genetic codes, ncRNA are not “non-coding”, but have to be read in another “language alphabeth”. They code algorithmic [necessity] rather than stochastic [chance] and heuristic [trial/error] regulatory processes. CONCLUSIONS: The results suggest the epigenetic code consists of different intrinsic and extrinsic interactive imprints and factors: [1] Non-Mendelian nucleic acid 3D-episcripts. Some are non-complimentary ncRNA derivatives of genomic DNA. [2] Conserved homologous domains in epigenetic regulator protein and nucleic acid matrices of Mendelian genotype origin in helix-nucleating interaction with [1], comprising variant and heritable disease implications. [3] Extrinsic and intrinsic factors upon which formation of [1] and interaction with [2] depends [e.g. redox- and metalloregulation]. Thus, the epigenetic code comprises more diversity, complexity and plasticity repertoires than genetic codes. It conforms to Darwin-Mendel’s principles in synergism with some [Lamarck’s] environmental influences for epigenetic imprinting and inheritance.

O-GlcNAc Cycling Enzymes Associate with the Translational Machinery and Modify Many Core Ribosomal Proteins.
Q. Zeidan¹, Z. Wang¹, A. De Maio², G. W. Hart¹; ¹Biological Chemistry, Johns Hopkins University, Baltimore, MD, ²Surgery, University of California San Diego, La Jolla, CA

Post-translational modifications of translation factors represent essential mechanisms for regulating global protein synthesis. High-throughput studies have identified several translation factors and ribosomal proteins (RPs) that are modified by O-GlcNAc. Employing subcellular fractionation, followed by galactosyltransferase labeling with UDP-[3H]Gal or Western blotting, we find that O-GlcNAc is present on many proteins from actively translating polysomes. Using reverse phase-high pressure liquid chromatography (RP-HPLC) and MS/MS we identify at least twenty GlcNAcylated RPs, of which only seven had been previously reported. Chemoenzymatic labeling combined with β-elimination followed by Michael addition with DTT (BEMAD), allow us to map sites of O-GlcNAc modification on four RPs (RPL6, RPL29, RPL32 and RPL36). RPS6, a component of the mammalian target of rapamycin (mTOR) signaling pathway, follows different dynamics of GlcNAcylation than nutrient-induced phosphorylation. In addition to GlcNAcylated RPs translational preparations also contain both O-GlcNAc cycling enzymes. O-GlcNAc Transferase (OGT) and O-GlcNAcase (OGAse) strongly associate with ribosomes. Both enzymes are present in sub-polysomal fractions (40S, 60S and 80S monosomes), as well as in light and heavy polysomes. Immunofluorescence microscopy shows that OGAse, but not OGT, is present within the nucleolus and co-localizes with fibrillarin, a ribosome-processing factor. Disruption of nucleolar structure by inhibition of rRNA synthesis results in loss of OGAse staining within the nucleolus. Adenoviral-mediated over-expression of OGT, but not of OGAse or GFP control, causes a dramatic accumulation of 60S subunits and 80S monosomes. Our results not only establish that GlcNAcylation extensively modifies RPs, but also suggest that O-GlcNAc may play important roles in regulating translation and ribosome biogenesis. Supported by NIH grants R01 DK61671 and R01 CA42486. Dr. Hart receives a share of royalty received by the university on sales of the CTD110.6 antibody. Terms of this arrangement are managed by JHU.

517/B464
microRNA Activity Is Regulated by Poly(ADP-ribose).
A. K. Leung¹, S. Vyas¹,², P. Chang¹,², P. A. Sharp¹,²; ¹Koch Institute, MIT, Cambridge, MA, ²Department of Biology, MIT, Cambridge, MA

microRNAs (miRNAs) are a class of ~22 nucleotide non-coding RNAs predicted to regulate at least 50% of mammalian mRNAs. Emerging data suggest that some miRNAs are instrumental for cellular stress responses by regulating the stability and translation of existing mRNAs post-transcriptionally through the activity of Argonaute protein. I previously demonstrated that Argonaute/miRNA complexes localize to cytoplasmic organelles called Stress Granules (SGs), which assemble immediately upon stress stimuli such as heat shock, oxidative stress, hypoxia, UV irradiation or hypoglycemia. SGs contain stalled translation initiation complexes, poly(A)+ mRNA and their associated RNA-binding proteins (RBPs). During normal, non-stress conditions, miRNA targets are typically repressed and translation occurs preferentially on non-miRNA targets. Here I will present data showing that a member of the Argonaute family, Ago2, is directly modified by poly(ADP-ribose) (pADPr) - a large, branched, negatively charged polymer - during both normal and stressed conditions. As a result of the modification, the proportion of miRNA targets being translated relative to non-miRNA targets increases when translation becomes limiting upon stress. I also show that the modification is mediated through the activity of 2 SG-localized, pADPr polymerases (PARPs) that co-bind with Ago2 to miRNA targets. These results identify a new mechanism for attenuating silencing by miRNA during stress. In addition to Ago2, I also identified other SG-localized RBPs as targets of increased pADPr activity upon stress. I will conclude by discussing how pADPr could reprogram the expression of pre-existing mRNAs selectively and immediately as a general mechanism for cells to respond stress.

The Paraneoplastic Neurologic Disease Antigen Nova Regulates Transcript Levels through Occult Nmd Exons and 3'UTR Interactions.

T. Eom1, C. Zhang1, J. Fak1, R. Darnell1, 2; 1Rockefeller University, New York, NY, 2HHMI, New York, NY

RNA binding proteins (RBP) play many important roles to regulate the alternative splicing, translation, stability and localization of RNAs. It has been known that Nova plays a role as a splicing factor in neurons through previous work. Nova proteins do shuttle between nucleus and cytoplasm by using a Nuclear Localization Signal and a Nuclear Export Signal and it suggests to have other functions in the cytoplasm besides the splicing in nucleus. Immunohistochemical and biochemical studies have demonstrated that Nova proteins are enriched in the nucleus and also distributed in the cytoplasm. A new method, HITS-CLIP (high-throughput sequencing crosslinking immunoprecipitation) has identified many In Vivo RNA targets through covalent cross-linking of Nova proteins and RNAs. Sub-fractionationed HITS-CLIP can show live Nova-RNA interaction sites in nucleus and cytoplasm, respectively. Microarray data showed transcripts levels of many Nova’s target RNAs were not only up-regulated but also down-regulated in KO. Distribution of HITS-CLIP tags among top 229 transcripts exhibited 3'UTR in the minority of instances (23.9%), and instead the dominant location of CLIP tags was intronic. It suggests the possibility that Nova act through occult elements with annotated introns. RT-PCR and sequence analysis showed there are many unknown Nova-dependent alternative splicing events which can remove or introduce premature stop codons. It can turn off/on the nonsense-mediated decay (NMD) pathway regulating gene expression posttranscriptionally. Nova proteins are important to set a balance of many protein expression through this mechanism. To determine whether these genes regulated by Nova proteins is NMD-dependent, siRNA to upf1 and emetine drug were used to block NMD pathway and then see if transcript levels were rescued. Additionally, cytoplasmic fractionationed HITS-CLIP showed many tags in 3'UTR and these YCAY elements among transcripts having mild change only in DKO are involved to increase mRNA stability. It is the first example to demonstrate that an RBP, Nova, up/down-regulates transcripts through occult NMD exons and up-regulates transcripts through 3'UTR interactions as well.

Exploring Template Utilization by Telomerase with Saccharomyces cerevisiae Yeast.

R. C. Bairley1, G. Guillaume2, K. Friedman1; 1Vanderbilt University, Nashville, TN, 2Barry University, Miami Shores, FL

<T> Telomerase is a reverse transcriptase enzyme required for the maintenance of simple DNA repeats at the ends of most linear eukaryotic chromosomes (telomeres). The catalytic core of yeast telomerase includes the Est2 protein and the TLC1 RNA. We have shown that mutations in the N-terminus of Est2p cause telomere over-elongation and alter the sequence of the telomere repeats (Ji et al., 2008). This change in telomere sequence is seen in strains expressing est2 alleles that cause telomere over-elongation through genetically distinct pathways (e.g. est2-LTE76K is RAP1 dependent; est2-up34 is PIF1 dependent) suggesting that an altered telomere sequence may be a consequence, rather than a cause, of over-elongation. RAP1 Interacting Factors 1 and 2 (RIF1 and RIF2). Our data show that the telomere sequences of these strains are similar to those of WT. The altered sequence phenotype is also not seen with mutations in genes that indirectly regulate telomere length, ELG1 and SSN8. These data suggest that the altered telomere sequence and length phenotypes are separate. est2 mutations that affect telomere length through different pathways give rise to similar changes in telomere sequence may be reconciled through understanding the mechanism through which the telomere sequence is generated. We know that the sequence change generated by est2-LTE76K is not due to an increased processivity of nucleotide addition by mutant telomerase (Ji et al., 2008). Rather, the est2 alleles may change alignment of the TLC1 RNA with the DNA substrate. To test this hypothesis, I have incorporated tlc1 template mutants in the WT and est2 strains. Our data show that the sequences added by WT and mutant telomerase are drastically affected by changes in the template region, supporting our hypothesis. We are in the process of examining telomere addition to a short telomere seed In
Vivo and monitoring activity of WT and mutant telomerase on a series of differing DNA primers in vitro.

Novel Role for Nup98 as a Component of a Regulatory Germline RNP.
E. Voronina, G. Seydoux; MBG, Johns Hopkins University/HHMI, Baltimore, MD

Germ granules are cytoplasmic ribonucleoprotein complexes essential for differentiation and function of germ cells. Germ granules are often found at the cytoplasmic face of the nuclear envelope, close to nuclear pores (Strome and Wood 1982; Pitt et al., 2000; Pavrinen et al., 2005). To investigate a potential link between nuclear pore components and germ granules, we performed an RNAi screen depleting annotated nucleoporins in C. elegans. We found that Nup98/96, Nup153, and Nup155 are essential for germ granule integrity and perinuclear localization. Localization analysis suggested that Nup98 is unique among these proteins as it localizes to the germ granules in addition to its expected localization at the nuclear pores. Importantly, Nup98 localization to germ granules is disrupted when Nup155 or Nup153 are depleted. We have found that Nup98 critically contributes to germ granule function. *nos-2* codes for a translationally-repressed mRNA that localizes to germ granules. In the absence of Nup98, *nos-2* mRNA no longer associates with P granules and is translated precociously. Immunoprecipitation of Nup98 brings down *nos-2* mRNA, suggesting that the two exist in a repressive complex in germ granules. Consistent with this hypothesis, tethering of Nup98 to the 3’ UTR of a heterologous mRNA causes its translational repression in Hela cells. Immunoprecipitation of Nup98 from mouse testes brings down MVH, a mouse germ granule protein, suggesting a conserved role in cytoplasmic mRNPs. We hypothesize that Nup98 is recruited to a subset of regulated mRNAs to direct them to repressive complexes in the cytoplasm. Nup98 has been implicated in regulation of mRNA export from the nucleus (Pritchard et al., 1999, Enninga et al., 2002). Our results support expanding Nup98’s role to include regulation of mRNA fate in the cytoplasm.

Recognition of Ribosomal RNA by Rprotein S4.
M. Mayerle¹, S. A. Woodson²; ¹Biology, The Johns Hopkins University, Baltimore, MD, ²Biophysics, The Johns Hopkins University, Baltimore, MD

Ribosome assembly is a vital cellular process that demands a large amount of energy. A cell can create more than 2000 ribosomes per minute under ideal growth conditions. In yeast, rRNA transcription accounts for over 60% of all transcription, while the transcription of associated r-proteins accounts for 50% of all pol II transcription events. Ribosomal proteins are directly involved in the regulation of ribosome biosynthesis in both yeast and bacteria. In E. coli, free r-protein S4 inhibits the translation of an operon encoding S4, along with ribosomal proteins S13, S11, and L17. In addition, S4 inhibits the termination of pre-rRNA transcription. Bacterial 30S ribosome subunit assembly requires the proper folding of the 16S rRNA and the hierarchical association of over 20 individual r-proteins. S4 binds to the 5’domain of the 16S rRNA at a five-way helical junction (5WJ). Once bound to the rRNA, S4 nucleates assembly of the 30S subunit by bringing many helices in the 5’ domain into close proximity. In addition, both S4 and the 5’domain undergo changes in structure upon binding. Interactions between S4 and the 16S rRNA were probed through protein engineering and footprinting of the RNA. Recently, time resolved hydroxyl radical footprinting data from our lab demonstrated that, although early steps in ribosome assembly are linked to intrinsically stable RNA structure, later regions correspond to regions of induced fit between the protein and rRNA. A series of S4 truncation and point mutants were created at residues likely to be critical for rRNA recognition by S4. An N-terminal truncation mutant, as well as a single point mutant completely abolished 5WJ rRNA binding, while other point mutants showed varied decreases in affinity, from a 5-fold to nearly 50-fold reduction in affinity. Hydroxyl radical and SHAPE experiments are currently underway to determine the effects of the various mutant proteins on folding of the 5WJ RNA and 30S assembly.

Removal of introns from pre-mRNAs (splicing) requires the coordinated action of Uridine-rich small ribonucleoprotein particles (UsnRNPs). UsnRNPs comprise a RNA moiety, transcribed in the nucleus, as well as different proteins. E.g. most UsnRNPs share seven Sm proteins, which assemble around the RNA in a heptameric ring. Sm ring formation occurs in the cytoplasm and involves the Survival of Motor Neurons (SMN) Complex. The SMN complex is believed to accompany the maturing UsnRNPs back into the nucleus and to Cajal bodies, where SMN catalyzes further maturations steps in UsnRNPs. UsnRNPs then reach sites of active splicing, while the nuclear SMN complex accumulates in Cajal bodies. The specific functions of the SMN complex in the nucleus or the cytoplasm, and exchange and distribution of the SMN complex between the two compartments are expected to be tightly regulated. It is now well established that the phosphorylation state of subunits of the SMN complex differs significantly between the nucleus and the cytoplasm. We recently could show that the PPM1G phosphatase is required to maintain SMN in a hypophosphorylated form in the nucleus to allow accumulation of SMN in Cajal bodies (Petri et al., JCB, 2007). In order to systematically identify regulators of SMN localization and function, we now screened a siRNA library for the knock-down of all human phosphatase gene products. In a semi-automated screen, we determined the specific localization pattern of SMN in the nucleus and in the cytoplasm after knock-down of ca. 300 human phosphatases and phosphatase-related gene products. Besides PPM1G itself, our screen reveals several novel potential regulators of the SMN complex, which are required for proper Cajal body accumulation, distribution of the SMN complex between the nucleus and the cytoplasm and its overall stability. Our data suggest direct regulators of the SMN complex as well as integration of SMN complex function into the overall proliferation state of human cells.

Human mRNA Decapping Enzyme, hDcp2, Stability May Be Regulated According to mRNA Substrate Levels.
S. Erickson1,2, C. Fillman2, J. Dennis2, J. Lykke-Andersen1,2; 1Biology, UCSD, La Jolla, CA, 2Molecular, Cellular & Developmental Biology, UCSD, Boulder, CO

mRNA decay is a key step in the regulation of gene expression. A critical step in several mRNA decay pathways is decapping. Here we present evidence that mRNA decapping in human cells may be regulated through the stability of the decapping enzyme, hDcp2. We have observed that exogenously expressed hDcp2 is highly unstable. By contrast, all tested non-catalytic decapping factors are stable. The following lines of evidence suggest that the C-terminus of hDcp2 is critical for hDcp2 instability. First, its deletion renders exogenous hDcp2 stable and second, overexpression of Hedls/Ge-1/Edc4, a decapping factor that interacts with the hDcp2 C-terminus causes stabilization of full-length hDcp2. Interestingly, hDcp2 is stabilized by a single point mutation that renders hDcp2 catalytically inactive. This correlates with the entrapment of the decapping complex on mRNA substrates upon expression of catalytically inactive hDcp2, as evidenced by the accumulation of the decapping complex in cytoplasmic mRNP granules called P-bodies under these conditions. Based on these observations, we hypothesize that hDcp2 stability is regulated according to the levels of its mRNA substrate. This may provide a mechanism to prevent promiscuous mRNA decay by an excess of hDcp2, and to rapidly upregulate hDcp2 when conditions require decapping of a large number of mRNAs. These results provide novel insights into the regulation of mRNA decay enzymes.

Ultrastructural Analysis of the Biogenesis of Lacandonia Granules.
L. T. Agredano-Moreno, L. F. Jiménez-García; Cell Biology, Faculty of Sciences, Universidad Nacional Autónoma de México (UNAM), México, D.F., Mexico

Lacandonia granules are extranucleolar ribonucleoprotein (RNPs) particles, 32 nanometers in diameter intermixed with fibrils that were first described in the plant Lacandonia schismatica but are also present in the close relative Triuris brevistytilis and the gymnosperm Ginkgo biloba. Ultrastructural cytochemical, immunocytochemical and in situ hybridization studies suggest that these particles are equivalent to perichromatin and Balbiani ring granules described in mammals and insects. However, no studies have been done to know the biogenesis of Lacandonia granules. In the present work we analyze the spatial relations between the granules and surrounding fibres in the nuclei of Lacandonia schismatica by an ultrastructural approach that includes the use of a goniometer adapted to the transmission electron microscope, to produce three-dimensional images as stereopairs. Our results show that Lacandonia granules are associated to fibrils suggesting several steps in the formation. The first one consists of very small granules associated to thick fibrils forming an amorphous cumuli most of the cases associated to chromatin. The second step consist in more abundant granules of heterogeneous size distributed along the interchromatin and perichromatin space that are intermixed with more thin fibrils and the last step consists of the 32 nm particle which is associated to thin fibers and could represent mature granules. Our results suggest that during the biogenesis of the granules, they originate from surrounding fibrils (supported by UNAM DGAPA-PAPIIT IN-206307).

Exploring Assembly Intermediates of the 30S Ribosomal Subunit Using Single Particle EM.
A. M. Mulder, C. Yoshioka, A. Beck, A. Bunner, R. Milligan, C. Potter, B. Carragher, J. Williamson; Cell Biology, TSRI, La Jolla, CA

Ribosomes are self-assembling macromolecular machines responsible for translating the cell’s genetic code into the workhorses of life, proteins. Given their fundamental importance, an understanding of ribosome synthesis, regulation, and assembly is imperative. Extensive studies on the accepted model for ribosome assembly, the E. coli 30S subunit, suggest that ribosome assembly is (1) cooperative, (2) hierarchical, and (3) occurs via multiple, parallel pathways rather than through a single rate-limiting step. We have taken EM snapshots of assembling 30S subunits at 8 different time points and determined the compositions and 3D structures of more than 10 assembly intermediates. The data confirm the existence of multiple assembly intermediates that are variously populated over time and illustrates parallel assembly in the 3’ domain. This combined with previous studies suggest a mechanism for 30S assembly that includes binding dependencies and kinetics.

3D Structure of Human Dicer by Single Particle Electron Microscopy.
P. Lau1,2, C. Potter2, B. Carragher1, I. MacRae2; 1Cell Biology Department, The Scripps Research Institute, La Jolla, CA, 2Molecular Biology Department, The Scripps Research Institute, La Jolla, CA

Dicer is a specialized ribonuclease that initiates RNA interference (RNAi) by cleaving double-stranded RNA into RNA fragments about 22 nucleotides in length. Dicer also serves as a scaffold for the initiation of RNAi by bringing together multiple factors required for the correct processing of small RNAs. Here, we present the 3-D structure of human Dicer bound to the protein TRBP at approximately 20 angstrom resolution determined by electron microscopy (EM). A robust and reliable 3-D model of the complex was generated using a combination of random conical tilt and projection matching refinement methods. Our analysis reveals that the Dicer-TRBP complex is an L-shaped molecule. Docking the crystal structure of Giardia Dicer, which represents the nuclease core of human Dicer, into the EM map suggests two possible overall molecular architectures for human Dicer. These results offer insights into the structure of Dicer proteins found in multi-cellular organisms and provide a conceptual framework for understanding the initiation of RNAi.
Structure of the Nuclear Envelope (527 – 538)

LRMP Is a Nuclear Envelope Protein That Interacts with IP3R.
L. K. Fishwick1, B. Burke1,2, K. J. Roux1; 1Anatomy and Cell Biology, University of Florida, Gainesville, FL, 2Institute of Medical Biology, Singapore, Singapore

The LINC-complex is a protein structure that spans the nuclear envelope (NE) to connect the nucleoskeleton to the cytoskeleton. This complex consists of translumenal associations between inner nuclear membrane SUN-domain proteins and outer nuclear membrane KASH-domain proteins. We propose that lymphocyte restricted membrane protein (LRMP) is a fifth member of the mammalian KASH-family based on its C-terminal KASH-like domain. We can demonstrate that this domain is sufficient for NE targeting and is dependent on association with SUN domain proteins. Unlike conventional KASH family members whose cytoplasmic domains bind to cytoskeletal constituents, LRMP was instead found to interact with inositol triphosphate receptors (IP3R), ER-resident calcium channels. Furthermore, we have characterized the regions of LRMP required for its association with IP3R. Our data suggest a model in which LRMP modulates IP3R at the NE, thus potentially regulating perinuclear cytosolic calcium in lymphocytes.

Mechanisms for Active Transport of the Large Sun Protein UNC-84 to the Inner Nuclear Membrane.
E. Tapley, N. Ly, D. Starr; Molecular and Cellular Biology, University of California-Davis, Davis, CA

Inner nuclear membrane (INM) proteins must be trafficked from their sight of synthesis, the ER. INM proteins move along continuous membrane domains from the ER to the outer nuclear membrane before crossing the pore membrane to reach the INM. Proteins are retained at the INM by interacting with the nuclear lamina. Three different models have been proposed for the mechanisms of INM trafficking: diffusion-retention and active import using either soluble machinery with a classical nuclear localization signal (cNLS) or a membrane-bound INM-sorting motif (INM-SM). The larger the size of the INM protein, the more difficult it is to cross the nuclear pore membrane. The C. elegans SUN protein UNC-84 is the largest known component of the INM, making it an excellent model to elucidate mechanisms of targeting proteins to the INM. In Vivo deletion analysis suggested that UNC-84 has one membrane spanning domain that separates its 56 kDa N-terminal nucleoplasmic domain from its 64 kDa C-terminal luminal domain. The N-terminus of UNC-84 was necessary and sufficient to target UNC-84 to the nucleus when it was either membrane-bound or soluble. A soluble N-terminal fragment of UNC-84 containing the first 370 amino acids was sufficient for active transport into the nucleus and retention at the nuclear periphery. Further deletion mapping studies revealed that residues 174-370 contained signals that were both sufficient for active import and nuclear envelope retention. Two putative NLSs that resembled classical NLSs were not required for UNC-84 trafficking, but an inner nuclear membrane sorting motif (INM-SM) was required for efficient NE targeting in early embryogenesis. A novel NLS conserved in other SUN proteins was found to be essential for UNC-84 trafficking. These data show for the first time in metazoans that large integral membrane proteins are actively trafficked to the inner nuclear membrane and that the mechanisms used to target SUN proteins to the INM may be conserved.

The Reformation of Post-Mitotic Nuclear Envelope by Endoplasmic Reticulum Cisternae Followed by the Insertion of Nuclear Pore Complexes.
During interphase, the Endoplasmic Reticulum (ER) of mammalian cells is made of a continuous network of cisternae and tubules. During mitosis, the ER is mainly reorganized into a network of cisternae, into which the nuclear envelope merges. The disassembly of nuclear pore complexes coincides with the disappearance of the nuclear envelope. How are the nuclear envelope and nuclear pore complexes reformed at the end of mitosis? Using fast live cell 3D-imaging combined with electron microscopy tomographic reconstructions of high pressure freeze/substituted cells, we show that mitotic ER cisternae directly generate the nuclear envelope upon their contact with the surface of the chromosome mass. Formation of nuclear pores is defined here as the sequential recruitment of Nup133 and Nup62, components of the Nup107-160 and Nup62 complexes, respectively. Data obtained by fast live cell imaging show that de novo formation of nuclear pores is strictly constrained to sites already containing nuclear envelope. In contrast, prior to nuclear envelope formation there is no recruitment of Nup133 onto the surface of the chromosome mass. We propose that the assembly of nuclear pore complexes on the nuclear envelope at the end of mitosis is based on an insertion mechanism, probably similar to the process during interphase.

Phosphorylation of Nuclear Pore Complex Proteins by ERK Map Kinase Regulates Interaction with Transport Receptors.
H. Kosako, S. Hattori, C. Aranami, S. Kose, H. Suzuki, H. Taniguchi, E. Nishida, N. Imamoto; Inst. for Enzyme Research, The University of Tokushima, Tokushima, Japan, Sch. of Pharmaceutical Sciences, Kitasato University, Tokyo, Japan, Advanced Science Inst., RIKEN, Saitama, Japan, Grad. Sch. of Biostudies, Kyoto University, Kyoto, Japan

Though many substrates have already been identified for ERK, its roles in regulating various physiological processes suggest that the list is not complete. Recently, we have developed a phosphoproteomic approach to identify putative ERK targets by combining the steroid receptor fusion system, IMAC, 2D-DIGE, and phosphomotif-specific antibodies. As a result, 24 novel targets were identified of which 13 were validated as direct substrates for ERK in vitro. Of these, the nucleoporin Nup50/Npap60 was further verified as an In Vivo ERK substrate by generating phospho-specific antibodies. Nup50 contains an N-terminal domain that binds to importin-α, a central FG repeat domain that binds to importin-β, and a C-terminal Ran binding domain. Interestingly, ERK phosphorylation of the FG repeat region of Nup50 was found to reduce its affinity for importin-β family proteins, importin-β and transportin. In contrast, interaction with importin-α, Ran-GTP, CAS, and Nup153 did not change upon phosphorylation of Nup50 by ERK. Phosphate-affinity polyacrylamide gel electrophoresis using Mn²⁺-Phos-tag followed by Western blotting revealed that ERK stoichiometrically phosphorylates other FG nucleoporins including Nup214, Nup153, Nup98, and Nup62 in intact cells. Of these, phosphorylation of Nup214 and Nup153 by ERK also inhibited their interaction with Importin-β. Furthermore, energy-independent nuclear migration of importin-β and transportin was impaired in ERK-activated, digitonin-permeabilized cells. Finally, RNAi and rescue assays showed that ERK phosphorylation of Nup50 was responsible for this impairment. We propose that ERK may phosphorylate various nucleoporins to regulate functions of importin-β family proteins.

Emerin Binding to Lmo7 Inhibits Lmo7 Binding to the Pax3 and MyoD Promoters and Expression of Critical Myoblast Differentiation Genes.
M. Cetera, J. Holaska; Medicine/Section of Cardiology, University of Chicago, Chicago, IL, Committe on Developmental Biology, University of Chicago, Chicago, IL

Mutations in the gene encoding Emerin cause X-linked Emery-Dreifuss muscular dystrophy. Recent evidence suggests the disease phenotype is caused by defective muscle regeneration.
Lmo7 was previously identified as an emerin-binding transcription activator that regulates a number of muscle genes. We report here that Lmo7 regulates C2C12 myoblast differentiation by regulating the expression of critical myoblast proliferation and differentiation genes, including Pax3, Pax7, Myf5 and MyoD. Lmo7 associates with these promoters in myoblasts and binds directly to the promoters of Pax3 and MyoD in vitro. Emerin was previously predicted to inhibit transcription regulator activity by binding transcription regulators at the nuclear envelope and block transcription factor binding to their promoters. Here we directly tested this model and report that emerin binding to Lmo7 inhibits Lmo7 binding to Pax3 and MyoD promoters. We conclude that the physiological interaction between emerin and Lmo7 is critical for myogenic differentiation and muscle regeneration. These data further suggest that loss of emerin in X-EDMD might lead to muscle regeneration defects by causing aberrant temporal activation of myoblast differentiation genes by failing to regulate Lmo7 activity.

Net37, a Nuclear Envelope Transmembrane Protein with Glycosidase Homology, Is Involved in Myoblast Differentiation.
K. Datta, T. Guan, L. Gerace; Cell Biology, The Scripps Research Institute, San Diego, CA

The nuclear lamina and its associated proteins are important for nuclear structure, chromatin organization, regulation of cell signaling and gene expression. Mutations in several nuclear envelope (NE) proteins have been shown to cause human genetic disorders, including several types of muscular dystrophy. NET37, which was initially identified in our lab, is highly expressed in muscle and up-regulated in differentiated C2C12 cell (Chen et al., 2006). NET37 protein has been shown to be highly concentrated at the NE and lamina-associated (Chen et al., 2006). Here we demonstrate that NET37, a member of glycosidase family 31, is required for myogenic differentiation of C2C12 cells. By protease mapping we show that its glycosidase homology domain is located in the lumen of the NE/ER. When NET37 is depleted from proliferating myoblasts by RNAi, myogenic differentiation is significantly impaired, and there is a concomitant delay in up-regulation of the late myogenic transcription factor myogenin. We expressed silencing-resistant NET37 mutated at a conserved residue in the glycosidase domain and found that this predicted catalytically inactive protein is unable to support myogenesis in cells depleted of wild type NET37. Therefore the enzymatic function of NET37 appears to be important for myogenic differentiation. C2C12 cells depleted of NET37 have reduced activation of Akt after shifting to differentiation medium, and are defective in IGF-II secretion, an autocrine/paracrine factor involved in Akt activation. We also observed that pro-IGF-II co-immunoprecipitates with NET37. Based on our results, we propose that NET37 has a role in IGF-II maturation in the secretory pathway during myoblast differentiation. The localization of NET37 at the NE raises the possibility that it may coordinate myogenic events between the nuclear interior and the ER lumen via transmembrane communication.

Protein Components of the Nuclear Pore Complex [NPC] and Epigenome Have Conserved Domains for Interaction with Functional Non-Coding ncRNA.
J. E. Wissler; ARCONS Institute for Applied Research & Didactics, Postfach 1327, D-61231 Bad Nauheim, Germany

OBJECTIVE: Functional small hairpin ncRNA may address defined homologous helix-nucleating domains shared in epigenetic regulator proteins entangled in growth, metabolic syndromes, vascular, cancer and epigenetic and genetic information indexing of the epigenome. They occur in the extracellular matrix, cytoplasm and the nucleus. Whether or not such ncRNA may be subject to traffic through the NPC escaped consideration, so far. Therefore, as a requisite, protein components of the nucleus [epigenome] and NPC were investigated for interaction domains with such ncRNA. METHODS are described in Ann. N.Y. Acad. Sci. 1137: 316-342, 2008. RESULTS: As marker for the search, functional edited, modified, redox- and metalloregulated small hairpin ncRNA [<200n] as bioaptamers in RNP complexes were isolated from transcriptional RNA output of cells activated by extrinsic [environmental] factors. Some address homologous helix-nucleating
structural proteomic domains, termed K/RxxH [K/R3H], i.e.-t/s/xK/R/q/n/hxxH/y/n/q/e/d/r/kx7-9h/xx7-9h/xx5-20K/R/q/n/e/h- with accessory canonical basic [R/K]n, R/K-zipper, SR/K/RS, EF-hand and/or HxxxH/y/n/q segments. Several components of chromatin formation modulation and NPC were now found which show up such homologous domains highly conserved. Most prominent representatives are of the nucleosomal assembly, histone deacetylase, DNA-C5-methyltransferase, sirtuin, hypoxia-inducible factor, nuclear pore complex, nucleoporin, importin, exportin and nuclear transport factor protein families. CONCLUSIONS: Based on these molecular imprints, the results suggest that functional small hairpin ncRNA participate in functions of the nucleus [epigenome] and the NPC by redox- and metalloregulated interaction with some of their protein components. By this interaction on molecular imprints, they may be subject to traffic or shuttles through the nuclear pore.

535/B482
Two Distinct Pathways of Nuclear Pore Complex Assembly in Higher Eukaryotes.
J. Talamas, C. Doucet; The Salk Institute for Biological Studies, La Jolla, CA

In metazoa, the formation of nuclear pore complexes (NPCs) occurs at two different stages during the cell cycle. at the end of mitosis, NPCs are reassembled concomitantly with the reforming nuclear envelope (NE) and in interphase pores form de novo into fully formed NE sheets. The molecular mechanisms and potential differences between post-mitotic and interphase pore assembly are not well understood. Here we show that the RNAi-mediated knockdown of Elys, a nucleoporin that is required for the recruitment of the essential Nup107/160 complex to chromatin, blocks post-mitotic assembly, but is dispensable for interphase assembly in cultured cells. Conversely, depletion of the transmembrane NPC component POM121 specifically inhibits interphase pore formation. Furthermore, POM121 function depends on a functional nuclear localization signal, suggesting that it is required from both sides of the NE. Importantly, pores are located at fusion sites between the inner and outer nuclear membranes, which exhibit high curvature. Nup133, a member of the Nup107/160 complex, has been shown to contain a domain, called ALPS, which exhibits specificity towards highly curved membranes. Strikingly, a single mutation in the ALPS domain, which inhibited membrane-sensing activity of Nup133, resulted in the mislocalization of the Nup107/160 complex to the cytoplasm. Moreover, replacement of Nup133 by the point mutant inhibited new pore insertion during interphase, but had no effect on post-mitotic assembly. In the Nup133 mutant background we also observed at high frequency the appearance of pore intermediates containing POM121 but not the Nup107/160. This suggests that POM121 is present at new pore sites before the Nup107/160 complex. Taken together, our data provide the first evidence for the existence of two distinct NPC assembly pathways in metazoa. Post-mitotic assembly involves ELYS-dependent recruitment of the Nup107/160 complex to chromatin. In contrast, targeting of the Nup107/160 complex to new assembly sites at intact NEs requires POM121 and the ability of Nup133 to sense curved membranes.

536/B483
Direct Actin Binding to A- and B-Type Lamin Tail Domains, and Unique Actin Filament Bundling Activity of the Lamin a Tail In Vitro That Is Disrupted by EDMD-Causing Mutations.
D. Simon, M. Zastrow, K. L. Wilson; Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Nuclear intermediate filament networks formed by A- and B-type lamins are major components of the nucleoskeleton with growing links to human physiology and disease including Emery-Dreifuss muscular dystrophy (EDMD), lipodystrophy, cardiomyopathy, neuropathy, cerebellar disorders and segmental accelerated ‘aging’ syndromes. How lamins interact with other nucleoskeletal components, and the identities of these other components, are open questions. Two previous studies suggested lamins might bind actin. We report that the C-terminal tail domain of human A- and B-type lamins bind directly to purified actin in high-speed pelleting assays. This interaction maps to residues 461-536 within the Ig-fold region of lamin A, which is 54% identical in lamin B1
and defines a conserved Actin Binding site (AB-1). Two EDMD-causing missense mutations (R527P and L530P) in lamin a that are predicted to disrupt the Ig-fold, each reduced F-actin binding by ~66%, whereas the surface-exposed lipodystrophy-causing R482Q mutation had no significant effect. The lamin a tail was unique among all lamin isoforms in having a second actin-binding site (AB-2). This second site was mapped to lamin a tail residues 563-606, based on comparison to the lamin C tail and internal deletions in the lamin a tail that cause Hutchinson-Gilford Progeria Syndrome ($\Delta 35$, $\Delta 50$) or restrictive dermopathy ($\Delta 90$). Supporting the presence of two actin-binding sites, both the precursor and mature lamin a tails (not C or B1 tails) bundled F-actin in vitro. F-actin bundling was reduced 25-40% by the R527P, L530P, $\Delta 35$ and $\Delta 50$ mutations, and was abolished by $\Delta 90$. However the mature lamin a tail unexpectedly both bound, and bundled, F-actin significantly more efficiently than did the prelamin a tail. We therefore suggest that residues 647-664, unique to prelamin A, auto-inhibit binding to actin (and potentially other partners) as a mechanism to regulate its interactions prior to maturation and assembly. These results suggest lamins and actin associate directly in the nucleus, with implications for many pathways including transcription, nuclear export, chromatin remodeling, chromatin movement and nuclear assembly that require lamins, nuclear myosin, and polymerizable actin.

Nuclear-Cytoskeletal Coupling in Muscular Dystrophies.
M. L. Lombardi¹, D. E. Jaalouk¹, C. Shanahan², B. Burke¹, K. J. Roux¹, J. Lammerding¹; ¹Cardiovascular and Bioengineering Research Group, Brigham and Women’s Hospital/Harvard Medical School, Cambridge, MA, ²Cardiovascular Division, King’s College London, London, United Kingdom, ³Institute of Medical Biology, Singapore, Singapore, ⁴Anatomy and Cell Biology, University of Florida, Gainesville, FL

Nuclear-cytoskeletal coupling is essential for force transmission from the extracellular matrix to the nuclear interior and participates in a wide range of physiological processes, ranging from nuclear positioning to cell polarization. The major molecular components involved in nuclear-cytoskeletal coupling known to date are SUN proteins and nesprins, which form the LINC complex, physically linking the nucleus to the cytoskeleton. However, it remains unknown whether the LINC complex is the major physical component responsible for transmitting intracellular forces to the nuclear interior. Objective and Methods: to test the hypothesis that the LINC complex is the major contributor in nuclear-cytoskeletal force transmission, we used a microneedle manipulation assay to quantify induced cytoskeletal and nuclear deformations after localized cytoskeletal force application in cells in which the LINC complex had been disrupted by dominant negative mutants and in wild-type controls. To explore whether altered nuclear-cytoskeletal force transmission may affect cellular polarization, we evaluated centrosome positioning in a wound healing assay. Results: Cytoskeletal strain transmission across the nucleus was significantly reduced in cells with a disrupted LINC complex compared to wild-type and mock control cells. Interestingly, similar results were found in cells lacking the nuclear envelope proteins lamin A/C. Induced nuclear strain, near the force application site (cis) and across from it (trans), was significantly reduced in LINC disrupted cells, suggesting a loss of force transmission from the cytoskeleton to the nucleus. In lamin A/C-null cells, induced nuclear strain across from the force application site, but not near the application site, was reduced compared to wild-type cells, providing evidence for a dissipation of forces across the softer nucleus. Preliminary results from the wound healing assay showed an impaired centrosome polarization in the LINC disrupted cells, which indicates a disruption in nuclear-cytoskeletal force transmission. Conclusions: Disruption of the LINC complex results in impaired force transmission from the cytoskeleton to the nucleus and may contribute to defects in cellular functions.

Architectural Nucleoporins Nup157/Nup170 and Nup133: A Structural Perspective on Ancestral Elaboration within the Nuclear Pore Complex.
J. R. Whittle, T. U. Schwartz; Biology, M.I.T., Cambridge, MA
The nuclear pore complex (NPC) is one of the largest protein assemblies in the eukaryotic cell; it forms the exclusive gateway to the nucleus. In the NPC, the stable, ~15-20 MDa scaffold ring is built with eight-fold symmetry from two multiprotein subcomplexes. These subcomplexes are assembled from large architectural nucleoporins. Among these nucleoporins are Nup120 and four ancestral coatamer element (ACE1) nucleoporins. We present here crystal structures of two further large architectural units, γNup170 and hNup107-hNup133. Nup170 and Nup133 have conserved domain arrangements and, as we now show, conserved tertiary structures, distinct from all other nucleoporins and vesicle coat proteins. This conservation suggests that Nup170 and Nup133 derive from a common ancestor. These units, constituted, along with the ACE1 nucleoporins, the major alpha-helical building blocks of the NPC scaffold and define its branched, lattice-like architecture, similar to vesicle coats like COPII. We hypothesize that the extant NPC evolved early in eukaryotic evolution, by gene duplication and diversification, from a simpler structure that had several identical copies of a few ancestral elements.

**539/B486**

**Passive Diffusion of Naltrexone into Human and Animal Cells and Upregulation of Cell Proliferation.**

I. S. Zagon¹, F. Cheng¹, W. A. Banks², P. J. McLaughlin¹; ¹Neural & Behav Sci, Penn State Univ Coll Med, Hershey, PA, ²Internal Medicine, St. Louis University School of Medicine, St. Louis, MO

Naltrexone (NTX) is a potent opioid antagonist that promotes cell proliferation by upregulating DNA synthesis through displacement of the tonically active inhibitory peptide, opioid growth factor (OGF), from its receptor (OGFr). To investigate how NTX enters cells, NTX was fluorescently labeled (FNTX, 1-(N)-fluoresceinyl naltrexone thiosemicarbazone) to study its uptake by living cultured cells. When human head and neck squamous cell carcinoma cell line SCC-1 was incubated with FNTX for as little as 1 min, cells displayed nuclear and cytoplasmic staining of FNTX as determined by fluorescent deconvolution microscopy, with enrichment of fluorescent signal in the nucleus and nucleolus. The same temporal-spatial distribution of FNTX was detected in a human pancreatic cancer cell line (MIA PaCa-2), African green monkey kidney cell line COS-7, and human mesenchymal stem cells (hMSCs). FNTX remained in cells for as long as 48 h. FNTX was internalized in SCC-1 cells when incubation occurred at 4°C, with signal being comparable to that recorded at 37°C. A 100-fold excess of NTX or a variety of other opioid ligands did not alter the temporal-spatial distribution of FNTX. Neither fluorescein labeled dextran nor fluorescein alone entered the cells. To study the effect of FNTX on DNA synthesis, cells incubated with FNTX at concentrations ranging from 10⁻⁵ to 10⁻⁸ M had a BrdU index that was 39-82% greater than for vehicle treated cells, and was comparable to that of unlabeled NTX (37-70%). Taken together, these results suggested that NTX enters cells by passive diffusion in a non-saturable manner.

**Nuclear Import of the Opioid Growth Factor Receptor (OGFr) to Regulate Cell Proliferation Is Dependent on Karyopherin β and Ran.**

P. J. McLaughlin, F. Cheng, I. S. Zagon; Neural & Behav Sci, Penn State Univ Coll Med, Hershey, PA

The Opioid Growth Factor (OGF) Receptor (OGFr) is an integral component of the OGF-OGFr axis which regulates cell proliferation in normal and neoplastic tissues and cells. Regulation of cell proliferation by the OGF-OGFr axis is dependent on translocation of OGFr from the cytoplasm into the nucleus. Using the human squamous cell carcinoma of the head and neck cell line SCC-1, and OGFr fused to enhanced GFP (OGFr-eGFP), we examined the nuclear import of OGFr with particular focus on karyopherin β₁, karyopherin α, and Ran. Transfection of SCC-1 cells with karyopherin β₁ siRNA down-regulated protein expression of karyopherin β₁ by 54%, and prevented transport of ~50% of OGFr-eGFP into the nucleus. Transfection of SCC-1 cells
with Ran specific siRNA inhibited the nuclear import of OGFr-eGFP by ~55%. Downregulation of karyopherin proteins α1, α2, α3, α4 or α6, which serve as adaptor proteins for karyopherin β1, blocked less than 4% of OGFr-eGFP transport into the nucleus, suggesting that they do not play an integral role in OGFr transport. To determine whether karyopherin α/β or Ran is(are) a requirement for normal function of the OGF-OGFr axis in cell proliferation, DNA synthesis was monitored using BrdU-labeled cells transfected with karyopherin α, karyopherin β, Ran siRNAs, or scrambled siRNA. Scrambled siRNA transfected cells, as well as karyopherin α groups, with OGFr-eGFP staining had 50% BrdU-positive cells, whereas cells transfected with karyopherin β1 or Ran siRNA had a 70% labeling index. These data indicate that disabling of karyopherin β1 or Ran using siRNA upregulates cell proliferation by blocking the tonically active inhibitory pathway of OGF-OGFr. Therefore, the regulation of cell proliferation by the OGF-OGFr axis is dependent on the integrity of karyopherin β1 and Ran.

‘Rotation/Twist’ Model for the Mechanism of the EGF/ErbB Receptor Activation.
I. Maruyama, A. S. Adenan, H. Miyagi; Okinawa Institute of Science and Technology, Okinawa, Japan

The epidermal growth factor (EGF)/ErbB receptor family consists of four members, and plays pivotal roles in the development of organisms ranging from worms to humans. Furthermore, aberrant activation of the receptors is frequently implicated in a variety of human cancers. Ligand-induced dimerization is proposed as a molecular mechanism underlying the activation of all the growth factor receptor tyrosine kinases including the ErbB receptor family. Before ligand binding, however, it remains controversial whether the receptors have a monomeric or dimeric structure. We have shown that most, if not all, molecules on the cell surface of all the ErbB receptors have preformed, yet inactive, homo- and heterodimeric structures in living cells by using chemical cross-linking, cysteine disulfide bridge formation, sucrose density gradient centrifugation, Förster resonance energy transfer (FRET), fluorescence cross-correlation spectroscopy (FCCS), and fluorescent protein and luciferase fragment complementations. The spontaneous dimerization occurs in endoplasmic reticulum, where ligands are unlikely to be available, before newly synthesized receptors reach the cell surface. Together with the transmembrane and extracellular juxtamembrane domains, the cytoplasmic domains seem to be mainly responsible for the spontaneous inactive dimer formation. Based on crystal structures of the cytoplasmic domains recently determined, we have artificially made several mutations of residues residing in the interface between the homodimeric structure of the cytoplasmic kinase domains, and have found that these mutations induce spontaneously the receptor autophosphorylation. These results indicate that the receptor exist as a preformed dimer mainly through interaction between the kinase domains. Based on current and previous results, we will propose a ‘rotation/twist’ model for the molecular mechanism of the ErbB receptor activation by ligand, in which ligand binding to the extracellular domains of the receptor dimer induces rotation/twist of the receptor’s transmembrane domains, and rearrange the intracellular kinase domains for activation.

Young and Aged Human Muscle Satellite Cells Show Differential Expression of S100b Protein and Rage.
S. Beccafico1, F. Riuzzi1, C. Puglielli2, S. Fulle2, G. Sorci1, R. Donato1; 1Department of Experimental Medicine and Biochemical Sciences, University of Perugia, Perugia, Italy, 2Department of Basic and Applied Medical Sciences, University G. d'Annunzio Chieti, Chieti, Italy

During aging, skeletal muscles show reduced functional capacity due to loss of the regenerative ability of satellite cells (SCs), the quiescent stem cells located beneath the basal lamina surrounding each myofiber. Both age-related extrinsic factors and age-related intrinsic properties of SCs appear to contribute to SC efficiency (Aging Cell 7 (2008) 590-8). In the present work we analyzed several parameters of SCs derived from biopsies of Vastus Lateralis muscle from healthy non-trained young and aged humans (male and female, divided into young [mean age 31.0 ± 5.35 years; n=7] and aged [mean age 76.44 ± 6.12 years; n=9]). Compared to young SCs,
Aged SCs showed impaired differentiation, i.e. reduced myotube formation and reduced expression of myogenin and myosin heavy chain when cultured in differentiation medium (DM), and exhibited the following: i) reduced proliferation; ii) higher expression levels of S100B, a Ca2+-binding protein and negative regulator of myoblast differentiation (submitted for publication); iii) undetectable levels of full-length RAGE (receptor for advanced glycation end products), a multiligand receptor of the immunoglobulin superfamily, the engagement of which enhances myoblast differentiation (Mol Cell Biol 24 (2004) 4880-4894; J Biol Chem 281 (2006) 8242-8253), and presence of a truncated form of RAGE in growth medium (GM) the amount of which decreased in DM in parallel with appearance of full-length RAGE; and iv) lower expression levels of the transcription factors, MyoD and Pax7, in both GM and DM. Also, transient transfection of young SCs with S100B expression vector resulted in reduced differentiation compared to controls (i.e., acquisition of an aged phenotype), while either transfection of aged SCs with full-length RAGE expression vector or knocking down S100B by siRNA resulted in enhanced differentiation (i.e., acquisition of a young phenotype). These data point to an important role for intrinsic factors (e.g., MyoD, Pax7, S100B and RAGE) in defective SC function in aged skeletal muscles.

Vascular Endothelial Growth Factor Is Involved in Bone Bridge Formation at the Physeal Injury Site.
E. E. Fischerauer1, M. Seles1, M. Manninger1, K. Kraitsy1, T. Kroneis2, H. Hutter2, A. M. Weinberg1; 1Department of Pediatric and Adolescence Surgery, Medical University of Graz, Graz, Austria, 2Institute of Cell Biology, Histology and Embryology, Medical University of Graz, Graz, Austria

Physeal injuries can initiate the formation of reversible bone-bridges resulting in bone length discrepancy, axis deviation or joint deformity. We hypothesized that vascular endothelial growth factor (VEGF) and its receptors R1 and R2 are involved in the vascularization process leading to bone bridge formation at the site of physeal injury. 35 male Sprague Dawley rats (4 weeks old, 100g) were subjected to a unilateral drill injury through the proximal tibial physis. After euthanasia on days 1, 3, 7, 14, 28, 42 and 82 both tibiae were extracted. Tissue samples of the growth plates were processed for immunohistochemical staining of VEGF and VEGFR1 and -R2 and Hematoxylin and Eosin staining. The contra-lateral intact growth plate samples served as controls. Histological staining displayed a hematoma on days 1 and 3 containing displaced bone fragments at the site of physeal injury. on day 7, reorganization of these fragments was observed prior to bone bridge formation seen on day 14. By day 82, this bone bridge was replaced by lamellar bone. Immunohistochemical staining showed clear positivity for VEGF, VEGF-R1 and VEGF-R2 of the displaced bone fragments on days 1 to 7. While the bone bridge remained VEGF positive, with descending intensity from proximal to distal within the bone bridge on day 82, VEGF-R1 and -R2 were initially absent. VEGF-R2 was positive in the early lamellar bone formation on day 42. Displaced chondrocytes bordering the physis at the injury site were VEGF, VEGF-R1 and -R2 positive throughout the days, showing maximums of R1 on day 14 and of R2 on days 14 to 42. These data suggest that bone fragments from the physeal injury are interacting with cells bordering the physeal injury site and together initiate bone bridge formation via expression of the angiogenic growth factor VEGF, and its receptors R1 and R2.

Thrombomodulin Domain Promotes Angiogenesis through FGFR1 Pathway.
G. Shi1,2, C. Kuo1,2, M. Sun1,2, H. Wu1,2; 1Department of Biochemistry and Molecular Biology, College of Medicine, National Cheng Kung University, Tainan, Taiwan, 2Cardiovascular Research Center, National Cheng Kung University, Tainan, Taiwan

Thrombomodulin (TM) is a type I glycoprotein on endothelium, which serves as a receptor for thrombin. TM/thrombin complex catalytically activates protein C and thus triggers anticoagulation cascade with protein S. The recombinant EGF-like domain plus serine/threonine rich domain of TM (rTMD23) has been shown to promote angiogenesis In Vitro and in vivo. Concurrently, activated protein C has also been demonstrated to induce angiogenic responses. However, the
mechanism of rTMD23 on inducing angiogenesis is unclear and whether the angiogenic activity of rTMD23 is protein C dependent or not is obscure. rTMD23 proteins lacking protein C activation ability were prepared by site-directed mutagenesis. All three mutant proteins without protein C activation activity showed similar activity as rTMD23 in promoting endothelial cells proliferation, migration and tubular morphogenesis in vitro. In addition, we demonstrated that rTMD23 interacted with heparin Sepharose, syndecan 4 and type I fibroblast growth factor receptor (FGFR-I). rTMD23 effectively induced phosphorylation of tyrosine residue 653/654 of FGFR-I in human umbilical vein endothelial cells and in exogenously FGFR-1 over-expressed human embryonic kidney 293 cells. The activation of FGFR-I induced by rTMD23 was attenuated by PD173074, a specific inhibitor to FGFR-I. Furthermore, the rTMD23-induced angiogenic responses in vitro, such as cell proliferation, migration and tubular morphogenesis in human umbilical vein endothelial cells, were significantly inhibited by PD173074. In conclusion, rTMD23 interacts with heparan sulfate proteoglycans thereby activating FGFR-I and consequently turns on the angiogenic reaction through a protein C independent pathway.

545/B492
The Bile Acid, Taurocholate, Prevents Biliary Damage Induced by In Vitro Hypoxia by Changes in the Expression of Angiogenic Factors in Cholangiocytes.

R. Mancinelli6,5, H. Francis4,5, A. Franchitto6, P. Onor1, E. Gaudio6, J. Venter5, S. Kopriva5, S. S. Glase5,3, G. Carpino8, M. White5,3, W. Butler1, D. Alvaro9, L. Pannarale6, F. Meng5,3, G. Alpini1,2,3; 1Research, Central Texas Veterans Health Care System, Temple, TX, 2Medicine and Systems Biology and Translational Medicine, Texas A&M HSC COM, Temple, TX, 3Scott & White Digestive Disease Research Center, Scott & White, Temple, TX, 4R&E, Scott & White, Temple, TX, 5Medicine, Texas A&M HSC COM, Temple, TX, 6Human Anatomy, University of Rome "La Sapienza", Rome, Italy, 7Experimental Medicine, University of L'Aquila, L'Aquila, Italy, 8Dept Health Science, University of Rome "Foro Italico", Rome, Italy, 9Gastroenterology, Polo Pontino, University of Rome "La Sapienza", Rome, Italy

The function of the biliary tree is linked to the vascular supply sustained by the peribiliary vascular plexus, and its circulating angiogenic factors such as VEGF and angiopoietin (Ang). VEGF regulates the recovery phase of reperfusion injury. We have shown that: (i) taurocholic acid (TC) prevents bile duct damage by changing VEGF expression; and (ii) enhanced expression of cholangiocyte angiogenic factors regulates biliary functions in an In Vivo model of ischemia/reperfusion injury. Using an In Vitro system, we aimed: (i) to elucidate if reoxygenation of ischemic cholangiocytes regulate changes in the expression of angiogenic factors; and (ii) if TC protects cholangiocytes against ischemic damage. Methods: Rat cultured cholangiocytes (NRICC) were maintained under standard conditions in normoxic atmosphere of 21% O2, 74% N2 and 5% CO2 or under a hypoxic environment of 5% O2, 90% N2 and 5% CO2 for 4 hours and transferred to normal conditions for different times (1-4 hours) in the absence/presence of TC (40 μM). Then, we collected NRICC protein, mRNA and supernatants to measure changes in: (i) proliferation by PCNA immunoblots, (ii) apoptosis by Bax immunoblots, (iii) expression of VEGF-A/-C, VEGFR-2/-3, Ang1/2 and Tie1/2 by immunoblots and real-time PCR, and (iv) VEGF secretion. Results: Under hypoxic conditions, there was decreased NRICC growth, and increased cholangiocyte apoptosis and expression of VEGF-A/-C, VEGFR-2/-3, Ang1/2 and Tie1/2 coupled with enhanced NRICC VEGF secretion. Recovery of the normoxic conditions led to restoration of cholangiocyte proliferation and the expression of cholangiocyte angiogenic factors in a time-dependent manner. TC protected against biliary damage and upregulation of angiogenic protein expression under the hypoxic conditions. Conclusion: We hypothesized that: (i) hypoxia increases damage of cholangiocytes and alters the expression of biliary angiogenic factors and VEGF secretion in NRICC likely due to an autocrine compensatory mechanism; and (ii) TC prevents biliary damage in pathological conditions of lowered oxygen supply. Altered expression of biliary angiogenic factors through modulation of oxygen content may be important in the management of liver diseases.

The Role of Rin1 Mutants in EGFR Internalization and Cell Signaling.
A. Galvis, J. Zayas, T. Ta, S. Mustafi, N. Villaverde, M. Barbieri; Biology, Florida International University, Miami, FL

The internalization and further activation of the epidermal growth factor receptor (EGFR) is required for several intracellular processes, including membrane transport, fusion, and signaling. Several intracellular molecules, including Ras Interference 1 (Rin1), have been shown to play a key role during internalization and signaling of the EGFR. In this study, we examined the role of key conserved amino acids in the Vps9 domain of Rin1 on the EGFR internalization and cell signaling. In addition, we investigated the role of these conserved residues in the fusion reaction. Six of the ten mutants were unable to stimulate and rescue the fusion reaction. Two of them, Rin1: D537A and Rin1: Y561F, drastically inhibited the fusion reaction. Furthermore, these two mutants, but not Rin1: wild type, failed to block the Ras/MAP kinase cascade activated by EGF. Taken together, these data suggest key amino acids in the Vps9 domain of Rin1 play an important role on the regulation of EGFR trafficking and signaling.

R. Perrault¹,², P. Zahradka¹,²; ¹Physiology, University of Manitoba, Winnipeg, MB, Canada, ²Saint Boniface Research Center, Winnipeg, MB, Canada

An important component of the vascular wall repair process is the recruitment of smooth muscle cells (SMC) from the existing contractile coat. Phenotypic modulation of these SMCs enables them to proliferate and migrate into the vessel intima. Despite its importance in vessel repair, this plasticity of SMCs can promote both the pathogenesis of atherosclerosis as well as neointimal formation following revascularization-induced injury. Vascular growth factors contribute significantly to the migratory and proliferative component of the response to injury. IGF-1 is one such growth factor which elicits a response via its receptor, the IGF-1R, a classical tyrosine kinase receptor. However, it has also been reported to couple to a heterotrimeric G protein in rat fibroblasts. The objective of this study was to investigate the structural aspects of the association between the IGR-1R and heterotrimeric G proteins in SMCs, as well as the contribution of this pathway to cellular responses. In a porcine primary smooth muscle cell culture model, the IGF-1R was found coupled to a Gβ subunit in the quiescent state. Cellular activation with IGF-1 decreased this interaction by nearly 60%, while inhibition of the IGF-1R tyrosine kinase with AG1024 returned G protein coupling to basal levels. A Gβγ modulator, Gallein, was used as a tool to determine the role of this subunit in the response. It was found that phosphorylation, and thus activation, of p42/44 MAPK was only inhibited by 50% by AG1024, but returned to basal levels when treated with Gallein. The data thus far support the conclusion that IGF-1 elicits its response on vascular SMCs at least partially via a non-classical G protein-coupled receptor, although activation of the tyrosine kinase receptor also plays a role. In addition, at least one of the phenomena responsible for revascularization injury, proliferation, is modulated via the Gβγ subunit of the pathway.

Sciatic Nerve Conditioned Medium (CM) Increases NG2, Nestin and Galectocerebroside Positive Cells and Reduces the Complexity of Dendritic Process.

L. García, M. Longart, G. Correa, J. Nuñez, C. Castillo; Instituto de Estudios Avanzados, Sartenejas, Venezuela

In the Peripheral (PNS) and Central (CNS) Nervous Systems there are different kinds of glial cells responsible for releasing factors that affect the regeneration process after injury; being the regeneration in the PNS more efficient than in the CNS. In previous works, we had demonstrated that factors released by sciatic nerves in culture, increased the number of type 2 astrocyte, promoted the differentiation of type 1 astrocytes and decreased the neuron population in primary hippocampal cultures. Additionally, we observed a different population of cells in the culture that were negative for astrocyte and neuronal markers. To evaluate the proportion of mature
oligodendrocytes, oligodendrocyte precursors and neural precursors, hippocampal cultures were immunostained with antibodies against galactocerebroside (GalC), chondroitin sulfate proteoglycan (NG2) and nestin, respectively. We found that CM increased GalC positive cells from 11.15% (2 days) to 23.63% (15 days). CM also increased NG2 positive cells from 5.17% (2 days) to 26.79% (7 days). In contrast, in the control condition the proportion of GalC positive cells were similar at all days (5.06%), while NG2 positive cells were absent at 2 and 5 days but started to show at 7 days (10.19%). Nestin positive cells were similar at 2d in both condition (Control: 11.43%, CM: 11.2%) but at 7d there was an increase on nestin positive cells (CM: 33.85%, Control: 16.32%). On the other hand, we investigated if the CM had any effect on the neuronal morphology. Immunostaining with MAP2 and SMI35 antibodies showed that the CM decreased the complexity of the dendritic processes compared with the control condition. These and previous results suggest that CM strongly favors glial cells, whereas decreasing both number and neurons complexity.

Hyper-Activation of STAT5a Is Associated with LEF-1 Down Regulation and Leukemic Transformation in Patients with Severe Congenital Neutropenia.
K. Gupta, J. Skokowa, K. Welte; Dept of Molecular Hematopoiesis, Hannover Medical school, Hannover, Germany

Severe Congenital Neutropenia (CN) is a preleukemic syndrome characterized by maturation arrest of granulocytes in bone marrow at the promyelocytic stage. Cumulative incidence of developing AML/MDS in CN is 20%. Since AML/MDS are not observed in cyclic or idiopathic neutropenia patients treated with G-CSF, an underlying defect down stream of G-CSF signaling rather than G-CSF therapy per se predisposes to malignant transformation in CN. Also, though G-CSF and G-CSFR levels are considerably elevated in CN, high pharmacological doses of G-CSF (100-1000 times higher than the physiological levels) are required to increase neutrophile counts in CN. Therefore, G-CSF signaling is severely affected in CN patients. STAT5 is a downstream effector of G-CSF signaling pathway and is found to be activated in AML. LEF-1 transcription factor and its target gene C/EBPα are severely abrogated in CN. Therefore, we investigated the effects of G-CSF on the phosphorylation status of STAT5a in CN and if it leads to down modulation of LEF-1 expression and functions. We found that G-CSF stimulation resulted in a significantly higher phosphorylation of STAT5a in CD34+ cells of CN patients as compared to healthy volunteers. Transduction of constitutive active STAT5a (STAT5a 1*6) in CD34+ cells of healthy individuals resulted in severe downregulation of LEF1 expression in a dose dependent manner. A screen of 10 kb upstream region of LEF1 gene revealed two putative STAT5 binding sites, confirmed by ChIP assay and No shift assay using nuclear extracts of CD34+ cells and U937 respectively. We found enhanced and prolonged STAT5a binding to the LEF-1 promoter in G-CSF treated CD34+ cells from CN patients, as compared to healthy individuals. Additionally, transfection of CD34+ cells with LEF-1 cDNA resulted in elevation of LEF-1 promoter activity and co-transfection with STAT5a 1*6 significantly disrupted LEF1-dependent activation of LEF-1 promoter. Moreover STAT5a 1*6 severely abrogated the LEF1 dependent regulation of C/EBPα gene promoter. Taken together phosphorylation of STAT5 is enhanced in hematopoietic progenitors of CN which subsequently down regulates LEF1 and may contribute to the malignant transformation of myelopoiesis in CN.

Interaction of Growth Hormone Receptor (GHR) and Jak2: A Model System to Study GHR Signaling.
T. Nespital1,2, G. Strous1, E. W. Meijer2; 1Celbiologie, UMC Utrecht, Utrecht, Netherlands, 2SymoChem B.V.; Technical University Eindhoven, Eindhoven, Netherlands

The Growth Hormone Receptor (GHR) is a single membrane spanning protein of 620 aa, that belongs to the class I cytokine receptor superfamily. Upon binding of Growth Hormone (GH) to the dimeric receptor at the plasma membrane, Janus kinase 2 (Jak2)/STAT5b and downstream signalling pathways are activated via reciprocal phosphorylation, which regulate somatic growth,
substrate metabolism and body composition. The number of GHRs at the cell surface determines GH sensitivity of the cells and needs, therefore, to be tightly regulated. In severe diseases, like cancer and AIDS, the number of GHRs decreases and the body becomes GH insensitive, leading to muscle wasting (cachexia). Understanding GHR endocytosis and degradation will provide new insights how to increase the GH sensitivity of cells, and increase our capabilities to fight serious diseases. Members of the Jak2 kinase family initiate the majority of downstream signalling events of the cytokine family of receptors. Although the diversity of cytokine receptors is large, the prevailing principle is that Jak kinases act as twins: Two similar or different Jaks bind to two cytosolic tails of the homo- or heteromeric cytokine receptor complex and start their signalling activity upon a conformational change in the receptor complex, induced by their cognate cytokine. We have expressed growth hormone receptor tails together with Jak2 in mammalian cells to study the molecular principles of Jak/Stat signalling. Cytosolic tails of the GHR provided with leucine zippers were stabilized if co-expressed with Jak2. This system provides a good model to study early events in growth hormone receptor signalling and the interaction between the GHR and its binding proteins.

Detection of Intracellular and Secreted Neurturin.
S. Leppänen, L. Lonka, M. Saarma; Institute of Biotechnology, University of Helsinki, Helsinki, Finland

Neurturin (NRTN), a member of GDNF family ligands, is a neurotrophic growth factor that regulates the development and maintenance of neuronal populations in the brain and in the periphery. NRTN has functions outside the nervous system too. NRTN is a secreted protein, which is synthesized in a form of precursor, pre-pro-NRTN. NRTN is a potential therapeutic agent for neurodegenerative diseases as Parkinson's disease. Because of the neurotrophic effects of NRTN, it is important to study its poorly known cell biology. Our aims are to detect mouse nrtn intracellularly and to study nrtn protein secretion in non-neuronal cell lines. The tested tissues included kidney, ovary, adrenal medulla, cervix, retina, skeletal muscle and glioma. Second aim is to detect human NRTN mRNA from neuronal and non-neuronal tissues and identify possible splice variants. Non-neuronal cells were first overexpressed with wt mouse nrtn. Intracellular and secreted nrtn was detected in western blotting (WB). The specificity of anti-nrtn antibodies was analysed in WB and immunocytochemistry. Because of the poor quality of the available anti-nrtn antibodies, mouse nrtn was cloned with HA- and FLAG-tags. Tagged nrtn proteins were detected in WB by anti-HA- and anti-FLAG-antibodies. The biological activities of tagged nrtn proteins were confirmed in neurite outgrowth assay in PC6 cells. Human NRTN was detected by reverse transcriptase-PCR from selected tissues, sequenced and cloned into mammalian expression vectors. Our preliminary results suggests that mouse wt nrtn and tagged nrtn proteins are translated and can be detected intracellularly but are not secreted or poorly secreted to the growth medium. Secretion may require a cell specific stimulation, for example a hormonal or electronic factor to induce nrtn secretion. Human NRTN mRNA was detected from fetal and adult brain tissues and from several non-neuronal tissues. One transcript was identified and cloned.

TBC1D3, a Hominoid-Specific Protein, Modulates Insulin Signaling by Interacting with Cul7 and Delaying Insulin-Dependent Phosphorylation and Degradation of IRS-1.
M. Wainszelbaum1, P. Srikanth1, C. Kong1, X. Su2, A. Charron1, P. D. Stahl1; 1Cell Biology & Physiology, Washington University Medical School, St. Louis, MO, 2Department of Internal Medicine, Washington University School of Medicine, St. Louis, MO

TBC1D3 is a hominoid-specific gene. Recent work showed that TBC1D3 expression enhances the signaling properties of growth factor receptors resulting in Ras activation enhanced cell proliferation (J Biol Chem 283:13233, 2008). We carried out a yeast two-hybrid screen using TBC1D3 as bait and identified Cul7, a Cullin family ubiquitin E3 ligase, as a TBC1D3-interacting protein. TBC1D3-Cul7 interaction was confirmed by immunoprecipitation and In Vitro transcription/translation experiments. Cul7 is reported to mediate the degradation of the insulin
receptor adapter, IRS-1 (Mol Cell 30:403, 1008). We found that expression of TBC1D3 suppressed degradation of IRS-1 and increased Akt signaling pathways in response to insulin treatment. Phosphorylation of IRS-1 at key residues, responsible for Cul7-dependent IRS-1 degradation, was suppressed by TBC1D3 expression. Moreover, TBC1D3 formed a complex with Cul7-FBXW8- and IRS-1 in cells stimulated with insulin. Lastly, insulin stimulation led to the degradation of TBC1D3 suggesting a negative modulatory feedback loop. These data suggest that TBC1D3 provides a regulatory mechanism in humans to control insulin signaling via the phosphorylation and degradation of IRS-1.

Identification of Cellular Targets of Naringenin via Restriction Enzyme Mediated Integration in Dictyostelium.
K. Perez, P. Steimle; Biology, University of North Carolina at Greensboro, Greensboro, NC

Naringenin, a flavanone compound highly enriched in grapefruits, has been identified as an inhibitor of cell proliferation; and thus has the potential to act as an anti-tumorigenic agent. At this time, the mechanism by which naringenin is able to suppress cell growth is unclear since this compound appears to have multiple cellular targets including cytochrome P450 enzymes, the PI3 kinase pathway, glucose uptake pathways, among others. Studies from our lab using Dictyostelium as a model system have revealed that naringenin is a potent inhibitor of eukaryotic cell motility, as well as cell proliferation. However, a common cellular target for naringenin that is shared among different cell types and in varying cellular contexts has eluded identification. As a means of identifying such targets, we used restriction enzyme mediated integration (REMI) to create a library of Dictyostelium mutants that were then screened for resistance to naringenin-induced suppression of cell proliferation. Such mutants are of interest since they are missing some factor (presumably the product of a gene disrupted by REMI) that is necessary for the bioactivity of naringenin. To this end, REMI mutants were generated by electroporating Dictyostelium AX2 cells with BamHI-linearized pBSR-Δ-Bam plasmid, along with 20 U of BamHI enzyme, and then selecting for REMI mutants in HL5 culture medium containing 10 μg/ml blasticidin. We then isolated four naringenin-resistant REMI mutants (of greater than 200 screened) that grow normally in the presence of 300 μM naringenin. These results indicate that the REMI based approach in Dictyostelium is a viable means for identifying genes that required for the bioactivity of naringenin. We are continuing to screen more REMI mutants and are in the process of pulling out and identifying the genes that have been disrupted in the four naringenin-resistant mutants.

Quantitative Spatiotemporal Analysis of K-Ras Activation Using Live Cell Redistribution Assays.
D. J. Anderson, P. K. Jackson, M. J. Ludlam; Cell Regulation Department, Genentech, Inc., South San Francisco, CA

Activating mutations in the Ras protein occur in 33% of human cancers with mutations in the K-Ras isoform being most prevalent. Ras signals through multiple downstream effectors, including PI3K, Raf and RalGEF, which bind to activated Ras, triggering downstream signaling and tumorigenesis. K-Ras is anchored to the plasma membrane (PM) by virtue of a C-terminal farnesy1 group and polybasic region. Activated, GTP bound K-Ras causes c-Raf to redistribute from the cytoplasm to the PM whereupon downstream MAP Kinase signaling is initiated. Assays that measure the activation of K-Ras have relied on PM targeting of the Ras-binding-domain of c-Raf or other Ras effectors. We show that full-length c-Raf and RalGDS can be visualized targeting to the PM in the presence of RasGTP. Fluorescent protein fusions of Ras and effectors were imaged in live cells using confocal microscopy. We have developed an automated image analysis procedure to measure the ratio of PM:cytoplasm localized effector and thus calculate the
percentage of redistribution events per cell. Our quantitative redistribution assay can distinguish changes in Ras activation conferred by activating mutations in the Ras proteins compared with wild-type Ras. Furthermore, the time-course of wild-type K-Ras activation upon stimulation with epidermal growth factor can be visualized and quantified. We validate the assay by demonstrating that a dominant-negative K-Ras S17N mutant fails to cause localization of effectors to the plasma membrane. The assay and analysis we present are valuable tools to identify molecules that are specific in disrupting the interaction of Ras and effectors in the cellular context and that may thus have therapeutic potential.

CXCL1 and CXCL8 Induce Morphological Changes in SKMEL 28 and 1205 Lu Melanoma Cells.

D. R. Felling, R. W. Baer; Physiology, A. T. Still University of Health Sciences, Kirksville, MO

The chemokines CXCL1 and CXCL8 are released by melanoma cells and potentially participate in melanoma progression. This study was designed to determine whether CXCL1 and CXCL8 significantly alter melanoma cell morphology or β-catenin localization. Images of fluorescent antibody-tagged cells were obtained with a Zeiss Axiovert 200M microscope with or without 24h treatment with these chemokines. CXCL1 and/or CXCL8 treatment led to an elongated (1205Lu cell line) or stellate (SKMEL 28 cell line) morphology compared to control. CXCL8 treatment caused a decreased presence of β-catenin at cell-cell junctions as well as a decrease in the number of cell-cell junctions. In both cell lines, regardless of treatment, β-catenin localized on the same side (leading edge) of the nucleus as the Golgi and mitochondria but did not strictly co-localize with either organelle. Control cells in both lines stained with wheat germ agglutinin conjugates, revealed the unexpected presence of glycosylated, branching, extremely thin and long (less than 1 μm in diameter and up to 500 μm long) filopodia-like structures extending from the cell membranes. The branching occurred at blebbed, dot-like regions along the structures as extensions continued from these regions at differing angles. CXCL1 and CXCL8 treatment increased the number of these filopodia-like structures. The structures, regardless of treatment condition or cell line, stained for actin, cytosol, β-catenin, focal adhesion kinase, E-cadherin (low levels), N-cadherin, β1 integrin, β3 integrin (localized in blebbed regions of the structures), as well as CXCL1 and CXCL8 receptors CXCR1 and CXCR2. When CXCR1 and/or CXCR2 were blocked in SKMEL 28 cells (1205Lu yet to be explored), CXCR1 was revealed to be vital in mediating CXCL8’s effect on morphology while CXCR2 was vital in mediating CXCL1’s effect on morphology. Blockade of both chemokine receptors eliminated CXCL1’s and CXCL8’s previously seen increase in the number of filopodia-like structures. We conclude that CXCL1 and CXCL8 have the potential to affect melanoma progression by inducing changes in cell morphology and the formation of filopodia-like structures, and thus, possibly altering intercellular communication.

556/B503

The E1A-Associated p400 Protein Modulates Cell Fate Decisions through the Regulation of ROS Homeostasis.

L. Mattera, C. Courilleau, G. Legube, M. Chevillard-Brief, Y. Canitrot, F. Escaffit, D. Trouche; 1LBCMCP, CNRS, Toulouse, France, 2LBCMCP, UPS, Toulouse, France

The p400 E1A-associated protein, which mediates H2A.Z incorporation at specific promoters, plays a major role in cell fate decisions control: it promotes cell cycle progression and inhibits induction of apoptosis or senescence. Here, we show that siRNA-mediated depletion of p400 induces an oxidative stress transcriptional signature. Moreover, it leads to an increase in intracellular ROS levels and to the appearance of DNA damage and γH2AX foci, indicating that p400 maintains oxidative stress below a threshold at which DNA damage and DNA damage signalling occur. Suppression of these DNA damage response pathways using a siRNA against ATM inhibits the effects of p400 on cell cycle progression, apoptosis induction or senescence, demonstrating the importance of ATM-dependent DDR pathways in cell fates control by p400. Finally, we identify HSP70 as an important target of p400 for ROS modulation since we show that the HSP70-encoding gene promoter is directly activated by p400-mediated H2A.Z incorporation.
and since we can partially restore normal ROS levels in p400-depleted cells by preventing HSP70 decrease. Altogether, our results uncover an unexpected link between p400 and ROS metabolism and allow us to decipher the molecular mechanisms largely responsible for cell proliferation control by p400.

The Role of Phosphoinositides as Co-Activators of p21-Activated Kinase 1 (Pak1).
T. I. Strochlic1, U. Rennefahrt1, J. Viaud1, J. R. Peterson1; 1Dept. of Basic Science, Fox Chase Cancer Center, Philadelphia, PA, 2Metanomics GmbH, Berlin, Germany

The Rho-family GTPases Cdc42 and Rac1 have been implicated in signaling pathways that contribute to cancer via the activation of a diverse array of downstream effector proteins. One important effector of these Rho GTPases is the serine/threonine kinase p21-activated kinase 1 (Pak1), whose activity has been implicated in tumorigenesis and metastasis. In its inactive state, Pak1 adopts an autoinhibited conformation that is relieved upon binding to Rac1 and Cdc42, although whether this is the sole mechanism of activation is currently unknown. We have obtained evidence that the phosphoinositide phosphatidylinositol 4,5-bisphosphate (PIP2) is capable of activating Pak1 in a manner that is highly cooperative with Rac1/Cdc42. We have demonstrated that Pak1 binds directly to PIP2 and that this interaction requires a positively-charged basic region in Pak1 adjacent to the N-terminal GTPase binding domain. In cytoplasmic extracts from Xenopus laevis oocytes, PIP2-mediated activation of Pak1 is dependent on this stretch of N-terminal basic residues. In mammalian cells, growth factor-stimulated activation of Pak1 requires these same basic residues as does the localization of active Pak1 to PIP2-enriched plasma membrane ruffles. Since both PIP2 and the active GTP-bound forms of Cdc42/Rac1 are localized to the plasma membrane, we hypothesize that Pak1 functions as a coincidence detector, whose full activation depends upon Rho GTPases present in phosphoinositide-rich membrane contexts. As the distribution of various phosphoinositides within the cell is relatively restricted, this mechanism may contribute, in part, to GTPase effector selectivity, ensuring that only a subset of Rac1/Cdc42 effectors are activated in a spatially and temporally appropriate manner. These results also suggest that pathologically elevated levels of PIP2 might contribute to the Pak1 hyperactivity associated with certain human cancers.

The Adaptor Protein EBP50 Cooperates with EGFR to Control Biliary Cancer Cell Scattering and Migration.
A. Clapéron1, N. Guedj2, M. Mergey1, B. de Singly1, Y. Chrétien1, V. Paradis2, C. Housset1, L. Fouassier1; 1Inserm UMRS_938 & Univ Paris 06, Paris, France, 2Department of Pathology, Beaujon Hospital, Clichy, France

The adaptor protein EBP50 (Ezrin-radixin-moesin Binding Phosphoprotein 50) binds membrane receptors including Epidermal Growth Factor Receptor (EGFR). EBP50 and EGFR are both expressed in the biliary epithelium. While EGFR participates in biliary carcinogenesis, implication of EBP50 in this cancer is unknown. The aim of the study was to determine the potential links between EBP50 and EGFR in human biliary carcinoma. Methods: In Vitro studies were performed in the human biliary epithelial cell line, Mz-ChA-1, that retains epithelial phenotype and endogenous expression of EBP50 and EGFR. The role of EBP50 was examined using siRNA. Proliferation was analyzed by MTT test, PCNA expression and Ki67 immunolabeling. Cell scattering and migration were evaluated using E-cadherin immunostaining and Boyden chamber, respectively. for In Vivo study, 111 patients who underwent surgical resection for cholangiocarcinoma were analyzed retrospectively. Immunohistochemistry on tissue microarrays was performed to assess EBP50 and EGFR expression. Results: EGF activates EGFR and the signaling pathways, ERK1/2, STAT3 and Akt, in Mz-ChA-1 cancer cells. Inhibition of EBP50 in EGF-treated cells increases and maintains activation of EGFR, ERK1/2 and STAT3 but not Akt. In response to EGF, EGFR activation is unable to drive proliferation but activates cell scattering by inducing disruption of adherens junctions. In addition, EGF activates formation of lamelipodia structures and cell migration. Inhibition of EBP50 in non EGF-stimulated cells has the same
effects on cell scattering and migration as those observed with EGF alone. Cell dispersion due to EBP50 inhibition is abolished in the presence of gefitinib, an inhibitor of EGFR. Impact on cell scattering and migration is even greater when both EGF addition and EBP50 siRNA are combined. In vivo, delocalization of EBP50 normally expressed beneath the apical membrane is associated with EGFR expression in human biliary carcinoma tissues (p=0.002). Conclusion: These data provide evidence for a role of EBP50 in repressing EGFR-induced signaling pathway and migration. EBP50 at the membrane may be critical to confine cancer progression by preventing migration of biliary cancer cells.

The Effects of Polyphenolic Induced Differentiation on HO-1, Human Melanoma Cells.
C. A. Joseph¹, V. Parmar², A. L. DePass³; ¹Biology, Long Island University, Brooklyn, NY, ²University Of Delhi, Delhi, India

Plant polyphenolic compounds have been found to exhibit anti-cancer effects such as changes of expressions in genes that control proliferation, differentiation and apoptosis. Consistent with our interest to investigate cellular differentiation as a therapeutic target for cancer, we investigated the effects of several synthetic polyphenolic compounds on HO-1 human melanoma cells. We now present data that shows VSP-15 (plant derived polyphenolic compound) exhibiting a dose- and time-dependent terminal differentiated effect on HO-1 cells. Proliferation assays and gene expression analysis using PCR arrays indicate the mechanism of action employed by the compound and indicate changes in gene expression indicative of the anti-proliferative and pro-apoptotic effects hypothesized. Morphological changes and melanin synthesis along with changes in the expression of the tumor suppressor genes MDA-7/IL-24 (melanoma differentiation gene-7/Interleukin-24) and p53 were also exhibited and were clear indication of VSP-15 induced differentiation.

A Novel Role of RF-Cp145 in DNA Damage Induced Signaling.
F. Menaa¹,², H. Brickner³, A. Munshi⁴, R. Fotedar¹,³, A. Fotedar¹; ¹Cancer Cell Biology, Sidney Kimmel Cancer Center, La Jolla, CA, ²Scripps Research Institute, La Jolla, CA, ³Burnham Institute for Medical Research, La Jolla, CA, ⁴Dermato-Oncology, School of Medicine, Wuerzburg, Germany

The Replication Factor-C (RF-C) is a heteropentameric protein that is relatively well conserved among eukaryotes. The major established role of RF-C complex is to load PCNA onto DNA. PCNA in turn functions as a sliding clamp that recruits DNA polymerases to allow DNA synthesis. We have discovered that the largest RF-C subunit, RF-Cp145, has a novel effect on DNA damage signaling. Chk1 and Chk2 kinases are activated by ATR/ATM kinases in response to DNA damage, and in turn propagate the downstream DNA damage response. We found that down-regulation of RF-Cp145 by siRNA in UV- but not in ionizing-irradiated cells prevents significatively Ser317 and Ser345 phosphorylation and activation of Chk1 and, in a less extend, prevents Thr68 phosphorylation of Chk2. The protein levels of other RF-C subunits are unaffected by RF-Cp145 siRNA. In contrast, RF-Cp145 protein levels are affected by the other RF-C subunits. Interestingly, the failure of Chk1 phosphorylation caused by RF-Cp145 down-regulation does not prevent UV induced phosphorylation of Ser15 in p53 nor does it prevent phosphorylation of H2AX which is increased when Chk1 is down-regulated. Furthermore, downregulation of ATRIP, a binding partner of ATR, destabilizes ATR and prevents UV induced phosphorylation of Chk1 and Ser15 phosphorylation of p53. It is therefore likely that RF-Cp145 does not act via ATR/ATRIP to inhibit selectively Chk1 phosphorylation, highlighting the emerging complexity of the DNA damage pathways. Finally, RF-Cp145 downregulation increases apoptosis, consistent with our published effect of RF-Cp145 on cell survival [1]. Eventually, RF-Cp145 plays a critical role in the UV surveillance during DNA replication by controlling the cell survival mainly through Chk1 phosphorylation. [1] Pennaneach V, Salles-Passador I, Munshi A, Brickner H et al. The large subunit of replication factor C promotes cell survival after DNA damage in an LxCxE motif- and Rb-dependent manner. Mol Cell 2001 Apr; 7(4):715-27.
Characterization of MUF1/LRRC41, a Binding Partner of Atypical Rho GTPases of the RhoBTB Family.

K. Schenkova¹, M. Kopp², S. Ramos², F. Rivero¹; ¹Centre for Biomedical Research, The Hull York Medical School, University of Hull, Hull, United Kingdom, ²Center for Biochemistry, Medical Faculty, University of Cologne, Cologne, Germany

Rho proteins have been implicated mainly in the regulation of the cytoskeleton, but also in vesicle trafficking, phagocytosis and transcriptional activation. RhoBTB proteins constitute a subfamily of atypical Rho GTPases represented by three isoforms in vertebrates. They consist of a GTPase domain followed by a proline-rich region and two BTB domains. BTB domains are involved in the formation of cullin 3-dependent ubiquitin ligase complexes therefore the function of RhoBTB proteins seems to be distinct from that of the classical Rho GTPases. In our working model RhoBTB proteins play roles in targeting of substrates for ubiquitinylation and degradation via cullin 3-dependent ubiquitin ligase complexes, but the substrates remain unknown. In order to identify binding partners (and possible substrates) of RhoBTB we performed a two hybrid screening on a mouse brain cDNA library and identified MUF1 (LRRC41) as a potential interaction partner of RhoBTB3. MUF1 is a leucine rich repeat containing protein that, interestingly, also contains a BC-box that serves as a linker in multicomponent, cullin 5-based ubiquitin ligases. We confirmed the interaction of MUF1 with all three RhoBTBs using immunoprecipitation. The interaction of MUF1 and RhoBTB3 seems to be direct, cullin 3 and 5 independent. We determined the expression profile of the LRRC41 gene using a Human Multiple Tissue Expression Array and RT-PCR and found that MUF1 is ubiquitously expressed, with the highest expression in testis. A GFP fusion of MUF1 localizes in the nucleus but RhoBTB3 causes it to be partially retained in the cytoplasm. MUF1 is able to make homodimers and appears to be degraded in the proteasome in a cullin 5 independent manner. This raises the question whether MUF1 and RhoBTB3 are together involved in multiprotein complexes containing cullin 3 and cullin 5 simultaneously. We envision two possible models: a) MUF1 is ubiquitylated by a cullin 3 complex dependent on RhoBTB, which acts as the substrate specific adaptor; b) RhoBTB is ubiquitylated by a cullin 5 complex dependent on MUF1, which acts as the substrate specific adaptor.

Para-Phenylenediamine-Induced Autophagy in Human Uroepithelial Cell Line Mediated Mutant p53 and Activation of ERK Signaling Pathway.

Y. Huang³, W. Hung⁴, S. Chye⁶, W. Chen², C. Chai¹,²,⁵; ¹Dept. of Pathology, Kaohsiung Medical University, Kaohsiung, Taiwan, ²Dept. of Pathology, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan, ³Graduate Institute of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan, ⁴Institute of Biomedical Sciences, National Sun Yat-Sen University, Kaohsiung, Taiwan, ⁵National Sun Yat-Sen University-Kaohsiung Medical University Joint Research Center, Kaohsiung, Taiwan, ⁶Dept. of Human Biology, School of Medicine, International Medical University, Kuala Lumpur, Malaysia

Para-Phenylenediamine (p-PD) is a major aromatic amine that is widely used as a component of engineering polymers and commercial oxidative type hair dyes. Some epidemiologic studies suggested that the use of p-PD-based hair dyes might be related to increased risk of human malignant tumors including bladder cancer. However, it has been suggested that programmed cell death is composed of two different pathways for active cellular self-destruction as reflected by different morphology: apoptosis and autophagy. Previously, we have demonstrated that p-PD can induce apoptosis in urothelial cells. However, the molecular mechanism of p-PD on autophagy in human uroepithelial cells (SV-HUC-1) is still unclear. Our previously study had shown that the exposure of SV-HUC-1 cells to p-PD caused oxidative DNA damage and increased mutant p53 expression respectively, by using Comet assay and Western blotting. In this study, we demonstrate that p-PD could activate the extracellular signaling-regulated protein kinase 1/2 (ERK1/2) signaling pathway in p-PD-treated SV-HUC-1 cells. In addition, the substantial
morphological changes in cells after treatment of different concentrations of p-PD were examined. By electron microscopy, we found that the autophagosomes were increased in p-PD-treated SV-HUC-1 cells. Furthermore, our results showed incrementally increasing the p-PD concentrations, the expression of Beclin-1 and microtubule-associated protein light chain 3B (LC3B) which are important regulators of autophagosomes, were increased in a dose-dependent manner. In contrast, the inhibition of autophagy by treatment with MEK inhibitor (U0126), and the effect of p-PD on ERK1/2, Beclin-1 and LC3B proteins expression were suppressed, except mutant p53. Finally, our results provide the notion that p-PD can activation of ERK1/2 signaling pathway via mutant p53, led to stimulate autophagy in SV-HUC-1 cells. Therefore, these results provide us new insights for the understanding of the mechanism of p-PD-induced cell death in urothelial cells.

Transforming Growth Factor β Inducible Early Response Gene 1(TIEG1) Is a Novel Substrate of Atypical Protein Kinase Cs (aPKCs).
E. A. Alemu, E. Sjøttem, H. Outzen, T. Holm, G. Bjørkøy, T. Johansen; Biochemistry, University of Tromsoe, Tromsoe, Norway

The protein kinase C (PKC) family of serine/threonine kinases consists of ten different isoforms that can be grouped into three classes denoted classical-, novel- and atypical PKCs. λι and ζPKCs constitute the atypical PKCs, which serve important roles during development and in processes subverted in cancer such as cell-and tissue polarity, cell proliferation, differentiation and apoptosis. In an effort to find novel interaction partners for aPKCs, a yeast two-hybrid screening of a HeLa cell cDNA library was carried out using the regulatory domain of λιPKC as bait. This screen yielded three independent clones of TIEG1 as a putative interaction partner for λιPKC. We have confirmed the interaction In Vitro and In Vivo using pull-down- and co-immunoprecipitation assays and confocal microscopy. In addition, we report that aPKCs phosphorylate the DNA binding domain (DBD) of TIEG1 on two critical residues. We further show that aPKC-mediated phosphorylation of TIEG1 affects its DNA binding activity, subnuclear localization and transactivation potential.

Cinnamaldehyde Impairs High Glucose-Induced Hypertrophy in Renal Interstitial Fibroblasts.
J. Huang; Biological Science and Technology, Chung Hwa University of Medical Technology, Tainan Hsien, Taiwan

Cinnamaldehyde is a major and a bioactive compound isolated from the leaves of Cinnamomum osmophloeum kaneh. To explore whether cinnamaldehyde was linked to altered high glucose (HG)-mediated renal tubulointerstitial fibrosis in diabetic nephropathy, the molecular mechanisms of cinnamaldehyde responsible for inhibition of HG-induced hypertrophy in renal interstitial fibroblasts were examined. We found that cinnamaldehyde caused inhibition of HG-induced cellular mitogenesis rather than cell death by either necrosis or apoptosis. There were no changes in caspase 3 activity, cleaved poly(ADP-ribose) polymerase (PARP) protein expression, and mitochondrial cytochrome c release in HG or cinnamaldehyde treatments in these cells. HG-induced the extracellular signal-regulated kinase (ERK)/c-Jun N-terminal kinase (JNK)/p38 mitogen activated protein kinase (MAPK) (but not the Janus kinase 2/signal transducers and activators of transcription) activation were markedly blocked by cinnamaldehyde. The ability of cinnamaldehyde to inhibit HG-induced hypertrophy was verified by the observation that it significantly decreased cell size, cellular hypertrophy index, and protein levels of p27Kip1, p21Waf1/Cip1, collagen IV, and fibronectin. The results obtained in this study suggest that cinnamaldehyde in HG-induced hypertrophy in renal interstitial fibroblasts may serve a potential anti-fibrotic function through mechanism dependent of its inactivation of the ERK/JNK/p38 MAPK pathway.

Flip S-Nitrosylation Modulates Protein Processing and NF-κB Activation through Changes with RIP1.
S. Talbott2,1, Y. Rojanasakul1; 1Dept of Basic Pharmaceutical Sciences, West Virginia University, Morgantown, WV, 2Mary Babb Randolph Cancer Center, West Virginia University, West Virginia University, WV

Elevated nitric oxide (NO) production and FLICE-inhibitory protein (FLIP) expression have been associated with many human disorders such as cancer and cardiovascular diseases. However, their role and relationship in the disease process are not well understood. FLIP is a known regulator of death receptor (DR)-mediated apoptosis, but recent studies suggest that it also plays a role in inflammatory and proliferative pathways through NF-κB (Nuclear Factor kappaB) activation. DR signaling is tightly regulated since they are key players in determining cellular fate in response to cytokine stimulation. Disruption of these pathways is well documented in chemotherapy-resistant cancers and autoimmune diseases. The objective of this study was to determine the role NO has on FLIP signaling in the DR pathways. High levels of NO lead to an increase in protein S-nitrosylation, a post translational modification. Our studies show that the ability of FLIP to activate NF-κB is dependent upon FLIP S-nitrosylation. Mutation of cysteine residues at positions 254 and 259, prevent S-nitrosylation and abolishes its NF-κB inducing effect, as demonstrated by reporter gene assays. Immunoprecipitation, Western blot, and immunofluorescence studies further show that S-nitrosylation of FLIP modulates its interaction with a protein upstream of NF-κB activation, RIP1 (Receptor Interacting Protein 1). RIP1 also responds to DR-stimulation. We also show that the S-nitrosylation of FLIP is required for its processing to shorter forms suggesting that S-nitrosylation of FLIP promotes its ability to act as a substrate. Together, our results indicate a novel pathway for FLIP regulation of NF-κB through NO signaling. This provides a key mechanism for determining cell death and survival in the DR-mediated pathways.

Loss of Calreticulin Suppresses NFκB Activity by Increasing IκB Stability.
S. Jalali1,2, M. Aghasi1,2, N. Mesaeli1,2; 1Biochemistry and MedicalGenetics, University of Manitoba, Winnipeg, MB, Canada, 2Institute of Cardiovascular Sciences, St. Boniface Research Centre, Winnipeg, MB, Canada

Calreticulin (CRT) is an endoplasmic reticulum chaperone which has high capacity for Ca2+ binding. Previously we showed that CRT knockout mouse embryonic fibroblasts (crt-/-) are resistant to UV-induced apoptosis. Recently, we also demonstrated that the activity of the PI3-kinase/Akt signaling pathway and the proteasome are significantly elevated in the CRT deficient cells. Given that NFκB signaling is induced by active Akt, enhanced ER stress and elevated proteasome activity, we hypothesized that NFκB signaling is activated in the absence of CRT. To test this hypothesis we compared the activity of a NFκB reporter gene in wild type (wt) and crt-/- cells. Surprisingly, we showed that the basal transcriptional activity of NFκB is significantly lower in the CRT deficient cells as compared to the wt cells. In addition, treatment of crt-/- cells with LPS failed to increase the transcriptional activity of NFκB to the level observed in the wt cells. Western blot analysis showed that the decreased NFκB activity was not due to a decrease in either the p65 or p50 subunits but was instead due to a significant increase at the level of IκBα protein level in the crt-/- cells. Interestingly, the level of IκBα and IκBβ mRNA were both significantly reduced in the CRT deficient cells. The observed increase in the IκB could be partly mediated by the rapid dephosphorylation and accumulation of IκB protein in these cells. Indeed, our data illustrated a significant increase in the activity of a serine-therionine phosphatase (PP2A). Furthermore, we showed that inhibition of PP2A by okadaic acid significantly reduced the IκBα protein level. In conclusion, we have demonstrated for the first time that loss of calreticulin diminishes NFκB activity by increasing IκBα stability due to activation of PP2A.

Quantitation of ERK Activation via Automated Cellular Imaging and Analysis.
J. Anderl, A. Ball; Millipore Corporation, Temecula, CA

- 271 -
Extracellular signal-regulated kinase (ERK) signaling controls cell growth, differentiation and survival. ERK is activated by dual phosphorylation on tyrosine and threonine residues (pERK). This pathway is often upregulated in tumors and is a target for cancer therapy. Evidence suggests that pERK may also represent a generic readout for GPCR activation. Our aim was to develop an immunofluorescence-based cellular imaging assay for ERK activation, in order to quantitate the activity of agents modulating pERK. We characterized multiple pERK antibodies via automated cellular imaging. By using image analysis algorithms, antibodies were eliminated if they displayed low signal, inappropriate localization, or minimal ERK activation upon treatment with ERK modulators. This approach enabled selection of an optimal pERK antibody for use in all further assay development. Treatment of HeLa cells with PMA (30min) in growth media (100nM max.) led to dose-dependent increases of nuclear and cytoplasmic pERK signal. Maximum increases in HeLa pERK nuclear and cytoplasmic intensity (compared to control) at 100nM PMA treatment were 115% and 87% respectively. A549, HeLa and HepG2 cells were used to generate ERK activation time courses for EGF and PDGF, showing maximal activation after 15-30min of treatment. Cell type-specific dose responses were also generated for PMA, EGF and PDGF. Dose-dependent inhibition of pERK was demonstrated using 1h pre-treatments (100µM max.) of LY294002, PD98059 and U0126, followed by 30min 100nM PMA activation. LY294002 produced minimal inhibitory effect in each cell type; IC50 values for PD98059 and U0126 ranged from 0.7-2µM and 67-740nM, respectively. We performed further experiments demonstrating the application of this assay to screen for GPCR activation in response to receptors activating three classes of G proteins: Gαs, Gαi and Gαq. In summary, we have developed of a robust assay for pERK screening via quantitative imaging. The assay utilizes sensitive, highly specific immunofluorescent detection of pERK, and may be used to rapidly visualize and quantify expression of this protein in a variety of cell types. This assay shows applicability for multiple ERK screening and drug discovery applications.

The Atypical Mitogen-Activated Protein Kinase ERK3, a Novel Substrate for p-21-Activated Kinase Activity.
A. M. De La Mota-Peynado1, J. Chernoff2, A. E. Beeser1; 1Biology, Kansas State University, Manhattan, KS, 2Tumor Cell Biology, Fox Chase Cancer Center, Philadelphia, PA

Extracellular signal-regulated kinase 3 (Erk3/MAPK6) is a member of the mitogen-activated protein kinase (MAPK) family of serine/threonine kinases that transduce extracellular signals into discrete intracellular responses. The MAPK signal transduction pathways are among the most widespread and conserved mechanisms of eukaryotic cell regulation and their mechanism of action in cell cycle progression and differentiation are well established. The lesser known isoform, Erk3, differs from other MAPKs in that it does not contain a true canonical MAPK Th-X-Tyr motif, but contains a single phosphorylation site in its activation loop (Ser-Glu-Gly). Erk3 also has very restricted substrate specificity, and does not phosphorylate any of the known MAPK substrates, nor is it a target of the established MAPK kinases. Very little is known about the regulation, substrate specificity and physiological functions of Erk3. Recent studies suggest it may be involved in the regulation of the cell cycle and has been linked to some cancers. Our objective is to elucidate how Erk3 is regulated and the physiological implications of its regulation by identifying upstream effectors of Erk3. Using a high throughput protein array we found that Erk3 functions as a direct substrate for p-21 activated kinase 2 (Pak2), suggesting a relationship between Pak2 and Erk3. To confirm our findings, we purified full length Erk3 and performed phosphorylation studies confirming that Erk3 is indeed a direct In Vitro substrate for Pak2 kinase activity. In addition, we mapped the key residues phosphorylated by Pak2 using activation loop specific phospho-antibodies. An In Vivo confirmation of Pak2/Erk3 interaction was also demonstrated by immunoprecipitation assays. These finding support our hypothesis that Pak2 kinase activity may directly contribute to Erk3 activation. Furthermore, based on the similarity of Erk3 to Erk1/2, Pak2 might function analogously to MEK and be directly responsible for Erk3 activation. Further studies into how Erk3 is regulated will shed light into the role of the enzyme in cell cycle regulation and cancer.
Rewiring of JNK Map Kinase Signaling Pathway through Artificial Assembly of JIP-1 Scaffold Complex.
J. Moon, S. Park; Department of Biological Sciences, Seoul National University, Seoul, Korea, South

Scaffold proteins are crucial for proper signaling of MAP kinase cascades in eukaryotic cells. Scaffold proteins are known to bind to component kinases of signaling pathway and to mediate signaling by formation of functional signaling complexes. It is also proposed that scaffolds could facilitate phosphorylation of member kinases, and presumably increase the efficiency and specificity of signaling. Although several scaffold proteins have been identified, it is still unclear how the scaffold proteins participate in the regulation of signaling and contribute to the signaling integrity. In this study, we have attempted to elucidate the assembly mechanism of mammalian scaffold protein, JIP-1 in JNK MAP kinase signaling pathway. First, JNK docking mutation was introduced in JIP-1 which disrupted signal transduction as well as interaction with JNK. Then, JNK MAP kinase and mutant JIP-1 were fused to nNOS and syntrophin PDZ domains, respectively, to reinforce JNK into JIP-1 complex via heterologous PDZ-PDZ interaction. We observed that the pathway output was functionally restored by rewiring JNK-JIP-1 docking using heterologous protein interaction, and that the non-natural assembly of scaffold complex mediated by heterologous PDZ domains is sufficient to restore JNK MAP kinase signaling. It seems that scaffold proteins serve as a platform for dynamic organization of signaling proteins and therefore, artificial assembly of scaffold complex should allow for the rewiring of signaling information.

The Tail Anchored Membrane Protein (SLMAP) Regulates Cell Growth by Targeting the Map Kinase Pathway and PP2A.
M. Nader1, M. Salih1, F. H. Leenen1, B. S. Tuana2; 1Cellular and Molecular Medicine, University of Ottawa Heart Institute, Ottawa, ON, Canada, 2Hypertension Unit, University of Ottawa Heart Institute, Ottawa, ON, Canada

The aim of this study is to evaluate the role of the tail anchored membrane protein (SLMAP) in cell signaling and growth. Knockdown of SLMAP using RNA interference was found to inhibit cell proliferation ~60% with no evidence of cell death and was associated with a ~68% inhibition of MEK activity and a marked hyperphosphorylation of p42/44. Although the MEK inhibitor (U0126) inhibited p42/44 activity, the phosphorylation of p42/44 remained higher in cells with reduced levels of SLMAP. Protein levels of p44 were increased ~85% while those of p42 were decreased ~64% upon SLMAP knockdown. The expression of the phosphatase MKP-1 that is believed to dephosphorylate p42/44 was unchanged while PP2A protein levels were decreased ~83% upon SLMAP knockdown. In contrast, overexpression of SLMAP depressed p42/44 phosphorylation and was associated with increased PP2A and p42 protein levels without any effects on MEK phosphorylation. Changes in SLMAP expression did not affect the mRNA levels of PP2A and p42. Confocal imaging of C2C12 cells demonstrated a colocalization of SLMAP, PP2A and striatin while immunoprecipitation assays revealed that SLMAP exists in complex with striatin and PP2A. These data demonstrate that SLMAP can critically impact cell growth through the MAP kinase pathway by specifically targeting MEK activity as well as PP2A and p42/44 protein levels. In conclusion, we propose a novel role for SLMAP as an adaptor/scaffold which serves to specifically integrate signaling through a multiprotein complex involving PP2A, striatin and components of the MAP Kinase pathway.

Role of Ppq1 Phosphatase in Mating Map Kinase Pathway in Budding Yeast.
E. Shim1,2, S. Park1,2; 1Seoul National University, Seoul, Korea, South, 2Department of Biological Sciences and Research Center for Functional Cellulomics, Seoul, Korea, South
Cells process signaling information through biochemical networks of signal transduction proteins. Maintenance of signaling specificity by temporal and spatial regulation of protein complex formation is critical for cell survival. To understand regulation mechanism and kinetics of cell signaling, we have chose the mating MAP kinase signaling pathway in the budding yeast as a model. Upon stimulation by mating pheromone yeast cells transmit mating responses through the MAP kinase cascade composed of three kinases and Ste5 scaffold protein. Phosphatases are known to play a critical role for the precise regulation of signaling at each stage such as activation, duration, and adaptation. Identification and functional analysis of pathway-specific phosphatase is critical for understanding of the regulatory mechanism of cell signaling. We have developed a novel screening strategy for pathway-specific phosphatases, in which an entire repertoire of phosphatases in organism were tethered to the scaffold and the changes in the signaling response were monitored. Using the strategy, a putative Ser/Thr phosphatase, Ppq1, was identified as a negative regulator of the mating signaling. Results show that Ppq1 can directly interact with members of mating pathway. Catalytically active Ppq1 was able to lower the phosphorylation level of mating components In Vivo and in vitro, which suggests that Ppq1 might function as a negative regulator of mating MAPK pathway by dephosphorylating target protein. It seems that Ppq1 plays a critical role in the acute signaling propagation and signal adaptation via controlling the level of active MAP kinase.

Systematic Quantification of Crosstalk and Feedback Interactions in Signal Transduction Networks.
M. Cirit, C. Wang, J. Haugh; Chemical & Biomolecular Engineering, North Carolina State University, Raleigh, NC

Historically, intracellular signal transduction has been characterized in terms of linear pathways, exemplified by the canonical mitogen-activated protein kinase (MAPK) cascades, such as the Ras → Raf → MEK → extracellular signal-regulated kinase (Erk) pathway in mammals. Our conceptual understanding of signal transduction networks now includes more complex interactions, including those between the classically defined pathways (crosstalk) and those responsible for feedback regulation/reinforcement; however, little has been done to move beyond hand-waving models of signaling networks to systematically quantify the relative magnitudes of classical, crosstalk, and feedback interactions. Through quantitative measurements and computational modeling, we recently characterized crosstalk mechanisms in the platelet-derived growth factor (PDGF) receptor signaling network, in which phosphoinositide 3-kinase (PI3K) and Ras/Erk pathways are prominently activated [Wang C-C, Cirit M, Haugh JM. PI3K-dependent crosstalk interactions converge with Ras as quantifiable inputs integrated by Erk. Mol Syst Biol, 5: 246 (2009)]. Unique in its coverage of time, dose, and molecular perturbation conditions, our data set was comprised of >3,000 biochemical measurements, yielding 169 processed data points that were used to constrain the accompanying model. We have since refined this approach with additional measurements that push even further the boundary of data-driven mechanistic modeling. With nearly double the number of data constraints, we have identified at least four distinct modes of negative feedback regulation and pinned down with even greater precision the magnitude of crosstalk from PI3K-dependent signaling to the Ras/Erk pathway. We further demonstrate that the model in its current state is a predictive tool that successfully forecasts outcomes of experiments that perturb the feedback structure of the network.

PEA-15 Re-Programs the Output and Duration of Growth Factor Signaling.
J. Halig, M. Ginsberg; Medicine, UC San Diego, La Jolla, CA

PEA-15 is a highly-conserved widely-expressed mammalian protein. Changes in PEA-15 expression are linked to insulin resistance, tumor cell invasion, and cellular senescence. The ERK1/2 MAP kinase pathway is a central regulator of cellular behaviors and PEA-15, an ERK1/2 binding protein, has profound effects on the activation and output of this pathway. Previous work has shown that increased PEA-15 expression leads to dramatically increased activation of the
ERK1/2 MAP kinase pathway. Here we have defined the mechanism whereby PEA-15 promotes and sustains growth factor signaling. In addition to increasing ERK1/2 activation, our data show that PEA-15 binds to ERK1/2 thereby preventing their membrane recruitment. In consequence, ERK1/2 are unable to threonine phosphorylate FRS2α, thereby prolonging its capacity to activate the MAP kinase pathway. We report that PEA-15 increases activation of the ERK1/2 MAP kinase pathway by interrupting a negative feedback loop formed by ERK1/2 phosphorylation of FRS2α. Furthermore, genetic deletion of FRS2α blocks the capacity of PEA-15 to activate the MAP kinase pathway. Thus, PEA-15 serves as a modulator of the classical MAP kinase pathway by preventing its localization to the plasma membrane thereby inhibiting, ERK1/2-dependent phosphorylation of FRS2α.

Different Cell Proliferation Pathways Induced by FGF-2 through p27 Degradation via ERK1/2 and PI 3-Kinase in Human and Rabbit Corneal Endothelial Cells.
J. Lee1, J. Song1,2,3, R. E. Smith1,2, E. Kay1,2; 1Doheny Eye Institute, Los Angeles, CA, 2Ophthalmology, Keck School of Medicine of the University of Southern California, Los Angeles, CA, 3Ophthalmology, Korea University College of Medicine, Seoul, Korea, South

The cyclin-dependent kinase inhibitor p27Kip1 (p27) is an important regulator of G1 progression. To induce cell proliferation, p27 must undergo proteolysis through its phosphorylation mechanism. Fibroblast growth factor 2 (FGF-2) is known to stimulate cell proliferation of rabbit corneal endothelial cells (rCECs) by degrading p27. We investigated the effect of FGF-2 on cell proliferation and p27 degradation in human corneal endothelial cells (hCECs) in both In Vitro and ex vivo studies. IL-1β induced FGF-2 expression through PI 3-kinase, as observed in rCECs. FGF-2, and IL-1β dramatically stimulated cell proliferation in hCECs; these effects were blocked by use of pathway specific inhibitors for PI 3-kinase and ERK1/2, respectively. We further defined whether the induction of cell proliferation by FGF-2 is caused by p27 degradation. Cells maintained in serum-starved medium were stained for p27 in the nuclei, but not for pp27Thr187. However, FGF-2 abolished the staining of p27, while nuclear staining of pp27Thr187 was observed. This effect of FGF-2 on p27 expression and on phosphorylation of p27 at Thr187 site was completely blocked by LY294002 treatment. We used immunoblotting to define whether both PI 3-kinase and ERK1/2 pathways are independently involved in cell proliferation induced by FGF-2, as observed in rCECs. In the FGF-2-treated cells, the activation of Akt, p38, and ERK1/2 were determined, and its activation was also completely blocked by LY294002: ERK1/2 activation involves the cell proliferation induced by FGF-2 as a downstream molecule to PI 3-kinase, which differs from rCECs in which the ERK1/2 pathway is parallel to PI 3-kinase pathway. With these results, we, thus, reveal for the first time that FGF-2 stimulates proliferation of hCECs through PI-3 kinase and its downstream target ERK 1/2 pathways and that FGF-2 significantly down-regulates p27 through the phosphorylation mechanism.

Role of T34 Phosphorylation in Akt Dissociation from Membrane during Akt Activation.
M. Akbar, B. X. Huang, R. Lee, H. Kim; LMS, NIAAA, NIH, Rockville, MD

Akt is a critical serine-threonine kinase that controls cell survival, growth and differentiation. The regulation and function of Akt involves multi-step processes. Cytosolic Akt is recruited to the plasma membrane through the binding of the PH domain to membrane PIP3 generated by growth factor receptor stimulation. The membrane interaction causes interdomain conformational change of Akt allowing Akt activation by phosphorylation at T308 and S473 by PDK1 and mTOR. The activated Akt is then released from the membrane to phosphorylate downstream targets in various subcellular localizations. It has been demonstrated that the phosphorylation of T308 by PDK1 not only is important for Akt activity but also play a role in the detachment of Akt from the plasma membrane. However, detailed mechanism by which phosphorylated Akt dissociates from the membrane is still unclear. In the present study, we investigated the involvement of Akt phosphorylation in dissociation of Akt from the membrane. We found that Akt phosphorylation by PDK1 is required for Akt release from the membrane. We also found that PDK1 not only
phosphorylates T308 but also T34 in the PH domain. Biomolecular interaction analysis indicated that a mutant mimicking the phosphorylation of T34 (T34D) resulted in less membrane affinity compared to the wild type Akt. Consistently, the membrane translocation observed by time lapse fluorescence microscopy was impaired by the T34D mutation. Akt phosphorylation at both T308 and S473 in IGF-stimulated Neuro 2A cells was significantly inhibited in the T34D mutant, further supporting the impaired Akt interaction with membrane. The observed decrease in Akt-membrane interaction by T34 phosphorylation by PDK1 may be an important mechanism to mobilize activated Akt for downstream target protein phosphorylation inAkt signaling.

Profiling of mTOR Phosphorylation Pathway in Rat Liver Using Mass Spectrometry.
G. Demirkan1, 2, A. Salomon1, P. Gruppuso1, 2, *MCB (Molecular Biology, Cell Biology and Biochemistry), Brown University, Providence, RI, 2Rhode Island Hospital, Providence, RI

Cell growth is a very complex and highly coordinated process. The Mammalian Target of Rapamycin (mTOR) is at the center of a nutrient and growth factor-responsive cell growth signaling network. mTOR is the only known target of the naturally occurring fungicide, rapamycin. Previous studies have identified mTOR as a serine/threonine kinase that signals to a spectrum of downstream events, including activation of translation and ribosomal biogenesis, inhibition of autophagy, regulation of cell size and cell cycle progression. However, the functions of both proximal and distal components of the TOR pathway are incompletely understood and many potential substrates of mTOR and its downstream effectors remain unidentified. With recent advances in mass spectrometry technology, investigation of global and quantitative dynamics of phosphorylation events is possible. Our aim in this project is to gain a better understanding of how the mTOR pathway regulates cell growth by characterizing the global In Vivo phosphoproteome and its temporal dynamics under physiological conditions that modulate mTOR activity. Our work has thus far focused on developing a phosphoproteomic approach to enrich phosphorylated proteins from liver homogenates for identification of unknown phosphorylation sites regulated by mTOR signaling. By applying multiple proteomic chromatography methods and MS/MS sequencing, we have been able to identify known mTOR targets. We anticipate that our optimized phosphoproteomic strategy will allow us to enrich for and identify proteins from liver homogenates whose phosphorylation is modulated by the whole animal administration of rapamycin.

Caveolin-1 Binding with β-Dystroglycan Modulates Gαq-PLCβ1 Mediated Calcium Release in Smooth Muscle Cells.
P. Sharma1,4, S. Ghavami1,4, G. L. Stelmack1,4, K. D. McNeill1,4, T. Klonisch3, H. Unruh2, A. Halayko1,2,4; 1Physiology, University of Manitoba, Winnipeg, MB, Canada, 2Section of Respiratory Disease and Thoracic Surgery, Internal Medicine, Pediatrics and Child Health, University of Manitoba, Winnipeg, MB, Canada, 3Department of Human Anatomy and Cell Science, University of Manitoba, Winnipeg, MB, Canada, 4Biology of Breathing, Manitoba Institute of Child Health, CIHR National Training Program in Allergy and Asthma, University of Manitoba, Winnipeg, MB, Canada

β-Dystroglycan (β-DG), the core transmembrane subunit of the dystrophin-glycoprotein complex (DGC), links the extracellular matrix to intracellular actin, and the DGC colocalizes with membrane caveolae arrays in smooth muscle. We tested whether association of caveolin-1 with the DGC dictates caveolae distribution, affecting pathways for [Ca2+]i mobilization by contractile agonists. Using confocal microscopy of cultured primary canine airway smooth muscle (ASM) and immunoblot analysis of canine and human ASM tissue, we observed colocalization of caveolin-1 and β-DG. Immunoprecipitation confirmed a direct association of caveolin-1 with β-DG. Disruption of filamentous actin with latrunculin (LAT) caused loss of organized caveolae membrane arrays.
(electron microscopy) and markedly reduced β-DG and caveolin-1 protein in isolated lipid raft-rich fractions. Actin-linked caveolae disruption also had significant functional consequence: in fura-2-loaded ASM cells, LAT decreased sensitivity to methacholine (MCh) (EC50Con = 50.3 ±14nM; EC50LAT = 220 ±24nM; p<0.01), and reduced maximum MCh-induced [Ca2+]i by 34% (p<0.01). To study the role of the interaction between β-DG and caveolin-1 we used lentiviral delivered shRNAi to stably silence β-DG in human ASM cells. In the absence of β-DG, caveolae distribution was clearly disrupted, and key GPCR machinery (PLCβ-1 and Gq) required for Ca2+ mobilization, was lost from caveolae microdomains as confirmed by subcellular fractionation. These changes correlated with a marked reduction in sensitivity to MCh-induced [Ca2+]i mobilization in β-DG null cells (EC50 = 50.3 ±14nM) compared to cells transduced with non-coding scrambled shRNAi (EC50 = 220 ±24nM; p<0.01). These data demonstrate for the first time a direct interaction between endogenous caveolin-1 and β-DG that is essential for caveolae-sequestration of signaling effectors for GPCR-mediated [Ca2+]i release, and indicate a critical role for the cortical actin cytoskeleton and the DGC in the spatial organization of caveolae that underpins [Ca2+]i release.

Role of Intracellular S100B in the Transition of Myoblasts from Quiescence to Proliferation and from Proliferation to Quiescence, and in Apoptosis.
C. Tubaro, C. Arcuri, I. Giambanco, R. Donato; Department of Experimental Medicine and Biochemical Sciences, University of Perugia, Perugia, Italy

S100B is a Ca2+-binding protein of the EF-hand type with both intracellular and extracellular regulatory roles. Within cells, S100B regulates the activities of certain enzymes and transcription factors, cell shape and migration, proliferation and differentiation. Recent evidence suggests that S100B is expressed in satellite cells (SCs), the quiescent stem cells located beneath the basal lamina surrounding each myofiber in skeletal muscles, as well as in myoblast cell lines, and that increases (by either stable or transient overexpression) or decreases (by RNA interference) in S100B levels result in the blockade and enhancement of myogenic differentiation, respectively. S100B stimulated the transcriptional activity of NF-κB by acting upstream of IKKβ thereby inhibiting the expression of the muscle-specific transcription factor, MyoD, and its downstream targets, myogenin and p21WAF1, and augmenting the expression of the anti-myogenic factor, Yin Yang1. Thus, S100B might exert a physiological role in the process of activation and expansion of SCs in the course of muscle regeneration, e.g. by reducing their premature differentiation. The ability of S100B to modulate MyoD expression raised the possibility that the protein might have a role in the transition of myoblasts from proliferation to quiescence and/or from quiescence to proliferation, as downregulation of MyoD expression is required for proliferating myoblasts to acquire a quiescent status, and activation of quiescent myoblasts results in expression of MyoD. We show here that increasing the S100B levels in myoblasts results in a reduced acquisition of quiescence (via ERK1/2-dependent activation of NF-κB) and an accelerated resumption of proliferation when the cells are being switched from quiescence medium to growth medium (via ERK1/2- and Akt-dependent activation of NF-κB). Moreover, enhancing S100B levels results in resistance to apoptotic stimuli, again in an NF-κB-dependent manner. Thus, intracellular S100B might have a role in the expansion of activated SCs during the muscle regeneration process.

Phosphorylation of the Endoplasmic Reticulum Calcium Sensor STIM1 Underlies Suppression of Store-Operated Calcium Entry during Mitosis.
J. T. Smyth1, J. G. Petranka1, R. R. Boyles1, W. I. DeHaven1, M. Fukushima1, K. L. Johnson2, J. G. Williams2, J. W. Putney1; 1Laboratory of Signal Transduction, NIEHS/NIH, Research Triangle Park, NC, 2Laboratory of Structural Biology, NIEHS/NIH, Research Triangle Park, NC

When endoplasmic reticulum (ER) Ca2+ stores are depleted due to physiological Ca2+ release or pharmacological perturbation, Ca2+ influx via plasma membrane (PM) Ca2+ channels is activated by store-operated Ca2+ entry (SOCE). SOCE involves Orai1 Ca2+ influx channels and STIM1 ER Ca2+ sensors. ER Ca2+ depletion induces rearrangement of STIM1 from a diffuse
localization throughout the ER membrane into punctate structures near the PM, where it activates Orai1 channels. Thus, rearrangement of STIM1 into near-PM puncta is a critical step in the SOCE pathway. Interestingly, SOCE is strongly suppressed during mitosis, the only known physiological situation in which SOCE is negatively regulated; however, the mechanisms that underlie SOCE suppression during mitosis are unknown. We found that both endogenous STIM1 and expressed eYFP-tagged STIM1 (eYFP-STIM1) immunoprecipitated from mitotic but not interphase HeLa and HEK293 cells were recognized by the phosphospecific MPM-2 antibody, suggesting mitosis-specific phosphorylation of STIM1. We also found that rearrangement of eYFP-STIM1 into near-PM puncta in response to ER Ca2+ depletion was suppressed during mitosis. We therefore hypothesized that STIM1 phosphorylation underlies prevention of STIM1 puncta formation and suppression of SOCE during mitosis. MPM-2 recognizes phospho-serine or threonine followed by proline, and human STIM1 contains 10 occurrences of S/T-P, all downstream of amino acid 482. eYFP-STIM1 truncated at amino acid 482 (482STOP) was not recognized by MPM-2 when immunoprecipitated from mitotic cells, suggesting lack of phosphorylation. In support of our hypothesis, non-phosphorylatable 482STOP co-expressed with Orai1 rearranged into near-PM puncta in response to ER Ca2+ depletion in mitotic cells, and also significantly rescued mitotic SOCE. A combination of mass spectrometry and site-directed mutagenesis identified S486 and S668 as mitosis-specific phosphorylated residues, and mutation of both to alanine also resulted in partial but significant rescue of SOCE in mitotic cells. Therefore, our data suggest that phosphorylation of S486 and S668 underlies suppression of SOCE during mitosis, although additional phosphorylation sites are likely involved.

Deletion Mutation Analysis Demonstrates a Biphasic Response to an Extracellular Calcium Pulse in Saccharomyces cerevisiae: Implications for a Mathematical Model of Calcium Homeostasis.

P. A. Marshall, F. J. Solis, H. Wang; Division of Mathematical and Natural Sciences, Arizona State University, Phoenix, AZ

We are interested in identifying and mathematically modeling the roles of the key proteins involved in regulation of calcium homeostasis in Saccharomyces cerevisiae over a time frame of thirteen minutes post calcium pulse. We assay this by transforming the yeast cells with a cytosolic aequorin reporter gene that gives off light in proportion to cytosolic calcium. Cells are placed in a luminometer and are pulsed with 100mM (final concentration) calcium chloride. Luminosity is followed over a 13 minute time period. Deletion strains of VCX1, PMR1, and PMC1 demonstrate an immediate phenotypic deviation from the wild type response to calcium, as they are not able to regulate their cytosolic calcium levels as well as the wild type strain (Marshall et al., 2009, Discrete and Dynamical Systems Series B, volume 12: 439). Wild type cells respond to this calcium pulse with a transient increase in their cytosolic calcium, and then the cytosolic calcium level of these cells returns to approximately pre-pulse baseline concentration, where it remains steady for the entirety of the assay time. At early time points after the calcium pulse, a calmodulin mutant (cmd1-6), deletions of CNB1, CRZ1, CMK1, and CMK2 behave as wild type, with cytosolic calcium rising to over 10 micromolar and then dropping back to approximately baseline. However, 6 minutes post calcium pulse, cytosolic calcium levels again rise above baseline in these mutants. Based upon this data, we propose that yeast respond immediately to intracellular calcium with sequestration into the endoplasmic reticulum/Golgi and vacuole via Pmr1p, Pmc1p, and Vcx1p, and that, at 6 minutes, a second response occurs mediated by calmodulin through calmodulin kinases, calcineurin, and Crz1p. We propose a new mathematical model to account for this biphasic response; the model incorporates a time delay in the feedback loop associated with the activity of calmodulin, calcineurin, and Crz1p.

Clathrin Function Is Essential for Centrosome Maturation and Maintenance of Normal Centrosome Number.

A. B. Foraker, C. Chen, T. M. Evans, C. Esk, F. M. Brodsky; Biopharmaceutical Sci., University of California San Francisco, San Francisco, CA
Clathrin (clathrin heavy chain 17 (CHC17)) is known for its role in endocytosis and membrane traffic. Recent studies further implicate CHC17 in centrosome maturation (Shimizu et al., J Cell Sci., 2009). Objective: The aim of this study is to demonstrate if and how clathrin affects mechanisms of centrosome duplication and maturation. Methods: HeLa cells stably expressing GFP-α-tubulin or centrin-2-GFP were depleted of clathrin proteins (CHC17, clathrin light chain (CLC), or muscle-enriched clathrin heavy chain (CHC22)) using siRNA-mediated RNAi and compared to cells treated with non-silencing siRNA. Cells were examined for the subcellular localization (immunofluorescence (IF) confocal microscopy) and centrosome protein levels (western blotting) for γ-tubulin, pericentrin and centrin-2. Results: Clathrin depletion in mitotic HeLa-GFP-α-tubulin cells resulted in an increase in amplified centrosomes (>2 centrosomes) as evidenced by γ-tubulin staining. Silencing of CHC17 or CLC alone resulted in a 2-fold increase in amplified centrosomes, and co-depletions (CHC17 + CLC) enhanced this effect by 3-fold. These results correlated with an increase in multipolar mitotic spindles. Furthermore, centrosome integrity was compromised as evidenced by a loss in the fluorescence intensity and focusing of γ-tubulin and pericentrin. In contrast, CHC22 depletion did not reveal significant spindle or centrosome defects. Interphase HeLa-centrin-2-GFP cells depleted of CHC17 revealed a 1.5-fold increase in centriole amplification (> 4 centrioles). Centrosome fragmentation was also evident by satellite formation of centrin-2-GFP foci and non-clustered pericentrin staining. Mitotic HeLa-centrin-2-GFP cells depleted of CHC17 and/or CLC also revealed amplified centrosomes and centrioles. Again, CHC22 depletion did not result in significant aberrations in centrosome or centriole number. Conclusions: CHC17 and CLC are revealed to be important in maintaining normal centrosome and centriole numbers and organelle maturation. This process may reflect the interaction between clathrin and cyclin G-associated kinase (GAK) as reported by Shimizu and colleagues (2009).

Spatial Regulation of the Spindle Assembly Checkpoint in Aspergillus and Disruption of BubR1 Localization by a Gamma-Tubulin Mutation.
H. D. Edgerton-Morgan1, T. Nayak1,3, B. Oakley1,2; 1Molecular Genetics, The Ohio State University, Columbus, OH, 2Molecular Biosciences, University of Kansas, Lawrence, KS, 3Pathology and Cell Biology, Columbia University, New York, NY

We have previously found that mutations in the Aspergillus nidulans γ-tubulin gene, mipA, cause defects in mitotic regulation. To clarify the role of γ-tubulin in mitotic regulation, we have C-terminally tagged a number of mitotic regulatory proteins under the control of their own promoters and examined, by time-lapse microscopy, their localization patterns in control strains and in strains carrying a γ-tubulin mutation, mipAD159. Here, we report the localization patterns of the spindle assembly checkpoint (SAC) proteins Mps1, Mad2, Bub3, and BubR1. In interphase, as recently reported (De Souza et al., 2009, Mol. Biol. Cell, 20:2146-2159) Mad2 is located in dots at the nuclear periphery. Mps1 localizes to the spindle pole body/kinetochore (SPB/K) complex beginning in S/G2, with the fluorescence gradually becoming brighter as the cell proceeds through G2. Bub3 is present in the nucleoplasm in interphase, and BubR1 does not show a distinctive localization. It is excluded from nuclei and appears to be diffuse in the cytoplasm. at mitotic onset, Mad2 and BubR1 translocate to the SPB/K complex and Bub3 is reduced in the nucleus except at the SPB/K complex. Thus, all four components come together at the SPB/K complex at mitotic onset, allowing formation of the mitotic checkpoint complex (MCC). Since the MCC components are physically separated until mitotic onset, it follows that the SAC cannot be activated until this point and, thus, that there is a precise spatial regulation of the SAC. In a mipAD159 strain, Mps1 and Bub3 localize normally, but BubR1 fails to localize to the SPB/K complex in a subset of nuclei. This indicates an important role of γ-tubulin in the accumulation of BubR1 upon mitotic onset and shows that BubR1 is not required for localization of Mps1 or Bub3 to the SPB/K complex. Previous work in our lab shows that mipAD159 causes constitutive activation of the anaphase promoting complex/cyclosome (APC/C) in a subset of nuclei. Since BubR1 has two KEN boxes that are predicted to be recognized by the APC/C, it is probably being continuously
targeted for degradation by the APC/C in these nuclei. Supported by grant GM031837 from the NIH.

Testing a Licencing Model for DNA-Damage Induced Centrosome Amplification.
B. Inanc, H. Dodson, C. G. Morrison; Centre for Chromosome Biology, School of Natural Sciences, National University of Ireland Galway, Galway, Ireland

The centrosome, which is the major microtubule organizing center in eukaryotic cells, duplicates once, and only once, during each cell division cycle. This limitation is due to a centrosome-autonomous inhibition of reduplication after S phase. However, centrosome overduplication can occur in cells exposed to various forms of DNA damage. In these cells, centrosome duplication is uncoupled from the DNA replication cycle and this can result in the formation of multipolar mitotic cells, and in some cases cell death. To understand how DNA damage-induced centrosome amplification occurs, we have explored two hypotheses. According to an ‘activation model’ an activating signal stimulates centriole duplication, whereas in a ‘licencing model’, an inhibitory signal that normally limits the duplication of the centrosome to once per cell cycle is lost as a result of DNA damage. In this study we investigated which model applies to DNA damage-induced centrosome amplification. Synchronized populations of human U2OS osteosarcoma cells were irradiated at defined stages in the cell cycle and then fused using polyethylene glycol treatment. Live cell imaging of fusions between wild-type U2OS cells and Nedd1-GFP or Centrin2-GFP expressing U2OS cells revealed that the Nedd1-GFP or Centrin2-GFP incorporates into the centrosomes of the wild-type fusion partner. These findings were consistent with our preliminary fluorescence recovery after photobleaching (FRAP) analysis of Nedd1 and Centrin2, which suggests that both proteins recover rapidly. Therefore, we used immunofluorescence microscopy to score the number of heterotypic cell fusions with amplified centrosomes. We saw significantly more centrosome amplification in cell fusions of irradiated G2 cells than in irradiated G2-unirradiated G2 fusions. These findings suggest that an inhibitory signal intrinsic to G2 centrosomes is lost upon IR treatment and that this leads to the overduplication of only the irradiated G2 centrosomes in fused cells. We suggest that a licensing model applies to centrosome amplification after DNA damage.

584/B531
Causes and Consequences of Centrosome Amplification.
P. C. Conroy, C. Saladino, C. G. Morrison; Centre for Chromosome Biology, School of Natural Sciences, National University of Ireland, Galway, Galway, Ireland

Genome instability and aneuploidy are common characteristics of many tumours. Supernumerary centrosomes are also observed in many tumour cell lines, leading to the model that during mitosis, cells with multiple centrosomes fail to divide properly. This may result in progeny with an unbalanced complement of chromosomes. One model for how centrosome amplification occurs is that centrosomes amplify during an extended cell cycle arrest following DNA damage. We wished to investigate mechanisms by which centrosome/centriole amplification can occur and the outcome of such amplification. A range of candidate centrosomal genes were also screened by quantitative RT-PCR to investigate possible differences in transcriptional levels after DNA damage. The mRNA levels of several candidates altered following ionising radiation. We will examine how these candidates affect centrosome activity after ionising radiation. Inhibition of CDK1 leads to an extended delay in G2 phase, as cells cannot enter mitosis. Following CDK1 inhibition by the small molecule RO3306 in untransformed hTERT-RPE1 cells, we observed up to 26% of cells with more than two centrosomes after 30 hours. After RO3306 washout, ~20% of cells quickly re-entered the cell cycle into mitosis, with many of the cells with multiple centrosomes forming multipolar spindles when released from the cell cycle block. Immunoblot analysis of phospho-H2AX levels following RO3306 treatment indicated that DNA damage had not occurred. In addition, we have generated an inducible PLK4 allele in human osteosarcoma U2OS cells. PLK4 overexpression induces rosettes of daughter centrioles around a single mother centriole. These centriole rosettes are able to form a bipolar spindle leading to a seemingly
normal cell division. However, the subsequent cell division is not so organised. Multipolar spindles form, or bipolar divisions with multiple centrosomes occur leading to a disorganised cell division. Using live cell imaging, we aim to follow the fate of cells in which we have caused multipolar spindles and determine if and how they can complete mitosis. We also aim to determine what death mechanisms are involved in the cells which fail to complete mitosis.

Cdk2 and Cdk4 Prevent Centrosome Amplification by Restricting Excessive Centrosome Cycle Licensing and Duplication.
A. M. Adon, X. Zeng, M. Harrison, H. I. Saavedra; Radiation Oncology, Emory University, Atlanta, GA

The centrosome maintains euploidy by directing the formation of two spindle poles and equal segregation of sister chromatids during mitosis. To maintain a normal content of one or two centrosomes, the centrosome duplication cycle is tightly regulated. Aberrant centrosome duplication or cytokinesis results in centrosome amplification (CA) and aneuploidy, a major form of chromosome instability (CIN). As most human cancers display elevated frequencies of CA and CIN, they may contribute to the genesis and sustenance of most cancers. Cyclin E1-//-E2-//- or Cdk2-//- mouse embryonic fibroblasts (MEFs) grow slowly and harbor normal centrosomes, suggesting redundancy in the regulation of the cell and centrosome duplication cycles. Here we find that ablated Cdk2 or Cdk4 abrogates centrosome amplification and chromosome instability in p53-/- MEFs. They both inhibit centrosome amplification by restricting centriole reduplication in p53-/- MEFs. Ablated Cdk2 or Cdk4 regulate normal licensing by restoring normal levels of NPMT199 in p53-/- MEFs to wild-type levels. Our findings demonstrate that Cdk2 and Cdk4 restrict centrosome amplification.

A Novel Microtubule-Binding Agent Induces Centrosome Hyperamplification and Multipolar Mitosis Causing Mitotic Death, Slippage and Aneuploidy to Facilitate Apoptosis.
V. Pannu1, P. Karna1, R. Padmeshree2, R. Aneja1; 1Biology, Georgia state university, Atlanta, GA, 2Cell biology, Emory university, Atlanta, GA

Aberrant spindle organization leading to chronic mitotic arrest and eventually, apoptosis is a characteristic feature of most tubulin-binding drugs. However, the exact nature and mechanism of the arrest, and factors dictating abnormal spindle construction remain elusive. Precise regulation of the centrosome duplication cycle is a prerequisite for the prevention of chromosome missegregation that results in aneuploidy. Although induction of centrosome amplification and aneuploidy have been long considered as characteristics of malignant tumors, it is becoming appreciated that induction of high-grade aneuploidy is in fact, death-inducing. Here we show that a novel microtubule-modulating agent, 9-bromonoscapine, targets the centrosome duplication cycle, uncoupling it from DNA replication during early S phase resulting in centrosome hyperamplification and formation of aberrant multipolar spindles. Using synchronized HeLa cells, cell-cycle phase-specific treatments show that excluding S and early G2 phase from drug treatment results in loss of both spindle multipolarity and consequent cell death. These data demonstrate that the drug cytotoxicity window is the S/early G2 phase during which 9-bromonoscapine alters the expression of an array of key centrosome duplication regulators, such as Plk4, cdk2/cyclin A/E, pRb, and Aurora A. Supernumerary centrosomes and multipolarity lead to an activated mitotic checkpoint resulting in a prolonged mitotic arrest. The durability of this mitotic arrest appears to be a determinant of drug-induced cell death. Complex signaling networks then dictate decisions made by cells to choose among mitotic death, mitotic exit, abnormal cytokinesis and ensuing aneuploidy, as various available strategies to die. Our data show that drug-induced centrosome hyperamplification, causing multipolar mitosis and high-grade aneuploidy followed by cell death, is a novel chemotherapeutic strategy.

cIAP1 Is a New Activator of E2F-1 Transcription Factor.
J. Cartier1,3, A. Marivin1,3, A. Dupoux1,3, V. Edmond2, S. Plenchette1,3, E. Solary1,3, B. Eymin2, L. Dubrez-Daloz1,3, 1Mort cellulaire et Differentiation des monocyte, INSEM U866, Dijon, France, 2Equipe Bases Moléculaires de la Progression des Cancers du Poumon, Inserm U823, Grenoble, France, 3Institut Fédératif de recherche (IFR) 100, University of Burgundy, Dijon, France

The inhibitor of apoptosis protein cIAP1 (cellular inhibitor of apoptosis protein-1) is an E3 ubiquitin ligase that displays oncogenic properties. In the cytoplasm, the protein is a potent regulator of TNF receptor family and NF-κB signalling pathways. In many cell types, however, cIAP1 is mainly expressed in the nucleus which is not in accordance with its cell signalling activity. The study objective was to investigate the nuclear function of cIAP1. We showed that cIAP1 is a regulator of cell proliferation. We demonstrate by GST-pull down and immunoprecipitation of endogeneous proteins that cIAP1 directly interacts with E2F1 transcription factor. It stimulates its transcriptional activity in a gene reporter assay, as efficiently as the well-known E2F-1 co-activator DP1. We demonstrate by ChIP experiments that cIAP1 is recruited, along with E2F1, on E2F binding site of the promoter of cyclin E and A, in a cell cycle dependent manner. cIAP1-siRNA inhibits the recruitment of E2F-1 on cyclin promoters and reciprocally, E2F-1 si-RNA blocks the DNA recruitment of cIAP1. cIAP1 can stimulate the cyclin E promoter in gene reporter assay which is completely abolish by a mutation into E2F binding site. Lastly, we demonstrated that cIAP1 modulates the transcriptional expression of cyclin E and interferes with the progression of cell into S phase of cell cycle. The ability of cIAP1 to stimulate E2F-1 transcription activity may account for its oncogenic properties.

588/B535
CKβ8/CCL23 Induces Up-Regulation of Cyclins via Gi/Go Protein/PLC/PKCδ/ERK Leading to Cell Cycle Progression.
J. Kim1, Y. Kim2, J. Ko1; 1School of Life Sciences and Biotechnology, Korea University, Seoul, Korea, South, 2Department of Biomedical Laboratory Science, Yonsei University, Wonju, Korea, South

CKβ8/CCL23 is a CC chemokine and alternative splicing of the CKβ8 gene produces two mRNAs that encode CKβ8 and its isoform CKβ8-1. Chemokines play a critical role in leukocyte trafficking and development of inflammation and a kind of chemokines are also known to be involved in cell proliferation. To investigate implication of CKβ8 and CKβ8-1 in cell proliferation, we examined the effects of CKβ8 and CKβ8-1 in cell cycle. CKβ8 and CKβ8-1 induced cell cycle progression. Next, we investigated whether MAPKs are involved in CKβ8- and CKβ8-1-induced cell proliferation. CKβ8- and CKβ8-1-stimulated cells showed phosphorylation of ERK1/2 and inhibitor study indicated that CKβ8- and CKβ8-1-induced activation of ERK1/2 is mediated by Gi/Go protein, PLC and PKCδ. CKβ8 and CKβ8-1 regulated expression of cell cycle regulators including cyclin D3 and cyclin B1 and immediate early response genes such as c-Myc and Egr-1. These results suggest that CKβ8 and CKβ8-1 are involved in cell proliferation by modulating cell cycle regulators.

The Abbreviated Self-Renewal Cell Cycle of Human Embryonic Stem (hES) Cells Depends on Cyclin D2 Related Activation of the CDK Substrate p220/NPAT at Histone Locus Bodies.
P. N. Ghule, K. A. Becker, J. B. Lian, J. L. Stein, A. J. van Wijnen, G. S. Stein; Center for Stem Cell Biology and Regenerative Medicine, Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA

We have examined fundamental parameters of hES self renewal, and the molecular mechanisms that control progression into S phase. BrdU incorporation, FACS analysis, and Ki67 staining revealed that the G1 phase of hES cells is abbreviated (~2.5 h). Autocrine mechanisms sustain this abbreviated cell cycle and mitotically synchronized hES cells are competent to initiate two consecutive S phases in the absence of exogenous growth factors. Differentiation of hES cells alters cell cycle kinetics by lengthening G1 within 72 h. Thus, the abbreviated G1 phase is
functionally linked to pluripotency. We also find that histone H4 gene expression is cell cycle regulated in hES cells and linked to CDK phosphorylation of the NPAT/HiNF-P complex interacting with histone genes at Histone Locus Bodies (HLBs). We show that HLBs in hES cells represent cell cycle dependent microenvironments that integrate transcriptional initiation and 3' end processing of histone gene transcripts. Molecular analyses demonstrate that Cyclin D2 is prominently expressed in pluripotent hES cells, but cyclin D1 eclipses cyclin D2 during differentiation. Depletion of cyclin D2 or NPAT causes a cell cycle defect in G1 and diminishes (i) phosphorylation of NPAT, (ii) histone H4 expression and (iii) S phase progression. Thus, cyclin D2 and NPAT are principal cell cycle regulators that determine competency for self-renewal in pluripotent hES cells. While pRB/E2F checkpoint control is relinquished in human ES cells, fidelity of physiological regulation is secured by cyclin D2 dependent activation of the NPAT/HiNF-P mechanism that may explain perpetual proliferation of hES cells without transformation or tumorigenesis.

Transcription Factor II(TFII) Expression of Liver Regeneration and Development in Mouse.
Y. Hwang, Y. Choi, H. Choi, D. Kwak, S. Hong, D. Kim, Y. Jeung; Division of Biological Science, Incheon, Korea, South

BACKGROUND and PURPOSE: Liver has a strong ability of regeneration after hepatic injury or resection. It has been reported that growth factors such as hepatocyte growth factor(HGF), epidermal growth factor(EGF), transforming growth factor(TGF) and cytokines including interleukins -1(IL-1) and -6(IL-6), tumor necrosis factor-alpha(TNF-α) participate in liver regeneration. However, the correct mechanism of liver regeneration is not fully understood. To understand liver regeneration process, we compare the genes involved in liver regeneration and development. METHOD: We used ICR mice and divided into 4 groups; fetus, adult mice operated hepatectomy, adult mice treated carbon tetrachloride (CCl4), and normal adult mice. Developing livers are obtained from E10.5, E12.5, and E14.5. Regenerating livers are acquired from operated adult mice and CCl4 treated mice. Hepatectomy is 68% resection of adult liver and liver cirrhosis is induced by intraperitoneal (IP) injection of CCl4. After hepatectomy and carbon tetrachloride treatment, TFII protein expression of 4 groups are analyzed by western blot. RESULT: TFII expression of regenerating liver reveals that genes associated with metabolism are somewhat down-regulated. The genes related to DNA synthesis and cell cycle regulation are up-regulated. We studied the expression TFII protein of developing liver, the data suggest that some genes associated with regeneration are also expressed in the mouse fetus liver. Our study suggests that these genes may have crucial roles in the liver growth.

The Mitosis to Interphase Transition Is Coordinated by Crosstalk between the SIN and MOR NDR Kinase Pathways in the Fission Yeast S. Pombe.
S. Ray¹, K. Kume², D. Hirata², D. McCollum¹; ¹Molecular Genetics and Microbiology, University of Massachusetts Medical School, Worcester, MA, ²Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashi Hiroshima, Japan

The NDR/LATS family of kinases are highly conserved from yeasts to humans and function at the end of related signaling cascades. Fission yeast, like humans, possess two NDR kinase pathways, one called the SIN (LATS pathway in humans) is required for cytokinesis and the other called the MOR (human NDR1/2 pathway) is required for interphase polarity. In animal cells the LATS and NDR1/2 pathways also function in cytokinesis and cell polarity respectively as in yeast. In addition both these pathways have been implicated in regulation of tumor formation. However it is unclear whether the activities of these pathways are coordinated. Our work in fission yeast shows that cross-talk between the SIN and MOR pathways is required to coordinate the discrete programs for cytoskeletal remodeling that exist in interphase and mitosis. at the end of mitosis the SIN pathway not only promotes cytokinesis, but also inhibits the MOR pathway to block reformation of the interphase cytoskeleton until cytokinesis is complete, presumably to keep the
MOR from competing for shared components such as actin. SIN signaling inhibits the kinase activity of the most downstream MOR component, the Ndr-family kinase Orb6. We show that the SIN regulates the localization of the upstream activators of Orb6 called Nak1 and Pmo25, providing a potential mechanism by which the SIN inhibits Orb6 activity. Inactivation of the MOR pathway stabilized the actomyosin ring in SIN mutants allowing them to complete cytokinesis. Together our results identify a mutually antagonistic relationship between the SIN and MOR pathways that is crucial for establishing and maintaining the discrete cytoskeletal arrangements that occur in cytokinesis and interphase. Given the functional conservation of these pathways our results may define general mechanisms by which mitotic and interphase cytoskeletal arrangements are coordinated.

The Spindle Position Checkpoint Requires Positional Feedback from Cytoplasmic Microtubules.
J. Moore¹, V. Magidson², A. Khodjakov², J. A. Cooper¹; ¹Cell Biology, Washington University, St Louis, MO, ²Wadsworth Center, Albany, NY

The objective of mitosis is to provide a copy of the genome to each progeny of a cell division, which requires the separation of duplicate chromatids by the spindle apparatus, and the delivery of one set of chromosomes to each of the daughter cells. In budding yeast, the fidelity of chromosome delivery depends on the spindle position checkpoint, which inhibits mitotic exit until one end of the anaphase spindle arrives in the bud. Here, we tested the hypothesis that activating and maintaining the spindle position checkpoint depends on persistent interactions between cytoplasmic microtubules and the mother-bud neck, the future site of cytokinesis. We used laser ablation to disrupt microtubule interactions with the bud neck, and we found that loss of microtubules from the neck leads to mitotic exit in checkpoint-activated cells. Our findings suggest that cytoplasmic microtubules are used to monitor the location of the spindle in the dividing cell, and in the event of positioning errors, relay a signal to delay the completion of mitosis until the spindle is appropriately positioned.

Regulation of G1-S Transition by a Hyperfused Form of Mitochondria.
K. Mitra, R. Rikhy, C. Wunder, J. Lippincott-Schwartz; CBMP, NICHD, Bethesda, MD

Mitochondria undergo fission-fusion events that render these organelles highly dynamic in cells. By using tissue culture cells and drosophila as model systems we report a relationship between mitochondrial form and cell cycle control at the G1-S boundary. Live cell imaging of mitochondria in tissue culture cells revealed that at G1-S transition mitochondria convert from isolated, fragmented elements into a hyperfused, giant network. The network was electrically continuous and exhibited greater ATP output than mitochondria at any other cell cycle stage. Depolarizing mitochondria at early G1 specifically prevented progression into S, suggesting that increased mitochondrial function at G1-S is necessary for progression into S phase. Inducing hyperfusion of mitochondria in quiescent cells (i.e., maintained without growth factors) by acute inhibition of dynamin-related protein-1 (DRP1) led the cells to begin replicating their DNA, and coincided with buildup of cyclin E, the cyclin responsible for G1 to S phase progression. Prolonged or untimely formation of hyperfused mitochondria in cells, through chronic inhibition of DRP1, caused defects in mitotic chromosome alignment and S phase entry defect characteristic of cyclin E overexpression. As these defects were found to be dependent on p53 in tissue culture cells we hypothesized that in absence of p53 hyperfusion of mitochondria would induce hyperproliferation by overexpressing cyclin E. Indeed, constitutive maintenance of hyperfused mitochondria in drosophila, by inducing DRP1 knockout, leads to aberrant increase in cyclin E levels and activity in the somatic follicle in the ovary. This results in hyper-proliferation of the DRP1 knockout somatic follicle cells and they escape differentiation into epithelial cells, thus, producing aberrations in ovariole formation. Based on these findings, we conclude that changes in mitochondrial morphology during the cell cycle underlie proper cell cycle progression. Moreover,
we propose that a hyper-fused mitochondrial system with specialized properties is formed at G1-S and is linked to cyclin E buildup for regulation of G1 to S progression.

**Cyclin Limitation and Nuclear Size Promote Asynchronous Division of Nuclei in a Common Cytoplasm.**  
D. Nair, C. D’Ausilio, P. Occhipinti, M. E. Borsuk, A. S. Gladfelter; Biological Sciences, Dartmouth College, Hanover, NH

Genetically identical cells that share the same environment vary in the length of their cell division cycles. In some multinucleate cells, variable and asynchronous nuclear division cycles are observed in nuclei residing in the same cytosol. How temporal variation is generated and tolerated within the precise regulatory controls of the cell cycle is not well understood. Here we show in a model multinucleate fungus, *Ashbya gossypii*, that variability and asynchrony in nuclear division timing require an Rb-analogue, Whi5p, a transcriptional repressor of the G1/S transition. Mutants lacking Whi5p or proteins that act upstream or downstream of Whi5p all have significantly more synchronous nuclear division cycles. Unlike in *Saccharomyces cerevisiae*, in *A. gossypii* Whi5p is nuclear across all stages of the cell cycle, indicating that Whi5p is inhibited within the nucleus. Doubling the gene dose of CLN1/2 is sufficient to induce partial synchrony, suggesting that Whi5p may contribute to variable cycle times by limiting the levels of Cln1/2p. Additionally, we observed that nuclear volume is highly variable in a population of nuclei and not equally partitioned in mitosis. We use mathematical modeling to examine how limited G1 cyclin levels can combine with variable nuclear size to promote heterogeneous nuclear division kinetics. This work indicates that nuclear geometry can amplify cell to cell variability and influence timing of the division cycle.

**Nup2, and a Novel Nucleoporin NupA, Have Essential Functions at Mitotic Chromatin Controlled by the Nima Kinase.**  
S. Markossian, A. H. Osmani, S. A. Osmani; Molecular Genetics, The Ohio State University, Columbus, OH

In *Aspergillus nidulans*, the NIMA kinase is required for the transition from G2 into mitosis by regulating the reversible mitotic disassembly of nuclear pore complexes (NPCs), the gateways between the nucleus and the cytoplasm. How NIMA regulates this process, and the mitotic functions of nuclear pore proteins, are not understood. The potential mitotic role of Nup2 is of particular interest because it has the unique ability to transfer from NPCs exclusively to chromatin at mitosis, a translocation observed in *A. nidulans* and vertebrate cells. This remarkable feature, and the fact that Nup2 is essential in *A. nidulans*, suggest Nup2 might play essential mitotic roles downstream of NIMA that are conserved from fungi to humans. We have determined that induction of NIMA promotes both Nup2 phosphorylation and its relocation from NPCs onto chromatin, even in S-phase arrested cells. To help define Nup2’s function at mitotic chromatin, we affinity purified Nup2 from G2 and mitotic samples. Mass spectroscopy identified a novel nucleoporin, NupA, that copurified with Nup2 from both samples. Like Nup2, NupA transfers from NPCs in interphase to mitotic chromatin and is also essential. Deletion analysis and heterokaryon rescue revealed that the function of NupA is to tether Nup2 to both the NPC and mitotic chromatin. Like Nup2, NupA is highly phosphorylated during mitosis and deletion of either does not cause defects in nuclear transport but does cause identical mitotic DNA segregation defects. These studies demonstrate that the mitotic promoting functions of NIMA involve not only disassembly of NPCs but also the translocation of Nup2, and the newly discovered NupA protein, onto mitotic chromatin. The studies also reveal that the function of NupA is to locate Nup2 to NPCs and mitotic chromatin where both are required for normal mitosis.

**Evolution of Combinatorial Phosphoregulation in the Cell Cycle.**
Complex cellular processes are often orchestrated by master regulatory kinases. As organisms evolve, these kinases coordinate the functions of a shifting set of substrates, and as new kinases emerge through gene duplication and divergence, combinatorial control of substrate activities can provide a selective advantage. To better understand the evolution of phosphoregulation, we analysed the position and conservation of large numbers of phosphorylation sites for the cyclin-dependent kinase, Cdk1, and the related kinase, Ime2, in the budding yeast Saccharomyces cerevisiae. We used quantitative mass spectrometry to identify about 300 Cdk1 substrates and 400 Ime2 substrates in vivo. We found that Cdk1 and Ime2 phosphorylate a highly overlapping set of proteins at distinct sites that often cluster together. Comparisons of S. cerevisiae kinase substrates with orthologues throughout the ascomycete lineage allowed inference of the evolutionary dynamics of phosphoregulation. The precise position of most phosphosites is not conserved; instead, they often drift within rapidly evolving disordered regions. We propose that most phosphoregulation depends on simple non-specific mechanisms involving the disruption of protein complexes or the generation of interactions with modular phosphopeptide-binding domains. The gain or loss of phosphosites in rapidly evolving regions could facilitate the evolution of kinase signaling circuits and enable the integration of inputs from multiple kinases as new circuits evolve.

Vasa Is Essential for Cell Cycle Progression.
M. Yajima, G. Wessel; Brown University, Providence, RI

Several genes expressed in germ cells and stem cells are conserved throughout the animal kingdom. Recently some of these genes were found to function more broadly than originally anticipated. Vasa is a conserved ATP-dependent RNA helicase that functions in germ cells and many stem cells from cnidarian to mammals. Although implicated in translational regulation, the function of Vasa is poorly understood. Here we report a novel function of Vasa in sea urchin embryos. We found that Vasa protein is present in all blastomeres of the early embryo, and that its abundance oscillates with the cell cycle. During M-phase, Vasa selectively accumulates in the perinuclear region, and then enters the nuclear region following nuclear envelope breakdown. It associates with the spindle and the separating sister chromatids at metaphase, and then quickly disappears after telophase. Vasa organization during M-phase appears to be independent of microfilaments, but requires microtubules. Inhibition of Vasa protein synthesis slowed the cell cycle, maybe caused by chromosomal segregation deficiency. Further, the knock down of Vasa protein reduces general translation. These results demonstrate an active and selective role for an RNA-helicase in microtubule dynamics that implicates a regulatory role for RNA structure in spindle function. In addition, this work describes a novel function of Vasa as a general translation factor in embryonic stem cells.

CyclinB1 Is Essential for the First Divisions of the Mouse Embryo.
B. Strauss, M. Zernicka-Goetz, J. Pines; Zoology, The Gurdon Institute, University of Cambridge, Cambridge, United Kingdom

The Cyclin B-Cdk1 complex is required in all eukaryotes to initiate entry into mitosis. Although it has been shown that mice lacking Cyclin B1 cannot be detected in late embryogenesis, the stage in development at which Cyclin B1 becomes essential is unknown. Furthermore, many functional aspects of Cyclin B1, including its highly dynamic subcellular localization, are not yet fully understood. Most of the data on Cyclin B1 function and localization have been generated in cultured cell lines in which the effects of Cyclin B1 depletion by RNAi are difficult to interpret due to variable levels of knock down. To set up a system with a clean Cyclin B1 null background we have re-established a knock-out mouse line that was generated by Michael Brandeis and
colleagues in 1998 (a kind gift of Dr Tim Hunt). We have set up live-imaging of pre-implantation embryos to analyse the phenotype of Cyclin B1 null cells in greater detail, as well as to be able to use such cells to study Cyclin B1 function by re-expressing mutants of Cyclin B1. Here we show that Cyclin B1 null embryos arrest at day 2 of development after only one or two divisions. Thus Cyclin B1 is the earliest Cyclin required for development to date. Using live imaging we characterise the arrest phenotype and show at which stage in the cell cycle the arrest occurs.

Role of MAPKAP-K2 in the G2/M Transition and Apoptosis in Response to Oxidative Stress.
N. de Olano, R. Aligué; University of Barcelona, Barcelona, Spain

The p38 MAPK is involved in the transmission, amplification and diversification of extracellular signals by initiating different cellular responses including the regulation of cell proliferation. p38 is phosphorylated and activated in response to cellular stress by MKK3/6 and in turn phosphorylates a number of substrates, including MAPKAP-K2 (MK2). It has been demonstrated that MK2 can directly phosphorylate Cdc25B and Cdc25C, inhibiting the G2/M transition. In addition, a similar mechanism of cell cycle control has been described for this kinase in fission yeast: Srk1, a downstream kinase of yeast Sty1 (p38 MAPK), controls mitotic entry by directly phosphorylating and inhibiting Cdc25 during osmotic stress. Here we show that MK2 and MK3 are necessary to inhibit the G2/M transition in response to non-genotoxic stress. Moreover, stress conditions induce MK2-dependent apoptosis through activation of the E2F1 transcription factor.

Meiosis and Mitosis I (600 – 627)

DALEK6: The Missing LINC for Mammalian Meiosis.
K. J. Roux1, D. Kim1, H. Horn2, C. L. Stewart2, B. Burke1,2; 1Anatomy and Cell Biology, University of Florida, Gainesville, FL, 2Institute of Medical Biology, Singapore, Singapore

A striking characteristic of meiotic prophase is an association between the ends of condensed chromosomes with the nuclear envelope (NE). During the zygotene stage of prophase these NE-attached telomeres are transiently redistributed towards the centrosomal pole of the nucleus, forming a structure called the meiotic bouquet that is believed to facilitate homologous chromosome alignment. In mammals the inner nuclear membrane protein Sun1 is required for this chromosomal-NE attachment. Sun1 is a constituent of the LINC-complex that together with outer nuclear membrane (ONM) KASH proteins forms a translumenal link spanning the NE. The LINC-complex physically connects the cytoskeleton to the nucleoskeleton and, in the case of meiosis, to the chromosomes. What remains unclear is the identity of ONM proteins required for bouquet formation and how they associate with the cytoskeleton to elicit chromosome movement. We have identified a novel ONM protein whose lumenal domain interacts with Sun1 and cytoplasmic domain binds the dynein motor complex. We have named this protein DALEK6. Expression of DALEK6 appears restricted to the testis in males, where it is found to colocalize with Sun1 at telomeres in primary spermatocytes. It is our hypothesis that DALEK6 is the mammalian constituent of the LINC complex that utilizes its association with the minus-end motor, dynein, to generate the meiotic bouquet. We are now in the process of deriving knockout mice in order to examine the role of DALEK6 in vivo.

Mechanisms of Chromosome Segregation on Acentrosomal Spindles during C. elegans Oocyte Meiosis.
S. Wignall, A. Villeneuve; Developmental Biology, Stanford University, Stanford, CA

Although centrosomes serve to organize microtubules in most cell types, oocyte spindles form in their absence. We are investigating how these acentrosomal spindles assemble and...
promote proper chromosome partitioning, using *C. elegans* oocyte meiosis as model. 

Recently, we reported that oocyte spindles have a surprising organization; homologous chromosome pairs (bivalents) are ensheathed by microtubule bundles that run along their sides, whereas microtubule density is low at chromosome ends. Moreover, our previous studies revealed a distinctive feature of bivalent organization. We found that the chromokinesin KLP-19 is targeted to a ring around the center of each bivalent and provides a polar ejection force that is required for congression. The chromosome passenger complex (CPC) also localizes in mid-bivalent rings and is required for proper KLP-19 localization. These observations create a new picture of chromosome/microtubule association in acentrosomal spindles and reveal strategies that oocytes use to achieve chromosome alignment. We are now extending our findings by further analyzing the composition of the midbivalent rings and by investigating how chromosome segregation is accomplished in the context of this distinct organization. 

First, we find that the checkpoint protein BUB-1 (which has been shown by others to colocalize with both outer kinetochore and midbivalent proteins) forms a ring around the center of each bivalent. Localization of BUB-1 to the midbivalent rings (but not to the kinetochores) is regulated by the CPC. Proteins that form midbivalent rings leave the chromosomes in anaphase as the two homologs separate. Interestingly, while members of the CPC appear to associate broadly with the anaphase spindle, BUB-1 and KLP-19 persist in ring structures that remain in the center of the spindle, distant from the segregating chromosomes. Moreover, depletion of KLP-19 causes defects in spindle morphology during anaphase in some oocytes, raising the possibility that these rings may play a role in organizing microtubules at this stage. Current work is focused on testing this hypothesis and on analyzing the forces that drive chromosome segregation during meiosis.

**602/B549 ABSTRACT WITHDRAWN**

**603/B550 Conserved Male-Specific PP1 Phosphatases GSP-3 and GSP-4 Regulate Chromosome Segregation during Spermatogenesis in *C. elegans*.
J. Wu, D. S. Chu; Biology, San Francisco State University, San Francisco, CA**

Proper chromosome partitioning into each haploid sperm during meiosis is important for sperm function. Our lab has previously identified two PP1 phosphatases, GSP-3 and GSP-4, that are required for normal sperm formation in *C. elegans*. GSP-3/4 are 98% identical and are homologous to the mammalian male-specific PP1 phosphatases PP1γ. In mice, knock out of PP1γ results in male infertility. Consistent with the evolutionarily conserved function of these proteins, male worms lacking *gsp-3* and *gsp-4* are infertile and produce anuclear sperm or sperm with a single aberrant bar-like chromosomal mass, indicating defective chromosome segregation. Because GSP-3/4 localize to chromosomes undergoing division, we hypothesize that GSP-3/4 regulate the function of chromosomal proteins that are required for proper chromosome segregation. We have established a protocol that allows live imaging of male meiosis in *C. elegans*. Through live imaging, we found that in *gsp-3 gsp-4* mutant spermatocytes homologous chromosomes are separated at a speed comparable to the wild type. However, the second meiotic division is defective in the absence of *gsp-3* and *gsp-4*. During meiosis II in *gsp-3 gsp-4* mutant spermatocytes, the chromosomes align at the equator at metaphase II but fail to separate from each other when anaphase II starts, resulting in stretched chromosomes. Further cytological analyses show that *gsp-3 gsp-4* chromosome segregation defects do not originate from the failure to remove chromosomal cohesin between sister chromatids, a process facilitated by the aurora B kinase. We found that cohesin REC-8 is normally removed from *gsp-3 gsp-4* mutant spermatocytes. Moreover, the aurora B kinase AIR-2 is normally localized to the chromosomes in the absence of *gsp-3* and *gsp-4*. We are currently investigating if the chromosomes are correctly oriented to face the opposite spindle poles at metaphase II in *gsp-3 gsp-4* mutants. We are also testing if the kinetochore structure is defective in *gsp-3 gsp-4* mutants. These experiments will shed light on the male-specific modulation of molecular mechanism by male meiosis occurs.

**604/B551 The Role of Myosin Phosphorylation in Anaphase Chromosome Movement.**
This work deals with myosin function during cell division. Previous studies indicated that myosin might be involved in anaphase force production (Silverman-Gavrila and Forer, Cell Motil Cytoskeleton, 2003, 55:97; Fabian and Forer, Protoplasma, 2005, 225:169). Fabian et al. [Cell & Chromosome, 2007, 6:1] showed that CalyculinA (CalA), which blocks dephosphorylation of myosin, accelerates chromosome movement, presumably due to hyper-phosphorylation of myosin regulatory light chain (MRLC). They showed also that Y-27632, which inhibits myosin phosphorylation via the Rho-kinase pathway, slowed or stopped anaphase movements, consistent with the possible role of myosin in force production. CalA should not have reversed the effect of Y-27632, since the drug already blocked myosin phosphorylation, but it did. Fabian et al. therefore hypothesized that myosin can be phosphorylated by alternate pathways. We tested this by drug treatments using Y-27632, ML-7 and staurosporine which inhibit Rho-kinase, myosin regulatory light chain kinase and non-specific kinases respectively. Singly or triply all stopped or slowed chromosome movement. CalA did not reverse the effect of staurosporine treatment individually or in combination with Y-27632 and ML-7, consistent with myosin being phosphorylated by alternate pathways. To test the effects of the drugs on MRLC phosphorylation we studied treated cells using four different antibodies against phosphorylated MRLC. Chromosomal spindle fibres in control cells were stained with all antibodies, and there was reduced staining in cells treated with either staurosporine or all three drugs together. This is consistent with drugs causing slowed or stopped chromosome movement via effects on phosphorylation of spindle fibre myosin.

605/B552
Rapid Poleward Movement of Chromosomes Following Laser Microsurgery.
J. R. LaFountain, C. S. Cohan, R. Oldenbourg; Biological Sciences, University at Buffalo, Buffalo, NY, Pathology and Anatomy, University at Buffalo, Buffalo, NY, Marine Biological Laboratory, Woods Hole, MA

The objective was to elucidate the roles of kinetochores of lagging X-Y chromosomes in (a) normal segregation during anaphase B and (b) their rapid poleward movement upon release from its bipolar attachments following laser microsurgery. For normal segregation, X and Y sex univalents in crane-fly spermatocytes each have two sister kinetochores, one attached to a leading kinetochore fiber that shortens and the other to a trailing fiber that elongates. Both leading and trailing kinetochores maintain a “polymerization” state during anaphase. This results in poleward microtubule flux in leading and trailing fibers as anaphase progresses, and thus shortening of leading fibers must occur at their polar ends. Flux was visualized directly via fluorescent speckle microscopy at velocities away from kinetochores of about 0.4μm/min. A laser microbeam was used either (a) to separate sisters or (b) to ablate trailing kinetochores. In either case, resultant poleward movement of a released leading kinetochore was both immediate and impressively more rapid than normal, ranging between 0.8 and 1.7μm/min, the latter being over four times the average flux rate mentioned above. To account for such rapid post-op movement, our interpretation is that following microsurgery, kinetochores may have shifted from a polymerization state (adding tubulin subunits to growing plus ends) to a depolymerization state (removing subunits from shrinking plus ends). After such a shift, leading kinetochore fibers could then shorten from both ends. If so, that leads us to conclude that kinetochores of univalents may indeed have the potential for “Pac-man” activity, but they appear to be maintained in a polymerization (“reverse Pac-man”) state by the resistive tension imparted by kinetochore fibers attached to trailing kinetochores. Upon detachment of a trailing fiber through microsurgery, such tension would be lost and the activation of kinetochore-based depolymerization (Pac-man) could occur.

606/B553
Aurora-C, but Not Aurora-B, Is Required for Meiosis in Mouse Oocytes.
The Aurora kinases play essential roles in many aspects of cell division including the control of centrosome function, kinetochore-microtubule interactions, and cytokinesis. In mammals, three distinct aurora kinase members (Aurora-A, -B, and -C) have been identified and all share similar structures at their central catalytic kinase domains. We previously isolated a novel kinase Aie1, now renamed as Aurora-C, in a screen for kinase expressed in mouse sperm and eggs (DNA Cell Biol. 17, 823-833, 1998). Aurora-C, a close homolog of Aurora-B, is enriched in testicular germ cells and appears to be essential for male mouse meiosis (Dev. Biol. 290, 398-410, 2006). However, the functions of Aurora-C in female meiosis have not been explored. Herein, we examined the roles of Aurora-C during female meiotic divisions in mouse oocytes. Our immunoblotting and immunofluorescence analysis revealed that endogenous Aurora-C kinase protein, but not Aurora-B, was detected in mouse oocytes. Aurora-C was found at the chromosome axes and centromeres at meiotic metaphase I and concentrated at centromeres at meiotic metaphase II. During the anaphase I/telophase I and anaphase II/telophase II transitions, Aurora-C was relocalized to the midzone and midbody. Microinjection of the kinase-deficient Aurora-C (AurC-KD) mRNA into mouse oocytes significantly inhibited endogenous Aurora-C activity in mouse oocytes and caused multiple defects, including lagging chromosomes, aberrant spindle formation, abnormal kinetochore-microtubule attachment, premature chromosome segregation, and interkinesis failure. Furthermore, microinjection of AurC-KD mRNA also reduced histone H3 phosphorylation, Aurora-C phosphorylation, and inhibited centromere/kinetochore localization of Bub1 and BubR1. Interestingly, oocytes with defective Aurora-C kinase activity accumulate kinetochore-microtubules in syntelic attachments and reveal premature segregated chromosomes (most were univalent). We thus propose that Aurora-C may function as a chromosomal passenger protein that regulates chromosome segregation, kinetochore-microtubule attachment and interkinesis during female meiosis in mammals.

Molecular Distinctions between Mammalian Aurora A and B: A Single Residue Change Transforms Aurora a into Correctly Localized and Functional Aurora B.
F. Hans2, D. A. Skoufias3, S. Dimitrov2, R. L. Margolis1,3; 1Burnham Institute for Medical Research, La Jolla, CA, 2INSEM, Institut Albert Bonniot, Grenoble, France, 3Institut de Biologie Structural Jean Pierre Ebel, Grenoble, France

Mammalian Aurora A and Aurora B are paralogue mitotic kinases that share highly similar primary sequence, especially in their catalytic domains. Both are important to mitotic progression, but their localizations and functions are distinct. Aurora a associates with centrosomes and with centrosome proximal microtubules, and both binds to and is activated by TPX2, a microtubule binding protein that localizes Aurora a to the mitotic spindle. In contrast, Aurora B exhibits passenger protein behavior, first associating with the inner centromere, then separating from centromeres to relocate to the spindle midzone during cell cleavage. It binds to and is activated by INCENP, another passenger protein. Aurora B is absolutely required for spindle assembly checkpoint function, correct chromosome segregation and for cell cleavage. Despite their structural similarities, the two proteins have unique spectra of binding partners and of phosphorylation substrates. We have combined shRNA suppression with overexpression of Aurora mutants to address the cause of the distinction between Aurora a and Aurora B. Aurora a glycine residue G198, mutated to asparagine to mimic the aligned asparagine residue N142 of Aurora B, causes Aurora a to bind the Aurora B binding partner INCENP, but not the Aurora a binding partner TPX2. When Aurora B is ablated and replaced with G198N Aurora A, the Aurora a mutant rescues Aurora B mitotic function. We conclude that binding to INCENP is alone critical to the distinct function of Aurora B. Although G198 of Aurora a is required for TPX2 binding, N142G Aurora B retains INCENP binding and Aurora B function. Thus, while a single residue change transforms Aurora A, the reciprocal mutation of Aurora B does not create Aurora a
function. An Aurora A-delta120 N-terminal truncation construct reinforces Aurora A similarity to Aurora B, as it does not associate with centrosomes, but instead associates with kinetochores.

An Enhanced Chemical Genetic Strategy to Allow Covalent Inhibition of the Fission Yeast Aurora Kinase.
A. Koch\textsuperscript{1}, H. B. Rode\textsuperscript{2}, D. Rauh\textsuperscript{2}, S. Hauf\textsuperscript{1}; \textsuperscript{1}Friedrich Miescher Lab., Max Planck Society,Tuebingen, Germany, \textsuperscript{2}Chemical Genomics Centre, Max Planck Society, Dortmund, Germany

Analog-sensitive (as) kinases differ from their natural counterparts by a single amino-acid change in the ATP binding pocket. This so called gatekeeper mutation enlarges the ATP binding site and makes the kinase susceptible to specific inhibitors that typically do not target unmodified kinases. The high conservation of the kinase domain allows identification of the gatekeeper residue in most kinases, and as-kinases have been successfully created in organisms from yeast to human. Here we report on the introduction of a second mutation to successfully target a serine/threonine as-kinase with covalent inhibitors. Through structure-based design we identified a residue close to the ATP binding pocket, whose mutation to cysteine creates an anchor point for irreversible kinase inhibitors. We demonstrated the feasibility of this approach for an as-version of the conserved fission yeast (Schizosaccharomyces pombe) Aurora kinase Ark1. Aurora is essential for the proper execution of mitosis and small-molecule inhibitors selective for Aurora have been crucial to decipher its role during the cell cycle. We employed structure-guided chemical synthesis of a focused library of 4-anilino-quinazolines equipped with diverse reactive groups and show that some of the compounds specifically inhibit Ark1 carrying the gatekeeper mutation as well as the engineered cysteine, but not the kinase with only one of these mutations.

Functional Characterisation of Newly Identified Protein-Interactions of the Cell Cycle Regulatory Kinase Aurora-A.
A. Scholz, T. Kessler, J. Gobom, E. Nordhoff, B. Lange; Max Planck Institute for Molecular Genetics, Berlin, Germany

Besides the centrosome’s classical function as the major microtubule organising center, it has also been implicated in cell cycle control and progression. Identification of cell cycle regulatory proteins at the centrosome strongly argues in favour of this model. Aurora-A is one of these proteins and functions in centrosome maturation. Centrosome maturation describes recruitment of additional proteins to the pericentriolar matrix to increase the microtubule nucleation capacity of the centrosome during mitosis. Furthermore, Aurora-A is involved in cell cycle regulation and is overexpressed e.g. in breast tumours and pancreatic tumours. To define substrate proteins of Aurora-A and the proteins that modulate Aurora-A activity during the cell cycle, we isolated Aurora-A interaction partners via Tandem Affinity Purification (TAP). Using mass spectrometry we identified a total number of 60 interactants. Among these proteins were cell cycle regulatory phosphatases and centrosomal proteins. We identified and confirmed the protein phosphatase 6 as one of the Aurora A interacting proteins. To analyze the functional relevance of this interaction we employed siRNA mediated RNAi in mammalian cells. Knock-down of the protein phosphatases catalytic unit leads to a change in the mitotic index implicating a role in cell cycle control. Using an RNAi approach we investigate the function of the fly homologues of Aurora-A and the protein phosphatases catalytic unit on a cellular and organism level. We demonstrated by immunoprecipitation that the interaction is conserved between human and the fly. Knock-down of aurora in SL2 cells strongly reduces the number of prophase cells with Microtubule Organising Centres (MTOCs) in a protein phosphatase 6 dependent manner. The functional and molecular characterisation of the interplay between the centrosomal kinase Aurora-A and its interacting proteins will contribute to further understanding of this kinases important role in cell cycle control, centrosome structure and microtubule organisation.

Insights into the Role of Aurora B and Mps1 in the Spindle Assembly Checkpoint.
The Spindle Assembly Checkpoint (SAC) is a safety device that monitors microtubule-kinetochore attachment and delays anaphase onset until all sister chromatids have achieved bipolar attachment to the mitotic spindle. Protein phosphorylation by mitotic kinases is crucial for the SAC. Among the core components of the SAC, several proteins, including Aurora B, Bub1, BubR1, and Mps1, have a kinase domain. Here, we report the characterization of two checkpoint kinases, Aurora B and Mps1, using cell-permeable small molecules selectively targeting their kinase activities. Firstly, we describe the characterization of a new Mps1 inhibitor named Reversine as an inhibitor of the SAC. Importantly, Reversine treatment led to undetectable levels of Zwilch and Mad1 at unattached kinetochores, which is consistent with the powerful SAC override observed in the presence of this inhibitor. Intriguingly, we found that after a recovery from a STLC block (that leads to a monopolar spindle with several synthetical KT-MT attachments), Reversine-treated cells show a large number of mis-aligned chromosomes, indicating that besides its role in the SAC, Mps1 also plays a role in the correction of improper kinetochore-microtubule attachments. Aurora B was also implicated in error correction whereas its role in the SAC is controversial. Using the Aurora B inhibitor Hesperadin, we demonstrate that Aurora B, like Mps1, is strictly required for the SAC. While partial inhibition of Aurora B is still compatible with the checkpoint response to unattached kinetochores, complete ablation of its kinase activity leads to severe impairment of localization of SAC proteins at unattached kinetochores. Our findings suggest that a core component of the SAC, including the Aurora B and Mps1 kinases, responds to unattached as well as tensionless kinetochores. Thus, error correction is intimately intertwined with the SAC, establishing a new paradigm in the SAC.

**FRET-Based RNAi Screen Identifies New Regulators of Aurora B.**
C. Wurzenberger¹, M. Held¹, M. Lampson², D. Gerlich¹; ¹Institute of Biochemistry, ETH Zuerich, Zuerich, Switzerland, ²Department of Biology, University of Philadelphia, Philadelphia, PA

Aurora B kinase controls various aspects of mitosis and cytokinesis. How Aurora B controls these different processes, particularly during late stages of cell division, is not fully understood. Using an Aurora B phosphorylation FRET-sensor targeted to chromatin (Fuller et al., Nature 2008), we here established live imaging-based RNAi screening for Aurora B regulators in human cells. We used supervised machine learning for automated annotation of mitotic stages to detect alterations in Aurora B phosphorylation. Within a siRNA library targeting genome-wide sets of phosphatases and kinases, we identified two phosphatases as new candidate regulators of Aurora B phosphorylation during anaphase. Ongoing experiments aim to validate and dissect their exact function.

**Epigenetic Centromere Specification Directs Aurora B Accumulation at the Inner Centromere but Is Insufficient for Mitotic Error Correction.**
E. A. Bassett¹, S. Wood¹, S. Ajith¹, D. R. Foltz², B. E. Black¹; ¹Department of Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, ²Department of Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA

The nearly ubiquitous presence of repetitive centromere DNA sequences across eukaryotic species is in paradoxical contrast to their apparent functional dispensability. Recent examples of intact human chromosome variants in which the centromere has moved to a new location lacking detectable α-satellite DNA provide prime examples of the epigenetic nature of centromere identity. Centromeric chromatin is spatially delineated into the kinetochore-forming array of CENP-A-containing nucleosomes and the inner centromeric heterochromatin that lacks CENP-A but recruits the Aurora B kinase that is necessary for correcting erroneous attachments to the
mitotic spindle. To investigate the structural features of centromeric chromatin required for its diverse functions in centromere segregation, we examined a patient-derived cell line containing a chromosome 4 variant that is intact in primary DNA sequence but has moved its centromere to a site that lacks repetitive DNA and is 25 Mbp away from the original, epigenetically silenced locus. We found that the self-perpetuating network of centromere proteins at the foundation of the kinetochore is intact at the neocentromere. Surprisingly, we found that the neocentromeric chromosome is >5-fold more likely than normal chromosomes to fail to correct spindle attachment errors, indicating that the Aurora B-dependent error correction mechanism is severely compromised at the neocentromere. Indeed, Aurora B is mis-positioned at the neocentromere at a site distal from its kinetochore targets. We monitored phosphorylation of a known Aurora B kinetochore target (Ser7 of CENP-A) in monopolar cells where spindle biorientation is impossible and Aurora B kinase activity at kinetochores is known to be high and found a >4-fold reduction in its kinase activity at the neocentromere compared to normal centromeres. Thus, the inner centromere architecture of the neocentromere is insufficient to support the robust error correction mechanisms present at centromeres with normal inner centromere geometry. Our data supports a model wherein a neocentromere represents a primordial inheritance locus that requires subsequent recruitment of repetitive DNA to enhance fidelity of chromosome transmission.

Bod1 Regulates Mitotic Progression and Chromosome Segregation by Modulating Aurora B and Plk1 Activity.
I. M. Porter, J. J. Blow, J. R. Swedlow; Wellcome Trust Centre for Gene Regulation and Expression, University of Dundee, Dundee, United Kingdom

Biorientation defective 1 (Bod1) is a 22 kDa protein conserved across metazoans that we recently demonstrated was required for proper chromosome biorientation (Porter et al. J Cell Biol (2007)). Detailed examination of mal-oriented chromosomes in Bod1 depleted cells revealed a high incidence of syntelic attachments which we demonstrated was due, at least in part, to the failure of the Aurora B kinase to phosphorylate MCAK. Here we present data that demonstrates Bod1 also has a critical role modulating the function of Plk1 at centrosomes and kinetochores. After siRNA depletion of Bod1 Plk1 is partially delocalised from centrosomes and kinetochores during mitosis. Consistent with this γ-tubulin localisation was reduced ~3 fold at the centrosomes of Bod1 depleted cells. In addition, Plk1-dependent phosphorylation of the kinetochore constituent PBIP was also reduced after Bod1 depletion. Sgo1 and the splice variant sSgo1 localise to kinetochores and centrosomes, respectively, preventing precocious separation of sister chromatids and mother and daughter centrioles prior to anaphase onset. Sgo1 is required, at least partially, to localise Plk1 to kinetochores and phosphorylation of sSgo1 by Plk1 is required for its localisation to centrosomes, suggesting a reciprocal requirement for localisation of these proteins to kinetochores and centrosomes. Depletion of Bod1 reduced localisation of Sgo1 and sSgo1 to kinetochores and centrosomes, respectively. Consistent with this result, we observed precocious separation of sister chromatids in fixed and living cells. Other factors implicated in the localisation of Sgo1, such as Bub1, Sgo2 and PP2A all localise properly in Bod1 depleted cells suggesting that the failure of Sgo1 to localise properly is a result of delocalisation of Plk1. Finally, we also show that in the absence of Bod1 Plk1 is more sensitive to the small molecule inhibitor BI 2536 and that mitotic entry is also slowed suggesting that Bod1 is also required to modulate Plk1 activity during mitotic entry. These data, in combination with our previous work indicate that Bod1 modulates the activity of both Aurora B and Plk1 kinases and thus is a critical regulator of mitotic progression and chromosome segregation.

Two Kinesin-Like Motors Spatially Regulate Chromosome Movements during Mitosis.
J. Stumpff, A. Franck, C. Huseby, C. Asbury, L. Wordeman; University of Washington, Seattle, WA

During mitosis in vertebrate cells, chromosomes oscillate with periods of smooth motion interrupted by abrupt reversals in direction. The molecular mechanisms that spatially constrain
these movements to facilitate the alignment and segregation of chromosomes with high fidelity are not well understood. Through spatially resolved analyses of chromosome movements in live cells, we have identified a strong correlation between the rate of directional switches and chromosome position within the spindle. Our studies indicate that two kinesin-like motors, Kif18A and Kid, synergistically provide this spatial regulation and promote congression. Depletion of Kif18A or Kid produces chromosome alignment defects and a reduced dependence of switch rate on position within the spindle. Co-depletion of Kif18A and Kid further increases the severity of these phenotypes. While these motors similarly affect chromosome positioning, Kif18A and Kid have opposite effects on the directional switch rate and velocity of chromosome movement. In cells depleted of both kinesins, these effects are additive such that kinetochore movement parameters are similar to those measured in control cells despite the severe disruption of chromosome alignment seen under these conditions. These data indicate that two kinesin-dependent mechanisms act in parallel to provide position-dependent regulation of chromosome movement and facilitate alignment at the spindle equator.

A Countdown Clock in Mitotic Prophase.
K. Kaseda, A. McAinsh, R. A. Cross; Molecular Motors, Marie Curie Research Institute, Oxted, United Kingdom

Mitotic progression is controlled by a set of clocks and dominoes that time key mechanical events and ensure accurate chromosome segregation. It is currently unknown how the earliest mechanical events of mitosis, centrosome separation and nuclear envelope breakdown (NEBD), are timed. Here we track centrosome separation using high-resolution time-lapse imaging of HeLa cells that express Eg5-mEYFP and mCherry-α-tubulin. We show that the rapid loading of Eg5 motor onto centrosomes at the outset of prophase indexes the early mechanical events of mitosis relative to a countdown clock that controls NEBD. Following Eg5 loading this clock sanctions a 9-minute time window during which the cell attempts to separate the centrosomes using Eg5-driven antiparallel microtubule sliding. 1µM EII, an Eg5 specific inhibitor, delays centrosome separation whilst leaving the NEBD-clock intact. After 9 minutes, NEBD ensues, whether or not centrosome separation has completed. Our results reveal the design logic of mitotic prophase: it makes sense to spend the time sanctioned by the NEBD-clock attempting to drive the incipient spindle poles to opposite sides of the DNA, because, as we show, this speeds up the subsequent steps of bipolar spindle assembly by ~3 minutes. but there is no point in delaying NEBD, because following NEBD, spindle assembly can, in any case, proceed by alternative pathways that incur only a slight time penalty.

P38 Activity Is Required for Timely Satisfaction of the Mitotic Checkpoint but Not for Normal Chromatid Segregation.
K. Lee, C. L. Rieder; New York State Department of Health Wadsworth Center, Albany, NY

p38 mitogen-activated protein (MAP) kinase is activated in response to various stresses but its role, if any, during mitosis is unclear. We found that activated (phosphorylated) p38 weakly associates with the centrosome during G1 and with the oldest centrosome during S and G2. However, near the time of nuclear envelope breakdown its activity significantly increases and it becomes associated both with the new (daughter) centrosome and to a lesser extent with each half-spindle. Active p38 also strongly targets the centrosomes in nocodazole-treated mitotic cells lacking microtubules, and during the mitotic block its activity slowly diminishes until it is reduced by ~95% after 16 hrs. Thus active p38 is a bona-fide component of the mitotic centrosome. To determine whether its activity is required during mitosis for normal spindle function we asked how the duration of mitosis (DM) is affected in RPE-1 cells after inhibiting p38 with small molecule inhibitors (SB2035580 or SB202190) or RNAi knockdown. We found that although under these conditions chromatid segregation and cytokinesis was normal, the DM was prolonged by ~50%. To determine if the upstream p38 activator (MKK3/6) or downstream target (MK2) of p38 are also required for timely progression through mitosis we studied the DM in MEF cells lacking MKK3/6.
and in RPE-1 after MK2 RNAi. We found that DM was also significantly prolonged in both the former (≈25%) and latter (≈50%) cells. Finally, we found that the prolongation of mitosis in cells lacking p38 activity occurs selectively during prometaphase and, as a result inhibiting p38 leads to an accumulation of prometaphase cells. We propose that p38 activity is required for the timely stable attachment of all kinetochores to the spindle, i.e., satisfaction of the mitotic checkpoint, and not for normal APC or proteasome activity.

An Automated Method for Multi-Object Tracking in Crowded Environments.
J. Metz, A. Ma, D. Sharp, U. Rath, T. Sonbuchner; Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, NY

Recent advances in novel imaging techniques have sparked an exciting new era for cell biology. However, extracting the biologically relevant information from these data remains challenging, and the problem is often tackled by laborious manual tracking of objects in the fluorescence images. Here we outline a novel algorithm for automated object tracking in crowded environments with single particle resolution. The method utilizes two-stage cross-correlation based template matching and is shown to be efficient on data from a broad range of systems. The algorithm has been applied to track individual kinetochores during Anaphase in human U2OS cells, and to uncover the precise dynamical behavior of growing microtubule (MT) plus-ends in Drosophila S2 cells. In the latter, an extremely unexpected result was discovered, namely that MT growth slows down in cells lacking a particular mitotic protein, KLP59D. This result is surprising because KLP59D is known to be responsible for depolymerizing MTs and is a member of the Kinesin-13 family of MT depolymerases. In addition the algorithm has also been used to follow centrosomes during FRAP assays during which the centrosomes were seen to move appreciably, thus requiring tracking for more accurate fluorescence recovery data by removing a systematic component of the noise in the signal.

A Critical Role of PRC1 in Controlling Microtubule Assembly and Dynamics That Regulate Spindle Formation and Integrity in Mitosis.
T. Tsuji, W. Jiang; The Burnham Institute for Medical Research, San Diego, CA

Microtubule-associated proteins (MAPs) play critical roles in controlling microtubule (MT) assembly and dynamics especially during spindle formation. However, the mechanisms by which MAPs regulate these complex processes are poorly understood. Here, we use Xenopus egg extracts to reveal a new function for the mitotic MAP, protein regulator of cytokinesis 1 (PRC1), in controlling MT assembly and dynamics, thereby regulating spindle formation and integrity in mitosis/meiosis. Perturbation of XPRC1 (Xenopus PRC1) function inhibits MT assembly and formation of normal size asters and spindles. XPRC1 inhibition also causes reductions in aster/spindle density and the efficiency of bipolar spindle formation. Although XPRC1 is not an essential factor for Ran-dependent MT assembly, XPRC1 functions as a general MT stabilizing protein that acts synergistically with the MT polymerase XMAP215 and antagonistically with the MT depolymerase XKCM1 to regulate MT assembly. Time-lapse microscopy reveals that XPRC1 controls MT assembly and dynamics by reducing the MT shrinkage rate and increasing the MT nucleation frequency. Inhibition of XPRC1 function in anaphase spindles severely inhibits spindle midzone formation, resulting in MT depolymerization, spindle shrinkage and ultimately disintegration. Together, our results demonstrate that, besides its well-characterized anti-parallel MT bundling activity, PRC1 also controls MT assembly and dynamics to modulate spindle formation and maintain spindle integrity in mitosis/meiosis.

619/B566
Dissecting the Roles of Ndel1 N-Terminal Binding Partners in Microtubule Self-Organization.
The cytoplasmic dynein motor complex is involved in a variety of cellular processes. Nde1 and Nde1 are well characterized regulators of dynein. We find that the Nde1 protein is developmentally regulated and is detected at very low levels in CSF-arrested Xenopus extracts. Nde1, on the other hand, is present in Xenopus egg extracts and involved in the 'self-organization' of microtubules into asters, which is a dynein-dependent process. Interestingly, the N-terminal coiled-coil of Nde1 is sufficient to carry out this function of Nde1, demonstrating that the N-terminus of Nde1 constitutes its functional domain. We propose that the C-terminal unstructured tail inhibits this active domain, until the proper signals are generated. We have mapped Nde1 interactions with other proteins and tested their requirements to focus microtubules. First of all, the presence of the Lis1 binding domain within residues 100-160 is critical. Second of all, we have identified a novel dynein-interacting site in the N-terminus of Nde1. Truncated Nde1 proteins, which do not have this domain, do not rescue aster formation in Nde1 depleted extracts. We took a closer look at Nde1 interactions with Lis1 and dynein. We show that Lis1 binding is critical for the Nde1 function in extracts. In addition, Lis1 is required for proper function of microtubules independent of Nde1. We have also mapped the dynein interacting domain within the coiled-coil of Nde1. Together, our data suggest that the N-terminus of Nde1 acts as a structural scaffold bringing cytoplasmic dynein together with its regulators.

620/B567
Identification and Characterization of a Novel Kinesin-Like Protein (KifX) Necessary for Bipolar Spindle Assembly.
J. Torres, M. Summers, L. Belmont, M. Brauer, P. K. Jackson; 1Stanford University School of Medicine, Stanford, CA, 2Genentech, South San Francisco, CA

During mitosis chromosome segregation relies on the proper formation and stabilization of the mitotic spindle. Although many proteins have been identified that contribute to spindle formation, presumably many others are involved. To identify novel proteins involved in mitotic spindle formation, mitotic HeLa cell extracts were used for in vitro microtubule polymerization reactions and proteins co-pelleting with microtubules were identified by mass spectrometry. We generated a Dharmacon siRNA library directed against 600 microtubule binding proteins for use in high throughput genetic screens, including mitotic spindle assembly, mitotic arrest, mitotic bypass, and apoptosis. Among the positive hits from these screens was a novel kinesin-like protein termed KifX. KifX is ubiquitously expressed at low levels among all tissues examined, including skin, brain, and spinal cord. KifX localizes to the centrosome and more specifically to the centrioles in a cell cycle specific manner, from prophase to anaphase. Depletion of KifX resulted in multipolar spindle formation, however no centrosome over-duplication was observed. KifX-depleted cells exhibit pericentriolar material (PCM) fragmentation, indicated by multiple Pericentrin and gamma-Tubulin foci, but only two centrosomes by Centrin staining. Moreover, this defect can be rescued by inhibition of the mitotic kinesin Eg5 or the mitotic kinase PLK1 prior to mitotic entry. This implicates KifX as having a role in early mitosis, post centrosome separation, which is required to keep the PCM intact. Localization of spindle focusing activities (TPX2, Eg5, NUMA, etc) to spindle poles is not affected in KifX-depleted cells as these factors localized to ectopic spindles. Live time-lapse microscopy shows that KifX-depleted cells enter mitosis but fail to align chromosomes at the metaphase plate. These cells do not exit mitosis, condense their chromatin, and apoptose in mitosis. KifX-depleted cells have increased caspase 3/9 activity along with DNA fragmentation and decreased cell viability. KifX represents a novel factor in spindle formation and may help to elucidate the requirements for triggering mitotic apoptosis, sought after in antimitotic therapeutics.

Analysis of Mph1 Kinase and Its Substrates in Spindle Checkpoint Signalling.
Accurate chromosome segregation is crucial as mis-segregation results in aneuploidy and this can result in severe diseases such as cancer. The spindle checkpoint monitors sister-chromatid attachment to the mitotic spindle and inhibits the onset of anaphase until all chromosomes are correctly bi-oriented on the mitotic spindle. The anaphase promoting complex/cyclosome (APC/C) is an E3 ubiquitin ligase that drives cells into anaphase by targeting the separase inhibitor securin and cyclin B for degradation by the 26 S proteasome. Upon spindle checkpoint activation the APC/C is inhibited by the mitotic checkpoint complex (MCC) composed of Slp1/Cdc20, Mad2 and Mad3. The spindle checkpoint machinery of \textit{S. pombe} is composed of many proteins, one of which is the kinase Mph1 (Mps1p-like \textit{pombe} homolog). It previously has been shown that Mph1 is essential for the spindle checkpoint (He et al., 1998) but not whether this is due to its kinase activity. The aim of this study is to determine whether Mph1 kinase activity is required for the spindle checkpoint and to test whether any of the known spindle checkpoint proteins are Mph1 substrates. Furthermore, we wanted to test whether Mph1 has a regulatory role in MCC binding to the APC/C. Using a kinase-dead allele of Mph1, that had no detectable \textit{In Vitro} kinase activity, we showed that lack of Mph1 kinase activity abolished the spindle checkpoint and led to chromosome mis-segregation. In addition, lack of Mph1 kinase activity severely impaired Mad2 and Mad3 binding to the APC/C. Using \textit{In Vitro} kinase assays, Mad2 and Mad3 were identified as \textit{In Vitro} substrates of Mph1. Phosphorylation sites in Mad2 were determined by mass spectrometry. A phosphorylation mutant of Mad2 with 5 Mph1 sites replaced with alanine showed reduced APC/C binding and spindle checkpoint defects, indicating that it is an important Mph1 substrate.

\textbf{Lamin B Restrains the Activity of Kinesin Eg5 in Spindles Assembled in Xenopus Egg Extracts.}

B. Goodman\textsuperscript{1,2}, W. Channels\textsuperscript{3}, P. Iglesias\textsuperscript{3}, Y. Zheng\textsuperscript{1,2}; \textsuperscript{1}Embryology, Carnegie Institute of Washington, Baltimore, MD, \textsuperscript{2}Biology, Johns Hopkins University, Baltimore, MD, \textsuperscript{3}Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD

Lamin B3 (LB3) is a structural component of the membranous mitotic spindle matrix and is important for proper spindle morphogenesis. However, how LB3 regulates spindle assembly remains unclear. We have developed assays in Xenopus egg extracts to study whether LB3 could regulate spindle assembly by balancing forces generated by the microtubule (MT)-based motors. We report here that LB3 antagonizes Eg5 kinesin activity in spindles stimulated by either Aurora a (AurA) beads plus RanGTP or sperm chromatin. LB3 inhibits Eg5’s ability to drive the separation of AurA beads that mark MT organizing centers (MTOCs) and spindle poles. Similarly, LB3 restrains Eg5 activity to help in maintaining spindle length and spindle pole focusing in spindles assembled from sperm chromatin. Since previous studies have shown that dynein and LB3 coordinate in the spindle matrix through interactions between Nudel and LB3, our studies provide evidence that LB3 restrains the forces produced by Eg5 during spindle morphogenesis as part of the spindle matrix.

\textbf{Kinesin-8 Kif18A Regulates Spindle Length in a K-Fiber Independent Mechanism Separate from Its Role in Chromosome Congression.}

L. N. Weaver\textsuperscript{1}, S. Cai\textsuperscript{2}, C. Walczak\textsuperscript{3}; \textsuperscript{1}Biology Program, Indiana University, Bloomington, IN, \textsuperscript{2}Biochemistry Program, Indiana University, Bloomington, IN, \textsuperscript{3}Medical Sciences Program, Indiana University, Bloomington, IN

During mitosis the cell assembles the mitotic spindle, a macromolecular structure composed of numerous proteins, which is utilized to segregate the chromosomes. The spindle microtubules (MTs) are highly dynamic polymers that are constantly undergoing polymerization and depolymerization within the spindle, and yet the spindle apparatus maintains a constant length
during mitosis. There are many molecules proposed to regulate its length, but how these molecules coordinate to maintain an average spindle length is currently unknown. Kinesins are a superfamily of molecular motor proteins that play multiple roles during mitosis, including regulating MT dynamics, spindle assembly, and chromosome segregation. We previously showed that the minus-end directed Kinesin-14 HSET regulates spindle length through its ability to crosslink and slide MTs of the spindle in a kinetochore fiber (K-fiber) independent pathway. Overexpression of HSET results in long bipolar spindles, whereas knockdown produces shorter spindles. The Kinesin-8 Kif18A is a plus-end directed motor and MT depolymerase that is important for chromosome alignment and for regulating chromosome oscillations. Knockdown of Kif18A causes chromosome misalignment and also results in abnormally long bipolar spindles, similar to those observed in HSET overexpression. Here we show that knockdown of both HSET and Kif18A rescues bipolar spindle length, however chromosome alignment remains perturbed. These results suggest that Kif18A has two distinct and independent roles in mitosis to regulate spindle length and to congress chromosomes. In addition, we show that the MT depolymerization activity of Kif18A is not restricted to K-fibers as proposed. Knockdown of Kif18A in combination with knockdown of the Ndc80 component hNuf2 results in longer spindles compared to Kif18A and hNuf2 single knockdowns, suggesting that Kif18A also acts on the more dynamic spindle MTs. Together these results suggest that 1) Kif18A regulates chromosome congression and spindle length through two separable pathways; and 2) Kif18A and HSET may coordinate within a K-fiber independent pathway to maintain an average spindle length through regulation of MT depolymerization and MT sliding.

Promoting Error-Free Mitosis: Regulation of the Kinesin-13 Kif2b through Phosphorylation.
E. A. Hood1, A. N. Kettenbach2, S. F. Bakhoum1, A. L. Manning1, S. A. Gerber2, D. A. Compton1; 1Biochemistry, Dartmouth Medical School, Hanover, NH, 2Genetics, Dartmouth Medical School, Hanover, NH

Accurate chromosome segregation during mitosis is an essential process mediated by the microtubule-based spindle. To achieve proper segregation, kinetochores of sister chromatids must attach to microtubules extending from opposite poles. A common cause of chromosome mis-segregation is the persistence of improper attachments between kinetochores and spindle microtubules. The kinesin-13 Kif2b is required for the correction of these improper kinetochore-microtubule attachments (Bakhoum et al, 2008). Kif2b localizes to kinetochores in prometaphase where it promotes the correction of attachment errors through its microtubule destabilizing activity. We propose that the spatially and temporally-specific nature of Kif2b activity is regulated by unique phosphorylation events. Consistent with this proposal, localization of a GFP-Kif2b fusion protein to kinetochores is abolished by treatment with the Aurora kinase inhibitor Hesperadin. Conversely, the fluorescence intensity of GFP-Kif2b at kinetochores is significantly increased with treatment with the Polo kinase inhibitor BI-2536. To identify specific sites regulated by phosphorylation, we immunoprecipitated GFP-Kif2b from stably-expressing U2OS cells synchronized in prometaphase and metaphase as well as cells in interphase. Using mass spectrometry we identified 13 residues specifically phosphorylated in mitosis, three of which are phosphorylated only in metaphase. To determine which of these are the critical regulatory sites, we are systematically mutagenizing each residue, both individually and in combination, and determining the ability of each mutant to localize to kinetochores and correct kinetochore-microtubule attachment errors.

625/B572
Phosphorylation of the Kinesin-13 MCAK Regulates a Conformational Change between the Neck and C-Terminal Domain.
S. C. Ems-McClung1, J. Devare2, S. G. Hainline3, S. K. Lamb2, C. Walczak1; 1Medical Science Program, Indiana University, Bloomington, IN, 2Biochemistry Program, Indiana University, Bloomington, IN, 3Biology, Indiana University, Bloomington, IN
MCAK is a Kinesin-13 that uses the energy of ATP hydrolysis to disassemble MTs and regulate MT dynamics. MCAK MT depolymerization activity is inhibited by phosphorylation at a single residue (S196) within the positively charged neck; however, the biochemical mechanism by which this phosphorylation regulates depolymerization activity is unknown. The activity of MCAK is also modulated by its C-terminal domain (CT), although this domain is not essential for activity. These findings imply that there is an interplay between the neck and CT that might regulate MCAK activity. We propose that the neck and CT physically interact and that phosphorylation regulates this interaction to modulate MT depolymerization activity. To test this model we performed In Vitro pull-down assays with GST-tagged CT and MCAK proteins containing various combinations of the N-terminal domain (NT), neck, and motor domains. We found that the CT interacted best with the construct containing only the neck and motor domain. Furthermore, Aurora B phosphorylation of the neck+motor construct resulted in significantly decreased binding to the CT that was due to phosphorylation at S196. To assess whether the regulated interaction between the CT and the neck exists in the context of full-length protein, we engineered fluorescence resonance energy transfer (FRET) biosensors with mCitrine on the N-terminus and mCerulean on the C-terminus of MCAK. We hypothesized that biosensors containing the CT of MCAK would display a high FRET ratio, whereas biosensors not containing the CT would display a low FRET ratio. Indeed, full-length MCAK displayed high FRET, and MCAK missing the CT displayed significantly reduced FRET. Interestingly, MCAK missing the NT, but containing the neck, motor, and CT domains displayed higher FRET than full-length MCAK, consistent with our binding data and suggesting that the neck is the important domain for the interaction. Phosphorylation of the biosensors by Aurora B significantly reduced the FRET ratio, suggesting that phosphorylation opens up the conformation of MCAK. Together these data indicate that MCAK is active in a closed state, but is inactive in an open state, and that phosphorylation regulates this conformational change.

Roles of Drosophila Kinesin-13s in the Regulation of Spindle Microtubule Dynamics.

U. Rath, J. Metz, D. W. Buster, A. Ma, D. Sharp; Physiology & Biophysics, Albert Einstein College of Medicine, Bronx, NY

Microtubule destabilizing kinesin-13s are important regulators of microtubule (MT) dynamics. Interestingly, many systems require the activities of multiple distinct kinesin-13 family members to successfully complete mitosis: for example, mitosis in Drosophila involves the activities of three kinesin-13s, KLP10A, KLP59C and KLP59D. The specific individual and collective influence of these proteins on the dynamic behaviors of distinct spindle MT subsets, particularly non-kinetochore microtubules, remains relatively unexplored to elucidate the effects of the Drosophila Kinesin-13s on non-kinetochore MTs we tracked trajectories of GFP-EB1, which tracks polymerizing MT plus-ends, in living cells depleted of the proteins individually and in combination by dsRNAi, using a novel in-house tracking algorithm. Our data indicate some intriguing and unexpected Kinesin-13 functions, for example, KLP10A and KLP59D, which both localize to mitotic centrosomes, strongly but distinctly alter astral MT behaviors. Depletion of KLP59D decreases astral MT growth rate, resulting in shorter astral arrays. Depletion of KLP10A, on the other hand, results in elongated astral MTs by inhibiting rescue events. This latter finding indicates a difference between KLP10A’s mitotic and interphase activities (in interphase, KLP10A promotes plus-end catastrophes). The roles of KLP59C are currently under investigation. Together, our data expand and specify the roles of distinct kinesin-13s in mitosis.

The Drosophila Kinesin-13, KLP10a, Transits from Centrosomes to Spindle Poles.

U. Rath, J. Metz, A. Ma, D. Sharp; Physiology & Biophysics, Albert Einstein College of Medicine, Bronx, NY

The Drosophila kinesin-13, KLP10A, performs multiple roles in mitosis ranging from the regulation of astral microtubule dynamics to the stimulation of poleward flux and poleward chromosome movements. To a large measure, this functional diversity can be attributed to KLP10A’s complex localization pattern: KLP10A targets mitotic centrosomes, spindle poles, microtubule tips and
centromeres/kinetochores. Here, we focus on the cellular dynamics of this kinesin-13 using FRAP and photoactivation to follow the movement and turnover of GFP-KLP10A and PA-GFP-KLP10A, respectively, to and from these primary sites of action. These analyses have revealed KLP10A to be extremely dynamic and move rapidly throughout the spindle. This is particularly so at centrosomes: the motile fraction of centrosomal KLP10A turnover with a t1/2 of 2.5 sec. Interestingly, the localization and turnover of KLP10A at centrosomes is regulated by a second kinesin-13, KLP59D. We have also used a variety of approaches to follow the movement of KLP10A from centrosomes and found a directional flow to spindle poles. Indeed, the presence of centrosomes in the cell, but not their association with the spindle, is required for the cumulation of normal levels of spindle pole-associated KLP10A. KLP10A induced depolymerization of microtubule minus-ends at spindle poles is believed to be a primary mechanism for stimulating poleward flux. We propose a model wherein passage of KLP10A through centrosomes activates its spindle pole activity.

**Investigating the Role of Lipids in Cytokinesis.**

G. E. Attila-Gokcumen, U. Eggert; 1Cancer Biology, Dana-Farber Cancer Institute, Boston, MA, 2BCMP, Harvard Medical School, Boston, MA

Cytokinesis is the last phase of cell division, where cells physically separate. It involves the distribution of membranes, the cytoskeleton, organelles and proteins into two daughter cells. Understanding the mechanism of cytokinesis is a fundamental question in cell biology, which also has clinical relevance since failed cytokinesis has been linked to tumorigenesis. Although cells undergo dramatic shape changes during cytokinesis, the role of the plasma membrane and lipids is poorly understood. It is known that a few lipids localize to the cleavage furrow and that the specific distribution of these lipids is necessary for cleavage. However, the identity of other lipids that may be involved in cytokinesis, their precise function, how they are transported to the cleavage furrow and maintained there are still unclear. Hence, to identify further lipids that are involved in cytokinesis, and to develop tools to study these lipids, we perturbed the activity of enzymes that play a part in lipid biosynthesis and determined if this has an effect on cytokinesis. Specifically, we identified known small molecule regulators of lipid metabolism, and in particular targeting fatty acid, sphingolipid or cholesterol biosynthesis. We tested these compounds in HeLa cells and observed if incubation with these compounds caused cytokinesis failure, using both fixed and live imaging. We identified several regulators of lipid biosynthesis that induce the formation of binucleated cells. We are currently investigating the mode of action that results in cytokinetic failure and individual lipids that are enhanced/depleted due to compound treatments.

**Sweeping of Actin into the Incipient Contractile Ring by Dynamic Microtubules.**

K. Tseng, D. Zhang; 1Zoology Department, Oregon State University, Corvallis, OR, 2CGRB, Oregon State University, Corvallis, OR

It is known that contractile ring assembly involves interactions between spindle microtubules and the cell cortex. The nature of such interactions, however, remains to be determined. Here, we have directly probed the interactions between peripheral spindle microtubules and cortical actin filaments by micromanipulation in living grasshopper spermatocytes. Microtubule-actin interactions were demonstrated by pushing on the spindle or asters with a micromanipulation needle while rapidly imaging the interactions using a spinning disc confocal microscope equipped with an EM-CCD digital camera. When microtubules were tugged with a microneedle, the actin filaments at the cortex were concurrently dragged inward, causing the cell membrane to invaginate. The membrane relaxed once the needle was released. These interactions were first apparent during late anaphase and continued throughout assembly of the contractile ring. We also tested the interactions in the presence of cytochalasin D, which disassembled actin filaments.
into small aggregates that were mobile and readily visible. These cortical actin aggregates could ride on the tips of dynamic microtubules that were waving within and/or elongating towards the cortex. In light of our recent findings in silkworm spermatocytes (Chen et al., 2008, PLoS Biology), these results demonstrate a mechanism by which peripheral spindle microtubules could mechanically sweep cortical actin filaments into the incipient contractile ring.

A Quantitative Study of Cell Shape and Spindle Orientation in Sea Urchin Embryos.

N. Minc, D. Burgess, F. Chang; 1Microbiology, Columbia University, NYC, NY, 2Dept of Biology, Boston College, Boston, MA

The proper orientation of the mitotic spindle is critical for placement of the division plane for cytokinesis, cell shape, tissue architecture and development. Although several molecular aspects of spindle and nuclear positioning have been identified, in general little is known about the larger question of how cells sense their cell shape at a global level. Here, we investigated the effects of cell geometry in the sea urchin zygote, an otherwise symmetric cell that lacks inherent polarity cues. To alter geometrical parameters in a systematic and quantitative manner, we produced cells of different shapes (triangles, rectangles, squares and cones) by placing them into microfabricated PDMS chambers of different shapes and observing them using medium-throughput time-lapse imaging. Our results show that the spindles position along the long axis of the cell, and centers by somehow sensing cell volume, rather than cell length or surface area. The cleavage furrow forms in a plane perpendicular to the spindle regardless of distances between the cortical sites and the spindle. This approach associated with theoretical modeling will allow us to test and develop models for spindle positioning in mitosis and the division plane positioning in cytokinesis.

CaM Has Distinct Role on Plk1’s Function during Cytokinesis Initiation and Completion.

J. Liang, F. Meng, G. Dai, S. Wang, F. Pan, B. Xue, C. Li; 1Medical School, Nanjing University, Nanjing, China, 2College of Life Sciences, Nanjing Normal University, Nanjing, China

Objective: It has demonstrated that Plk1 activation is essential not only for the initiation of cytokinesis but also for successful furrow ingression once constriction has commenced, even for intracellular bridge abscission. Although the downstream targets of Plk1 have been dedicated examined, only few upstream regulator has been explored. Here we will confirm that CaM might be such a molecule that control Plk1’s activity and localization in a spatial-temporal dependent manner. Methods: We used FRET method to examine the In Vivo interaction between CaM and Plk1, applied chromophore-assisted laser inactivation (CALI) technique to acute inactivate CaM after cytokinesis onset, and during intracellular bridge stage. Results: We found that CaM interacted with Plk1 during early anaphase while fell apart during intracellular bridge stage. Kinase activity assay also showed that CaM could enhance Plk1’s activity during anaphase while inhibit Plk1’s activity during intracellular bridge stage. When we acute inactivated CaM with CALI technique after cytokinesis onset, the CaM-Plk1 interaction was broken and Plk1’s activity was diminished. Meanwhile, the cleavage furrow ingression was blocked and the mitosis exit was also stopped. The result indicates that the interaction between CaM and Plk1 contributes to the cleavage furrow ingression. but the situation was totally different during intracellular bridge stage when CaM has been separated from Plk1 at midbody. Although CaM inactivation blocked intracellular bridge abscission, even resulting in a binucleate cell (50% of observed cells), Plk1 inactivation accelerated intracellular bridge abscission. Plk1 overexpression could prolong intracellular bridge abscission. Conclusions: The results suggest that the spatiotemporal interaction between CaM and Plk1 plays different roles at different cytokinesis stages. CaM can positive regulate Plk1’s activity through direct physical interaction during anaphase, while decrease Plk1’s activity through a negative mediator when CaM and Plk1 are spatially separated during intracellular bridge stage.

Differential Midbody Fate between Neural Stem Cells and Cancer-Derived Cell Lines.

A. W. Ettinger1, M. Wilsch-Braeuninger1, A. Marzesco1, D. Corbeil2, W. B. Huttner1; 1Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, 2Tissue Engineering Laboratories, BIOTEC, Technical University of Dresden, Dresden, Germany

During mouse neurogenesis, neuroepithelial progenitor cells release midbodies while switching from proliferative to differentiative divisions. In order to get insight into this cell biological process, we studied midbody release in the neural stem cell line NS-5. To assay for released midbodies, we subjected conditioned culture medium of NS-5 cells and various cancer-derived cell lines to differential centrifugation followed by immunoblotting for two midbody markers, citron rho-interacting kinase (CRIK) and mitotic kinesin-like protein 1 (MKLP1). Strikingly, the extent of midbody release was significantly greater from NS-5 cells than from cancer-derived cells, and was increased upon differentiation of NS-5 cells. Interestingly, inhibition of autophagy by chloroquine or ammonium chloride increased persistence of midbody markers in HeLa, but not NS-5, cells. Thus, our results suggest that cultured neural stem cells can be used as a cellular model for midbody release. Moreover, the differential fate of the midbody between neural stem cells and cancer-derived cell lines suggests that there are two principally different routes of midbody disposal after cell division; (i) the transient retention of midbody constituents in cells, as exemplified in HeLa cells, and (ii) the release of midbody constituents from cells, as exemplified in neural stem cells. We propose that midbody release may be involved in cell differentiation, and that, conversely, midbody retention may contribute to the transformation of stem cells into cancer cells.

633/B580
Mitotic Regulation of Septin 9 Is Important for the Completion of Cytokinesis.

M. Estey1,2, C. Di Ciano-Oliveira1, C. Froese1, J. Steels1,2, D. Litchfield3, W. Trimble1,2; 1Program in Cell Biology, Hospital for Sick Children, Toronto, ON, Canada, 2Department of Biochemistry, University of Toronto, Toronto, ON, Canada, 3Department of Biochemistry, University of Western Ontario, London, ON, Canada

Proper cell division is essential for multicellular development, and defects in this process have been linked to cancer. Septin 9 (SEPT9) is a GTP-binding protein that has been implicated in cell division, and linked to a variety of cancers including breast, ovarian and leukemia. In addition, a SEPT9 DNA methylation assay was recently developed that allows sensitive detection of colorectal cancer, further linking SEPT9 expression to cancer. However, the precise role of SEPT9 during cell division and its mechanism of regulation during this process remain elusive. Here we demonstrate that SEPT9 is phosphorylated upon mitotic entry, which controls association with the proline isomerase, Pin1. Surprisingly, we find that SEPT9 is dispensable for the early stages of cell division, but both SEPT9 and Pin1 are critical for mediating the final separation of daughter cells. While wild type SEPT9 expression rescued the cytokinetic defect seen upon SEPT9 depletion, expression of mutant SEPT9 that is defective in Pin1 binding or a SEPT9 isoform that lacks the Pin1 binding site led to severe defects in cytokinesis. These results suggest that mitotic regulation of SEPT9 is important for the completion of cytokinesis.

Centralspindlin and the Chromosomal Passenger Complex Coordinate the Promotion of Furrow Ingression in the C. elegans Embryo.

L. Lewellyn1, A. S. Maddox2, A. Desai1, K. F. Oegema1; 1Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, La Jolla, CA, 2IRIC, Universite de Montreal, Montreal, QC, Canada

Cytokinesis is the final step of mitosis that physically divides a single cell into two daughter cells following chromosome segregation. Although it is known that the anaphase spindle is continuously required for cytokinesis, the precise signaling mechanisms that promote formation and constriction of the contractile ring are not known. The spindle midzone, which is an array of antiparallel microtubule bundles that forms during anaphase, serves as a scaffold for the

- 302 -

2009 ASCB Regular Abstracts
localization of two key complexes that are required for cytokinesis in all systems - Centralspindlin and the Chromosomal Passenger Complex. Here, we use the C. elegans embryo to dissect the contributions of each complex during cytokinesis.

**A Novel Coiled-Coil Protein Is Required for the Localization of Plk1 to the Central Spindle.**
D. Pal, D. Wu, A. Haruta, Q. Wei; Department of Biochemistry, Kansas State University, Manhattan, KS

Polo-like kinase 1 (Plk1) localizes to the central spindle and plays a central role in regulating furrow formation and ingresssion. However, it is still not completely understood how Plk1 is concentrated to the central spindle. Here we report that a novel coiled-coil protein CCDC69 is required for the localization of Plk1 to the central spindle. Northern blot and immunoblot analysis show that CCDC69 is ubiquitously expressed in multiple human tissues and numerous human cancer cell lines. Immunofluorescence analysis shows that endogenous CCDC69 localizes to the nucleus during interphase and to the central spindle during anaphase. GST pull-down assays show that CCDC69 can physically interact with Plk1. Further, immunofluorescence analysis shows that CCDC69 and Plk1 colocalize to the central spindle and midbody during mitosis and cytokinesis. Depletion of CCDC69 by RNA interference (RNAi) disrupts the localization of Plk1 to the central spindle. Our results suggest that CCDC69 may play a role in localizing Plk1 to the central spindle.

**Analysis of Pathways Required for Nuclear Envelope Disassembly.**
S. Bahmanyar1, A. Audhya2, A. Desai1, J. E. Dixon3, K. F. Oegema1; 1Ludwig Institute, La Jolla, CA, 2University of Madison, Madison, WI, 3UC San Diego, La Jolla, CA

The nuclear envelope (NE) is a double-membrane sheet that is contiguous with the membranes of the endoplasmic reticulum (ER). Metazoans must disassemble the NE prior to chromosome segregation. In the C. elegans zygote, after the two pronuclei meet, the nuclear envelopes are permeabilized and cleared from the region near the centrosomes, promoting spindle assembly. After chromosome segregation, a single nuclear envelope reforms in each daughter cell, thereby mixing the haploid sperm and oocyte genomes. In embryos in which NE disassembly is partially inhibited, separate nuclear envelopes form around the sperm- and oocyte-derived chromosomes after their segregation, resulting in two nuclei in each daughter cell. Functional genomic analysis of cell division in the C elegans embryo uncovered relatively few proteins whose depletion caused the "four-eyes" phenotype suggesting that other proteins important for NE disassembly were missed or that redundant pathways exist. We identified a novel pathway that contributes to removal of nuclear membranes prior to completion of cytokinesis. We suggest that NE disassembly and cytokinesis are spatially and temporally coupled so that each daughter cell contains a single membrane-enclosed nucleus.

**Contractile Ring Asymmetry Is Regulated by Anillin Protein Level during Cytokinesis in C. elegans.**
L. Zhang, J. F. Dorn, D. Edoh-Bedi, C. Patino Descovich, A. S. Maddox; Institute for Research in Immunology and Cancer, University of Montreal, Montreal, QC, Canada

Anillin is a conserved cytoskeletal cross-linker that is important for cytokinesis, and localizes to the contractile ring with its structural binding partners: actin, myosin and septins. In the C. elegans early embryo, when Anillin is depleted by RNA-mediated interference, cytokinesis can occur, but the contractile ring displays several abnormalities, including circumferential symmetry. We are studying Anillin using C. elegans strains stably expressing GFP-tagged transgenes. Interestingly, our four different GFP-tagged full-length Anillin constructs are expressed at different basal levels and respond differently to depletion of endogenous Anillin. This could be due to the stochastic nature of transgene integration. Expression of each GFP-tagged Anillin can rescue
embryonic lethality caused by Anillin depletion, but none of the transgenes can fully replace function of endogenous Anillin in contractile ring asymmetry. To understand how Anillin protein level impacts ring asymmetry, we performed a depletion time-course, measuring Anillin levels by western blotting and monitoring asymmetry by live cell imaging of embryos expressing GFP-tagged myosin heavy chain. To quantify contractile ring constriction kinetics, asymmetry and protein distribution, we created custom image-processing software. Depletion of endogenous Anillin, either in the absence or presence of GFP-tagged versions, disrupted ring asymmetry in several distinct ways. Normally, the contractile ring closes across the division plane unilaterally and is maximally asymmetric. After thorough Anillin depletion, asymmetry often completely fails; the ring centroid stays very close to the cell center. Quantitative analysis revealed an unexpected class, in which the ring closes asymmetrically until it approaches the spindle midzone. Then, asymmetry decreases and the ring closes near the center of the division plane. We are also using GFP-tagged Anillin truncations to understand how this multidomain protein amplifies contractile ring symmetry breaking. Preliminarily, Anillin’s myosin- and septin-binding domains seem necessary for asymmetry in cytokinesis, suggesting that crosslinking within the actomyosin cytoskeleton is important for this process.

638/B585
Spatial-Temporal Control of Cytokinesis in Fission Yeast: Positioning of Mid1/Anillin by Cdr2 Kinase and Nuclear Export and Activation of Myosin II Recruitment by Plo1 Kinase.
M. Almonacid, A. Mayeux, A. Paoletti; Institut Curie/CNRS UMR144, Paris, France

Proper positioning of the cell division plane is required to maintain genome integrity and cellular function. In most eukaryotes, cytokinesis relies on a contractile actomyosin ring positioned by intrinsic spatial signals that are not well defined at the molecular level. Fission yeast cells assemble a medial contractile ring in response to positive spatial cues from the nucleus at the cell centre and negative spatial cues from the cell tips. These signals control the localization of the anillin-like protein Mid1, which defines the position of the division plane at the medial cortex where it recruits contractile ring components at the onset of mitosis. We have recently shown that Mid1 recruitment to the medial cortex is mediated by Cdr2 kinase which distribution is negatively regulated by Pom1 at cell tips (Almonacid et al.,CB 2009; Moseley et al.,Nature 2009; Martin and Berthelot-Grosjean,Nature 2009). In addition, Mid1 nuclear export links division plane position to nuclear position in early mitosis (Almonacid et al.,CB 2009). Cdr2- and nuclear export-dependent positioning of Mid1 constitute two overlapping mechanisms that relay cell polarity and nuclear positional information to ensure proper division plane specification. We now study how Mid1 gets activated at the onset of mitosis to recruit contractile ring components. We find that a region of 50 aa including Mid1 nuclear export sequence NES1 is required for Myosin II timely recruitment to medial cortical nodes at the onset of mitosis, even if Mid1 is forced out of the nucleus by additional mutations in Mid1 nuclear localization sequences (MidnsmΔ50-100 mutant). Mutations of 6 consensus phosphorylation sites for Plo1 kinase located between aa 1 to 100 produce a similar delay in Myosin II recruitment (Mid1nsm 6Ala mutant). We propose that Plo1 may activate Myosin II recruitment to medial cortical nodes by creating a binding site for Myo2 on Mid1 N-terminus at the onset of mitosis.

639/B586
PAR-4/LKB1 Regulates Actomyosin Contractility through Anillin during Early C. elegans Divisions.
N. Chartier1, P. Salazar1, A. S. Maddox1,2, J. Labbé1,2; 1Institute of Research in Immunology and Cancer, Université de Montréal, Montréal, QC, Canada, 2Department of Pathology and Cell Biology, Université de Montréal, Montréal, QC, Canada

We are using the early embryo of C. elegans as a model to understand how PAR-4/LKB1, a conserved serine-threonine kinase, regulates cell polarity. Whereas the tumor suppressor function of PAR-4/LKB1 is well established, the mechanism by which it regulates polarity and asymmetric cell division, and its key downstream effectors during these events, are still unclear. We investigated the involvement of PAR-4 in the regulation of actomyosin contractility, a process
known to be required for proper cell polarization in the C. elegans embryo and other systems. Using time-lapse imaging of embryos expressing non-muscle myosin fused to GFP (NMY-2::GFP), we observed severe actomyosin contractility defects during the first cytokinesis of par-4 mutants. par-4 mutant embryos display multiple furrow ingressions and extensive membrane blebbing, resulting in a delay in the completion of cytokinesis. Furthermore, the cortical site of NMY-2::GFP recruitment at the presumptive cytokinetic furrow during anaphase was mislocalized towards the posterior of the embryo. To identify proteins acting with PAR-4 during cytokinesis, we carried out an RNAi-based, genome-wide screen for suppressors of par-4 embryonic lethality and identified ani-2, one of the C. elegans homologues of the actin-bundling protein Anillin. ANI-2 has high sequence homology with C. elegans ANI-1 and other metazoan Anillinrs in the domains thought to confer binding to MgcRacGAP/CYK-4. Rho and the septins, but is not predicted to bind actin or myosin, suggesting that it negatively regulates actomyosin organization and/or function. ANI-2 depletion by RNAi reverted all actomyosin defects observed in par-4 mutant embryos, suggesting that an increase of ANI-2 function is responsible for these contractility defects. Strikingly, immunolocalisation experiments showed that the loss of PAR-4 activity promotes ANI-2 recruitment to the cortex during cytokinesis. Our results thus support a model in which PAR-4/LKB1 inhibits ANI-2/Anillin accumulation at the plasma membrane, enabling proper actomyosin contractility and cytokinesis completion during early C. elegans embryonic divisions. Such reciprocal interaction may also control actomyosin contractility during embryo polarization.

640/B587
A Two-Step Mechanism for Transport of the Rho GTPase Flux Regulator MgcRacGAP to the Equatorial Cortex Before Cytokinesis.
A. L. Miller1, W. M. Bement1,2; 1Zoology, University of Wisconsin-Madison, Madison, WI, 2Laboratory of Molecular Biology, University of Wisconsin-Madison, Madison, WI

The formation of the contractile ring during cytokinesis is dependent on the small GTPase RhoA, which is activated in a precise zone at the cell equator. In a departure from traditional thinking about Rho activity regulation, whereby guanine nucleotide exchange factors (GEFs) initiate a particular event and GTPase activating proteins (GAPs) terminate that event, we have shown that the GAP activity of MgcRacGAP is necessary throughout cytokinesis for the formation and maintenance the Rho activity zone by promoting the rapid flux of Rho between the active, GTP-bound state and the inactive, GDP-bound state. The GTPase Flux mechanism helps cells maintain a focused Rho activity zone, which is necessary for forming a focused contractile ring and for successful cytokinesis. Here we show that MgcRacGAP is delivered to the equatorial cortex by a two-step mechanism. We examined MgcRacGAP localization in cells within the intact vertebrate epithelium using a gene replacement approach. MgcRacGAP puncta decorate microtubules near the equatorial cortex before ingresson, and these puncta congress and concentrate at the site where the contractile ring forms. Some microtubules decorated with MgcRacGAP puncta appear to make stable contacts with the equatorial cortex. Furthermore, MgcRacGAP puncta undergo directed movement along microtubules, especially near cell-cell boundaries. MgcRacGAP does not move along the entire length of astral microtubules, but instead first appears in a broad region around the equator and then focuses. Photobleaching demonstrates that MgcRacGAP puncta are dynamic, recovering quickly after photobleaching. Together, these results imply that MgcRacGAP is delivered to the equatorial cortex initially by diffusion from the spindle to a broad region surrounding the equator then focused by directed transport on microtubules. These results also represent, to the best of our knowledge, the first time that a gene replacement approach has been successfully employed to monitor cell division in a living, differentiated vertebrate epithelium within the context of the intact organism.

641/B588
Large-Scale Chemical Screen for Cytokinesis Inhibitors.
A. Surcel, W. Ng, D. Robinson; Department of Cell Biology, Johns Hopkins School of Medicine, Baltimore, MD
Abnormalities in cytokinesis are often deleterious and can lead to aneuploidy and tumor formation in numerous cancer types. Understanding how cytokinesis is regulated is indispensable not only for gaining insight into this important biological process, but also for gaining information that be applied to cancer biology and genetic disorders, as well as to identifying new therapeutic drugs for these diseases. To address these objectives, we have designed a large-scale chemical screen using Dictyostelium discoideum. We have developed CYMPAQ - an analytical segmentation program used to identify both mitotic and cytokinesis inhibitors. We have screened over 22,000 compounds and have identified a number of inhibitors, which have been recapitulated in secondary screening. We are currently coupling these compounds with genetic screens to flush out cytokinesis regulators, as well as testing cross-reactivity in both mammalian cell lines and against organisms responsible for amebiasis.

642/B589
**Structural Studies of PRC1 (Protein Regulator of Cytokinesis).**
E. Wilson-Kubalek¹, R. Subramanian², R. Milligan¹, T. Kapoor²; ¹Cell Biology, The Scripps Research Institute, La Jolla, CA, ²Cell Biology, Rockefeller University, New York, NY

Members of the evolutionarily conserved MAP-65 (Ase1, yeast; AtMAP-65, Arabidopsis; PRC1, human) family of proteins are microtubule associated proteins (MAPs) that crosslink microtubules in an anti-parallel orientation. Recent studies have shown that PRC1 is required for the formation of the central spindle, an anti-parallel array of microtubules required for completion of cell division. However, how orientation-specific crosslinking of microtubules is achieved by these non-motor MAPs is not known. Using cryo-electron microscopy and helical image analysis we have visualized the interactions of monomeric and tetrameric constructs of PRC1 on single microtubules and between two microtubules. Surprisingly the 3D maps of these constructs look similar. We have also used total internal reflection fluorescence (TIRF) microscopy to examine PRC1-microtubule interactions and microtubule crosslinking in real time. Combining the structural work with In Vitro fluorescence microscopy based assays have provided a better understanding of how PRC1 interacts with the microtubule lattice and how it forms bridges to neighboring microtubules.

**MAP65-3 Mediates the Interaction between Kinesins and Microtubule Plus Ends during Cytokinesis in Arabidopsis.**
C. Ho¹, B. Liu²; ¹Biochemistry and Molecular Biology Graduate Group, University of California, Davis, CA, ²Department of Plant Biology, University of California, Davis, CA

During cytokinesis in plant cells, microtubules are organized in a bipolar phragmoplast array required for cell plate formation. Our previous work has shown that the Kinesin-12A B motors exclusively decorate the plus end of phragmoplast microtubules, and are required for the organization of anti-parallel microtubules in the phragmoplast in *Arabidopsis*. The MAP65/Ase1 family protein MAP65-3 cross-links microtubule plus ends in the phragmoplast. The loss of MAP65-3 leads to frequent failures in cytokinesis in *Arabidopsis*. In order to test whether MAP65-3 is required for the interaction between kinesins and phragmoplast microtubules, the *dyc283* mutant was used to determine how Kinesin-12A B and other phragmoplast-associated proteins behaved in the absence of MAP65-3. Our results showed that the localization of Kinesin-12A B at the plus end of phragmoplast microtubules was dependent on MAP65-3. Another phragmoplast specific kinesin, PAKRP2 became evenly localized along phragmoplast microtubules in the *dyc283* cells, instead of being concentrated in the phragmoplast midline as in the control cells. However, the localizations of the syntaxin KNOLLE and the dynamin DRP1C at the cell division site were not affected by the loss of MAP65-3. Our results suggest that MAP65-3 functions as a scaffolding factor for kinesins to interact with microtubule plus ends in the phragmoplast, but the protein is not required for vesicle transport along phragmoplast microtubules during cytokinesis.
Centralspindlin and SPD-1: Non-Redundant Interaction Partners Critical for the Central Spindle Formation during Cytokinesis.

K. Lee, M. Mishima; Gurdon Institute, University of Cambridge, Cambridge, United Kingdom

The central spindle and midbody are microtubule bundle structures that are critical for cytokinesis, providing sites for the accumulation of various factors essential for this process. Two evolutionarily conserved microtubule bundling factors, the centralspindlin kinesin/RhoGAP complex and PRC1 microtubule-associated protein, are essential for the formation of the central spindle and midbody. Although centralspindlin and PRC1 independently show microtubule bundling activity in vitro, it is poorly understood how both of them are required to form these microtubule bundle structures in vivo. Interestingly, a direct interaction between PRC1 and the RhoGAP subunit of centralspindlin has been reported. To gain insights into how this interaction might contribute to cooperative microtubule bundling, we have tested the evolutionary conservation of centralspindlin-PRC1 binding and found that it also occurs between C. elegans SPD-1/PRC1 and CYK-4/RhoGAP. Using yeast two-hybrid and In Vitro pull-down assays, we have narrowed down the binding domains on both SPD-1 and CYK-4. Furthermore, we have introduced several point mutations to the interacting regions and are now investigating the significance of the centralspindlin-SPD-1 interaction for central spindle/midbody organization using different biochemical and functional analyses.

Antigen Presentation by Ventral Midbrain Dopaminergic Neurons: Implications in Parkinson's Disease.

C. Cebrian\(^1\), J. D. Loike\(^2\), S. Budhu\(^1\), D. L. Sulzer\(^1\); \(^1\)Neurology Department, Columbia University, New York City, NY, \(^2\)Physiology and Cellular Biophysics Department, Columbia University, New York City, NY

Parkinson's disease (PD) exhibits a progressive degeneration of dopaminergic neurons in the ventral midbrain (VM) but the cause of this neuronal loss is still poorly understood. Recent data suggest that neuroinflammatory mechanisms might contribute to the cascade of events leading to a chronic neuronal degeneration. The present experiments explore the immunological function of neuronal MHC class I antigens in VM cells. We show that MHC class I proteins were induced in postnatally-derived cultures murine VM neurons by treatment with recombinant IFN-γ. Moreover, CD8+ cytotoxic T lymphocytes that selectively recognize SIINFEKL peptide dramatically enhanced killing of MHC class I positive SIINFEKL treated neurons. We also examined the induction of the MHC-I in other brain regions (such as the cortex), but the expression of this antigen-presenting molecule was statistically lower than in ventral midbrain dopaminergic neurons. In addition, conditioned microglial medium obtained from microglial cultures treated with neuromelanin, lipopolysaccharide or alpha-synuclein induced MHC-I expression in VM neurons. These data reveal a novel inflammatory mechanism in neurodegenerative processes that could lead to the chronic neuronal death observed in PD.

Martins\(^2\); \(^1\)Molecular Brain Group, Robarts Research Institute, London - ONtario, ON, Canada, \(^2\)Molecular and Cell Biology, LICR, São Paulo, Brazil, \(^3\)Biochemistry, University of São Paulo, São Paulo, Brazil, \(^4\)Centro de Tratamento e Pesquisa do Hospital AC Camargo, AC Camargo, São Paulo, Brazil, \(^5\)Molecular Pharmacology, UFMG, Belo Horizonte, Brazil, \(^6\)Instituto de Biofísica Carlos Chagas Filho, UFRJ, Rio de Janeiro, Brazil
The prion protein (PrPC) is a cell surface glycoprotein highly expressed in the nervous system, a conformationally modified isoform of which is associated with prion diseases. PrPC interacts with various proteins modulating neuronal survival, plasticity and memory. Transmembrane proteins are likely required for PrPC-mediated intracellular signaling with consequences for neuronal function/dysfunction. We show here that a laminin gamma-1 chain peptide induces PrPC-dependent neuritogenesis through an increase in intracellular Ca2+ and activation of PKC. Inhibition of phospholipase C, inositol 3-phosphate receptor and group I metabotropic glutamate receptors (mGluR1/5) abrogates both PrPC-dependent Ca2+ signaling and neuritogenesis. In addition, the expression of mGluR receptors in HEK 293 cells reconstitutes the signaling pathways mediated by PrPC-laminin gamma-1 chain peptide interaction. In agreement with a role of mGluR s in neuronal differentiation “in vivo”, treatment of neurons with mGluR1/5 agonist induces neuritogenesis. These data show that group I mGluRs are involved in neurotrophic properties of PrPC-laminin interaction.

Reduced Degradation of Myelin Basic Protein by Anti-Sulfatide Antibody, TNF-α and IFN-γ in the Absence of Glia Maturation Factor.
A. Zaheer1,2, K. Menon2, S. Zaheer2; 1Neurology, VA Medical Center & U of Iowa, Iowa City, IA, 2Neurology, University of Iowa, Iowa City, IA

Multiple Sclerosis (MS) is an inflammatory demyelinating disease of CNS. The complex process of demyelination in MS is poorly understood. Glia Maturation Factor (GMF), discovered and characterized in our laboratory, is a highly conserved brain-specific protein. Recent findings indicate that GMF plays a critical role in regulating proinflammatory cytokines in the CNS and that GMF-deficient (GMF-KO) mouse failed to develop experimental autoimmune encephalomyelitis (EAE), an animal model of multiple sclerosis. In this study we show the effect of anti-sulfatide (RmAb) antibodies and inflammatory cytokines, TNF-α and IFN-γ in inducing myelin basic protein (MBP) degradation in myelin isolated from control wild type (WT) and GMF-KO mice. GMF was not detected in isolated myelin from WT and GMF-KO mice although it is present in brains of WT mice. Our results show that calcium-dependent neutral protease activity caused significantly elevated degradation of 18.5 and/or 17.5 kDa isoforms of MBP in WT myelin treated with RmAb or IFN-γ. In contrast, MBP degradation in isolated myelin from GMF-KO mice remained unaffected following treatment with RmAb, IFN-γ, or GM-CSF. Neither the 14 kDa isoform of MBP nor proteolipid protein (PLP) showed an elevated degradation compared to controls. A virtual absence of GM-CSF, TNF-α and IFN-γ in GMF-KO brain compared to WT was also evident when the animals were challenged with MOG 35-55. Taken together, our data suggests a role for GMF in the biochemical organization of myelin and thereby its effect on MBP degradation induced by RmAb and IFN-γ.

Function of Rab5 Subfamily Members in Ngf-Induced Neuron Differentiation.
L. Wang, G. Li; Department of Biochemistry and Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK

NGF (nerve growth factor) signal transduction and membrane trafficking are key processes of neuronal development. Since Rab5 subfamily of small GTPases play important roles in regulation of early endosomal sorting and endocytosis of signaling receptors, we have investigated the requirement of each Rab5 subfamily member, including Rab5, Rab21, Rab22, and Rab31, in NGF-induced neurite outgrowth in PC12 cells. Wild-type (WT), dominant active (DA), and dominant negative (DN) mutants of each Rab was expressed in PC12 cells via the pBI/eGFP vector, which expressed eGFP (enhanced green fluorescent protein) simultaneously to identify the transfected cells by fluorescence microscopy. In the case of Rab22, shRNA was used to knock-down endogenous Rab22 due to low expression of its DN mutant. The effects on NGF-induced neurite outgrowth were determined and compared. Our results showed that the DN mutants of Rab5 and Rab21 dramatically increased neurite outgrowth in PC12 cells; while their WT and DA counterparts inhibited this differentiation process. Expression of Rab31, in any form,
showed no effects on the neurite outgrowth. In contrast, Rab22 knock-down by shRNA significantly inhibited neurite outgrowth, while Rab22 WT or DA mutant showed little effects. The data suggest that Rab22-mediated early endosomal sorting and membrane recycling is important for NGF-induced neurite outgrowth. Furthermore, we found that Rabex-5 functions as a Rab22 effector in promoting neurite outgrowth. Overexpression of Rabex-5 or Rabex-5:D314A, a mutant defective in the Rab5 GEF activity, significantly enhanced neurite outgrowth, suggesting that the Rab22-Rabex-5 signaling cascade in neurite outgrowth is independent of Rab5 activation.

Alterations of EHD1/EHD4 Levels Disrupt Axonal Targeting of L1/NgCAM.
C. Yap1, Z. Lasiecka1, S. Caplan1, B. Winckler1; 1University of Virginia, Charlottesville, VA, 2University of Nebraska Medical Center, Omaha, NE

Polarized targeting is crucial for maintenance of neuronal polarity. The molecular mechanisms on how membrane proteins are selectively enriched in specific compartments in neurons remain unknown. We demonstrated previously that L1/NgCAM travels to the axon on an indirect transcytotic route via the somatodendritic plasma membrane and subsequent sorting to the axon in somatodendritic endosomes. Here, we further characterize the role of endosomal-related protein, EHD1/RME-1, in regulating L1/NgCAM recycling in neurons. EHD1/Rme-1 is a member of the Eps15 homology domain (EHD) family that also consists of other three highly homologous paralogs, i.e. EHD2, 3 and 4 in mammalian cells. EHD1 has been reported to regulate the recycling of AMPAR and transferrin from endosome to plasma membrane. We show here that overexpression of EHD1 leads to impairment of L1/NgCAM endocytosis in neurons and reduces the polarization of NgCAM in axon. In contrast, the expression of EHD1 does not affect the internalization of transferrin receptor. Interestingly, the inhibition of NgCAM endocytosis by EHD1 is not observed in fibroblasts. This indicates that endocytosis defect caused by the overexpression of EHD1 is cell type and cargo specific. Intriguingly, overexpression of EHD4, but not of EHD3, also causes a defect in NgCAM endocytosis and leads to reduced axonal polarization of L1/NgCAM. EHD family of proteins contains a central helical region that mediates self-oligomerization and hetero-oligomerization within the members of the family. In fact, an endogenous complex of EHD1 and EHD4 has been previously described. We find that a mutant of EHD1 that is impaired for oligomerization does not inhibit L1/NgCAM endocytosis. Strikingly, simultaneous expression of EHD1 and EHD4 rescues the NgCAM endocytosis defect whereas simultaneous expression of EHD4 and the oligomerization-impaired EHD1 does not rescue NgCAM endocytosis. Our observations suggest a model in which the relative levels of EHD1 to EHD4 are important for NgCAM endocytosis in neurons. We propose that L1/NgCAM uses a specialized endocytosis pathway in neurons dependent on EHD1 and EHD4, which may act as hetero-oligomeric complexes in this pathway.

Functional Selectivity in Serotonin 2A (5-HT2A) Receptor Trafficking.
I. Raote, M. M. Panicker; Molecular Neurobiology, National Centre for Biological Sciences, Bangalore, India

The serotonin receptor 2A (5-HT2A) is the target of several drugs, including ones for the treatment of psychiatric disorders and also recreational hallucinogenic drugs. Signal transduction cascades modulated by these ligands are poorly understood. The 5-HT2A is also a useful model system to study functional selectivity in GPCRs. Functional selectivity refers to ligand-dependent selectivity for signaling cascades at a receptor - the degree to which a pathway is modulated depends on the ligand, challenging definitions of ‘agonist’ and ‘antagonist.’ We describe the effects of several ligands (agonists as well as antagonists) on signaling and trafficking of the rat-5-HT2AR-EGFP expressed in HEK293 cells. We have earlier shown that agonists serotonin (5-HT) and dopamine bring about receptor internalisation and recycling. Interestingly, so do several other ligands including antagonists such as some antipsychotic drugs. We show that different biochemical pathways are involved in receptor internalization mediated by various ligands. Thus, agonists DOI and dopamine and some antagonists (including some antipsychotic drugs) bring
about rat-5-HT_{2A}-EGFP internalization and do not require PKC activation. We show that by abrogating a putative PKC-phosphorylation site on the receptor, we selectively inhibit internalization by ligands that require PKC-activation, leaving others unaffected. Also, we show that levels of receptor internalization vary significantly with the ligand used. Post internalization, the rat-5-HT_{2A}-EGFP recycles to the cell surface in varying times, depending on the ligand used. We have previously described that in HEK293 cells, 5-HT and dopamine bring about receptor recycling in 2.5 hours. We now show that agonist DOI and antagonists bring about recycling in 7.5 hours. Finally, it appears that receptor recycling requires de-phosphorylation, as protein phosphatase 2A (PP2A) activity is required for receptor recycling brought about by ligands that require PKC-activation for receptor internalization while not required for recycling effected by other ligands. These differences in internalization and recycling highlight a novel form of functional selectivity in GPCRs.

Nociceptin and Nociceptin Derivatives Are Chemorepellents in Tetrahymena thermophila.

H. G. Kuruvilla, J. Weston; Science and Mathematics, Cedarville University, Cedarville, OH

Nociceptin is a cationic neuropeptide which has been implicated in myriad biological functions, including pain, cognition, memory, and addiction pathways. Since the nociceptin receptor was discovered over a decade ago, much has been learned about the physiology of this peptide. The mechanisms of nociceptin signaling appear to be diverse. In hippocampal tissue, pharmacological inhibition of ERK suppresses signaling through the nociceptin receptor (Goeldner et al., 2008). Nociceptin receptors appear to directly interact with, and inhibit, N-type calcium channels (Altier and Zamponi, 2008). Nociceptin signals activate neuronal nitric oxide synthase (nNOS) (Xu et al., 2007), and inhibit cAMP-induced gene transcription (Gottlieb et al., 2006). Tetrahymena thermophila, as a model system in which to study nociceptin pathways. In Tetrahymena, nociceptin, as well as the nociceptin derivatives nociceptin-NH_{2} and nociceptin-Arg_{14}Lys_{15} all serve as chemorepellents in our behavioral assay. All three compounds had EC_{100} values in the micromolar range in our behavioral assay. The chemorepellent activity of nociceptin was blocked by the addition of genistein (100 μg/ml), suggesting tyrosine kinase involvement in the avoidance response. Avoidance to nociceptin was unaffected by the addition of diadzein (100 μg/ml), GDP-μ-S (1 mM), Rp-cAMPs (50 μM), neomycin sulfate (5 μM), calphostin C (10 μM), or U-73122(1 μM), suggesting that G-proteins, cAMP, and phospholipaseC/PKC signaling are not involved in the nociceptin response in this organism. Further experimentation will reveal more information about the nature of the proposed tyrosine kinase cascade, and how this activity relates to the ciliary reversal, ultimately leading to avoidance behavior in Tetrahymena.

Myostatin Expresses in Neurons Related to Olfactory System in the Brain.

S. Iwasaki, M. Miyake, E. Kitagawa, K. Watanabe, S. Ohwada, H. Aso, T. Yamaguti; Tohoku university, Miyagi, Japan

Myostatin, which is a negative regulator of skeletal muscle growth, belongs to the transforming growth factor-β (TGF-β) superfamily. Recently, it has been reported that myostatin mRNA is expressed in different brain regions of different vertebrates. However, the details of myostatin localization and function in the brain remain to be investigated. Therefore, we tried to examine the intracellular expression of myostatin and activin receptor type II (ActRIIB), which is the receptor of both myostatin and activin in mouse brain, and to further reveal the influence on neural activation of myostatin by the intracerebroventricular injection. Expression of myostatin, ActRIIB and activin a was analyzed by RT-PCR, in situ hybridization and immunohistochemistry using Male C57BL/6 mice aged 14 weeks-old. An intracellular existence of myostatin was identified by the immunostainings using mABs of myostatin and its propeptide. Myostatin was restricted in the mitral cells of olfactory bulb and in the neurons of olfactory cortex. On the other hand, activin A, which is a member of TGF-β superfamily, localized in neural cells of the hippocampus CA1 region, paraventricular thalamic nucleus and solitary nucleus. ActRIIB was observed in the cells of olfactory bulb, olfactory cortex, the hippocampus CA1 region and paraventricular thalamic
nucleus except for solitary nucleus. The findings show that myostatin and activin are differentially localized in mouse brain. When myostatin or activin was injected in the lateral ventricle, c-Fos, an activation marker for neural cells, was detected in neuronal cells of olfactory bulb of myostatin-injected mice but not activin-injected mice. The present study first describes that myostatin is expressed in the mitral cells of olfactory bulb and affects the olfactory system by autocrine and paracrine pathway.

Synergy between Purinergic and Cholinergic Signalling in Rabbit Lacrimal Gland.
J. Gierow1, S. K. Carlsson1, D. Delbro1,2; 1School of Pure & Applied Natural Sciences, University of Kalmar, Kalmar, Sweden, 2Department of Chemistry & Biomedical Sciences, University of Karlstad, Karlstad, Sweden

Introduction. We have previously shown that simultaneous stimulation of the muscarinic M3 receptor and the purinergic A1 receptor results in a secretion from lacrimal cells larger than a purely additive response, indicating a synergy between the signalling pathways (Edman et al., Exp Eye Res:86:110, 2008). More recently, our results also indicates the presence of both the purinergic A2a and A2b receptors (Gierow et al, Invest. Ophthalmol. Vis. Sci. 49 (ARVO abstract) p. 2449, 2008). Therefore, it was of interest to investigate if a similar synergy could be observed between the A2 receptors and the cholinergic receptor. Methods. Rabbit lacrimal gland acinar cells were prepared according to our standard procedure (Gierow et al., Am. J. Physiol. (Cell Physiology) 271: C1685, 1996; Andersson et al, Glycobiol. 15: 211, 2005) yielding single cells that were placed in a serum-free culture medium on standard culture plates coated with Matrigel for two days. The cultured cells were rinsed briefly and secretion was measured after a pre-incubation for 30 min at 37 C, with buffer alone, followed by incubation for an additional 30 min w./w.o. secretagogues and/or inhibitors as indicated. Basal secretion and regulated secretion was determined enzymatically as secreted beta-hexosaminidase activity. Results. A strong synergistic effect was observed when carbachol, a cholinergic agonist, and CPCA, an A2-agonist, were combined. The synergy was observed already after 5 min of incubation and at a low concentration of CPCA (0.1 μM). A response more than two-fold higher than expected was observed after 30 min of incubation at 10 μM CPCA. The synergistic effect was significantly reduced to levels comparable with Cch alone by the A2b antagonist PSB 1115, but not by SCH 52261, an A2a antagonist. Conclusions. Our results indicate that also the A2b receptor can potentiate the response to carbachol. The mechanism of potentiation remains unclear but preliminary studies indicate that intracellular Ca2+ is involved in the process. Support. Supported by Crown Princess Margareta’s Eye Research Foundation (JPG) and University of Kalmar Faculty Research Grant (DD & JPG).

Characterization of Behavioral Defects in PAM-1 Mutants in Caenorhabditis elegans.
A. K. Shah, L. Khadaran, R. Kohn, R. Lyczak; Biology, Ursinus College, Collegeville, PA

<p>Puromycin-sensitive aminopeptidases (PSA) are a widely conserved family of metalloproteases that hydrolyze N-terminal amino acids. The PSA homolog in Caenorhabditis elegans, PAM-1, has been localized to neurons, intestinal cells, and embryos (Brooks et al). While it has been implicated in meiotic exit and anterior-posterior axis specification in the early embryo (Lyczak et al), its role in the nervous system remains largely unstudied. Recent findings have shown that human PSA protects against tau-induced neurodegeneration In Vivo and directly proteolyzes tau In Vitro (Karsten et al). Such findings underscore the need for a more comprehensive understanding of the role of PSA in the nervous system. The objective of this study is to elucidate the possible functions of PSA in neurons by characterizing the behavioral defects of PAM-1 in C. elegans. Preliminary results indicate that motor activity, osmosensitivity, and mechanosensitivity are significantly impaired in pam-1 mutants. The or282 (early stop codon) and or403 (late stop codon) pam-1 alleles exhibit 72% and 24% decreases in motor activity and 60% and 78% decreases in osmosensitivity, respectively, versus the wildtype. Mechanosensitivity is also impaired in pam-1 mutants with the or282 allele, which display a 48% decrease in nose

Comprehensive Labelling of Melanopsin Expressing Retinal Ganglion Cells and Mapping Their Central Projection in Mouse.

S. R. Keding, M. Hatori, H. Le, S. Panda; Salk Institute, San Diego, CA

Melanopsin is an opsin class of photopigment exclusively expressed in a small subset of retinal ganglion cells (mRGCs) that are intrinsically photosensitive. These mRGCs project their axons to the suprachiasmatic nucleus (SCN) and a few other brain regions that directly or indirectly regulate non-image forming visual processes including circadian photoentrainment, pupil constriction, pineal melatonin regulation and light regulation of activity/rest. Identifying the full complement of mRGCs and their central projection is critical to understanding the cellular basis of melanopsin function. However, the existing methods to mark melanopsin cells and map their projections are insufficient. Therefore, we have generated transgenic reporter lines to specifically label the mRGCs and comprehensively study the projections of mRGCs in adult mice. We generated a mouse with targeted insertion of Cre-recombinase into the native melanopsin locus and bred it with a Z/EG or Z/AP mice. This strategy allows Cre-dependent expression of green fluorescent protein (GFP) or human placental alkaline phosphatase (AP) from a strong β-actin promoter. In the resultant mice melanopsin cells are marked with a GFP or an AP marker which can be visualized by fluorescence or histochemical staining respectively. In the retina of Opn4Cre/+;Z/EG mice, GFP expressing cells were mostly found in the retinal ganglion cell (RGC) sub-layer, and these cells had extensive dendritic arborization characteristic of the mRGCs. An average of 131 GFP expressing cells/mm² (±25.4, SD, n = 3) were found in these retina, 42.6% of which also expressed immunologically detectable levels of melanopsin. In Opn4Cre/+;Z/AP mice, the mRGCs strongly innervate the SCN. Additionally, mRGCs axon termini also sparsely innervate various other hypothalamic regions. Surprisingly, the AP staining also revealed extensive projection of the mRGCs in the lateral geniculate complex which is involved in image-forming vision. This implies mRGCs may play some role in patterned vision. In summary, we found that the projection patterns of mRGCs were much more extensive than previously reported.

656/B603

Lysophosphatidic Acid (LPA) Is a Chemoattractant and a Mitogen in Tetrahymena: Separation of These Two Response Pathways by a GPCR Knockout Mutant.

T. J. Lampert, C. Diederich, K. D. Coleman, T. M. Hennessey; Biological Sciences, University at Buffalo, Amherst, NY

Tetrahymena are free-swimming eukaryotic unicells that change their swimming behavior in response to many types of stimuli to direct them away from dangerous areas and towards preferred areas, such as food sources. Some of the cellular receptors and pathways involved may be sufficiently conserved to allow the use of Tetrahymena as a simple model system for chemosensory transduction studies in these “free swimming sensory cells”. In general, chemoattractants cause somatic hyperpolarization, faster forward swimming and more linear swim paths while chemorepellents cause depolarizations, slower forward swim speeds and action potentials at threshold concentrations to cause bouts of backward swimming. Since many chemosensory receptors are GPCRs (G-protein coupled receptors) we identified several possible GPCR sequences in the Tetrahymena Genome Database and used them to generate knockout mutants by homologous recombination. One mutant, G6, is a complete macronuclear knockout of GPCR6 (THERM_00925490). This mutant is unresponsive to the chemoattractants lysophosphatidic acid (LPA,10μM) and proteose peptone (0.1%), suggesting that gpcr6 may be a chemosensory receptor. Since the LPA and proteose peptone responses cross-adapt in wild type and both chemoattractant responses are missing G6, it is possible that both stimuli share a common receptor. The G6 mutant is also more resistant to Ba++ paralysis than wild type,
suggesting that GPCR6 may have some constitutive effects on divalent ion permeabilities as well. The G6 mutant can be phenocopied by either pertussis toxin or calphostin C, suggesting a G-protein and protein kinase C involvement in this chemoresponse pathway. LPA is also a potent mitogen, causing a 2-3 fold increase in cell number when added to growing cultures in micromolar amounts. Since LPA is also a mitogen in the G6 mutant, the LPA chemotraction and mitogen pathways may be different in these cells and each may have different receptors. Supported by NSF grant MCB-0445362 to T.M.H.

**Neuferricin, a Novel Extracellular Heme-Binding Protein, Promotes Neurogenesis by Inhibiting Cell Proliferation.**

Y. Nakayama¹, I. Kimura¹,², M. Konishi², M. Mori¹, M. Ito¹, M. Ohta³, N. Itoh², M. Fujimoto¹; ¹Chiba Institute of Science, Choshi, Chiba, Japan, ²Kyoto University Graduate School of Pharmaceutical Science, Kyoto, Japan, ³Kobe Pharmaceutical University, Kobe, Japan

We identified a novel extracellular heme-binding protein and named it neufericin. The recombinant mouse neufericin produced in cultured cells was secreted efficiently into the culture medium. Mouse neufericin mRNA was expressed exclusively in the brain at the embryo stage and gradually increased during development. In contrast, it was widely expressed in postnatal tissues including the brain, heart, adrenal gland, and kidney. Mouse neufericin has 263 amino acids. It has a cytochrome b5-like heme/steroid-binding domain and appeared to bind hemin because neufericin solution, but not a solution of neufericinΔHBD (a mutant lacking the heme-binding domain), was tinged with brown and had an absorbance peak at 402 nm. In addition, the experiment with anti-neufericin antibody proved that the endogenous neufericin detected in the culture medium of Neuro2a cells using heme-affinity chromatography was associated with hemin. Inhibition of endogenous neufericin by RNA interference excessively promoted proliferation and suppressed neurite outgrowth during the induction of differentiation in Neuro2a cells. Addition of recombinant mouse neufericin, but not neufericinΔHBD, suppressed proliferation in Neuro2a cells and rescued from the effects of neufericin RNAi. In primary cultured mouse neural precursor cells, recombinant mouse neufericin exhibited the ability to promote neurogenesis. The identification of neufericin, a novel extracellular heme-binding protein with cytochrome b5-like heme/steroid-binding domain and its neurogenic activity, provide new insights not only into brain development but also the function of heme-binding proteins as extracellular signal transmitters.

**Existence of Secretory Granule (Large Dense Core Vesicle)-Based Inositol 1,4,5-Trisphosphate-Dependent Ca2+ Signaling System in Astrocytes.**

Y. S. Hur, K. D. Kim, S. H. Yoo; Biochemistry, Inha University School of Medicine, Incheon, Korea, South

Astrocytes are now known to secrete a number of signaling molecules that participate in the cell-to-cell communication, involving both the neurons and the glial cells. There exist generally two types of secretory vesicles in astrocytes, one being the translucent small synaptic-like vesicles and the other the large dense-core vesicles. To clarify the identity of the large dense core vesicles and to elucidate the IP3-dependent Ca2+ signaling mechanism in astrocytes, we investigated the presence of typical secretory granule marker proteins, chromogranin B (CGB) and secretogranin II (SgIIL), in astrocytes. We have also examined the potential presence of the IP3Rs in the large dense core vesicles of astrocytes. In the present study, we found the localization of two typical secretory granule marker proteins chromogranin B and secretogranin II in the large dense-core vesicle of astrocytes, thereby identifying the large dense-core vesicles as secretory granules. We also found the presence of large amounts of all three isoforms of the IP3Rs in secretory granules of astrocytes. Hence, in view of the roles of secretory granules in secretory cells as the major IP3-sensitive intracellular Ca2+ store, the existence of secretory granules in glial astrocytes strongly suggests the existence and operation of an IP3-sensitive intracellular Ca2+ store of astrocytes in the form of secretory granules (large dense-core vesicles).
Function of Semaphorin 6D on Cerebellar Granular Precursors and Medulloblastoma Cells.

P. Massoma1, C. Meissirel1, D. Meyronet1, V. Rogemond1, N. Chounlamountri1, T. Toyofuku2, A. Kumanogoh2, J. Honnorat1, N. Thomasset1; 1Faculty of Medicine, INSERM U842, Lyon, France, 2Dpt of Immunopathology, Osaka University, Osaka, Japan

During development, nervous progenitors are responsive to microenvironment. Precisely, under guidance cues progenitors migrate on long distances to their specific targets where they fully differentiate. During tumoral process, cell migration is often impaired leading to invasive growth. Semaphorins, first described as guidance cues for axons have been recently involved in cell migration, apoptosis, nerve regeneration and tumor progression. We focused on semaphorin 6D (Sema6D), first described in the collapse of DRG neurons and migration of embryonic cardiac cells (Qu et al., J. Biol. Chem. 2002; Toyofuku et al., Genes Dev. 2004). Our objective is to explore the role of Sema6D on cerebellar granule cell precursors (GCPs) compared to Medulloblastoma cell lines DEV and DAOY. We demonstrated that Sema6D is located in the external granular layer during cerebellum development and induced apoptosis in the granule cells (GC) expressing only Sema6D. Using a TUNEL and caspase 3 active assays, our results showed a 30% increase of GCPs apoptosis (92 ± 2.7) when seeded with GCPs expressing Sema6D versus (31 ± 1) with control cells (n=4; p<0.001). Furthermore, Sema6D acts as a repulsive guidance cue for GC axons. Medulloblastoma cell lines, Dev and Daoy, which expressed only plexinA1, did not undergo apoptosis but an increase of migration by 30% under Sema6D. Using a chemiotaxis assay, DEV cells migration is significantly increased when they are seeded with Sema6D (22.3 ± 2.3) compared without Sema6D (12 ± 0.7; p<0.01). The overexpression of mutated form of plexin A1 demonstrated the importance of plexinA1 in the migration of medulloblastoma cells. on medulloblastoma biopsies a large expression of plexinA1 is detected pointing out a role of Sema6D in the progression of Medulloblastoma. Conclusion : GCPs expressed Sem6D while Medulloblastoma cells expressed only the receptor PlexinA1. Apoptosis is observed under GCPs exposure to Sema6D while in Medulloblastoma cells ,migration is observed depending of plexinA1 under Sema6D

Chemical Transmission between Dorsal Root Ganglion Somata through Schwann Cell Intervention.

H. Kim1,2, F. K. Wong1,2, E. F. Stanley1,2; 1Genes and Development, Toronto Western Research Institute, Toronto, ON, Canada, 2Physiology, University of Toronto, Toronto, ON, Canada

Sensory neurons relay action potentials directly from the periphery to the spinal cord along a continuous axon that does not pass through the cell body located off a side branch in the dorsal root ganglion (DRG). Indeed, it is generally supposed that the neuronal somata are electrically independent. However, action potential backfiring from non-stimulated neurons has been reported and suggests at least some form of inter-neuron transmission. It has also been reported that DRG neurons activate their enveloping Schwann cells via purinergic transmission (Zhang et al., 2007 Proc Natl Acad Sci). Objective: to test if neighbouring DRG neuron somata can communicate via a di-synaptic mechanism through an intervening Schwann cell. Methods: Chick DRG neurons were gently dissociated to retain small clusters with their enveloping Schwann cells. The patch clamp technique was used to record ion currents from single cells or two cells simultaneously and variety of pharmacological agents were used to dissect the chemical signalling pathways. Results: Morphological studies confirmed that DRG neurons are separated by one or two glial cell layers. Direct recording from DRG-associated Schwann cells detected intermittent current transients that were identified as miniature excitatory spontaneous currents (mEPGs; n=5). Recordings from DRG neurons held at -80 mV detected variable membrane current noise current (n= 11) that was blocked by the nicotinic antagonist, d-tubocurarine (n=5) and that was enhanced by ATP application onto its associated Schwann cell. Depolarization of one DRG neuron in paired recordings triggered increased ACh noise 5 to 40 seconds later in one or both cells (n=9). Conclusion: Our results suggest a form of chemical transmission whereby a
DRG soma releases ATP to excite its enveloping Schwann cell which in turn secretes acetylcholine to activate neighbouring DRG somata. This ‘sandwich synapse’ represents a unique mechanism of inter somatal communication.

Structure of Botulinum Neurotoxin Serotype B in a Lipid Bilayer at Multiple pH Levels.
C. P. Arthur, R. Milligan; Scripps Research Institute, La Jolla, CA

Botulinum Neurotoxin (BoNT) is the most deadly bacterial neurotoxin known. Secreted by the bacteria *Clostridium botulinum*, it has seven serotypes (A-G). BoNT B is a Zn2+ -endoprotease that acts on the exocytotic machinery at the neuromuscular synapse by cleaving unique components of the SNARE complex thus inhibiting synaptic vesicle fusion and subsequent neurotransmitter release. BoNTs are produced as 150 kDa single polypeptide chains, which are cleaved into 100 kDa heavy chain (HC) and a 50 kDa light chain (LC) linked by a disulfide bond. The 100 kDa HC contains a 50 kDa translocation domain and a 50 kDa receptor binding domain. The 50 kDa LC is made up of a single catalytic domain. The pivotal event in the BoNT intoxication is the translocation of the LC across the cell membrane of the endocytosed vesicle into the cytosol. It has been postulated that upon a reduction in pH (7-4), BoNT undergoes a conformational change whereby the translocation domain inserts into the membrane forming some type of a channel through which the LC can be transported. Previous electron cryomicroscopy studies have shown the potential presence of a membrane channel, however, the resolution of these structures was at the outer limit of being able to detect a channel structure. Here, we have crystallized BoNT B at pH 6.0, 5.6, and 4.8 in the presence of lipid (DOPS) and ganglioside (GD1a). These structures show no presence of a membrane-spanning channel. These results lead us to believe that the presence of a protein channel may not be necessary for the translocation of the BoNT LC and that possibly the unfolding or conformational change of the LC itself disrupts the membrane enough to allow it to pass through.

Catharanthine Alkaloids Are Noncompetitive Inhibitors of Muscle-Type Nicotinic Acetylcholine Receptors.
J. Saghedejian1, D. Feuerbach2, A. Rosenberg3, K. M. Targowska-Duda4, K. Jozwiak4, R. Moaddel3, I. W. Wainer3, H. R. Arias1; 1Department of Pharmaceutical Sciences, Midwestern University, Glendale, AZ, 2Neuroscience Research, Novartis Institutes for Biomedical Research, Basel, Switzerland, 3Gerontology Research Center, National Institute of Aging, NIH, Baltimore, MD, 4Department of Chemistry, Medical University of Lublin, Lublin, Poland

This is an attempt to characterize the binding sites and the mechanisms of action of several catharanthine alkaloids including ibogaine, vincristine, and vinblastine, on muscle-type nicotinic acetylcholine receptors (AChRs), by comparing their pharmacological properties with that for the well characterized high-affinity noncompetitive antagonist (NCA) phencyclidine (PCP). In this regard, structural and functional approaches were used including radioligand equilibrium and competition binding assays using [3H]ibogaine and the analog of PCP, [piperidyl-3, 4-3H(N)]-N-(1-(2 thienyl)cyclohexyl)-3,4-piperidine ([3H]TCP), Ca2+ influx determinations, thermodynamic and kinetic measurements using column-immobilized Torpedo AChRs, and molecular docking and dynamics studies. The results established that: (a) the alkaloids inhibit (±)-epibatidine-induced Ca2+ influx in embryonic muscle AChRs with the following potencies (in μM): ibogaine > vinblastine > vincristine, that are slightly higher than that for PCP, (b) the alkaloids inhibit [3H]TCP binding, and ibogaine and PCP inhibit [3H]ibogaine binding, to the desensitized Torpedo AChR with higher affinity compared to the resting AChR, (c) ibogaine binds to the Torpedo AChR by an enthalpy-driven process, and (d) ibogaine interacts with a binding domain located between the serine (position 6') and valine (position 13') rings, by a network of van der Waals and polar interactions. Collectively our data indicate that catharanthine alkaloids block agonist-activated ion channels by interacting with a binding domain that is shared with PCP located between the serine and valine rings. This supports the view that the catharanthine moiety, which is shared by ibogaine and vinca alkaloids, is a minimum structural requirement for the interaction of these
molecules with the ion channel. In addition, ibogaine and vinca alkaloids may induce and maintain the desensitized state by a mechanism where their dissociation rates are decreased.

Glutamate Induces a Specific Nuclear Size Change in Astrocyte through Aquaporin 1.
A. C. Yu¹, C. Yang¹, Y. Zhou¹, J. Chen²; ¹Neurobiology, Peking University, Beijing, China, ²Cell Biology and Genetics, Peking University, Beijing, China

Glutamate (Glu), an evolutionary selected excitatory messenger between neurons and astrocytes, was found to specifically induce nuclear swelling in astrocytes, but not in any other cell types. This was a direct and specific effect of Glu uptake via transporters, and not receptors, metabolites, ion or osmotic changes. Interestingly, Glu-induced nuclear swelling was found to require aquaporin 1 (AQP1), which was uniquely expressed and located on the nuclear membrane of astrocytes. Moreover, over-expression of AQP1 in astrocytes accelerated and enhanced nuclear swelling and if inhibited would prevent swelling. Our study discovers a specific nuclear response in astrocytes to exogenous Glu. This new mechanism might be an unknown specialization in astrocyte to facilitate the communication of excitatory information between neuron and astrocyte.

M. Jiang, G. Chi, D. Kim, H. Choi, H. Hong, Y. Son; Tissue Engineering, Kyung Hee University, Yong In, Korea, South

Recent several evidence has demonstrated that neuropeptide, in particular substance P(SP), plays an important role in various wound healing. The inflammatory response is playing an important role in the acute and chronic phases of spinal cord injury(SCI). We explored the effect of exogenous SP on functional recovery after SCI. SP was intravenously injected three times, immediately, 24h and 48h after contusive SCI. RT-PCR analyses revealed that SP injection increased expression of IL-10 mRNA, an anti-inflammatory cytokine but decreases TNF-α, IL-6, iNOS expression, potent pro-inflammation cytokines. at five days after SCI, the immunohistochemical analysis showed that SP treatment dramatically reduced ED1 positive cells in the lesion site when compared to the vehicle control. In addition, SP treatment significantly reduced the number of TUNEL positive cells as compared to that of the vehicle control and Basso-Beattie-Bresnahan(BBB) locomotor open field behavioral scores were significantly higher in SP-treated rats than vehicle-treated rats. These data support that SP treatment modulated inflammatory responses in the SCI, resulted in lower cell death, and improved functional recovery after SCI, possibly by stimulating anti-inflammatory response and mitigate the injury-mediated cell death.

Role of the G-Protein Coupled Receptor, SER-7, in Adaptation and withdrawal Responses to Chronic Serotonin Exposure in C. elegans.
L. Carnell, J. Groves; Biological Sciences, Central Washington University, Ellensburg, WA

We are investigating the behavioral responses and neural pathways modulated by chronic elevations of serotonin (5-HT) levels using the roundworm, C. elegans. In C. elegans long-term exposure to 5-HT leads to a diminished response over time, a phenomenon referred to as behavioral adaptation. A subsequent rebound effect occurs upon removal of worms from 5-HT, which is referred to as withdrawal. Both of these responses associated with chronic 5-HT exposure can be quantified by examination of the worm's egg-laying behavior. Acute exposure to 5-HT normally increases egg-laying rate two to three fold in wild-type worms, while longer overnight exposure results in a return of egg-laying rates to untreated control levels. Removal from 5-HT results in a further decrease in egg-laying rates to about 20% of untreated control levels. We initiated a study using a candidate gene approach to identify proteins mediating...
adaptation and withdrawal responses. We identified SER-7, a 5-HT-dependent G-protein coupled receptor (GPCR), is important for mediating the withdrawal responses. SER-7 has previously been shown to couple to Gαs and mediate the stimulatory effects of 5-HT on egg laying along with another GPCR, SER-1. ser-7 mutant worms show a two-fold increase in egg-laying rate during withdrawal rather than a decreased egg-laying rate seen in wild-type worms. A quadruple mutant lacking all of the identified 5-HT receptors in C. elegans, except SER-7 was tested and displayed normal withdrawal responses further demonstrating a role for SER-7 in the withdrawal response. Double mutants lacking both stimulatory receptors, SER-7 and SER-1, are also deficient in withdrawal while ser-1 mutants alone show normal withdrawal responses. This result suggests that SER-7 acts downstream of the SER-1 pathway. Our results suggest a pathway for the withdrawal response involving SER-7 presumably through activation of a cAMP-dependent pathway.

A1 and A20 Expression in Cortex, Hippocampus and Brainstem Induced by LPS and Their Relationship with Apoptosis in a Shock Endotoxic Model.
E. Meza-Lamas; UAZ, Guadalupe, Zacatecas, Mexico

Endotoxic shock it’s a consequence of a poor regulated immune response when organisms are exposed to gram-negative bacteria and these release lipoposachryde (LPS). In this way LPS cause damage trough a badly immune response, release inflammatory substances like TNF-α, IL-1, IL-4 e IL-6. This event active regulatory signals of apoptosis induced by TNF-α, A1 and A20 proteins. Our aim was to study the A1 and A20 expression in Sprague-Dowley rat brain and the relationship between endotoxic shock-apoptosis in cortex, stem and hippocampus. We observed morphological changes in tissues related with apoptosis and necrosis using HE stain. With TUNEL, we can verify the cell death in different exposition times to LPS; this phenomenon can be observed in tissues with 30 minutes after exposition to LPS. The western blot assay shows the protein expression with evident changes in different exposition times. This pattern of antiapoptotic proteins expression was clear after 30 minutes after exposition to LPS. A1 and A20 proteins are expressed in endothelial cells in a proinflamatory response to protect it versus apoptosis mediated by TNF and ceramides. A1 and A20 are members of Bcl-2 proteins and blocks the transcriptional process mediated by NFkB. This investigation shows the rol of NF-kB in immune system with A1 and A20 expression.

A Novel Protein That Potentiates the Function of Mammalian Odorant Receptors.
Y. Li, H. Matsunami; Duke University, Durham, NC

Mammalian olfaction begins with the activation of odorant receptors (ORs), which are class a G-protein coupled receptors (GPCRs) expressed on the surface of olfactory sensory neurons (OSN), by volatile odorant molecules. While a large number of ORs have been identified, little is known about the complex mechanism behind OR ligand selectivity and combinatorial coding. Previous studies in our laboratory have demonstrated that OR expression in heterologous cells can be enhanced by a group of transmembrane proteins RTP1 and RTP2. Since OR activity remains lower in heterologous cells in comparison to that in the sensory neurons, we hypothesized that other proteins may form functional interactions with ORs that are required for OR activation or trafficking. To screen for accessory proteins that enhance the activity of ORs, we used a luciferase assay system that quantities OR activity upon odorant stimulation. Here, we report the discovery and characterization of an OR-Enhancing Protein 3 (OREP3) as a membrane receptor that potentiates the activation of a number of ORs when it was transiently expressed in HEK293T and Hana3A cells. Coexpression of OREP3 lowered the EC50 by a factor of 10 and increased the maximum luciferase response upon OR stimulation by 30-50%. Unlike RTP1 and RTP2, OREP3 did not seem to enhance cell-surface expression of the ORs, suggesting that the action of OREP3 is distinct from known accessory factors. Furthermore, the ability of OREP3 to enhance OR activation appeared to be significantly enhanced in the presence of RTP1, which indicated that the effect of OREP3 is synergistic. We have found that OREP3...
forms stable complexes with ORs when they are coexpressed in HEK293T cells. These results suggested that POREP3 and ORs may form heteromeric, functional interactions that leads to the potentiation of OR activation by POREP3. We have used POREP3 to develop a novel screening system that increased the efficacy of our screening system for the ligands of orphan ORs. This information will be integral to deciphering the molecular mechanism of olfaction in mammals.

Short-Chain Fatty Acids Regulate the Sympathetic Nervous System via the GPR41.
I. Kimura, D. Inoue, T. Maeda, S. Miyauchi, A. Ichimura, A. Hirasawa, G. Tsujimoto; Department of Genomic Drug Discovery Science, Kyoto University Graduate School of Pharmaceutical Science, Kyoto, Japan

Short chain fatty acids (SCFAs), including acetate, propionate and butyrate, are primary derived from bacterial fermentation of carbohydrates in the colon. They not only contribute significantly to caloric intake but also function as signaling molecules. GPR41 was identified as the G protein-coupled receptor for SCFAs. Recently, it was reported that regulation of colonic motility in small intestine and leptin production in adipocytes was induced by SCFAs through the GPR41. However, the physiological functions of GPR41 are little known, because GPR41 expression was low and species difference in these tissue. Here we report that mouse GPR41 mRNA is expressed most abundantly in sympathetic ganglion than other tissues during from developmental stage to adult stage. Therefore, we generated GPR41 knockout mice to elucidate the physiological roles of GPR41 in sympathetic nervous system. During developmental stage, the mildly differentiational retardation of sympathetic ganglion in GPR41-/- mice was observed. In adult stage, Deletion of the GPR41 led to a decrease of sympathetic activity with heart rate, blood pressure and an increase of noradrenaline concentration in heart and sympathetic ganglion but not catecholamine in adrenal gland. The heart rate had not been significantly different by the treatment with propranolol as beta-adrenoceptor blocker. In addition, in primary cultured mouse sympathetic neurons, the treatment with SCFAs promoted the release of noradrenaline and neurite extension. The sympathetic neurons from GPR41-/- mice did not exhibit these effects. Therefore, GPR41 may regulate the sympathetic nervous system by modulating the release of noradrenaline in sympathetic neuron. These results will provide new insights into SCFAs as a neurotransmission regulator and neurotrophic factor through the GPR41.

Maternal and Postweaning Diet Interaction Alters Hypothalamic Gene Expression and Response to a High-Fat Diet in Male Offspring.
K. C. Page¹, R. E. Malik¹, E. K. Anday²; ¹Biology, Bucknell University, Lewisburg, PA, ²Pediatrics, Drexel University College of Medicine, Philadelphia, PA

We tested the hypothesis that consumption of excess saturated fats during pregnancy and lactation contributes to adult metabolic dysfunction and that these disturbances can be further influenced by the postweaning diet. Adult male offspring from chow-fed dams were compared with males from dams fed a diet high in saturated fat (45 kcal/100 kcal) before mating, during pregnancy and lactation. Offspring were weaned to a standard chow diet or high fat diet. Animals were killed at 120 days after a 24-h fast. Although there was no difference in birth weight between offspring from dams fed control food compared to those fed a high-fat diet, wean weight was significantly higher in offspring from the high-fat fed dams. By day 120 of the postnatal period, weight gain and energy intake were significantly increased in the fat-fed offspring from fat-fed dams (P <0.001). Fat deposition, serum leptin, and insulin were significantly increased in offspring from control or high-fat fed dams if fed a high-fat diet from weaning to adulthood. However, only fat-fed offspring from fat-fed dams were hyperglycemic. Leptin receptor and neuropeptide Y (NPY) were also significantly increased in offspring exposed to excess saturated fat during gestation and into adulthood, whereas NPY1 receptor was downregulated. Signal transducer and activator of transcription 3 mRNA level was significantly higher in offspring from high-fat-fed dams compared with controls; however, no change was detected in cocaine and amphetamine-regulated transcript or suppressor of cytokine signaling 3. A significant reduction in
phosphatidylinositol 3-kinase regulatory subunit (p85α) mRNA (P < 0.001) and protein levels (P < 0.006) were coupled to an upregulation of protein kinase B mRNA (P < 0.014) in offspring from high-fat-fed dams transitioned to chow food. In contrast, p85α subunit mRNA was significantly increased in offspring from high-fat fed dams weaned to the high-fat diet (P < 0.05). These data support the hypothesis that early life exposure to excess fat is associated with changes in hypothalamic regulation of body weight and energy homeostasis and that postweaning diet influences the development of metabolic dysfunction and obesity.

Endoplasmic Reticulum (670 – 684)

Rab32 Inhibits Apoptosis and Disrupts Calnexin Targeting to the Mitochondria-Associated Membrane.
T. Simmen³, M. Bui³, J. D. Scott², S. Strack³; ³Department of Cell Biology, University of Alberta, Edmonton, AB, Canada, ²Department of Pharmacology, University of Washington, Seattle, WA, ³Department of Pharmacology, University of Iowa Carver College of Medicine, Iowa City, IA

The mitochondria-associated membrane (MAM) has emerged as an endoplasmic reticulum (ER) signaling hub that accommodates ER chaperones. At the MAM, these chaperones control ER homeostasis, but also play a role in the onset of ER-stress mediated apoptosis. These opposing roles of MAM-localized chaperones suggest the existence of mechanisms that regulate the composition and the properties of ER membrane domains. Our results now localize the GTPase Rab32 to the ER and identify this protein as a novel ER domain orchestrator. Consistent with such a role, active Rab32 disrupts MAM retention of the chaperone calnexin. Furthermore, Rab32 determines the targeting of PKA to membranes of the ER and mitochondria. This function of Rab32 controls the phosphorylation of Bad on serine 155 and of Drp1 on Serine 656. Through a combination of its functions as a PKA-anchoring protein (AKAP) and a regulator of MAM composition, Rab32 over-expression inhibits apoptosis.

Seipin, but Not a Point Mutant That Results in Lipodystrophy, Is a Component of a Discrete Proteinaceous Complex.
D. D. Binns, S. Lee, R. Liu, J. M. Goodman; Pharmacology, UT Southwestern, Dallas, TX

Seipin is an ER integral membrane protein that is important for cytoplasmic lipid droplet assembly and/or maintenance; droplet morphology is severely altered in yeast harboring a seipin gene disruption, and patients with mutated seipin (notably A212P) have an absence of subcutaneous adipose tissue and develop fatty liver and insulin resistance. (Other seipin mutations cause the neuropathic Silver syndrome.) Human seipin can complement the yeast null strain. We had observed by fluorescence microscopy that seipin-mCherry forms puncta at the junction of ER and droplets, suggesting that several seipin molecules associate in a complex (Szymanski et al., PNAS, 2007). To learn more about the nature of the seipin complex, we subjected to velocity sedimentation detergent-solubilized yeast ER membranes containing seipin tagged in the genome with 13 copies of the myc epitope (seipin-myc13). In a detergent glycerol gradient, seipin-myc13 behaves as a ~220 kDa protein (monomer MW=53 kDa) with respect to soluble protein standards. Overexpressed protein behaves similarly, and overexpressed seipin-mCherry or overexpressed untagged protein also are found in large discrete complexes. We employed the method of Clarke and Smigel (Meth Enzymol 1989) to assess the extent of detergent binding in the complex and to determine the MW of the proteinaceous component. Using H₂O- and D₂O-sucrose gradients and S500 gel filtration, we determined that seipin-myc13 is in a 498±6 kDa protein complex. The Stokes' radius of the protein-detergent complex was 113 Å (similar values using cholate or Triton X-100), indicating an elongated shape, probably a disk, in the membrane. The extrapolated S²₀,ₐ value of the protein-detergent complex was 11.1. Interestingly, in cells expressing a point mutation in seipin-myc13, G225P, orthologous to the A212P human mutation, the complex was smaller: The protein component was 316±6 kDa (S²₀,ₐ=8.0 for the protein-
Whether seipin is in a homo-oligomeric or hetero-oligomeric complex is not yet clear. These results suggest that assembly of the correct seipin complex is important for the function of seipin in droplet biology, and in the generation of normal adipose tissue in humans.

**Cadmium-Mediated Rescue from ER-Associated Degradation Induces Expression of Its Exporter.**

J. Lee, W. Wei, N. Smith; Biochemistry, University of Nebraska, Lincoln, NE

Endoplasmic reticulum-associated degradation (ERAD) ensures the secretion of correctly folded and assembled proteins, which is necessary for the prevention of toxic accumulation of aberrant proteins. Our data showed that in addition to quality control, cells utilize ERAD for regulating the expression of a plasma membrane protein in response to cellular signals. Turnover of Pca1, a functional and naturally expressing cadmium efflux pump in yeast Saccharomyces cerevisiae, is mediated by ERAD via a degradation signal that can be masked by cadmium. A cysteine-rich amino-terminal degron rapidly targets the constitutively expressing Pca1 to the ERAD pathway. However, in the presence of cadmium, direct sensing of metal ions within the degradation signal induces its conformational change, which leads to an escape of Pca1 from ERAD. This substrate-mediated rescuing from destruction at the ER allows secretion of Pca1 for cadmium extrusion at the cell surface. Given that delicate control of homeostatic acquisition and detoxification of metal ions is a vital biological process, this mode of regulation represents a unique interaction between organism and toxic metal ion. Yeast has likely evolved this regulatory mechanism for a rapid cellular response to environmental changes. The ERAD of a significant portion of the secretory proteome may not be only attributed to a failure of correct folding. Rather, secretion versus degradation at the ER might be coupled through cellular cues as demonstrated for Pca1.

**Hog1 MAP Kinase Coordinates a Late-Phase Endoplasmic Reticulum Stress Response Pathway in Budding Yeast.**

A. A. Bicknell, M. Niwa; Biological Sciences, University of California, San Diego, La Jolla, CA

In eukaryotic cells, nascent secretory proteins are translocated into the endoplasmic reticulum (ER), which promotes their proper folding and maturation before allowing them to be targeted to their final destinations. Under certain environmental or developmental conditions, unfolded proteins can overwhelm the protein folding capacity of the ER, thus leading to ER stress. Upon sensing ER stress, the Unfolded Protein Response (UPR) signaling pathway rapidly activates the transcription of genes that help expand the ER's protein-folding capacity. However, very little is known about how the cell responds if ER stress continues to persist after this initial wave of gene activation. We show that Hog1, a MAP kinase known to function in the osmotic stress response, coordinates a multi-faceted response to persistent ER stress. Under conditions of prolonged ER stress, Hog1 becomes phosphorylated through a unique mechanism, overlapping but distinct from the Hog1 activation mechanism of the osmotic stress response. This activation of Hog1 directly enhances the rate of recovery within the ER lumen. Upon phosphorylation, Hog1 is first translocated into the nucleus where it regulates a unique transcriptional program. Subsequently, although phosphorylation levels remain high, Hog1 returns to the cytoplasm. This step distinguishes the late-phase ER stress response from the osmotic stress response, in which Hog1 phosphorylation correlates strictly with nuclear localization. Upon returning to the cytoplasm, Hog1 activates autophagy by enhancing the production of Atg8, a critical autophagy protein. HOG1-mediated Atg8 production occurs at a post-transcriptional level through Hog1’s cytoplasmic target, Rck2. Mammalian cells also elicit a unique response to persistent ER stress, in this case marked by the specific activation of apoptotic pathways. Thus, understanding the distinction between early and persistent ER stress may be important for understanding the human pathologies that result from downstream effects of ER stress.

**An Essential Role for XBP-1 in Host Protection against Immune Activation in C. elegans.**

C. E. Richardson, T. Kooistra, D. H. Kim; Biology, MIT, Cambridge, MA

The detection and compensatory response to the accumulation of unfolded proteins in the endoplasmic reticulum (ER), termed the Unfolded Protein Response (UPR), represents a conserved cellular homeostatic mechanism with important roles in normal development and in the pathogenesis of disease. The IRE-1-XBP-1 pathway is a major branch of the UPR that has been conserved from yeast to human. XBP-1 is required for the differentiation of the highly secretory plasma cells of the mammalian adaptive immune system, but recent work also points to important reciprocal interactions between the UPR and other aspects of immunity and inflammation. We have been studying innate immunity in the nematode *Caenorhabditis elegans*, having established a key role for a conserved PMK-1 p38 mitogen-activated protein kinase (MAPK) pathway in mediating resistance to microbial pathogens. Here, we show that during *C. elegans* development, XBP-1 has an essential role in protecting the host during activation of innate immunity. Activation of the PMK-1 p38 MAPK-mediated immune response by infection with *Pseudomonas aeruginosa* induces the XBP-1-dependent UPR. We find that XBP-1 is required for development and that loss of XBP-1 activity leads to lethality. We find that this developmental phenotype is dependent on activation of the innate immune response. Our data establish innate immunity as a physiologically relevant and developmentally critical initiator of ER stress in *C. elegans* and suggest that an ancient, conserved role for XBP-1 may be to protect the host organism from the detrimental effects of mounting an immune response.

**Domain Regulation of Endoplasmic Reticulum-Associated Degradation.**

P. St-Pierre, T. Dang, I. R. Nabi; Cellular & Physiological Sciences, University of British Columbia, Vancouver, BC, Canada

Gp78 is an E3 ubiquitin ligase that targets proteins for proteasomal degradation through the endoplasmic reticulum-associated degradation (ERAD) pathway. The endoplasmic reticulum (ER) is organized into functionally distinct membrane domains, however ER domain regulation of ERAD functions remains poorly understood. Here, we show that gp78-mediated ubiquitylation is initiated in a peripheral ER domain to which gp78 recruits the p97 ATPase. However, derlin-1, derlin-2 and GFP-Sec61β, all involved in retrotranslocation of ERAD substrates, are localized to a central, juxtanuclear ER domain. Ubiquitylated protein accumulation in the central ER upon proteasome inhibition identifies this ER domain as the site of retro-translocation. Transfer of ubiquitylated substrate from the peripheral to the central ER is dependent on ubiquitin chain elongation, interaction with the ubiquitin-binding CUE domain and p97 recruitment. Spatial segregation of gp78 ubiquitin ligase activity from proteasomal degradation defines novel ER domain regulation of ERAD function. Supported by CIHR Grant MT-15132.

**Yip1A Regulates Mammalian Endoplasmic Reticulum Structure.**

K. M. Dykstra, J. Pokusa, J. Suhan, T. H. Lee; Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

The mechanisms that regulate cisternal and tubular endoplasmic reticulum (ER) membrane network morphology in animal cells are not fully understood. Here we report that Yip1A, a highly conserved multi-pass integral membrane protein that cycles between the ER and Golgi, is required for the maintenance of normal ER network structure and organization in mammalian cells. Yip1A depletion caused collapse of the typically dispersed ER network into multiple micron-sized concentric whorls of stacked ER tubules and sheets. The whorled ER phenotype was a specific consequence of Yip1A silencing because it was rescued by expression of wild type but not mutant Yip1A. Of the established Yip1A binding partners, DP1, a protein restricted to the tubular ER and implicated previously in ER membrane curvature, is a reasonable candidate for mediating its membrane dispersal function. Several observations suggested that Yip1A
functionally opposes DP1 and DP1L1, as well as PRA2, a membrane protein also localized to the tubular ER and predicted to possess a membrane topology similar to DP1. First, high level DP1, DP1L1 or PRA2 over-expression resulted in ER whorls similar to those induced by Yip1A loss. Second, modest DP1, DP1L1 or PRA2 over-expression enhanced the Yip1A knock down phenotype. Third, Yip1A bound both DP1 and DP1L1. These data suggest that Yip1A maintains a dispersed ER reticulum through its interactions with a special class of tubular ER membrane localized membrane proteins. Finally, the structural reorganization of the ER reticulum in response to Yip1A loss caused a marked delay in coat protein II (COPII)-mediated protein export. Thus ER network dispersal by Yip1A may provide a means of controlling the flow of cargo out of the ER.

The Mechanism of Ptc1p-Dependant Cortical ER Inheritance in Saccharomyces cerevisiae.
X. Li1, Y. Du2, S. Ferro-Novick3, P. Novick4; 1UCSD, La Jolla, CA, 2Yale University, New Haven, CT, 3UCSD, La Jolla, CA, 4UCSD, La Jolla, CA
In the yeast Saccharomyces cerevisiae, the peripheral Endoplasmic Reticulum (ER) forms a cortical network. It is inherited from mother to daughter cells in multiple stages including the extension of linear tubules along the mother-bud axis, anchorage at the bud tip, distribution along the bud periphery, and finally formation of a polygonal network in the daughter cell. Ptc1p, a type 2C serine/threonine protein phosphatase has been implicated at the late stages of cortical ER inheritance through regulation of the Cell Wall Integrity (CWI) MAP kinase, Slt2p. We have shown that inactivation of Slt2p by Ptc1p occurs concomitantly with the spread of cortical ER from the bud tip to the periphery after an ER tubule has reached the bud tip. Moreover, genetic analysis has shown that the pool of Slt2p controlling ER inheritance requires the CWI pathway scaffold, Spa2p, for its retention at the bud tip, while, the nuclear pool of Slt2p doesn’t contribute to its function in ER inheritance. We also show that the PI4P5-kinase, Mss4p, is an upstream activator of this pool of Slt2p. A family of cell surface sensors, Wsc1p or Mid2p, which is known to mediate Slt2p activation upon certain stresses, is not involved in Ptc1p regulation of ER inheritance. Rom2p acts downstream of the cell surface sensor in the CWI pathway, however, its localization at the tips of small buds is not affected in ptc1 deletion mutant. These observations together suggest a model in which Ptc1p acts well downstream of Wsc1p, Mid2p and Rom2p in the regulation of the CWI pathway by directly dephosphorylating Slt2p. Additionally, Ptc1 has also been indicated in vacuole and mitochondria inheritance. However, our data imply that different molecular mechanisms underly the inheritance of different organelles. While mitochondrial inheritance requires the down regulation of Slt2p, like ER inheritance, Spa2p is not needed for the activity of Slt2p and loss of Mss4p function does not suppress the mitochondrial inheritance defect of ptc1 mutant cells. In contrast, down regulation of Slt2p is not needed for the inheritance of vacuoles, but the loss of Mss4p function suppresses the vacuolar inheritance defect in ptc1 deletion cells.

Role of Reticulons and Phospholipid Biosynthesis in Maintaining ER Tubules.
C. Voss1, Y. Shibata2, G. K. Voeltz2, T. A. Rapoport2, W. A. Prinz1; 1NIH, Bethesda, MD, 2Harvard Medical School, Boston, ME, 3University of Colorado, Boulder, CO
The endoplasmic reticulum (ER) forms a highly dynamic network of tubules. In the yeast S. cerevisiae, the tubular portions of the ER are mostly near the cell periphery while the perinuclear ER is sheet-like. Recently we found that a family of membrane proteins required to maintain the tubular structure of the ER, the reticulons (Rtn1p, Rtn2p) and reticulon-like proteins (DP1/Yop1p), are localized exclusively in the peripheral ER. Our lab is interested in how these proteins shape the ER in S. cerevisiae. We found that these proteins must oligomerize to stabilize membrane tubules. To better understand the mechanism of their localization, we isolated mutations in Rtn1p that are distributed equally in the ER. Surprisingly, these mutants are still partly functional, because they are able to restore the sheet-like ER in a strain lacking tubule-shaping proteins. We demonstrated that these mutations decrease the ability of Rtn1p to oligomerize, suggesting that
the oligomerization of Rtn1p with itself or with other proteins is important to keep the protein in the highly curved membranes of the ER tubules. Interestingly, the mobility of Rtn1p within the ER membrane is affected by ATP-depletion, suggesting that Rtn1p oligomerization must be highly regulated. We would also like to understand why cells need tubular ER since cells lacking the reticulons and YOP1 have no apparent phenotype despite the absence of tubular ER. We identified mutations in genes that are synthetically lethal with deletion of RTN1, RTN2 and YOP1. Two of these have defects in the same lipid biosynthesis pathway. Loss of these proteins leads to overproduction of phospholipids, which affects ER structure. Interestingly, overexpression of Rtn1p in these strains restores tubules. These findings suggest that the phospholipids level in the ER and reticulons are required for proper ER function.

Usa1 Is a Key Regulator of the HRD1 ERAD Ligase.

S. M. Carroll, R. Y. Hampton; Biological Sciences, University of California, San Diego, La Jolla, CA

ER-associated degradation (ERAD) is a highly conserved process by which misfolded proteins are eliminated from the ER in order to prevent deleterious stress caused by their accumulation. Ubiquitin ligases in the ER ubiquitinate misfolded proteins, which are ultimately degraded in the cytosol by the 26S proteasome. Hrd1 is a conserved ERAD ubiquitin ligase with a multispansing transmembrane anchor and a catalytic RING motif in the cytoplasm. Hrd1 is part of the HRD complex required for the identification, ubiquitination, retro-translocation, and proteasomal degradation of a wide variety of luminal and integral membrane ERAD substrates. Usa1 is the newest and least characterized member of the HRD complex, inviting our study of its roles in ERAD and HRD function. Usa1 is required for optimal function of the HRD complex, promoting degradation of both luminal and membrane-associated substrates. Although the action of the HRD pathway is under intense study, little is known about the mechanisms by which this broadly active ligase is regulated to ensure efficient activity without cellular detriment. We now show that Usa1 is a key regulator of both Hrd1 levels and activity. When Hrd1 levels exceed those of Hrd3, Hrd1 undergoes rapid self-ubiquitination and degradation, limiting its levels to ensure HRD complex stoichiometry. Usa1 and specifically its Ubl domain are essential for Hrd1 self-destruction, by promoting trans-ubiquitination of one Hrd1 molecule by another Hrd1, in a variant of ERAD entirely specific for the Hrd1 protein. Because unregulated Hrd1 has been observed to be toxic to cells, we investigated Usa1’s role in this aspect of Hrd1 regulation. In addition to controlling Hrd1 stability (and hence, levels) Usa1 has an independent action in limiting Hrd1 activity to ERAD substrates, thereby protecting the cell from overactive ERAD in two ways. Thus Usa1 exhibits a dual role with respect to Hrd1 function - it governs the levels of Hrd1 and is required for auto-ubiquitination of Hrd1 in the absence of Hrd3, and has an additional role in modulating the activity and specificity of Hrd1. Thus, Usa1 is a key player in HRD ligase dynamics and function.

A Conserved Sterol-Dependent Interaction with Insig Mediates Destruction, Or Not.

C. Theesfeld, R. Y. Hampton; Division of Biological Sciences, University of California, San Diego, La Jolla, CA

Insig proteins are central regulators of sterol balance. They modulate the uptake and synthesis of sterols through interactions with Scap (bound to the transcription factor SREBP) and HmgCoA Reductase (HMGR). HMGR catalyzes the production of mevalonate, the rate-limiting step in isoprene and subsequent sterol synthesis. Lanosterol-mediated binding of Insig to HMGR drives the HMGR degradation, allowing feedback-regulated degradation of HMGR. The sterol-dependent Insig-HMGR interaction requires the sterol-sensing domain of HMGR. In yeast, there are two Insigs, Nsg1 and Nsg2 (pronounced “insig”). Both interact with Hmg2. Like mammalian HMGR, yeast Hmg2 undergoes feedback-regulated degradation in response to FPP levels, a sterol pathway intermediate. In contrast to mammals, the Hmg2 degradation is blocked by Nsg1
binding. This opposite effect may represent divergent requirements for the yeast Insig-HMGR interaction. Alternatively, a conserved interaction is affecting a distinct output as is fitting the specific biology of the organism. To test this we asked if a sterol molecule is required. We used drugs to block individual steps in sterol biosynthesis and then assayed the interaction. It is sterol-dependent and the responsible molecule is lanosterol, the same sterol used in mammals. Blocking lanosterol synthesis compromises the Nsg1/Hmg2 interaction but blocking a step downstream preserves the interaction. Thus both mammalian and yeast Insig-HMGR interactions integrate sterol levels with HMGR levels. Why is yeast Hmg2 stabilized by Nsg1? The hook-up between this integration point (Insig-HMGR interaction) and downstream events is tailored to biological context. Molecular oxygen is universally required for sterol synthesis. While mammalian cells are bathed in oxygenated blood, yeast may experience low/no oxygen. Since oxygen limits sterol synthesis and sterol levels are sensed by the Nsg1/Hmg2 interaction, perhaps the interaction is regulated by oxygen. We have tested this idea. Hmg2 and Nsg1 levels are low in anoxia relative to normoxia. In this way Hmg2 levels are calibrated for the production of essential isoprenes (early sterol pathway molecules), but not downstream sterols, when oxygen is limiting in yeast.

Live Cell Imaging of CD3delta Retrotranslocation.
H. Lorenz1, C. Wunder2, J. Lippincott-Schwartz2; 1ZMBH, University of Heidelberg, Heidelberg, Germany, 2CBMB, NICHD, NIH, Bethesda, MD

Many misfolded and unassembled secretory proteins are retrogradely moved from the ER into the cytosol for proteasomal degradation by a process known as ER-associated degradation (ERAD). Here, photoactivatable GFP (PAGFP) and a dual-fluorescence labeling approach have been employed to dissect the retrotranslocation pathway of the transmembrane T cell receptor subunit, CD3delta. CD3delta-PAGFP molecules “switched on” by photoactivation exhibited a half-life of ~2h irrespective of intracellular protein expression levels. The visible molecules were highly mobile throughout the ER with no significant cytoplasmic pool, indicating that membrane sorting in the ER, rather than retrograde translocation and proteasomal degradation, is the rate-limiting step for ERAD trafficking of CD3delta. Use of dual-labeled YFPCD3deltaCFP further revealed the fate of the CD3delta pool dislocated from the ER membrane. Upon inhibition of the proteasome, YFPCD3deltaCFP diffused within the cytosol and the nucleoplasm at dynamics significantly slower than YFP alone. However, no detectable aggregates were formed by the dislocated pool, which was rapidly degraded upon reestablishment of proteasomal activity. Together, these results show that retrotranslocated CD3delta, if not degraded immediately, remains soluble and capable of entering the nucleus.

Interactions among Endoplasmic Reticulum-Associated Degradation (ERAD) Complex Components Dynamically Change in Response to ER Stress In Vivo.
Y. Eura-Higuchi, T. Okuda, H. Yanamoto, T. Miyata, K. Kokame; National Cardiovascular Center Research Institute, Suita, Japan

Accumulation of misfolded proteins in the endoplasmic reticulum (ER) causes a cellular condition called ER stress. Herp is one of the representative proteins whose expression is induced under the condition. Herp contains 391 amino acid residues including an N-terminal ubiquitin-like domain and two contiguous transmembrane domains, and is embedded in the ER membrane. Although the molecular function of Herp remains unknown, recent studies suggested its contribution to the ER-associated protein degradation (ERAD) system. ERAD is a mechanism to deal with the undesirable proteins in the ER, where a number of proteins are involved. In the present study, we have generated Herp-deficient mice and analyzed the endogenous ERAD complexes. In the wild-type mouse liver, the levels of Herp, Derlin-1, Derlin-2, Derlin-3, HRD1, gp78, and VIMP were predictably elevated after the intraperitoneal injection of tunicamycin. In the Herp-deficient mice, the levels of these proteins were higher than those in the wild-type mice, suggesting that the deficiency of Herp caused sensitiveness to the experimental ER stress
condition. We have identified at least three distinct ERAD complexes. In the normal condition, Herp formed a complex with Derlin-2 and HRD1 (Complex Ia). In the ER stress condition, Derlin-3 was dramatically expressed and added to the complex, where the interactions among these proteins drastically altered (Complex Ib). In addition, a protein complex containing Derlin-1, Derlin-2, VIMP, and p97 appeared only in the ER stress condition (Complex II). In the Herp-deficient mice, the ER stress-dependent interactions among Derlin-1, Derlin-2, VIMP, and p97 were observed just like in the wild-type mice, suggesting that Herp does not affect the formation of Complex II. In contrast, the interaction between Derlin-2 and HRD1 in Complex Ia was significantly reduced as compared with in the wild-type mice, suggesting that Herp should be important for the formation of the complex. Taken together, our findings indicated that the ERAD complexes are dynamically changed in response to ER stress, where Herp may have a significant role.

Catecholamine-Induced Apparent Fragmentation of Lipid Droplets in Adipocytes.
M. Nagayama1, K. Shimizu2, T. Taira2, T. Uchida1, K. Gohara1; 1Applied Physics, Hokkaido Univ Grad Sch Engineering, Sapporo, Japan, 2Primary Cell Co., Ltd, Sapporo, Japan

The most characteristic organelle of adipocytes is the lipid droplet (LD), in which triglyceride (TG) is stored. Numerous studies have revealed that LDs act as highly dynamic organelles that play a crucial role in regulating energy homeostasis rather than as an inert reservoir for storing TG; in other words, mobilization of TG stored in LDs is also a major function of adipocytes. To date, the complicated molecular processes involved in lipolysis have been extensively studied; in contrast, studies on morphological changes of LDs during lipolysis are less. In the present study, we performed time-lapse microscopy of adipocytes stimulated with 1 × 10^-7 M norepinephrine to investigate morphological changes of LDs during lipolysis. The study used in vitro-differentiated adipocytes from stromal-vascular cells harvested from the mesenteric adipose tissue of rat. The results clearly show that the existing LDs shrank considerably and a part of them subsequently disappeared from immediately to 8 h after norepinephrine stimulation. However, such shrinking of the LDs did not occur in all adipocytes. Adipocytes in which the LDs were preserved or enlarged were also observed. Interestingly, although catecholamine stimulation would promote the release of FFA and glycerol from adipocytes, numerous small LDs (~1 μm) were newly developed in almost all the cells, including undifferentiated ones. Similar shrinking and development of LDs were also observed in adipocytes stimulated with 1 × 10^-7 M isoproterenol. Immunofluorescence imaging reveals that activation and localization of hormone-sensitive lipase (HSL), but not adipose triglyceride lipase, on the surface of LDs are necessary for their shrinking. In summary, the simultaneous shrinking and development of LDs yield apparent fragmentation and dispersion of LDs in adipocytes stimulated with catecholamine.

Trafficking of Endogenous Viral Antigens from Endoplasmic Reticulum-Derived Compartments to Phagosomes Contributes to MHC Class I Presentation.
L. English1, R. Lippé1, M. Desjardins1; 1Pathologie et Biologie Cellulaire, Université de Montréal, Montreal, QC, Canada, 2Microbiologie et Immunologie, Université de Montréal, Montreal, QC, Canada

Membrane trafficking events participate in several key aspects of cellular function, including immune defense mechanisms. Indeed, the formation of degradative organelles such as phagosomes and autophagosomes requires membrane rearrangements that imply complex membrane trafficking events. The endoplasmic reticulum (ER) compartment has been proposed to be a source of membrane for the biogenesis of both phagosomes and autophagosomes. In this study, we monitored the potential interaction between ER and phagosomes by following the trafficking of the glycoprotein B (gB) of Herpes simplex 1 (HSV-1) present in the ER of infected cells. Formation of latex bead-containing phagosomes in infected macrophages allowed us to observe ER-phagosome interactions during HSV-1 infection and the concomitant transfer of gB to phagosomes. The transfer of gB to phagosomes improves the processing and presentation of this
antigen on MHC class I molecules. Furthermore, our results indicate that phagosomes interact with autophagosomes highly enriched with gB, a process that also stimulates the MHC class I presentation of this antigen. Thus, membrane trafficking events involving ER-derived compartments and phagosomes enhance the ability of macrophages to promote CD8+ T cells activation.

Spatial and Temporal Regulation of Myosin-Driven Peroxisome Partitioning in Yeast.
A. Fagarasanu¹, F. D. Mast¹, B. Knoblach¹, Y. Jin², M. J. Brunner², M. R. Logan¹, J. N. Mark Glover³, G. A. Eitzen¹, J. D. Aitchison⁴, L. S. Weisman², R. A. Rachubinski¹; ¹Cell Biology, University of Alberta, Edmonton, AB, Canada, ²Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, ³Biochemistry, University of Alberta, Edmonton, AB, Canada, ⁴Institute for Systems Biology, Seattle, WA

Cells are equipped with a variety of cytoskeletal motors that drive intracellular motility. In Saccharomyces cerevisiae, the class V myosin motor Myo2p propels the movement of most organelles. Organelle-specific receptors for Myo2p present on the surface of various cargoes dictate the timing of Myo2p attachment to organelles to control their motility. How these receptors are regulated to ensure coordinated delivery of organelles is for the most part unknown. We recently identified Inp2p as the peroxisome-specific receptor for Myo2p. Here we delineate the region of Myo2p devoted to binding peroxisomes and show that this region partially overlaps the region that binds secretory vesicles. Using mutants of Myo2p specifically impaired in binding peroxisomes, we dissect cell cycle-dependent and peroxisome partitioning-dependent mechanisms of Inp2p regulation. We find that total Inp2p levels are controlled by peroxisome inheritance, as Inp2p aberrantly accumulates and decorates all peroxisomes in mother cells when peroxisome partitioning is abolished. We also find that Inp2p is a phosphoprotein whose level of phosphorylation is coupled to the cell cycle irrespective of peroxisome positioning in the cell. Our findings point to the existence of several regulatory mechanisms that control the activity of organelle-specific receptors for molecular motors in response to both organelle positioning and cell cycle progression to ultimately achieve an equidistribution of compartments between mother and daughter cells.

Phosphorylation-Dependent Trafficking of Peroxisome Proliferation Protein PEX11 from Endoplasmic Reticulum to Peroxisomes Controls Peroxisome Abundance.
B. Knoblach, R. A. Rachubinski; Department of Cell Biology, University of Alberta, Edmonton, AB, Canada

Peroxisomes are highly dynamic organelles that divide continuously in growing cell cultures and expand extensively in lipid-rich media. Peroxisome population control is achieved in part by Pex11p-dependent regulation of peroxisome size and number. Although the production and levels of Pex11p in yeast are tightly linked to peroxisome biogenesis by transcriptional regulation of the PEX11 gene, it remains unclear if and how Pex11p activity could be more rapidly modulated. Here we report the reversible phosphorylation of Saccharomyces cerevisiae Pex11p in response to nutritional cues and delineate a mechanism for phosphorylation-dependent activation of Pex11p through the analysis of phosphomimicking mutants. In fatty acid-grown cells, Pex11p is synthesized but spatially segregated from peroxisomes in a predominantly endoplasmic reticulum (ER)-bound state. A glucose stimulus causes the phosphorylation of Pex11p and its trafficking from the ER to peroxisomes. Pex11Ap and Pex11Dp mimicking constitutively dephosphorylated and phosphorylated forms of Pex11p, respectively, show differential association with the ER and are impaired in trafficking, which correlate with decreased levels of Pex11Ap, increased levels of Pex11Dp, and changes in peroxisome abundance. By analyzing wild-type Pex11p and Pex11Dp in a dose-independent manner, we demonstrate that
phosphorylation of Pex11p causes its activation and peroxisomal hyperproliferation. This work provides the first evidence for regulation of organelle dynamics by phosphorylation-controlled protein trafficking.

**Dictyostelium discoideum** Dynamin B Participates in Peroxisomal Division and Cell Adhesion.  
A. Rai¹, H. Nöthe², N. Tzvetkov¹, E. Korenbaum¹, D. Manstein¹,²,³; ¹Institut für Biophysikalische Chemie, OE 4350, Medizinische Hochschule Hannover, Carl-Neuberg-Str. 1, D-30623, Hannover, Germany, ²Max-Planck-Institut für Medizinische Forschung, Jahnstr. 29, D-69120, Heidelberg, Germany, ³Labor für Strukturanalyse, OE 8830, Medizinische Hochschule Hannover, Feodor-Lynen-Str. 5, D-30625, Hannover, Germany

 Dictyostelium discoideum (Dd) has five dynamins, dynamin A, dynamin B and the dynamin-like proteins Dlp A, Dlp B and Dlp C. Depletion of each of the dynamin-like proteins in Dd results in abnormal cytokinesis. Disruption of Dd dynamin A affects cytokinesis, endocytosis and organelle morphology. Here we describe the characterization of Dd dynamin B. Dynamin B contains an N-terminal sequence that targets it to mitochondria where processing of the protein takes place. We used a molecular genetic approach to manipulate the production levels of dynamin B in combination with a fluorescent tagging approach to visualize dynamin B localization, organelle morphology, and cytoskeletal filament dynamics. Dynamin B null cells and cells overproducing the protein do not show any obvious morphological alterations. They display normal uptake of fluid-phase markers, grow normally in the presence of axenic media, and form normal fruiting bodies during development. However dynamin B-depleted cells show a marked increase in the size of peroxisomes concomitant with a decrease in their number. A reduced tolerance of dynamin B-depleted cell towards the presence of long chain fatty acid indicates that peroxisome function is compromised. Additionally, we observed that phagocytosis is affected by changes in the expression level of the dynamin B gene. The absence of dynamin B correlates with increased cell to substrate and cell to cell interactions. Our results link the function of dynamin B to roles in the biogenesis and maintenance of peroxisomes and cell adhesion in *D. discoideum*.

**Ectopic PEX11β Alters Peroxisomal Gene Expression during Xenopus laevis Development.**  
M. A. Fox, M. A. Nieuwesteeg, S. Damjanovski; Biology, University of Western Ontario, London, ON, Canada

Peroxisomes are ubiquitous organelles responsible for fatty acid metabolism and H2O2 degradation. The biogenesis of fully functional peroxisomes is achieved by the coordinated activity of cytosolic and membrane-tethered proteins termed peroxins (PEX proteins). The objectives of the present study are to characterize the expression of specific peroxisomal genes, and to examine the onset and distribution of functional peroxisomes during Xenopus laevis development. The temporal and spatial expression of peroxisome related genes was determined by RT-PCR and whole-mount in situ hybridization, respectively, while the localization of functional peroxisomes was evaluated by microinjection of GFP tagged with a peroxisome targeting signal in early embryos. Five peroxisomal genes (PMP70, Catalase, PEX3, PEX5 and PEX11β) all showed increasing levels of expression as development proceeded. These genes had similar localization patterns in embryos at developmental stages 10, 20, 30 and 40, showing predominant anterior and dorsal expression. Microinjection of peroxisome targeted GFP demonstrated that at stage 10 no punctate GFP was visualized, suggesting no functional peroxisomes. However, functional peroxisomes were found at stage 20, and their number increased in later developmental stages in anterior and dorsal structures. Furthermore, microinjection of PEX11β (a known inducer of peroxisome division in yeast) into early embryos, followed by immunohistochemical analysis, was used to reveal whether PEX11β has a homologous function of increasing peroxisome numbers during X. laevis development. Microinjection of PEX11β mRNA resulted in the formation of peroxisomes by stage 10 as judged by use of a PMP70 antibody. Taken together, these results indicate that during X. laevis development
development, the formation of functional peroxisomes begins at stage 20 in anterior and dorsal structures. PEX11β may play a key role in peroxisome biogenesis, as overexpression of PEX11β induces the earlier formation of peroxisomes during X. laevis development.

Molecular Interrogation of the Role of the Endoplasmic Reticulum in Peroxisome Biogenesis.
A. P. Jamakhandi, R. S. Rogers, J. D. Aitchison; Institute for Systems Biology, Seattle, WA

The role proteins interactions and the resulting complexes play in regulating organelle biology are of fundamental importance in understanding cell biology at both reductionist and systems level. The hierarchical flow of information that enables organelle architecture, abundance and functions, although presumably cyclical with respect to the life cycle of a given cell type, are prone to genetic and environmental perturbations. These perturbations, as carried out in laboratory settings, enable systematic delineation of the underlying mechanisms that cell utilize in establishing homeostasis and evolutionary advantage. The peroxisome system in yeast Saccharomyces cerevisiae cells can be viewed as a good example of such a system. We employed a top-to-bottom approach to identify, protein complexes for Pex29 and Pex30, previously characterized as integral membrane proteins localized to peroxisomal membrane (peroxins). Unlike earlier efforts that enriched peroxisome fractions prior to immuno-isolation of peroxin complexes, we optimized the protocol to perform immuno-isolation from whole cell extracts so as to globally probe for all potential interaction partners for peroxins. This strategy is especially important given that de novo biogenesis of peroxisomes initiates on the ER template. We used biochemical isolation of protein complexes followed by mass-spectrometry based proteomics to identify the individual proteins in combination with yeast molecular genetics and dynamic quantitative microscopy. These studies have revealed a role for ER resident proteins in the emergence of peroxisomes from the secretory system. Taken together, these studies will further our knowledge regarding the role these protein complexes play in peroxisome biogenesis.

A Strong Association of 3β-Hydroxysteroid Dehydrogenase Type II (3βHSD II) with the Mitochondrial Membrane Is Essential for Steroidogenic Activity.
K. J. Pawlak1, J. L. Thomas2, H. S. Bose1; 1Biomedical Sciences, Mercer University, Savannah, GA, 2School Of Medicine, Mercer University, Macon, GA

Protein trafficking into a specific mitochondrial compartment is dependent on the proteins present at the outer and inner membranes. Mitochondrial human type 2 3β-hydroxysteroid dehydrogenase (3βHSD II) is a key steroidogenic enzyme, in the adrenals, gonads and brain that catalyzes, in three independent steps the production of steroid hormones: progesterone, aldosterone, cortisol, testosterone and estradiol. Thus any abnormal function will result in a fatal error in steroid metabolism. To explore the role of mitochondrial association with enzyme action, 3βHSD II was synthesized in a cell-free transcription system labeled with 35S-methionine and incubated with isolated mitochondria from steroidogenic tissues. The import reaction shows that 3βHSD II was associated with the mitochondrial membrane, since extraction with Na2CO3 retained the imported fraction in the pellet. To determine the nature of association with the mitochondrial membrane, we extracted with nonionic, anionic and zwitterionic detergents: digitonin, lauryl maltoside, taurodeoxycholic acid and CHAPS. These detergents yielded a high molecular weight complex, of approximately 500 KDa when analysed through a 3-16% gradient native PAGE. The integration of lauryl maltoside associated complex was stronger than the zwitterionic or anionic detergents: digitonin, lauryl maltoside, taurodeoxycholic acid and CHAPS. These detergents yielded a high molecular weight complex, of approximately 500 KDa when analysed through a 3-16% gradient native PAGE. The integration of lauryl maltoside associated complex was stronger than the digitonin isolated complex when proteolysed with proteinase K. The ionic detergent deoxycholic acid didn’t form any complex but taurodeoxycholic acid was very effective at isolating a 3βHSD II complex, because of its long aliphatic sidechain that contains a sulfonyl group. The zwitterionic, CHAPS, also formed a strong complex with 3βHSD II associated proteins because of a putative membrane-association loop of 26 amino acids present in the 3βHSD II, as determined by mutagenesis and computer modeling. The biological activity with lauryl maltoside extracted complex was higher than with the zwitterionic or anionic detergents. These experiments clearly
demonstrate a role of other mitochondrial proteins for the translocation of 3βHSD II into the mitochondrial membrane.

Mechanism of Import of Cytochrome P450 Side-Chain Cleavage Enzyme (P450scc) into Mitochondria.
M. Prasad, B. P. Adams, H. S. Bose; Biomedical Sciences, Mercer University, Savannah, GA

Cytochrome P450 side-chain cleavage enzyme (P450scc), a key component of the mitochondrial P450 complex, cleaves the side chain of cholesterol to form the first steroid in the tissue pregnenolone. To catalyze this reaction, P450scc accepts a pair of electron from ferrodoxin and ferrodoxin reductase at the matrix side of mitochondria. So, any change in P450scc function results in gross error in steroid metabolism and is fatal for survival of all species. P450scc is a 521 amino acid protein with a possible cleavage at 39th amino acid, as determined by indirect methods long time ago. The mechanism of action, import and processing of P450scc into the mitochondrial matrix remained unknown. Mitochondrial import of cell-free synthesized P450scc, labeled with 35S methionine cleaved it to an intramitochondrial smaller form. The shorter fragment remained in the pellet, suggesting a membrane association; but it was not integrated into the lipid membrane as it remained in the solution when extracted with sodium carbonate. We next determined the role of N- and C-terminal amino acids sequences for its mitochondrial import and translocation. We built several constructs, synthesized in cell-free system labeled with 35S methionine and imported into isolated mitochondria. The deletion of upto 50 AA from the C-terminus had no effect on import. Similarly, addition of extra 50 AA at the C-terminus showed unchanged import of P450scc, suggesting the C-terminal AA has no role on its translocation into mitochondrial compartment. Site directed mutagenesis of the amino terminal sequences from amino acids 35 to 50, did not affect the cleavage of P450scc. on the other hand internal deletion of 45 amino acids (Δ 15-60) showed no import, suggesting that the cleavage site is between 15-60 amino acids. A careful analysis of the mitochondrial import shows that the imported P450scc has two bands, suggesting that the cleavage sites are possible before 35th and after 50th amino acids. Thus the experiment clearly demonstrates a stepwise import and processing of P450scc into mitochondria.

Promoter Independent Regulation of Aldosterone Synthase.
B. P. Adams, H. S. Bose; Biomedical Science, Mercer University School of Medicine, Savannah, GA

Aldosterone controls blood volume by retention of sodium and release of potassium and hydrogen ions in the kidney. Aldosterone excretion can contribute to hypertension, which results from higher than normal blood pressure and is directly linked to coronary heart disease. Steroidogenic protein aldosterone synthase (AS) converts deoxycorticosterone to aldosterone in mitochondria. In order for AS to perform this function, the precursor form of the enzyme must be targeted to and translocated across the outer mitochondrial membrane (OMM) before arriving at its final destination. However, the mechanism of action has remained unknown. To understand the mechanism of AS translocation, we incubated cell-free synthesized radiolabeled AS with isolated adrenal mitochondria. We observed cleavage of precursor AS (57 kD) to a mature form (54 kD) that was protected from exogenous proteinase K activity, while uncleaved precursor was digested. This demonstrates that mature AS is translocated across the OMM, with cleavage occurring afterwards, and that precursor remains outside of the mitochondria. Translocation kinetics studies revealed that formation of the mature form occurs very rapidly, reaching a peak level within minutes. Once this peak is reached, processing is abruptly halted. In contrast, P450SCC (SCC), another steroidogenic protein localizing to the mitochondria, never reaches a maximum level of the mature form, alternatively showing a steady increase over time. In order to study AS activity, we transfected COS-1 cells with a fusion construct of AS and dihydrofolate reductase (DHFR). The construct was equally as active as wild type AS, and this activity was significantly reduced in the presence of methotrexate, which binds DHFR and prevents complete
translocation of the protein. This result confirms that translocation into the mitochondria is required for AS activity. In summary, we conclude that this promoter-independent regulation of translocation can potentially control the synthesis of aldosterone in response to cell stimulated expression of AS, thus preventing overproduction of aldosterone.

Disrupting the Drosophila Delta-1-Pyrroline-5-Carboxylate Dehydrogenase Gene Causes Mitochondrial Defects.
F. He, P. DiMario; Biological Sciences, Louisiana State University, Baton Rouge, LA

Delta-1-pyrroline-5-carboxylate dehydrogenase (P5CDH) is a mitochondrial matrix enzyme that catalyzes mainly the second step of proline degradation. Mutation of P5CDH in humans (called ALDH4A1) causes type II hyperprolinemia, a complex syndrome that includes mental disabilities and seizures in some patients (Geraghty et al., 1998, Hum. Mol. Genet. 7: 1411-1415). Two genes in Drosophila melanogaster display sequence similarities to the human ALDH4A1 gene. The protein encoded by Drosophila conceptual gene CG7145 has 62% sequence identity and 77% similarity of the human ALDH4A1 protein, while the protein encoded by the second gene, CG33092, shares 48% sequence identity and 66% similarity to the ALDH4A1 protein. To explore for possible symptoms of hyperprolinemia in Drosophila, we studied a mutant fly line CG7145 with a PBac transposon inserted into the CG7145 gene. The insertion introduces a stop codon in the coding sequence of CG7145 such that the protein product is 100 amino acids shorter than the full length protein. Heterozygous (CG7145/TM3) individuals develop normally, while homozygous (CG7145/CG7145) individuals display lethality during the second and third larval instar stages, and in the pupal stage. Transmission electron microscopy of CG7145 larval tissues showed swollen mitochondria with diameters approximately 1.5 times greater than those of mitochondria in control larvae. Mitochondrial matrices appeared devoid, while cristae appeared reduced in number. We believe this is the first demonstration that a mutation in a type P5CDH mitochondrial enzyme causes morphological defects in the mitochondria, perhaps explaining the complex phenotypes associated with type II hyperprolinemia.

Histone H3 Identified in Mitochondria: Key to Evolution and Nuclear-Mitochondrial Coordination?
M. B. Zanin1, J. Donohue2, B. Everitt1; 1Biology, The Citadel, Charleston, SC, 2Division of Rheumatology & Immunology, Medical University of South Carolina, Charleston, SC

The core histone proteins H2A, H2B, H3, and H4 are known to form nucleosomes with nuclear DNA, but are historically considered to be absent from mitochondria. The objective of this study was to determine if H3 is found in mitochondria. We found, by several different methods, that H3 is a dual-targeted protein, found in mitochondria as well as nuclei. Analyses of various H3 amino acid sequences with WoLF PSORT and MitoProt revealed mitochondrial targeting signals for all variants and all species of H3 sampled, and Western blots of Brassica oleracea (cauliflower) mitochondrial extracts were positive for H3. Tandem Mass Spectrometry analyses confirmed the Western blot data. Further Western blot analysis revealed N-terminal modification of mitochondrial H3 as compared to nuclear H3. We conclude that H3 is targeted to the mitochondria and that mitochondrial H3 has an N-terminal modification; and we hypothesize that since modifications of the core histone H3 (H3) are known to help control nuclear genes, future studies of the functions of mitochondrial H3 could lead to a greater understanding of the ability of a cell to synchronize nuclear and mitochondrial activities.

Dynamics of Axonal Mitochondria Is Regulated by Myelination in the Central Nervous System.
N. Ono, S. Kiryu-Seo, H. Komuro, B. D. Trapp; Department of Neurosciences, Cleveland Clinic, Lerner Research Institute, Cleveland, OH
Neurons are highly polarized cells with a single long axon, many of which are ensheathed by myelin. Although mitochondria are essential for axonal function and are transported and distributed throughout the axons, the transport, turnover and general behavior of mitochondria in myelinated axons are poorly understood. In this study, we established an In Vitro model for live imaging of mitochondria in myelinated central nervous system (CNS) axons, and compared mitochondrial distribution and motility at internodal and nodal regions. Organotypic slice cultures of cerebellum were prepared from P10 Sprague-Dawley rats, and mitochondria-targeted DsRed were expressed in Purkinje neurons. After myelination, mitochondrial distribution and movement were observed by time-lapse imaging using confocal microscopy. After imaging, slices were fixed, stained for nodal and paranodal proteins, and the time-lapse images were superimposed on the nodal, paranodal and internodal regions of the same fibers. Many Purkinje cell axons were myelinated during the 14 days in culture, and some contained DsRed-labeled motile and stationary mitochondria. We found that motile mitochondria stopped or slowed down around the nodes of Ranvier, and the mean velocity was significantly lower around nodal areas when compared to internodal areas of the same axons. Stationary mitochondria localized in juxtaparanodal and nodal regions of myelinated axons, but were less frequently found in paranodal regions. When the slices were treated with TTX to examine the effect of voltage-dependent Na current at the nodes, the number of motile mitochondria increased, and mitochondrial velocity was similar at nodal and internodal segments of the same axon. Furthermore, the sizes of stationary mitochondria decreased around the nodes. These results demonstrate myelination regulates mitochondrial motility in CNS axons by rendering topographical variance of axonal molecules and electrical activity. The focal modulation of mitochondrial dynamics at the nodes of Ranvier would be essential for efficient maintenance of axonal homeostasis upon neuronal activation.

Mitochondrial Fragmentation Is Required for Proper Mitotic Entry.
S. Lee1,2, Y. Park1,2, X. Sun3, G. K. Chan4, H. Cho1,2; 1Biochemistry, Ajou Univ. school of medicine, Suwon, Korea, South, 2Molecular Science and Technology, Ajou Univ. Graduate school, Suwon, Korea, South, 3Oncology, Cross Cancer Institute, Edmonton, AB, Canada, 4Oncology, University of Alberta, Edmonton, AB, Canada

DNA duplication and partition into daughter cells are tightly regulated by a series of cell cycle checkpoints during cell division. However, mechanisms on partitioning of cellular organelles remain largely unknown. In interphase, a highly interconnected tubular network of mitochondria is observed but it no longer exists in mitotic cells, showing rather fragmented mitochondria. Here, we addressed whether mitochondrial fragmentation is necessary for proper cell cycle progression and cellular function. Since mitochondrial fission and fusion determine the mitochondrial morphology, we suppressed the mitochondrial fission activity by depleting one of the fission modulator, hFis1 by using a shRNA system. Notably, cells lacking hFis1 showed significantly elongated mitochondria and in these cells, cell cycle progression into mitotic phase was significantly impaired. Few cells entered mitosis under time-lapse microscopy and mitotic accumulation of hFis1 RNAi cells was very limited by aceto-orcein staining. In these cells, cyclin B1 failed to accumulate and the phosphorylated form of histone H3 was not detected, indicating that mitochondrial fragmentation is indispensable for proper mitotic entry. When mitochondrial fragmentation is induced by double knockdown of hFis1 and Opa1, a component of mitochondrial fusion, the cells regained ability to enter mitosis. Moreover, besides of low cyclin B1, expressions of cyclin A, cyclin-dependent kinase 1(Cdk1), polo-like kinase 1 (Plk-1) and aurora B kinase are significantly low in hFis1-depleted cells. Interestingly, introduction of active Plk1 or FoxM1, but not of active cyclin B1/Cdk1, into hFis1 RNAi cells significantly restored the mitotic entry. Together, one of the key functions of mitochondrial fission would be mitochondrial reorganization at G2 phase that is essential for proper mitotic entry.

An Ultrasensitive Dual Emission Mitochondrial Membrane Potential Probe for Monitoring Mito-Toxicity in Live Cells.
Mitochondrial membrane potential (MMP) is a key indicator of cell health, mitochondrial permeability transition and apoptosis. Loss of MMP is often associated with early stages of apoptosis. Collapse of the MMP coincides with the opening of mitochondrial permeability transition pores, leading to the release of cytochrome c into the cytosol. This triggers downstream apoptotic events. Therefore, depolarization is a good indicator of mitochondrial dysfunction, and is increasingly utilized in drug toxicity measurements. JC-1, a lipophilic cationic carbocyanine dye, is widely employed to detect MMP. However, poor water solubility of JC-1 makes it difficult to use, especially in image-based and fluorescence plate reader-based applications wherein complete removal of un-dissolved fluorescent particles from the assay solution is critical for obtaining high-quality data. Additionally, spectral compensation is somewhat problematic in flow cytometry-based applications. We describe a new water-soluble dual emission MMP probe with similar fluorescent properties and subcellular localization as JC-1 dye. The performance of this dye was compared to JC-1 using various effectors of MMP and several different cell lines. The assay was also validated with a broad range of fluorescence detection platforms, including wide-field fluorescence microscopy as well as flow cytometry and microplate-based cytometry. Overall, the new dye is at least 10-fold more sensitive to MMP loss, is more photostable and more soluble than JC-1. Potential applications of the new probe include preclinical drug safety assessment (ADME-Tox) using In Vitro cell culture models to aid in the drug development process, especially to differentiate among compounds and rank order their potency.

MICS1 Is Involved in Maintenance of Mitochondrial Morphology and Apoptotic Release of Cytochrome C.
T. Oka¹, T. Sayano¹, S. Tamai¹, S. Yokota², K. Mihara¹; ¹Department of Molecular Biology, Graduate School of Medical Science, Kyushu University, Fukuoka, Japan, ²Faculty of Pharmaceutical Science, Nagasaki International University, Nagasaki, Japan

Mitochondrial morphology dynamically changes in a balance of membrane fusion and fission in response to the environment, cell cycle, and apoptotic stimuli. Here, we report that a new mitochondrial protein, MICS1, is involved in mitochondrial morphology in specific cristae structures and the apoptotic release of cytochrome c from the mitochondria. MICS1 is an inner membrane protein with a cleavable presequence and multiple transmembrane segments, and belongs to the Bi-1 super family. MICS1 downregulation causes mitochondrial fragmentation and cristae disorganization, and stimulates the release of pro-apoptotic proteins. Expression of the anti-apoptotic protein Bcl-XL does not prevent morphologic changes of mitochondria caused by MICS1 downregulation, indicating that MICS1 plays a role in maintaining mitochondrial morphology separately from the function in apoptotic pathways. MICS1 overproduction induces mitochondrial aggregation, and partially inhibits cytochrome c release during apoptosis, regardless of the occurrence of Bax targeting. Thus, MICS1 may facilitate the tight association of cytochrome c with the inner membrane during apoptosis. Furthermore, under low serum condition in which MICS1 is upregulated, the apoptotic release of cytochrome c is delayed without significant changes in mitochondrial morphology, suggesting that MICS1 individually functions in mitochondrial morphology and cytochrome c release.

Mitochondrial Characteristics Associated with Pluripotent Non-Human Primate Embryonic Stem Cells.
T. Lonergan¹, C. Brenner²,³, A. Harvey²; ¹Biological and Environmental Sciences, Western Connecticut State University, Danbury, CT, ²Physiology, Wayne State University School of Medicine, Detroit, MI, ³Obstetrics and Gynecology, Wayne State University School of Medicine, Detroit, MI

While embryonic stem cells have fostered optimism that these pluripotent cells could represent powerful models of human development and disease, there has been little characterization of the
cellular properties of ES cells compared to differentiated cells. Mitochondrial properties were compared in three Rhesus monkey embryonic stem (ES) cell lines, ORMES 6, 7 and 22 to determine their suitability as biomarkers of stem cell function. All lines expressed the pluripotency markers Oct 4 and Nanog, and 100% of the cells examined had a considerable mass of active mitochondria, as viewed by Mitotracker red staining. Cells exhibited a ‘capped’ mitochondrial localization pattern in which mitochondria cluster tightly to one side of the nucleus in 92-98% of the cells examined, depending on cell line. Undifferentiated ES cells had a 2-4 fold lower ATP content/cell (range 0.0354 to 0.0671 pmoles ATP/cell) compared to a differentiated monkey fibroblast control (0.163 pmoles ATP/cell). Upon removal of growth factor (bFGF) and feeder support, which releases cells from the pluripotent state, ORMES 22 cells lost expression of Nanog, associated with dispersal of mitochondria throughout the cytoplasm and a significant increase in ATP content/cell (0.110 p moles ATP/cell, P = 0.006). These results suggest that mitochondrial localization and ATP content per cell may be valid biomarkers of pluripotency, and that changes in these biomarkers may signal differentiation.

Docking Receptor Syntaphilin Is Required for Calcium-Dependent and KIF5-Miro-Mediated Immobilization of Axonal Mitochondria.

Y. Chen, Z. Sheng; NINDS, Bethesda, MD

The coordination of mitochondrial mobility with axonal physiology is crucial for proper neuronal development and synaptic function. Motile mitochondria are recruited to the stationary pool near synapses in response to elevated cytosolic Ca2+ and synaptic activity. The mechanisms as to how motile mitochondria are recruited to stationary pool in response to neuronal activity remain unknown. Recent advances in identifying syntaphilin as a mitochondrial docking receptor (Kang et al., Cell 2008) and KIF5 motor adaptor Miro as a calcium sensor arresting mitochondrial movement provide molecular targets for such regulation. Using snph KO mouse combined with time-lapse imaging we sought to address whether SNPH is required in Ca-dependent arresting of axonal mitochondrial movement. First, elevated cytosolic Ca2+ in axons by treating snph (+/+) neuron with 50 mM KCl and 10 μM FPL 64176, an agonist of L-type Ca2+ channels, significantly decreased the axonal mitochondria mobility (17 ± 6%, mean ± SD, p<0.01) relative to that from untreated control neurons (43 ± 10%). In contrast, the same treatment of snph (-/-) neurons failed to affect axonal mitochondria motility (82 ± 8%: before; 73 ± 15%: after the treatment, respectively, p>0.05). This result suggests that Ca2+-dependent and KIF5-Miro-mediated immobilization of axonal mitochondria requires SNPH as an anchor. Second, using GST pull-down and immunoprecipitation of brain homogenates, we identified SNPH as a specific binding partner of KIF5 motor. Furthermore, expressing Miro1 in neurons remarkably increased axonal mitochondria motility (77 ± 14%) compared with the control neurons (33 ± 9%, p<0.01). However, when co-expressing SNPH, Miro1 failed to facilitate mitochondrial transport. Altogether, these results allow us to propose a hypothesis that KIF5-Miro and SNPH share a single system of regulation and this could involve the physical displacement of motor-adaptor proteins by docking interactions (and vice versa). Further analysis of the snph-deficient neurons will provide mechanistic insights into the complex regulation of axonal mitochondrial transport and distribution. (Supported by the NINDS Competitive Fellowship Award and the Intramural Research Program of NINDS)

Q. Zhao, J. Liao, C. Wei, Z. Diwu; ABD Bioquest, Inc., Sunnyvale, CA

Mitochondrial membrane potential is a key indicator of cell health and apoptosis. JC-1, a lipophilic cationic dye, is predominantly used to detect mitochondrial de-polarization due to its selective mitochondrial localization and mitochondrial membrane potential-dependent fluorescence changes. However, the extremely poor water solubility of JC-1 makes it hard to be used for some biological applications. Although JC-1 is widely used with flow cytometry platform, there were few studies that were done with JC-1 using fluorescence microscope or fluorescence microplate
reader platforms due to the low ratio of signal background caused by the JC-1 precipitation in aqueous buffers. A new water-soluble mitochondrial membrane potential indicator JC-10 has been developed to overcome the poor water solubility of JC-1. JC-10 is selectively localized in mitochondria, and its fluorescence change is dependent on mitochondrial membrane potentials. We have used JC-10 to monitor the mitochondrial membrane potential changes in primary rat hepatocytes, CHO-K1, HeLa, Jurkat and HepG2 cells. The mitochondrial membrane potential changes were induced with mitochondrial membrane potential de-couplers and chemicals that induced apoptosis. The consistent EC50 were obtained for mitochondrial membrane potential de-couplers and chemicals that induced apoptosis on three different platforms: flow cytometry, fluorescence plate reader and fluorescence microscopy. JC-10 is characterized as a new robust fluorescent indicator for high throughput analysis of mitochondrial functions in live cells.

Effect of the Uncoupler CCCP on the Fatigue of the Slow Fibers of Skeletal Muscle.
R. Montoya-Pérez, A. Saavedra-Molina, X. Trujillo, M. Huerta, M. Ortiz-Mesina, Centro Universitario de Investigaciones Biomédicas, Universidad de Colima, Colima, Mexico, Facultad de Ciencias Médicas y Biológicas Dr. Ignacio Chávez, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mexico, Instituto de Investigaciones Químico-Biológicas, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mexico

The complex I and III of the mitochondrial respiratory chain are the sites where the superoxide anion is produced, on isolated mitochondria of skeletal muscle (Andreyev et al., 2005). However, mitochondria have a heterogeneous distribution which reflects the metabolic demand, associated with the kind of fiber and muscle (Hood, 2001). The velocity of production of reactive oxygen species (ROS) is related to membrane potential and proton gradient in the internal mitochondrial membrane (Brand et al., 2004). This state is favored in the state 4 of respiration. The carbonylcyanide-3-chlorophenylhydrazone (CCCP) reduced the production of hydrogen peroxide (H2O2) consistent with the fall of the membrane potential characteristic of the transition to state 3 or of a slight uncoupling, confirming that mitochondria is the main source of the production of H2O2 in the muscle. Fibers type I are those that produce less H2O2 (Anderson and Neufer, 2006). We made tension measurements of slow type I fibers of the chick, we realize a dose-response curve (0.5-50 μM). The initial contracture where taken as 100%, then when it fell the contracture to 78.34 ± 1.27 % (fatigued muscle) in maximum and total tension we apply CCCP and we saw an increase to 119.91 ± 41.78 %, (p = 0.028). We consider that the observed effect (in opposition to which we hoped) must be in relation that the application of CCCP eliminates the H2O2 production completely, in the transition to state 3 (slight undocking), which would suggest that mitochondria of skeletal muscle are the main source of the H2O2 production. We could observe as to low concentrations of the uncoupler the tension were increased post-fatigue, which allows us to assume that indeed the ROS production increases the fatigue and that the uncoupler could reduced the ROS production. Loss of MARCH5 Mitochondrial E3 Ubiquitin Ligase Induces Cellular Senescence through Drp1 and Mfn1.
Y. Park, S. Lee, M. Karbowski, A. Neutzner, R. J. Youle, H. Cho, Department of Biochemistry, Ajou university, Suwon, Korea, South, Medical Biotechnology Center, University of Maryland Biotechnology Institute, Baltimore, MD, Graduate School of Molecular Science and Technology, Ajou university, Suwon, Korea, South, Biochemistry section, SNB, NINDS, National Institutes of Health, Bethesda, MD

Mitochondria constantly divide and combine through fission and fusion activities. MARCH5, a mitochondrial E3 ubiquitin ligase, has been identified as a molecule that binds hFis1, Drp1 and Mfn2, key proteins in the control of mitochondrial fission and fusion. However, how these interactions control mitochondrial dynamics and cellular function has remained obscure. Here we show that shRNA-mediated MARCH5 knockdown promoted the accumulation of highly
interconnected and elongated mitochondria. Cells transfected with MARCH5 shRNA or a MARCH5 RING domain mutant displayed cellular enlargement and flattening accompanied by increased senescence-associated-β-galactosidase (SA-β-Gal) activity, indicating that these cells had undergone cellular senescence. Notably, a significant increase in Mfn1 level, but not Mfn2, Drp1 or hFis1 levels, was observed in MARCH5-depleted cells, indicating that Mfn1 is a major ubiquitination substrate. Introduction of Mfn1$^{T109A}$, a GTPase-deficient mutant form of Mfn1, into MARCH5-RNAi cells not only disrupted mitochondrial elongation, but also abolished the increase in SA-β-Gal activity. Moreover, the aberrant mitochondrial phenotypes in MARCH5-RNAi cells were reversed by ectopic expression of Drp1, but not by hFis1, and reversion of the mitochondria morphology in MARCH5-depleted cells was accompanied by a reduction in SA-β-Gal activity. Collectively, our data indicate that the lack of MARCH5 results in mitochondrial elongation, which promotes cellular senescence by blocking Drp1 activity and/or promoting accumulation of Mfn1 at the mitochondria.

Differential Distribution of Mitochondria at Nodes of Ranvier Determined by Focused Ion Beam-Based Three Dimensional Electron Microscopy.
G. Kidd1, N. Ono1, A. Avishai2, B. D. Trapp1; 1Department of Neurosciences, Lerner Research Institute Cleveland Clinic, Cleveland, OH, 2Department of Materials Science and Engineering, Case Western Reserve University, Cleveland, OH
Disrupted mitochondrial function in myelinated axons has been implicated in axonal pathogenesis in diseases affecting myelin but little is known about the factors that regulate mitochondria in myelinated CNS axons in vivo. Recent studies of mitochondrial dynamics in myelinating cultures suggested that axon regions close to nodes of Ranvier have different mitochondrial distributions. To investigate whether this was true In Vivo we compared lengths and volumes of mitochondria in nodal, paranodal, juxtaparanodal and internodal regions of cerebellar white matter axons using three dimensional electron microscopy. We used a focused ion beam "slice and scan" approach using an FEI Nova-200 Nano-lab dual beam system. Resin-embedded tissue was alternately milled using a gallium focused ion beam to remove a 40nm "slice" from the block face and then the milled surface was imaged using a scanning EM in backscatter mode. Automated cycles of milling and imaging produced stacks of 200-400 images representing slices separated by 40nm at x7500 containing sequential slices through 100-200 axons. Axons with nodal regions were traced and volumetric and positional data generated for each mitochondrion. Nodal axoplasm exhibited both reduced numbers and volumes of mitochondria compared with non-nodal regions. Small mitochondria (lowest quartile, <1.6 μm long) appeared uniformly distributed along the axon. Larger mitochondria were rare in the node but abundant in the juxtaparanodal and internodal regions and correlated with stationary mitochondria observed in dynamic studies. Nodal constriction was minor in these small axons, and compensation for changes in axonal diameter did not significantly affect the results. These results demonstrated that myelination can provide topographically differential distribution of mitochondria in the normal CNS axons, and support the hypothesis that mitochondrial dynamics can be focally regulated at the nodes in vivo.

Inner Mitochondrial Membrane Protein ChChd3, Is Essential for Cristae Biogenesis and Cellular Homeostasis.
M. Darshi1, M. Mackey2, S. Petrosyan4, A. Murphy4, G. Perkins3, M. H. Ellisman3, S. S. Taylor1, 2, 4; 1Howard Hughes Medical Institute, La Jolla, CA, 2Department of Chemistry and Biochemistry, University of California, San Diego, La Jolla, CA, 3Department of Neurosciences and National Center for Microscopy and Imaging Research, University of California, San Diego, La Jolla, CA, 4Department of Pharmacology, University of California, San Diego, La Jolla, CA
Mitochondrial cristae membrane serves as the site for ATP production by hosting the respiratory chain super complexes and ATP synthase. Disruption of the cristae structure has been implicated in wide variety of cardiovascular and neurodegenerative diseases. Here, we report that Coiled-coil-Helix-Coiled-coil-Helix Domain containing protein 3 (ChChd3), a previously identified
mitochondrial protein of unknown function, is a critical regulator of cristae biogenesis and oxidative phosphorylation. ChChd3 was originally identified in our laboratory as a PKA substrate in mitochondria, while screening for the potential substrates for PKA in mouse liver mitochondria. Though, ChChd3 was previously known as a mitochondrial protein by global proteomic analysis of mitochondria, so far there is no systematic study describing its localization or the functional role in mitochondria. In our study, we show that ChChd3 is anchored to the IM of mitochondria through its chch domain by associating with the IM protein Mitofilin, which is known to be involved in regulating cristae morphology. Additionally, N-terminal myristylation motif of ChChd3 recruits ChChd3 to the outer membrane (OM) of mitochondria, where it interacts with SAM50, which is known to be involved in the OM beta barrel protein import. Down regulation of ChChd3 in HeLa cells by RNA interference (RNAi) resulted in, major loss of the Mitofilin and Sam50 proteins, accompanied by altered levels in the proteins associated with mitochondrial dynamics and severe defects in the mitochondrial morphology. Mitochondria in cells lacking ChChd3 showed peri-nuclear clumping, fragmentation and loss of cristae followed by drastic decrease in both the cellular respiration and glycolysis, and impaired cellular metabolism. Our results clearly suggest that, ChChd3 is an important contributor to the cristae biogenesis and protein import in the mitochondria, thereby, regulating the mitochondrial function and cellular metabolism.

W. Li1, Y. Lim1, J. Cho1, J. Ahn1, S. Lee1; 1Life Sciences, Hanyang University, Seoul, Korea, South, 2Biology Education, Chosun University, Gwangju, Korea, South

Thioredoxin reductases are members of flavoprotein family of pyridine nucleotide-disulfide oxidoreductases. These enzymes use NADPH to reduce thioredoxin, a major protein disulfide reductase serving as electron donors for various enzymes including ribonucleotide reductase, peroxiredoxin scavenging H2O2. Therefore, this thioredoxin system is critical for redox regulation of protein function. In this study, we report that two thioredoxin reductases in C. elegans, trxr-1 and trxr-2. GFP reporter system revealed that both trxr-1 and trxr-2 are expressed in intestine as trx-1, a cytoplasmic thioredoxin of C.elegans. Mitotracker staining revealed that trxr-1 was localised in cytoplasm, and trxr-2 in mitochondria as predicted by their signal sequence analysis. It seemed that both trxr-1 and trxr-2 were induced by heat shock and paraquat treatment and less viable under stress condition. Interestingly,acridine orange uptake assay indicated that V-ATPase activity was reduced in trxr-1 and trxr-1;trxr-2 double mutants, while it was comparable to wildtype in trxr-2 mutant. These results suggest that spatial separation of trxr-1 and trxr-2 confer them with differential roles in oxidative stress defense and regulation of enzymatic activity. Oxidized protein levels, transcriptional regulation, and lifespans in different conditions of these mutants are currently under investigation.

Spatial Approximations between Mid-Region of Glucagon-Like Peptide 1 and Its Receptor Provide New Insights into the Molecular Basis of Natural Agonist Binding.
Q. Chen, D. I. Pinon, L. J. Miller, M. Dong; Mayo Clinic, Scottsdale, AZ

The glucagon-like peptide 1 (GLP1) receptor is an important drug target within the Family B G protein-coupled receptors (GPCRs). Its natural agonist ligand, GLP1, has incretin-like actions and holds promise for the management of type 2 diabetes mellitus. Despite the recent solution of the structure of the amino terminus of the GLP1 receptor and several close family members, the molecular basis for GLP1 binding to and activation of the intact receptor remains unclear. We previously demonstrated molecular approximations between two carboxyl-terminal residues of GLP1 and the amino terminus of its receptor. In this work, we extended the study to the mid-region of this peptide, synthesizing two photolabile probes that incorporated a benzyoyl
phenylalanine in positions 16 and 20 of the GLP1(7-36) peptide. Both probes bound the GLP1 receptor specifically and with high affinity (GLP1, $K_i=0.7\pm0.1$ nM; position 16 probe, $K_i=2.2\pm0.8$ nM; position 20 probe, $K_i=0.5\pm0.1$ nM). The probes represented fully efficacious agonists, stimulating cAMP accumulation in receptor-bearing-CHO cells in a concentration-dependent manner (GLP1, $EC_{50}=19\pm1$ pM; position 16 probe, $EC_{50}=36\pm8$ pM; position 20 probe, $EC_{50}=37\pm9$ pM). Both probes labeled the receptor specifically and saturably. Peptide mapping by proteinase cleavage of the receptor labeled with the position 16 probe identified the juxtamembranous region of the amino-terminal domain of the GLP1 receptor as the region of labeling, whereas the site of labeling with the position 20 probe was identified as a distinct region of the receptor that includes the second extracellular loop. Radiochemical sequencing will be used to identify the specific receptor residues labeled by each of the probes. Labeling of this region of a Family B GPCR is unique and may provide key spatial approximation to facilitate the meaningful orientation of the amino terminus relative to the helical bundle region of this receptor. This might also help provide insights into its mechanism of activation.

708/B655
A. G. Soto, J. Trejo; Pharmacology, UCSD, San Diego, CA

Protease-activated receptor-1 (PAR1) is a G protein-coupled receptor (GPCR) irreversibly proteolytically activated by the coagulant protease thrombin. Thrombin binds and cleaves the N-terminus of PAR1 unmasking a new N-terminus that functions as a tethered ligand by binding intramolecurally to the extracellular surface of the receptor to initiate transmembrane signaling. This unique activation mechanism suggests PAR1 may have distinct modes of signal regulation. N-linked glycosylation is a site-specific enzymatic process, which links saccharides to form glycans that are attached to asparagine (N) residues residing within the consensus sequence NXS/T (X=any amino acid except proline). PAR1 contains five consensus sites: two of which are localized within the second extracellular loop (EC2). To study the effect of EC2 N-linked glycosylation in PAR1 signaling and trafficking, we generated mutants in which the asparagines (N) of the consensus sites were converted to alanines (A). Here, we report that consensus sequences in both the N-terminus and EC2 serve as sites for PAR1 N-linked glycosylation. We found that the PAR1 mutant lacking both N-linked glycosylation modifications at EC2 (NA EC2) trafficked to the cell surface and was cleaved by thrombin like wildtype receptor. However, agonist-triggered PAR1 NA EC2 mutant endocytosis was impaired compared to wildtype receptor, whereas constitutive internalization remained intact. Moreover, activated PAR1 NA EC2 mutant displayed enhanced maximal signaling response compared to wildtype receptor. The effective concentration of thrombin to stimulate half-maximal response after 5 min was lower for PAR1 NA EC2 mutant compared to wildtype receptor. Thus, at face value these findings suggest that thrombin is more efficacious at activating PAR1 NA EC2 mutant than wildtype receptor, suggesting that each activated PAR1 NA EC2 mutant has a greater capacity to couple to signaling effectors than receptors with N-linked glycosylation at EC2. Thus, our studies reveal novel and distinct functions for N-linked glycosylation in regulation of GPCR signaling and trafficking.

Identification of a Sphingosine-1-Phosphate Receptor in Drosophila.
S. Attle, D. R. Herr, S. M. Walls, L. Morgan, G. L. Harris; Biology, San Diego State University, San Diego, CA

Sphingosine-1-phosphate receptors (S1P1-5) are a subclass of g-protein coupled receptors (GPCRs) that are stimulated by the bioactive lysophospholipid S1P. These receptors have been identified and characterized in various vertebrate models including human, mouse and zebrafish, however, they do not appear to be expressed in invertebrates. In the present studies we have used cell-based functional assays to characterize GPCR-mediated responses to S1P in Drosophila. In two-day old cultures of primary embryonic neurons, both S1P and the specific S1P
analog FTY720 induced rapid neurite retraction in a pertussis toxin (PTX) sensitive manner consistent with GPCR-mediated cytoskeletal rearrangement. In complementary experiments we used transgenic embryonic fly neurons expressing an arrestin2-GFP fusion protein; upon stimulation, the arr2-GFP was predicted to translocate from the cytoplasm to the plasma membrane as is observed in large cultured mammalian cells. Instead, in the relatively small embryonic fly neurons we observed a rapid accumulation of prominent fluorescent puncta along the neurites in response to either S1P or FTY720-P treatment consistent with GPCR activation. In order to identify candidate genes that encode fly S1P receptors, we used a variety of bioinformatic tools as well as microarray data from mutant fly lines in which the accumulation of S1P was genetically altered. Several putative S1P-receptor genes have been cloned into mammalian expression vectors and expressed in HEK293 cells. We are currently characterizing the encoded receptor responses to S1P and its analogs based on stimulation-induced receptor internalization. This characterization of S1P receptors in flies may lead to the subsequent identification of a new class of orthologous receptors in mammals as well as provide insight into their evolution.

M. Dong, D. I. Pinon, L. J. Miller; Mayo Clinic, Scottsdale, AZ

The secretin receptor, a prototypic Family B G protein-coupled receptor, forms a constitutive homo-dimeric complex that is stable even in the presence of hormone. Recently, a model of the agonist-bound secretin receptor was built based on high-resolution structures reported for the amino-terminal domains of other members of this family. While this model was fully compatible with all extant data, including ten photoaffinity labeling approximation constraints, a new such constraint now obtained with a position 16 photolabile probe appears to be inconsistent with this model. This has led us to explore whether secretin might dock across both protomers of the homo-dimeric receptor complex. To explore this, we prepared six secretin analogue probes that simultaneously incorporated two photolabile benzoylphenylalanine (Bpa) residues as sites of covalent attachment, in positions known to label distinct receptor domains. These included Bpa\textsuperscript{2,26}, Bpa\textsuperscript{16,21}, Bpa\textsuperscript{16,22}, Bpa\textsuperscript{16,26}, Bpa\textsuperscript{21,26}, and Bpa\textsuperscript{22,26} probes. Each of these dual-reactive probes was shown to represent a full agonist, stimulating cAMP accumulation in secretin receptor-bearing CHO cells in a concentration-dependent manner. Each probe labeled the secretin receptor specifically and saturably, with electrophoretic migration consistent with the labeling of a single protomer of the homo-dimeric secretin receptor. No band representing radiolabeled receptor dimer was observed for any probe except after the control representing covalent cross-linking of the protomers with exogenous disuccinimidyl suberate. The labeled receptor bands were cleaved with cyanogen bromide to demonstrate that both photolabile Bpa moieties had indeed established covalent adducts with a single receptor protomer in the complex. In conclusion, these data are consistent with a model of one molecule of secretin occupying a single secretin receptor molecule within the homo-dimeric receptor complex. This will necessitate developing a model that accommodates all spatial approximation constraints within a single receptor molecule.

711/B658
Palmitoylation of Gp78/Autocrine Motility Factor Receptor (Gp78/AMFR), an Endoplasmic Reticulum-Localized E3 Ubiquitin Ligase.
M. Fairbank\textsuperscript{1}, K. Huang\textsuperscript{2}, A. El-Husseini\textsuperscript{2}, I. R. Nabi\textsuperscript{1}; \textsuperscript{1}Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada, \textsuperscript{2}Psychiatry, University of British Columbia, Vancouver, BC, Canada

Palmitoylation, the covalent association of a lipid palmitate with one or more cysteine residues, is a dynamic post-translational modification important for receptor stability and intracellular trafficking. Using [H\textsuperscript{3}]-palmitate metabolic labeling and anti-Flag immunoprecipitation, we found that full-length and the N-terminal transmembrane domains (N-terminus) of Flag-gp78/AMFR are
both palmitoylated in COS7 cells. Next, we used site-directed mutagenesis to sequentially substitute all cysteines to alanines in the N-terminus of Flag-gp78/AMFR in order to identify the palmitoylation site(s). However, in the absence of all cysteines, the N-terminus Flag-gp78/AMFR construct was still labeled with [H3]-palmitate, suggesting that Flag-gp78/AMFR is undergoing a non-conventional palmitoylation. For most proteins, palmitate is bound to cysteine residues via sulfhydryl bonds, thus we used the Biotin-BMCC assay that reacts specifically with sulfhydryls to form stable thioether bonds to detect cysteine palmitoylation. While full-length gp78/AMFR is palmitoylated on cysteine residues, N-terminus Flag-gp78/AMFR is not, suggesting that N-terminus Flag-gp78/AMFR undergoes unconventional palmitoylation of the N-terminal Flag tag, as previously reported for Sonic Hedgehog (Buglino JA, Resh MD. J Biol Chem. 2008 Aug 8;283(32):22076-88). C-terminal gp78/AMFR cysteines are all located within the RING finger domain, critical to the ubiquitin ligase function of this protein, raising interesting questions as to the relationship between palmitoylation and the ERAD function of gp78/AMFR.

Study on Internalization Events and Signaling Compartmentalization of Human GM-CSF Receptors.
P. Chen; 1Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan, 2Institute of Biomedical Sciences, Taipei, Taiwan

Granulocyte-macrophage colony stimulating factor (GM-CSF) receptor consists of two subunits, α chain and common beta chain (βc). The βc chain is shared by IL-3, IL-5, and GM-CSF receptors, and the β chain is specific to its ligands. Upon GM-CSF binding, GM-CSF receptors transmit signals to modulate cellular proliferation, differentiation, and mobilization. Our laboratory previously found that βc chain recruited an apoptogenic protein, designated as common beta chain associating protein (CBAP), during GM-CSF deprivation and participated in apoptosis modulation. The mechanism by which βc chain distinguishes divergent signaling processes in hemopoietic cells is not well studied. Recently, many studies suggest that internalized receptors upon ligands binding not only were destined for degradation but also had active regulative roles in receptors signaling. Deletion of βc chain C-terminal retained the βc chain on plasma membrane. It indicates the C-terminal of βc chain has an internalization motif for its endocytosis. By serial and internal deleted mutants, we identify that amino acids 474-533 containing a proline-rich motif are responsible for βc chain internalization. The region is also necessary for JAK1 and JAK2 association. JAKs association and phosphorylation is required for activation of βc chain signaling. Some studies reported that JAKs association can target receptor surface expression. However, we found JAKs are dispensable for βc internalization by siRNA knockdown of endogenous JAKs but indispensable for βc signaling. within the region, proline-rich motif is important for both βc internalization and signal activation. Mass analysis of βc associated proteins is processed to identify proteins responsible for βc internalization and signal activation. The mechanism by which internalized GM-CSF receptors α and β chains used to modulate the survival and death signals will be explored.

Jak2 Sumoylation and Its Effect on GHR Function.
M. Sedek, G. Strous; Department of Cell Biology, UMC Utrecht, Utrecht, Netherlands

Jak2 kinase regulates the signal transduction of many cytokine receptors. Growth hormone receptor (GHR) signalling cascade triggered by GH binding is performed by Jak2, which leads to activation of the STAT pathway and activation of genes involved in growth and metabolism. We found that Jak2 is sumoylated by SUMO2 and SUMO3 up to high molecular weights. Sumoylation of Jak2 is connected with its phosphorylation. Kinase inactive mutants (K882E, Y1007F) have substantially reduced sumoylation signal and constitutively active mutant V617F is hypersumoylated. The significance of that is not yet clear. Currently experiments are being performed in order to identify sumoylation sites, to further investigate how this modification regulates Jak2 function and whether it is a general way of regulating Jak2 family of kinases.
Further experiments will also elucidate whether and how Jak2 sumoylation is connected with GHR signalling and endocytosis.

Inactivation of the Proximal NPXY Motif Impairs Early Steps in LRP1 Biosynthesis.
T. Pflanzner1, S. M. Reekmanns2, P. L. Gordts, S. Isbert1, A. J. Roebroek2, C. U. Pietrzik1; 1Institute of Physiological Chemistry and Pathobioc hemistry, University Medical Center of the Johannes Gutenberg University, Mainz, Germany, 2Experimental Mouse Genetics Center for Human Genetics, KU Leuven, Leuven, Belgium

The proximal NPXY and distal NPXYXXL motifs in the intracellular domain of LRP1 play an important role in regulation of the function of the receptor. The impact of single and double inactivating knock-in mutations of these motifs on receptor maturation, cell surface expression and ligand internalization was analyzed in mutant and control wild-type mice and MEFs. Application of a previously described RMCE strategy for generation of mutant Lrp1 knock-in mice was used to generate a mouse with combined inactivation of the proximal NPXY and distal NPXYXXL motifs in the intracellular domain of the endocytic receptor LRP1. Combined inactivation results in embryonic lethality at the latest at E13.5, reminiscent to the lethal phenotype of Lrp1 knock-out mice. Single inactivation of the proximal NPXY or in combination with inactivation of the distal NPXYXXL motif are both shown to be associated with an impaired maturation and premature proteasomal degradation of full-length LRP1. Therefore only a small mature LRP1 pool is able to reach the cell surface resulting indirectly in severe impairment of ligand internalization. Single inactivation of the NPXYXXL motif revealed normal maturation, but direct impairment of ligand internalization. In conclusion, the proximal NPXY motif proves to be essential for early steps in the LRP1 biosynthesis, whereas NPXYXXL appears more relevant for internalization.

Model for Activation-State Dependent Regulation of GPCR Availability.
A. Simon1, C. Loverdo2, A. Gaffuri1, A. B. Roland1, C. Leterrier1, O. Benichou2, M. Piel2, R. Voituriez2, Z. Lenkei1; 1Biology, Laboratoire de Neurobiologie, Paris, France, 2Physics, Laboratoire de Physique Théorique de la Matière Condensée, Paris, France

We present an experimental and theoretical study about the effects of permanent activation on availability and signaling of G-protein coupled receptors (GPCRs). By directly measuring endocytosis and sub-cellular distribution of a model GPCR, the type-1 cannabinoid receptor (CB1R), we first confirm that activation level, set by constitutive activity and/or chronic pharmacological treatment, and resulting endocytosis are key determinants of steady-state distribution. Kinetic modeling indicates that steady-state activation and relative rates of endocytosis/recycling impose previously unexpected constraints on receptor function. Thus, even at saturating activation levels, active membrane-bound CB1Rs can not exceed approximately 10% of total in HEK293 cells, the remainder forming a dynamic intracellular receptor reserve. Reduced availability is counterbalanced by high-gain coupling to cAMP mobilization (~40 fold), possibly explaining the relatively high efficacy of partial CB1R agonists. The resulting new theoretical framework for GPCR function suggests a spectrum of cell- and GPCR-dependent design trade-offs between maximal sensitivity and robustness. on this spectrum, cells expressing constitutively cycling GPCRs show relatively reduced availability and ligand selectivity counterbalanced by elevated robustness towards desensitization and intrinsic agonist efficacy.

The Cell Surface Targeting of Angiotensin II Type 1 and 2 Receptors: Roles of Rab GTPases.
X. Zhang, C. Dong, Y. Feng, E. Lazartigues, G. Wu; Pharmacology, LSU Health Sciences Center, New Orleans, LA
The angiotensin II (Ang II) type 1 (AT1R) and 2 receptors (AT2R) are the major cell surface mediators for the physiological functions of Ang II. However, the molecular mechanism underlying their targeting to the cell surface remains poorly defined. We found that expression of dominant negative Rab1 mutants (S25N and N124I) and siRNA-mediated depletion of endogenous Rab1 markedly attenuated cell surface expression of both AT1R and AT2R, indicating that their transport to cell surface is mediated through a Rab1-dependent pathway. Consistently, the Rab1 mutants inhibited receptor signaling measured as ERK1/2 activation. Interestingly, expression of wild-type Rab1 augmented the cell surface transport of AT2R, but not AT1R, suggesting that endogenous expression level of Rab1 may differentially modulate the cell surface targeting of AT1R and AT2R. It is of interest to note that expression of wild-type Rab1 increased overall expression of AT2R and its mRNA, whereas the Rab1 mutants attenuated total AT2R expression and enhanced ubiquitin-dependent AT2R degradation. In contrast, expression of Rab1 and its mutants did not alter total expression of AT1R. Furthermore, using similar strategies, we have also demonstrated that Rab2, Rab6 and Rab8 are involved in the regulation of AT1R maturation. These studies demonstrate that multiple Rab GTPases modulate the targeting of nascent AT1R and AT2 to their functional destination (R01GM076167).

**ARF1 GTPase Modulates A2b-Adrenergic Receptor-Mediating ERK1/2 Activation.**
C. Dong, G. Wu; Pharmacology, LSU Health Sciences Center, New Orleans, LA

ADP-ribosylation factors (ARFs) belong to the superfamily of Ras-related small GTPases and modulate multiple intracellular trafficking processes. Here we report that ARF1 is required for ERK1/2 activation by α2B-adrenergic receptor (α2B-AR). We demonstrated that α2B-AR associated with ARF1 in an agonist-dependent fashion as measured by co-immunoprecipitation. Interestingly, α2B-AR activation upon agonist stimulation also markedly activated the small GTPase ARF1. GST-fusion protein pull down assays combined with progressive deletion and site-directed mutagenesis studies further showed that double Trp residues (diW) located in the third intracellular loop mediated α2B-AR interaction with ARF1. Mutation of the diW motif dramatically disrupted the agonist-dependent association of α2B-AR with ARF1 and attenuated α2B-AR-mediated ERK1/2 activation, without altering the cell surface transport and internalization of α2B-AR. These data demonstrate that the diW motif-directed agonist-dependent α2B-AR interaction with the small GTPase ARF1 modulates ERK1/2 activation by the receptor.

**Characterization of the Intracellular Trafficking of the Inhibitory Leukocyte-Associated Ig-Like Receptor-1 (LAIR-1).**
G. Peruzzi1, K. Krzewski1, F. Borrego2, J. E. Coligan1; 1NIAID/National Institutes of Health (NIH), Rockville, MD, 2Laboratory of Molecular and Developmental Immunology, CDER/FDA, Bethesda, MD

Natural killer (NK) cells, generally recognized as sentinels of the innate immune system, express a variety of activating receptors that are prevented from inappropriately activating cells by co-expressed inhibitory receptors. Little is known about the endocytosis and trafficking of these receptors, which are of great relevance to understanding how NK cells maintain the balance of activating and inhibitory receptors on their cell surface. Our group has recently characterized the unique trafficking pattern of CD94/NKG2A, the ITIM-containing inhibitory receptor expressed by NK and T cells that recognizes HLA-E ligand expressed by most normal cells. We showed that CD94/NKG2A is endocytosed by a previously undescribed macropinocytic-like process that may be related to the maintenance of its surface expression. Here we show that another ITIM containing inhibitory receptor expressed by all leukocytes, the leukocyte-associated Ig-like inhibitory receptor (LAIR)-1, whose ligand are collagens, follow a similar unique endocytic mechanism described for CD94/NKG2A. Our studies suggest that ITIM-bearing receptors share a common bioprocessing pathway that may be related to their function and/or structure, at least in NK cells.
**Role of B Cell Receptor Ubiquitination in Regulating Antigen Processing.**

B. Katkere¹, M. Massimiano¹, L. Drake¹, A. Caballero², J. Drake¹; ¹Center for Immunology and Microbial Disease, Albany Medical College, Albany, NY, ²Department of Pharmacology and Experimental Therapeutics, Loyola University Chicago Stritch School of Medicine, Maywood, IL

B cell receptor (BCR) mediated antigen (Ag) processing and presentation is critical to the initiation of humoral immune response as it leads to B cell - T cell interactions, which support affinity maturation and immunoglobulin class switching. The mechanism of intracellular trafficking of Ag-BCR is not well understood. Our previous studies have established that, in a splenic B cell model, trafficking of Ag-BCR complexes to and within multi-vesicular body (MVB)-like compartments occurs by an ubiquitin-dependent mechanism. It was previously established that B lymphocytes posses at least two distinct endocytic pathways -- clathrin-coated pits and lipid rafts that deliver antigens to distinct intracellular compartments. It was also established that lipid raft endocytic pathway unlike its counterpart was signaling dependent. We hypothesized that ubiquitinated BCR was endocytosed via one of the two distinct endocytic pathways. To further establish the molecular mechanisms behind the ubiquitin-dependent trafficking of Ag-BCR to MVB, we confirmed in another model system, A20uWT (an Ag-specific B cell lymphoma), that BCR was ubiquitinated upon ligand stimulation. Acute treatment of A20uWT cells with proteasome inhibitor MG-132 inhibited BCR ubiquitination and delivery of Ag-BCR to β-hexosaminidase-positive-lysosomal compartment. In addition, treatment of cells with Src Kinase inhibitor PP1, followed by ubiquitin pull-down revealed that, BCR ubiquitination was dependent on Src kinase signaling. Interestingly, by isolating rafts and non-rafts followed by ubiquitin pull-down from each fractions, it was established that ubiquitinated BCR (Ub-BCR) was found predominantly in lipid raft. These results suggest that upon ligand stimulation, BCR ubiquitination is signaling dependent and Ub-BCR is trafficked via the lipid raft dependent endocytic pathway. Future experiments will define the molecular mechanism behind the ubiquitin-dependent trafficking of Ag-BCR to MIIIC.

**Aspirin Regulates Trafficking and Degradation of Membrane Proteins.**

K. Chiow, Y. Tan, S. Wong; Microbiology, National University of Singapore, Singapore, Singapore

Acetylsalicylic acid or aspirin is one of the most frequently used drug that acts as an analgesic, anti-pyretic, anti-inflammatory as well as anti-coagulant due to the inhibition of COX (cyclooxygenase). Nevertheless, studies have demonstrated that aspirin, at physiological concentration that was higher than those necessary to inhibit prostaglandin synthesis, profoundly inhibited maturation of dendritic cells (DC), thereby suggesting a COX-independent activity. There was a corresponding decrease in cell surface expression of membrane proteins essential for T cell activation (such as CD40, CD80, CD86, and MHC class II) in DCs upon treatment with aspirin. However, the underlying mechanism remains unknown. Hence, we hypothesized that aspirin regulates trafficking of cell surface membrane proteins in DCs. We used an epidermoid carcinoma cell line, A431, which expresses both Epidermal Growth Factor Receptor (EGFR) and Transferrin Receptor (TfR) as a model in our study to understand the regulation of cell surface membrane proteins by aspirin. We first examined the effect of aspirin on the distribution of EGFR and TfR in A431 cells, and show that aspirin decreases cell surface EGFR. We also demonstrate that aspirin significantly accumulates both EGFR and TfR in A431 cells and that both receptors are trapped in an aspirin-induced compartment (AMC). Further characterization studies show that AMC is EEA-1 and VAMP-3 positive but LAMP-1 negative. In addition, aspirin is shown to have significant effect on the recycling of TfR to cell surface. Thus, the AMC could likely be the early endosomes. Our results suggest that aspirin regulates trafficking of cell surface membrane proteins in mammalian cells, and may shed light on the underlying mechanism that govern the aspirin-induced downregulation of cell surface MHC II molecules in DCs and subsequently inhibition of DC-dependent T cell activation.
Andrographolide (ADO) is the active component of Andrographis paniculata, a plant used in both Indian and Chinese traditional medicine. Studies of ADO on cancer cells have shown that it is capable of inducing apoptosis and cell cycle arrest. However, not much is known about its effect on receptors known to be over-expressed in cancer. In this study, we utilised the well-characterized epidermal growth factor receptor (EGFR) and transferrin receptor (TfR) harbouring epidermoid carcinoma (A-431) cells as a model to study the effect of andrographolide on receptor trafficking. ADO treatment was found to inhibit cell growth, down-regulate EGFR on the cell surface and inhibit the degradation of EGFR and TfR. In addition, EGFR is internalized into the cell at an increased rate, and accumulated in a compartment that co-localizes with the lysosomal associated membrane protein (LAMP-1) in the late endosomes. Our study points towards a new mechanism by which ADO may induce cancer cell death through the down-regulation of cell surface EGFR.

Enhanced VirapowerTM lentiviral vectors provide a highly efficient solution for gene delivery and expression in primary and other cell types which are refractory to more traditional gene delivery methods. Previously we demonstrated optimizations to the VirapowerTM Lentiviral Expression vector line which include new HiPerformTM elements to increase the number of functional viral particles produced (functional titer) and a substantially boost protein expression. Here we demonstrate how these enhancements allow for high levels of transduction efficiency and protein expression in primary neurons and other difficult cell types at high efficiency and low MOI. We also demonstrate the ability of HiPerformTM constructs to deliver and express native, functional membrane proteins including G-protein coupled receptors (GPCRs) in host cells. The ability to produce active GPCRs, capable of antagonist ligand binding and displacement reactions, opens the door to creating novel tools for research, drug discovery and clinical applications.

The localization of Kv2.1 potassium channels into clusters is essential for cellular function, particularly for the determination of cellular excitability and the avoidance of disease. In spite of its clear physiological importance, the mechanism behind Kv2.1 cluster formation and maintenance is largely unknown. Here, we study the dynamics of Kv2.1 channels at the single-molecule level with nanometer precision. Single channels are localized using total internal reflection fluorescence microscopy (TIRFM) with 8 nm accuracy (473 nm laser, 2 mW, 50 ms exposure). Two different fluorophores are used to simultaneously track individual channels and visualize the location of channel clusters. Human embryonic kidney cells and rat hippocampal neurons are induced to express biotinylated Kv2.1 channels fused to green fluorescent protein (GFP) and individual channels are labeled with streptavidin-conjugated red quantum dots (QDs). GFP provides cluster characteristics while QDs enable tracking of individual molecules. Channels
inside GFP-Kv2.1 clusters are imaged in live cells for up to 10 minutes. Clustered channels are mobile with similar diffusion coefficients as that of non-clustered channels (0.03±0.02 μm²/s) but remain confined within the cluster perimeter throughout the imaging time. The mobility of the channels is analyzed by their mean square displacement (MSD) and cumulative distribution function (CDF). Brownian motion is expected to yield a linear MSD (for non-confined channels), and monoexponential CDF. We find that the MSD of non-clustered channel follows a power law instead of linear relation. The CDFs of confined and free channels deviate from the monoexponential form for all trajectories and time lags analyzed (n=900). Tracking single GFP molecules show the same characteristics of QDs, thus we can infer the anomaly effect is not induced by the QD labeling. Our results show that both clustered and non-clustered Kv2.1 channels experience anomalous subdiffusion. The CDF can be fit to a double exponential form that resembles two processes with slow and fast mobility respectively. Our data suggest Kv2.1 channels are mobile in a percolation matrix independent of cluster formation.

Long C Terminal Splice Variant Cav2.2 Identified in Presynaptic Membrane by Mass Spectrometric Analysis.
S. Gardezi1, P. Taylor2, R. Khanna3, E. F. Stanley1; 1Genes and Development, Toronto Western Research Institute, Toronto, ON, Canada, 2Hospital for Sick Children, Toronto, ON, Canada, 3Pharmacology and Toxicology, University of Indiana, Indianapolis, IN

Cav2.2 voltage gated calcium channels play a key role in the gating of transmitter release at presynaptic terminals. Recently we used mass spectrometry (MS) to analyze the protein complex associated with Cav2.2 in purified presynaptic terminal membranes (Khanna et al., J Biochem Mol Biol 40: 302, 2007). A number of known and new Cav2.2-associated proteins were identified, but not the channel itself. Objective: We set out to explore the above mentioned anomaly and tested the hypothesis that the channel was missed due to high concentrations of co-precipitated proteins. As previously, antibody Ab571 was used to capture the channel from purified synaptosome membrane lysate. Materials and Methods: Cav2.2 specific antibody, Ab571, (Li et al., J Neurosci 24:4074, 2004) was immobilized onto the Protein a agarose gel and incubated with purified synaptosome membrane lysates. Protein complexes captured by the immobilized Ab571 were subjected to a high salt treatment and the remaining proteins were eluted with high concentration urea. Urea eluted protein complexes were analyzed by Liquid chromatography tandem mass spectrometry (LC MS/MS). Results: LC MS/MS analysis of protein complexes that remained bound after the high salt treatment identified 12 distinct Cav2.2 peptides. These peptides were all from intracellular domains of the protein but otherwise their origins span almost the full-length of the protein, including 2 in the N terminus, 4 in the II-III loop, and 6 in the C terminus. One Cav2.2 peptide heralded from the alternatively spliced, long C terminal region. Conclusions: This finding is the first conclusive detection of a presynaptic Cav2-family calcium channel by mass spectrometry and the first detection of this particular channel type in any analysis. Furthermore, one peptide derived from the alternatively spliced, long-C terminal region, confirmed that this Cav2.2 splice variant is targeted to the presynaptic terminal.

A. R. Tufford, A. Weber, E. F. Stanley; TWRI, Toronto, ON, Canada

INTRODUCTION: CaV3x family channels serve as key conduits for the entry of Ca2+ in numerous processes such as the control of neuronal excitability and muscle contraction. While the ion conductance properties of this channel are well described with high Ba2+ concentrations as the permeant ion little is known about its permeability to Ca2+ at biologically relevant concentrations. Objective: to record single CaV3.x type calcium channel current transients at a external Ca2+ concentrations that span the physiological range. METHODS: Single calcium channels were recorded with the cell-attached version of the patch clamp technique from freshly isolated chick DRG neurons using low noise, quartz electrodes and a cooled-headstage patch clamp system as in1. CaV3.x channels were isolated by electrolyte concentration with ω-
conotoxin GIVA to block CaV2.2, the predominant DRG calcium channel type and 2 μM nifedipine, to block CaV1.x. Channels were evoked using a protocol that first hyperpolarizes to -100 mV to relieve inactivation and then steps from -80 to 0 mV. Channel amplitudes were measured using Clampfit, the Axon suite analysis program by positioning cursors at the closed and open levels by eye. The conductance was determined as the slope through individual channel openings in a current to voltage plot. RESULTS: At 30 mM Ca2+, the single channel conductance was ~6 ps, consistent with previous studies. This decreased monotonically to 1.7±0.1 ps (N=4) at 2 mM Ca2+. CONCLUSIONS: The T type Ca channel exhibits a significantly lower conductance for Ca2+ than the previously analyzed L type channel. This may account for why the other channel types are generally favored for single channel domain-regulated cell signaling processes such as exocytosis. Reference List 1. Church,P.J. & Stanley,E.F. Single L-type calcium channel conductance with physiological levels of calcium in chick ciliary ganglion neurons. J. Physiol 496 59-68 (1996).

Regulation of L-Type Ca2+ Channels by Synapse Associated Protein 97.
R. P. O’Connell2, R. Vaidyanathan1, T. J. Herron1, H. Colecraft1, J. M. Anumonwo1,2; 1Internal Medicine, University of Michigan, Ann Arbor, MI, 2Molecular and Integrative Physiology, University of Michigan, Ann Arbor, MI, 3Department of Physiology & Cellular Biophysics, Columbia University College of Physicians and Surgeons, New York, NY

Synapse associated Protein 97 (SAP97) is a modular, PDZ domain scaffolding protein important for ion channel targeting and clustering. The α1 subunit of the cardiac L-type (CaV1.2) calcium channel has a C-terminal peptide sequence (VSNL) that interacts with SAP97, however, the functional consequences of this association are unknown. We used a combination of optical and patch clamp techniques to examine the modulatory effects of SAP97 on L-type Ca2+ currents (ICa-L) in HEK293 cells and rat cardiac myocytes. Co-expression of the alpha and beta subunits of CaV1.2 (α1c & β2a) with SAP97 in HEK293 cells resulted in a two-fold increase of peak inward current (ICa,peak) at 0 mV compared to expression of α1c & β2a alone (control). ICa,peak (pA/pF) in control was -9.57 ± 1.37 (n=7) and -20.26 ± 3.93 (n=5) when α1c & β2a were co-expressed with SAP97 (p = 0.015). To test the functional role of SAP97 on ICa-L in native cells, we used a SAP97 adenovirus silencing construct to markedly suppress SAP97 expression in cultured ventricular myocytes (~90% knockdown after 3 days in culture). Whole-cell patch-clamp analysis in ventricular myocytes showed a 60% percent reduction of peak current amplitude. ICa,peak (pA/pF) at 0 mV was -11.24 ± 1.05 (n=6) in control vs. -4.65 ± 0.87 (n=7) following SAP97 silencing (p = 0.0005). Because the targeting of L-Type Ca2+ channels is essential for proper excitation contraction (EC) coupling we next examined the effects of SAP97 silencing on cell Ca2+ transients and contraction. Cells were loaded with a fluorescent calcium indicator (Fura2AM, 2 μM) for simultaneous measurements of intracellular Ca2+ transients and cell shortening (3 Hz, 40 V, 37°C). Ca2+ transients were smaller in SAP97 silenced than in control cells (SAP97 silenced 0.36 ± 0.04 (n = 5) vs. Control: 0.77 ± 0.05 (n = 5, ratio units); p = 0.0001). Cell shortening was also significantly affected in SAP97 silenced cells (SAP97 silenced 0.09 ± 0.01 vs. Control: 0.19 ± 0.03 (µm); p = 0.05). These results show that SAP97 regulates ICa-L targeting probably through PDZ domain interactions. This SAP97 induced regulation may be important in proper EC coupling in ventricular myocytes.

RIM1 Regulates Voltage-Gated L-Type Ca2+ Channel Inactivation.
M. A. Gandini1, A. Sandova2,1, R. González-Ramírez1, A. O. Monroy1, R. Felix1; 1Cell Biology, CINVESTAV, Mexico, Mexico, 2School of Medicine FES Iztacala, UNAM, Mexico, Mexico

Insulin secretion by pancreatic β cells involves a tight relationship between Ca2+ influx, via plasma membrane voltage-gated Ca2+ (CaV) channels, and the exocytotic fusion machinery. A molecular array where vesicles are docked in close proximity to CaV channels is necessary for triggering depolarization-induced Ca2+ influx hormone release. Distinct CaV channels have been described based on their biophysical and pharmacological properties. Insulin secretion is coupled to L-type
CaV channel activity, which is activated by strong depolarization and selectively blocked by dihydropiridines. These channels are hetero-oligomeric complexes of a pore-forming (α1) subunit, and auxiliary α2δ and β subunits. RIM1 is a putative effector protein for Rab3, a synaptic vesicle GTP-binding protein, which is a component of the active zone in presynaptic nerve terminals. Recently, it has been described that RIM1 modulates different neuronal CaV channels through interaction with the β subunit, modifying the inactivation rate which translates into a sustained Ca2+ influx and anchoring neurotransmitter-containing vesicles in the vicinity of the channels. Based on these findings, by using a strategy that combines patch clamp recordings with biochemical and molecular biology techniques, we investigated whether RIM1 regulates recombinant L-type CaV channels heterologously expressed in HEK293 cells, as well as native L-channels expressed in insulinoma RIN-m5F cells if this regulation is mediated by the β subunit as occurs in neurons. The most prominent effect of RIM1 on the macroscopic currents was observed on inactivation parameters. Channel inactivation significantly decreased. As expected, RIM1 was unable to affect channel activity in the absence of the β subunit indicating that the physiological association between this protein and the channels occurs via this auxiliary subunit. These results suggest that RIM1 might constitute a functional link between the L-type Ca2+ channels and the machinery for insulin release.

CFTR Interactions with the Adenosine 2B Receptor and the β2 Adrenergic Receptor Are Regulated via C-Terminal PDZ Binding.
M. J. Watson, M. Gentzsch, R. Tarran; CF Center, UNC Chapel Hill, Chapel Hill, NC

CFTR is a chloride channel that plays an important role in regulating airway fluid homeostasis. The β2 adrenergic receptor (β2AR) and the adenosine 2B receptor (A2BR) activate CFTR via G protein linked stimulation of the cAMP/PKA second messenger system. Our study examines the interaction of these two receptors with CFTR at the plasma membrane. In primary human bronchial epithelia cells (HBECs) treated with cytochalasin D (CytD) the ability of the A2BR, but not the β2AR, to stimulate CFTR is lost. In BHK cells expressing CFTR (BHKcftr) A2BR stimulation increased cAMP levels significantly more than in wild-type BHK cells (148±10% vs 24±8% respectively). β2AR stimulated cAMP production was insensitive to CFTR expression. We also confirmed these data in HBECs. Upon CytD treatment, cAMP stimulation in BHK cells was unchanged but in BHK cftr cells the increase in cAMP production was abolished. This effect of CytD was reversed in the BHK cftr cells expressing β2AR, where cAMP increased in CytD treated cells compared to untreated BHK cells (i.e. cAMP with β2AR stimulation was unaffected by CytD).

To determine spatial relationships between A2BR, β2AR, and CFTR we performed FRET analysis. We saw an adenosine (ADO) dose dependent increase (4 to 16%) in FRET between yfpA2BR and cfpCFTR (EC50 = 1.7 μM). Although we determined there was ≈4% FRET between β2AR and CFTR, it was insensitive to isoproterenol (ISO) stimulation. ADO stimulated FRET between A2BR and CFTR was abolished with CytD whilst yfpβ2AR and cfpCFTR FRET was CytD insensitive. We then made A2BR and β2AR constructs that had the c-terminal PDZ binding motifs switched (i.e. A2BRmut1 was switched from type 2 → type 1 and the reverse for the β2ARmut2). In A2BRmut1 cells the FRET response was now insensitive to ADO stimulation. Conversely, by switching PDZ motifs, the β2ARmut2 FRET response was now increased by ISO stimulation. Immunofluorescence in HBECs indicates that actin, ezrin, and NHERF2 were increased in normal compared to CF HBECs. In summary, we demonstrate that A2BR and β2AR interact differently with CFTR. The differences appear to be, at least in part, due to scaffold protein association via the c-terminal PDZ motifs on these receptors.

The SK3 (Kca2.3/KCNN3) Channel Is Expressed in Microglia In Vivo And In Vitro And Contributes to Microglial Activation and Neurotoxicity.
L. C. Schlichter1,2, V. Kaushal1,2, C. Vincent1,2, I. Moxon-Emre1,2, V. Sivagnanam1,2; 1Genes & Development, Toronto Western Research Institute, Toronto, ON, Canada, 2Physiology, University of Toronto, Toronto, ON, Canada
Apamin-sensitive, small-conductance Ca\textsuperscript{2+}-activated K\textsuperscript{+} channels (KCNN/KCa2/SK family), are expressed in the CNS, where they play roles in shaping neuron action potentials. KCa2.3/SK3 is considered a potential therapeutic target for several diseases and genetic disorders involving neuron hyper-excitability. Very little is known about the expression and roles of SK channels in non-neuronal CNS cells or how they are affected by CNS damage. The objectives of this study were to assess: 1) SK3 protein distribution in the rat striatum, before and after transient focal ischemia or intracerebral hemorrhage, and 2) whether the channel contributes to the activation of potentially cytotoxic properties of microglia, the brain’s innate immune cell. We observed extensive KCa2.3/SK3 immunoreactivity throughout the adult rat striatum, and it was especially prevalent in activated microglia/macrophages after stroke. Isolated cultures of rat microglia, neurons and astrocytes expressed transcripts for KCNN1, KCNN2 and KCNN3. Only KCNN3 was up-regulated with microglial activation. We then assessed its role in microglia-mediated neurotoxicity using SK channel blockers in a two-chamber system that restricted drug exposure to microglia (not neurons or astrocytes). Effects of two SK channel blockers were compared: apamin, which blocks SK2 and SK3; and a low concentration of tamapin, which blocks SK2. Our results implicate KCa2.3 channels in microglial activation and their subsequent ability to induce apoptosis of naïve neurons in neuron/astrocyte cultures. Blocking microglial KCa2.3 channels inhibited p38 MAPK activation, and reduced iNOS expression and nitric oxide production, without affecting NF-κB activation or phagocytosis. Consequently, there was less TUNEL, activated caspase 3 and tyrosine nitration in the target neurons. These results implicate KCa2.3 in detrimental aspects of microglial activation, which highlights the need to study functions of non-neuronal cells when considering KCa2.3 as a therapeutic target in the CNS. Supported by grants (LCS) and scholarships (CV, IM-E) from CIHR and HSF Canada.

Reduction of TRPM7 Expression Increases Resistance to Apoptosis Stimuli.
H. Chen\textsuperscript{1,2}, O. González-Pagán\textsuperscript{1,2}, L. Su\textsuperscript{2}, L. W. Runnels\textsuperscript{2}; \textsuperscript{1}Graduate School of Biomedical Sciences-UMDNJ, Piscataway, NJ, \textsuperscript{2}Pharmacology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ

TRPM7, a member of the transient receptor potential (TRP) channel family, is a unique bifunctional protein with kinase and ion channel activities. The channel-kinase is ubiquitously expressed and has been linked to various physiological roles, including magnesium homeostasis, melanopore formation, cell proliferation and cell adhesion. Deletion of TRPM7 in DT40 B cells causes cell cycle arrest followed by cell death. However, a recent study demonstrated that reduction of TRPM7 channel expression in neurons is protective against cell death caused by oxygen glucose deprivation. To better understand the role of TRPM7 in cell proliferation and cell stress we stably reduced TRPM7 expression in HEK-293 cells and Swiss 3T3 fibroblasts by RNA interference. As expected knockdown of TRPM7 in these cells reduced cell proliferation. Interestingly, knock-down of TRPM7 caused the cells to be more resistant to cell stress induced by several apoptotic stimuli, including the application of staurosporine, doxorubicin (adriamycin), and tumor necrosis factor - alpha (TNF-α). TRPM7-knockdown fibroblasts showed reduced apoptosis from these drug treatments as assessed by cleavage of PARP and caspase-3. Re-expression of TRPM7 restored the sensitivity of knockdown cells to apoptotic stimuli; however, TRPM7’s kinase activity was not required, as expression of the kinase-dead mutant TRPM7-G1618D was also successful in reversing the knockdown phenotype. We conclude that depletion of TRPM7 channel from cells enhances their resistance to various forms of apoptotic stimuli.

Structural and Mechanical Analysis of Dental Tissues in Mice Lacking the NBCe1 Na+/HCO\textsubscript{3}- Cotransporter.
R. S. Lacruz\textsuperscript{4}, A. Nanci\textsuperscript{4}, S. N. White\textsuperscript{3}, I. Kurtz\textsuperscript{3}, M. Paine\textsuperscript{3}; \textsuperscript{4}Univ. Southern California, Los Angeles, CA, \textsuperscript{3}University of Montreal, Montreal, QC, Canada, \textsuperscript{3}Univ. California Los Angeles, Los Angeles, CA
Patients with inherited proximal renal tubular acidosis (pRTA) may have extra-renal manifestations including short stature, bone growth delays, and ocular defects. Amelogenesis imperfecta (AI; imperfect enamel) is a group of diverse inherited disorders localized to the dental enamel not usually associated with other symptoms or diseases. The main causes of AI are mutations affecting the secreted enamel-specific proteins, amelogenin, enamelin, kallikrein 4 or matrix metalloproteinase 20. There are however, documented case reports of patients with pRTA who have mutations in the SLC4A4 gene encoding NBCe1 in which dental enamel have also been identified as part of the constellation of extra-renal findings. We recently reported the first evidence that NBCe1 is expressed in polarized rodent dental enamel cells (ameloblasts) at the basal pole. These observations suggest that NBCe1 plays an essential role in enamel formation. Mice with a targeted disruption of the Slc4a4 gene resulting in a total ablation of NBCe1 protein expression could therefore potentially be an excellent model for studying the role of NBCe1 in enamel formation. Here we present analysis of microstructural and mechanical data for the dental hard tissues in Slc4a4/- mice. These animals show hypoplastic enamel with severely disorganized prismatic structure creating an extremely brittle and non-functional tissue. The observed enamel phenotype on the Slc4a4/- animals is similar to AI. Mechanical analysis suggests that the mesenchymally-derived dentine tissue may also be affected although the mechanism responsible for its weaker structure is unknown given that NBCe1 variants are not expressed in dentine-like cells. Taken together these data indicate that abnormal pH homeostasis in developing teeth result in disruption to enamel crystallite formation, creating structurally weak enamel. Normal ameloblast bicarbonate transport/pH regulation is thus required for proper enamel formation.

Involvement of a Membrane Transporter, MDR1/ABCB1, in Apoptosis-Independent Sebum Secretion in Hamster Sebocytes.
H. Kurihara, T. Sato, N. Akimoto, A. Ito; Department of Biochemistry and Molecular Biology, Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan

Objective: Sebum secretion plays an important role for physiological barrier formation on the skin surface. Although sebum secretion is regulated by a holocrine mechanism that is associated with the apoptosis of sebaceous gland cells (sebocytes), we found a novel insight that sebum secretion is independent of apoptosis in hamster sebocytes. On the other hand, ATP-binding cassette (ABC) transporters participate in the membrane transport of various substrates including lipids. However, whether ABC transporters are associated with sebum secretion is not well understood. In the present study, we examined the involvement of ABC transporters in sebum secretion in hamster sebocytes. Methods: Membrane transport activity and apoptosis-tolerance in differentiated hamster sebocytes (DHS) were monitored by a calcium ionophore, A23187-induced Ca2+ influx, and phosphatidylserine (PS) exposure. ABC transporter activity was measured using an ABC transporter substrate, Rhodamine 123 in the presence or absence of an ABC transporter activator, 2′(3′)-O-(4-benzoylbenzoyl)adenosine 5′-triphosphate (bzATP). Sebocyte ABC transporter expression was characterized by PCR and Western blotting. Results: DHS that intracellularly accumulated and secreted sebum exhibited constitutive PS exposure without apoptosis. A23187 failed to augment Ca2+ influx and apoptosis in DHS, whereas both reactions were observed with undifferentiated hamster sebocytes (unDHS) that did not accumulate and secrete sebum. Transporter activity was highly detectable in DHS rather than unDHS. BzATP augmented not only transporter activity but also sebum secretion in DHS. PCR and Western blot analyses showed that DHS expressed an ABC transporter—multidrug resistance 1 (MDR1)/ABCB1. Furthermore, an antibody against MDR1 interfered with both ABC transporter activity and sebum secretion in DHS. Conclusions: These results provide novel evidence that sebum secretion is mediated by MDR1 in an apoptosis-independent manner in DHS. Finally, these findings should help accelerate the understanding of the functions of sebaceous glands, and may contribute to the development of therapies for skin diseases such as acne.

**Functional Role for Rho-Dependent, Non-Clathrin, Non-Caveolar Endocytosis in Membrane Recovery at the Apical Pole of Bladder Umbrella Cells.**

*P. Khandelwal, W. G. Ruiz, G. Apodaca; Medicine, University of Pittsburgh, Pittsburgh, PA*

Bladder filling stimulates exocytosis of subapical discoidal/fusiform vesicles at the apical surface of the outermost umbrella cells, but the mechanisms by which the added membrane is recovered after voiding and the fate of internalized apical membrane is unknown. Using an In Vitro system that simulates bladder filling/voiding, we observed that apical membrane added during a previous period of filling was rapidly (within 1 min) and completely recovered after experimental voiding. Clathrin/AP2, flotillin, and caveolin-1/-2 were absent from the apical membrane of umbrella cells and inhibitors of clathrin- or caveolar-mediated endocytosis had no effect on apical internalization. In contrast, dynamin-2 was localized along the apical membrane of the cell and apical endocytosis was inhibited by treatment with dynasore or expression of dominant negative dynaminK44A. Further study showed that apical endocytosis occurred in an actin-, Rho-, and Rho kinase-dependent manner, and was triggered by integrins, focal adhesion kinase, and PI-3 kinase. Following endocytosis, membrane bound and/or fluid phase endocytic tracers were initially delivered to ZO1-positive vesicular structures that were closely apposed to the apical junctional complex and were giantin, Rab11a, EEA1, and LAMP2 negative. However, in a subsequent chase the majority of internalized markers were found in LAMP2-positive late endosomes/lysosomes. Our results indicate that during voiding tension stimulates integrin-and possibly FAK/Pi3K-dependent activation of RhoA, which in a dynamin-dependent manner promotes apical endocytosis and subsequent degradation of internalized apical membranes/proteins.

**The Role of Sterol Binding of Oxyysterol Binding Protein (OSBP) Homologue ORP1L.**

*T. Vihervaara1, R. Uronen2, E. Ikonen2, V. M. Olkkonen1,2; 1National Institute for Health and Welfare, Helsinki, Finland, 2Institute of Biomedicine/Anatomy, University of Helsinki, Helsinki, Finland*

Methods to assess the role of sterol binding for ORP1L function we generated a sterol binding deficient mutant (mORP1L) using site-directed mutagenesis. Imaging was performed with confocal microscopy in HeLa cells transfected with tagged DNA constructs. To study binding of [3H] labeled oxysterols, an In Vitro charcoal dextran based assay was used. for cholesterol efflux experiments, foam cell formation was induced by loading RAW264.7 macrophages with [3H]-oleate labeled acetylated LDL. Efflux was determined by liquid scintillation counting. Results Both wt and mutant ORP1L colocalize with Rab7 and Rab7 interacting protein RILP, but not with Rab5, identifying these structures as late endosomes LE. Using live cell and confocal microscopy we show here that sterol binding affects the motility of ORP1L positive late endosomes. ORP1L clusters LEs, mORP1L results in dispersed localization of LEs. Cholesterol efflux is a process where intracellular cholesterol is transported to extracellular acceptor particles. Silencing of ORP1L in acLDL loaded RAW264.7 macrophages was shown to decrease cholesterol efflux to apolipoprotein AI cholesterol acceptor. Overexpression of the mORP1L did not inhibit cholesterol efflux to ApoAI, suggesting that ORP1L sterol binding is not required for the process. To further characterize sterol ligands for ORP1L we show that ORP1L binds 24(S)-hydroxysterol with highest affinity. This is highly interesting considering the fact that both are abundant in the central nervous system. Conclusions In this study we demonstrate that ligand binding affects the positioning and motility of ORP1L positive late endosomes. ORP1L also plays a role in reverse cholesterol transport but sterol binding may not be required for the process. The study supports the role of ORP1L as sterol sensor involved in late endosomal lipid transport.

735/B682

**Activation Mechanisms of the Nucleotide Exchange Factor Arno.**
Upon GDP to GTP exchange, small G proteins of Arf family bind to lipid membranes where they control protein coats, lipid modifying enzymes and other proteins that contribute to the remodeling of cellular membranes. The Arf guanine nucleotide exchange factor ARNO contains three domains: A coiled-coil region, a Sec7 domain and a PH domain flanked by a short polybasic tail. The mechanism by which the Sec7 domain promotes GDP to GTP exchange on Arf is well established but other issues remained to be addressed: which Arf isoform does ARNO activate in the cell and what are the mechanisms that control the membrane recruitment of ARNO? These issues are key for understanding the physiological role of this protein. Recently the group of J. Donaldson has suggested an intriguing cascade of activation (Cohen et al., 2007). Arf6-GTP would recruit ARNO at the plasma membrane, by binding to its PH domain. Thereafter ARNO, through its Sec7 domain would promote nucleotide exchange on Arf1. First, we study this cascade at the molecular level on artificial membranes. For this, we use artificial liposomes containing lipids that are characteristic of the plasma membrane. We observe a strong synergy between phosphatidylserine, PIP2 and Arf6-GTP on the catalytic activity of ARNO on Arf1. These experiments suggest that at least two membrane determinants (PS + Arf6GTP or PS + PIP2) must be present to turn on efficiently ARNO. By examining the activity of mutants of ARNO, we dissect the protein-protein and the protein-lipid interactions that are involved in the Arf6/ARNO/Arf1 cascade. We show that Arf1 activated by this cascade can in turn enhance the activation of other Arf1 molecules by interacting with ARNO in a similar manner as Arf6. We are currently characterizing this cascade of activation in cells, which may contribute to membrane maturation by changing the repertoire of Arf subtypes and specific lipids.

Cargo and Adaptor Specific Mechanisms Regulate Clathrin Mediated Endocytosis.
M. Mettlen, D. Loerke, G. Danuser, S. L. Schmid; Cell Biology, The Scripps Research Institute, La Jolla, CA

Diverse cargo molecules (i.e. receptors and ligand/receptor complexes) are taken into the cell by clathrin-mediated endocytosis (CME) utilizing a core machinery consisting of cargo-specific adaptors, clathrin, the GTPase dynamin and numerous endocytic accessory proteins. Previously, we have shown that a subset of accessory proteins, which mediate coat assembly, membrane curvature and cargo selection, can provide input into an endocytic restriction point/checkpoint mechanism that monitors CCP maturation. Furthermore, we showed that overexpression of the constitutively internalized, AP-2-dependent transferrin receptor (TfnR), increases the efficiency of CCP maturation without affecting the rate of CCV budding. Here we report that a different cargo receptor, the low density lipoprotein receptor (LDLR), which uses a distinct set of adaptors (Dab2 and ARH), alters a different aspect of CCP maturation. Using a combination of biochemistry, quantitative live-cell imaging and decomposition of CCP lifetime distributions under various conditions, we show that overexpression of a CD8/LDLR chimera increases the size of CCPs without effecting the efficiency or rate of maturation. This effect is dependent on Dab2 or ARH, but these two adaptors control clathrin polymerization through different mechanisms. We further show that the various adaptors are incorporated into the same CCPs and compete with each other for CCP occupancy. Hence, the ratio of a specific adaptor to clathrin is not fixed but variable. Cargo receptor over-expression also leads to saturation of endocytic efficiency, which we have attributed to saturation of adaptor-mediated cargo sorting into CCPs. Finally, we have identified two additional functions of ARH: as a nuclear protein, exhibiting regulated nucleocytoplasmic shuttling and as a regulator of the actin cytoskeleton. Altogether, our results underscore the highly dynamic and cargo-responsive nature of clathrin coats and illustrate the complexity of CCP maturation. Although it remains unclear what defines the overall CCP density at the plasma membrane, we established that even constitutively internalized cargo and their adaptors can regulate multiple aspects of CCP maturation.

Identification of the Switch in Early-To-Late Endosome Transition.
D. Poteryaev¹, S. Datta², M. Zerial², A. Spang¹; ¹Biozentrum, University of Basel, Basel, Switzerland, ²Max Planck Institute for Molecular Cell Biology and Genetics, Dresden, Germany

Sequential transport from early to late endosomes is an important step for protein sorting and degradation that requires the coordinated activities of the small GTPases Rab5 and Rab7. Little is known about the molecular mechanism underlying this transport process. The transition between early and late endosomes could be mediated either through transport carriers or by Rab conversion, a process in which the loss of Rab5 from an endosome occurs concomitant to the acquisition of Rab7. Here we demonstrate that Rab conversion is the mechanism by which proteins pass from early to late endosomes in *C. elegans* coelomocytes. Moreover, we identified SAND-1/Mon1 as the critical switch for Rab conversion in metazoa. SAND-1 serves a dual role in this process. First, it interrupts the positive feedback loop of RAB-5 activation by displacing RABX-5 from endosomal membranes and, second, it times the recruitment of RAB-7 to the same membranes. SAND-1/Mon1 thus acts as a switch by controlling the localization of RAB-5 and RAB-7 GEFs.

Isoform Specific Functions of Dynamin 2.
S. Neumann, Y. Liu, T. J. Pucadyil, S. Acharya, S. L. Schmid; Department of Cell Biology, The Scripps Research Institute, La Jolla, CA

Dynamin is best studied for its role in clathrin-mediated endocytosis (CME) and most of these studies have employed the first identified isoform, dynamin-1 (Dyn1). However, there are two major, mammalian isoforms of dynamin: the neuronal isoform, Dyn1, and the ubiquitously expressed isoform, Dyn2. It has been assumed that Dyn1 and Dyn2 function redundantly in CME. However, biochemical comparison using a recently developed In Vitro fission assay revealed that Dyn1 but not Dyn2 mediates efficient vesicle formation from planar membranes. However, when membrane tethers, which more closely resemble the highly curved necks of clathrin coated pits are presented as substrates, both isoforms are capable of scission. Consistent with this preference for curved templates, Dyn2 exhibits a much more robust assembly-stimulated GTPase activity in the presence of ~30 nm lipid nanotubes than in the presence of ~100 nm liposomes. These findings point to reduced membrane binding and/or curvature generation by Dyn2. We are currently testing whether interacting partners of dynamin, such as endophilin, amphiphysin or SNX9 that contain BAR domains, which are also involved in curvature generation might enhance Dyn2 activity in these assays. We also recently showed in conditional Dyn2 knock-out cells that CME was more efficiently restored by Dyn2 expression than by Dyn1. Together these In Vivo and In Vitro assays provide a means to identify which domain(s) confer these isoform-specific functional properties through analysis of Dyn1/Dyn2 chimeras.

739/B686
A Switch for Triggering Actin Assembly for Endocytosis.
R. Basu, F. Chang; Columbia University, New York, NY

Endocytosis in yeast is characterized by an orderly dynamic progression of events at the plasma membrane, starting with marking the site of endocytosis, followed by recruitment of WASp, and then Arp2/3 complex, leading to burst of local F-actin assembly, invagination of the membrane and then scission of an endocytic vesicle into the cell interior. Here we characterize *S. pombe* dip1p, an orthologue of WISH/DIP proteins, which have been proposed to regulate WASp, Arp2/3 and formins in mammalian cells. *dip1* mutants display a defect in endocytosis and possess a marked decrease in the number of active endocytic sites. Time-lapse analysis of actin patch components In Vivo reveal a striking defect in the dynamic progression in the endocytic process. In wildtype cells, the appearance of wsp1p (WASp) at the plasma membrane is followed quickly by actin assembly. In *dip1Δ* cells, wsp1p patches appear normally, but display significant delays (over 10-fold slower on average) in Arp2/3 recruitment, actin assembly and other downstream events. Quantitative kinetic analysis indicate that in the absence of dip1p, rapid activation of the
patch now appears at stochastic intervals, suggesting the presence of a switch mechanism for turning on actin assembly. We provide evidence for positive feedback loops responsible for this switch, which involve actin assembly, WASp and Arp2/3 recruitment, and binding of WASp WH2 domain to the barbed end of actin filaments. These studies thus begin to define a molecular switch triggered by dip1p for the rapid activation of Arp2/3 recruitment and actin assembly at the plasma membrane.

Family Ties: Complicated Relationships between the Connecdenn Family of Rab35 GEFs and the Clathrin Machinery.
A. L. Marat, P. S. McPherson; Neurology and Neurosurgery, McGill University, Montreal, QC, Canada

Rabs constitute the largest family of monomeric GTPases, yet for the majority of Rabs relatively little is known about their activation and recruitment to vesicle trafficking pathways. Herein we describe the connecdenn family of endocytic proteins. Each connecdenn contains an N-terminal DENN (differentially expressed in neoplastic versus normal cells) domain, a common and evolutionarily ancient protein module. We demonstrate that through their DENN domains, the connecdenns function enzymatically as guanine-nucleotide exchange factors for Rab35. The DENN domain of connecdenn 1 and 2 binds Rab35 whereas connecdenn 3 does not, indicating that Rab35 binding and activation are separable functions of the DENN domain. Through their highly divergent C-termini, each of the connecdenns binds to clathrin and to the clathrin adaptor AP-2. Interestingly, all three connecdenns use different mechanisms to bind AP-2. Characterization of connecdenn 2 reveals binding to the β2-ear of AP-2 on a site that overlaps with that previously described as the interface for autosomal recessive hypercholesteremia protein (ARH) and β-arrestins. However, deletion and mutational analysis reveals that the sequence used by connecdenn 2 is completely unique. The novel connecdenn 2-binding sequence, the K-motif is predictive of AP-2-binding in Rap1-GTP-interacting adaptor molecule (RIAM), which has not been previously linked to clathrin trafficking. Our studies reveal DENN domains as generalized GEFs for Rab35 and identify a new AP-2-binding motif, demonstrating a complex link between the clathrin machinery and Rab35 activation.

741/B688
Structural and Functional Organization of Phosphoinositide and Rab Effectors in the Early Endocytic Pathway.
D. M. Navaroli1,2, D. Leonard1, K. D. Bellve1, C. Standley1, L. M. Lifshitz1, K. E. Fogarty1, S. Corvera1; 1Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA, 2Graduate School of Biomedical Sciences Interdisciplinary Graduate Program, University of Massachusetts Medical School, Worcester, MA

Endocytosis is an essential function of eukaryotic cells, providing crucial nutrients and playing key roles in interactions of the plasma membrane with the environment. The classical view of the endocytic pathway, where vesicles from the plasma membrane fuse with a homogenous population of early endosomes from which cargo is sorted, has recently been challenged by the finding of multiple subpopulations of endosomes. These subpopulations vary in their content of phosphatidylinositol 3-phosphate (PI3P) and Rab binding proteins. The role of these endosomal subpopulations is unclear, as is the role of multiple PI3P effectors, which are ubiquitously expressed and highly conserved. One possibility is that the different subpopulations represent stages in the maturation of the endocytic pathway. Alternatively, endosome subpopulations may be specialized for different functions, such as preferential trafficking of specific endocytosed cargo. To determine whether indeed specific receptors are targeted to distinct populations of endosomes, we have built a platform for total internal reflection fluorescence (TIRF) microscopy coupled with structured illumination capabilities. This platform provides the spatial and temporal resolution to distinguish different populations of endosomes and the delivery of fluorescent internalized cargo to these populations in real time. Initial experiments have analyzed the dynamic distribution of two highly conserved Rab5 and PI3P effectors, EEA1 and Rabenosyn-5,
and two internalized cargo molecules, transferrin (Tf) and EGF. Our results indicate that EEA1 and Rabenosyn-5 are found in mostly non-overlapping endosome subpopulations. Rabenosyn-5 containing endosomes are more heterogeneously shaped and on average smaller and more dynamic than EEA1 containing endosomes. at early stages of endocytosis, (<5 min) both Tf and EGF populate Rabenosyn-5 positive endosomal populations, but while Tf remains associated with this population, EGF is transferred to EEA1 enriched endosomes. This approach reveals the detailed structural organization of the early endocytic pathway, and will allow us to determine the specific role(s) of PI3P and Rab effectors in the regulation of endocytic cargo fate.

Structural Insights into Dynamin GTP Hydrolysis.
J. Chappie1, S. Schmid2, F. Dyda1; 1LMB, NIDDK / NIH, Bethesda, MD, 2Cell Biology, The Scripps Research Institute, La Jolla, CA

Dynamin is a large, atypical GTPase that catalyzes membrane fission in the late stages of clathrin-mediated endocytosis. As an unassembled tetramer, dynamin exhibits a high basal rate of GTP hydrolysis that can be stimulated 100-fold by self-assembly on a lipid template. for each of these activities, the underlying mechanism of the hydrolysis reaction remains unknown and the essential catalytic machinery has yet to be identified. Assembly-stimulated activity of the N-terminal GTPase domain can, however, be modulated by mutations in the distal GTPase effector domain (GED). To elucidate the key structural components that facilitate dynamin GTP hydrolysis, we have engineered a minimal GTPase-GED fusion protein (GG) that reconstitutes a robust GTPase activity comparable to full-length dynamin. Using x-ray crystallography, we have solved the structure of GG in the presence of the transition-state analog GDP.AlF4- at 2.0Å resolution. This structure reveals the first high-resolution view of dynamin’s GTPase domain in an activated conformation and suggests a novel mechanism for dynamin stimulation that requires the dimerization of this domain.

743/B690
Sorting Nexin 9 Restricts Dynamin-Catalyzed Membrane Fission to Membranes of High Curvature.
T. Pucadyil, S. Schmid; The Scripps Research Institute, La Jolla, CA

The large GTPase dynamin is localized to clathrin-coated pits (CCPs) through interactions with multiple endocytic accessory proteins, where it catalyzes membrane fission to release clathrin-coated vesicles (CCVs). Whether such interactions serve as a passive recruitment platform for dynamin or actively modulate the efficiency of dynamin-catalyzed scission of CCPs remains largely unexplored. Sorting nexin 9 (SNX9) belongs to the family of endocytic accessory proteins that can independently bind membranes as well as interact with dynamin and the clathrin-coat components. Using a system of supported bilayers with excess membrane reservoir (SUPER templates), we have previously shown that dynamin alone is sufficient to catalyze fission of both planar and highly curved membranes. We now report that the presence of SNX9 potently inhibits dynamin-catalyzed fission of planar membranes. Interestingly, this inhibition is markedly diminished on highly curved membranes. These results point to a negative regulation of dynamin's function by SNX9 that is dependent on membrane curvature. Such regulation of dynamin's function by an endocytic accessory protein could explain how the growth of a CCP and the resultant increase in membrane curvature at the neck is temporally linked to dynamin-catalyzed scission of the CCP.

744/B691
Mechanism for the Selective Interaction of C-Terminal EH-Domain Proteins with Specific NPF-Containing Partners.
F. Kieken, M. Sharma, M. Jovic, S. Girdharan, N. Naslavsky, P. L. Sorgen, S. Caplan; Biochemistry and Molecular Biology, Univ. Nebraska Med Ctr, Omaha, NE
Eps15 homology (EH) domain proteins can be divided into two classes: those with an N-terminal EH-domain(s), and the C-terminal Eps15 homology domain-containing proteins (EHDs). Whereas many N-terminal EH-domain proteins regulate internalization events, the best characterized C-terminal EHD, EHD1, regulates endocytic recycling. Since EH-domains interact with the tripeptide Asn-Pro-Phe (NPF), the object of our study was to elucidate the molecular mechanisms that allow EHD1 and its paralogs to selectively interact with a subset of the hundreds of NPF-containing proteins expressed in mammalian cells. Here, we capitalize on our findings that C-terminal EH-domains possess highly positively charged interaction surfaces, and that many NPF-containing proteins that interact with C-terminal (but not N-terminal) EH-domains are flanked by acidic residues. Using the recently identified EHD1 interaction partner MICAL-L1 as a model, we have demonstrated that only the first of its two NPF motifs is required for EHD1 binding. As only this first NPF is followed by acidic residues, we have utilized GST-pull-downs, two-hybrid analysis and Surface Plasmon Resonance to demonstrate that the flanking acidic residues 'fine-tune' the binding affinity to EHD1. Indeed, our NMR solution structure complexed with the MICAL-L1 NPFEEEEED peptide allows us to conclude that the first three flanking Glu residues lie in a position favorable for the formation of hydrogen bonds with Lys residues within the EH-domain, and that the second Glu is particularly crucial. Our data provide a novel explanation for the selective interaction of C-terminal EH-domains with specific NPF-containing proteins and allow for the prediction of new interaction partners with C-terminal EHDs.

A Single β-Adaptin Contributes to AP1 and AP2 in Dictyostelium discoideum.
T. Sosa, T. J. O'Halloran; Molecular Cell & Developmental Biology, The University of Texas at Austin, Austin, TX

Eukaryotic cells use clathrin coated vesicles to traffic lipids and proteins to specific intracellular locations. The clathrin coat is composed of an outer shell of clathrin triskelions that surrounds an inner shell of clathrin assembly and accessory proteins. Among the most abundant of the assembly proteins are the tetrameric AP2 protein complex, associated with clathrin coated vesicles at the plasma membrane, and the tetrameric AP1 protein complex, found in clathrin coated vesicles associated with the TGN. Here, we describe new contributions of APβ1/2 (β-adaptin) to clathrin function in the soil amoeba Dictyostelium discoideum. We find that, unlike vertebrates, a single β-adaptin subunit functions in both AP1 and AP2 complexes in Dictyostelium cells. Moreover, we find that disruption of the gene encoding β-adaptin results in: (1) mislocalization of clathrin and AP2α, the other large subunit of the AP2 complex; (2) decreased protein levels of mu1 and mu2, the medium-sized subunits for the AP1 and AP2 complexes; (3) cytokinesis defects, and (4) osmoregulatory defects. Similar to β-adaptin, disruption of the gene encoding AP2α results in decreased levels of mu2, but not mu1, suggesting a role for the large subunits of the AP1 and AP2 complexes in stability of their respective mu subunits. Additionally, we find that the cytokinesis and osmoregulatory defects of β-adaptin closely resemble AP1 and clathrin mutants. Finally, differences in the localization of a marker for contractile vacuole membranes in various mutants suggest distinct roles for AP1 in contractile vacuole biogenesis and AP2 in contractile vacuole recycling. Together, our results identify a substantive role for AP1 in clathrin processes, and reveal that β adaptin is indispensable for these functions.

Vps45 Modulates Rabenosyn-5 Expression and Regulates Transport at Multiple Trafficking Routes.
J. Rahajeng, S. Caplan, N. Naslavsky; Dept. of Biochemistry and Molecular Biology, Univ. Nebraska Med Ctr, Omaha, NE

In several invertebrate organisms, the Sec1p/Munc18-like protein Vps45 interacts with the divalent Rab4/Rab5 effector, Rabenosyn-5. In mammalian cells, Vps45 and Rabenosyn-5 also interact, but to date the molecular characterization of this binding, and the functional relationship between these two proteins has not been well defined. Therefore, the objective of this study is to characterize the interaction between Rabenosyn-5 and hVps45 and their functional significance in
vesicular trafficking. Here we identify specific residues within Rabenosyn-5 and Vps45 required for their interaction, by yeast-two hybrid and co-immunoprecipitation assays. We demonstrate that hVps45-depletion leads to decreased expression levels of Rabenosyn-5, likely resulting from Rabenosyn-5 instability and degradation through the proteosomal pathway. Furthermore, we demonstrate that similar to Rabenosyn-5-depletion, hVps45-depletion leads to impaired recycling of β1 integrin receptors, and a subsequent delay in human fibroblast cell migration on fibronectin-coated plates. However, unlike Rabenosyn-5-depletion, which induces Golgi fragmentation and decreased recruitment of sorting nexin retromer subunits to the Golgi, the loss of hVps45 causes Golgi condensation and the accumulation of retromer subunits in the vicinity of the Golgi. Moreover, as a consequence, mannose-6-phosphate receptor retrieval from endosomes to the Golgi is impaired, and the lysosomal hydrolase Cathepsin D displays greater retention at the Golgi. These findings implicate hVps45 and Rabenosyn-5 in post early endosome transport, and we propose that their interaction serves as a nexus to promote bidirectional transport along the endosome to Golgi axis.

Potential Role of Pik3c3 in Regulating Neurotrophin Signaling during Sensory Neuron Development.
L. Wang, X. Zhou, F. Wang; Duke University Medical Center, Durham, NC

The class III PI3K (phosphoinositide 3-kinase) is a member of the PI3K family of lipid kinase. It specifically utilizes phosphatidylinositol as a substrate, producing the single lipid product phosphatidylinositol-3-phosphate (PI3P). While PIK3C3 has been studied in the context of endocytic vesicular trafficking and autophagy in non-neuronal cells, the exact functions of PIK3C3 and its product PI3P in neurons are unclear. We generated Pik3c3flox/flox conditional mutant mice, and crossed them with Wnt1-Cre transgenic mice to delete Pik3c3 in neural crest derived cells including peripheral sensory neurons. Homozygous mutant mice (Wnt1-Cre; Pik3c3flox/flox) are embryonic lethal, dying at E14.5. We found that Pik3c3-deleted dorsal root ganglia (DRG) sensory neurons undergo massive apoptosis beginning at E11.5, despite the fact that they express neurotrophin receptors (Trks) at this stage and all neurotrophins are expressed normally in the peripheral target tissues of DRG neurons. The apoptosis can be rescued when neurons are cultured in vitro, however, cultured neurons have severely retarded axon outgrowth. We hypothesized that in vivo, target-derived neurotrophin signaling, which is essential for the survival of developing sensory neurons, is affected when Pik3c3 is deleted. Indeed we found that pErK1/2 levels are significantly decreased in mutant DRG neurons. Further experiments are being conducted to support the hypothesis.

Characterization of Interactions between Clathrin and Its Instrinsically Unstructured Binding Partners.
Y. Zhuo, U. Ilangovan, R. Sousa, A. P. Hinck, E. M. Lafer; Biochemistry, University of Texas Health Science Center, San Antonio, TX

AP180 is a clathrin assembly protein containing a globular ENTH domain which interacts with the membrane, and a relatively unstructured C-terminal domain which contains multiple binding sites for clathrin, AP2 and Eps15. Indeed, all known clathrin binding domains (CBDs) are intrinsically unstructured, raising the question of how they interact with clathrin. We characterized how a fragment of the CBD of AP180 (M5), which contains two clathrin binding sites, interacts with the N-terminal domain of the clathrin heavy chain (TD) in solution by NMR spectroscopy. The most significant chemical shift perturbations in AP180 M5 upon clathrin TD binding were observed around the two clathrin binding sites. Results from $^{15}$N T$_2$ and $^1$H-$^{15}$N NOE relaxation measurements of AP180 M5 show that the disordered AP180 M5 polypeptide chain is less flexible at the clathrin binding sites, in both the free and clathrin TD bound states. The $^1$H-$^1$H NOEs of AP180 M5 in both the free and clathrin TD bound states show no NOEs representing alpha helices or beta sheets, indicating that disordered AP180 M5 does not adopt extensive regions of secondary structure upon binding to clathrin TD. However, $d_{NN}(i, i+2)$ NOEs, which are
typically found in beta-turn conformations, are observed between D and F of the DLF motif and between the D and L of the DLL motif, which suggest that M5 has some limited turn-like structure at both clathrin binding sites, whether free or bound to clathrin TD. These repetitive turn-like structures in this flexible and extended polypeptide chain may serve much like hooks on a fishing line, to allow AP180 to recruit clathrin and other accessory proteins from a large volume of cytosol and initiate coated pit formation. (This work was supported by NIH grant NS029051 to EML).

Calcineurin Differentially Regulates Dynamin-Dependent Endocytic Processes in C. elegans.
H. Song¹, J. Lee¹,², Y. Ji²,³, J. Cho⁴, B. Park⁵, J. Ahnn⁶; ¹Department of Life Science, Gwangju Institute of Science and Technology, Gwangju, Korea, South, ²Ernest Gallo Clinic and Research Center, Department of Neurology, Programs in Neuroscience and Biomedical Science, University of California, San Francisco, Emeryville, CA, ³Laboratory of Cell and Developmental Signaling, National Cancer Institute-Frederick, Frederick, MD, ⁴Division of Biology Education, College of Education, Chosun University, Gwangju, Korea, South, ⁵Department of Life Science, Hallym University, Chunchon, Korea, South, ⁶Department of Life Science, College of Natural Sciences, Hanyang University, Seoul, Korea, South

Objective: C. elegans has been an ideal model organism to reveal In Vivo mechanisms of clathrin-mediated endocytosis. One major clathrin-mediated endocytic process in C. elegans utilizes 6 macrophage-like scavenger cells called coelomocytes to endocytose foreign molecules in the body cavity. Recently, several genes are identified to be involved in coelomocyte endocytosis using C. elegans In Vivo monitoring assay system. However, the detailed mechanism is still unknown. Here, we report a possible function of calcineurin, which is evolutionally conserved a Ca²⁺/calmodulin-dependent Ser/Thr protein phosphatase, in coelomocyte endocytosis. Results: We observed that calcineurin mutants were defective for coelomocyte endocytosis. Genetic data suggest calcineurin functions upstream of the nicotinic acetylcholine receptor CUP-4 to regulate the receptor. Calcineurin also interacts directly with the C. elegans dynamin homolog DYN-1, a large GTPase protein that we show here also regulates CUP-4. Although calcineurin does not appear to be involved in receptor-mediated endocytosis in the oocytes, we observed that both calcineurin and dynamin are necessary for synaptic vesicle recycling in neurons. We speculate that calcineurin may regulate multiple endocytic processes in the nematode by dephosphorylating DYN-1. Conclusions: In this study, we propose a novel working model to control coelomocyte endocytosis in C. elegans. Until now, only a few identified genes involved in coelomocyte endocytosis have been cloned and studied. Therefore, our results showing the identification of a novel regulator and the genetic interaction between novel gene and previously identified genes may help to uncover the exact molecular pathway to regulate coelomocyte endocytosis.

The J-Domain and Clathrin Binding Domains Alone Are Sufficient for Gak Activity.
B. Park, X. Zhao, E. Eisenberg, L. E. Greene; LCB/NHLBI, National Institutes of Health, Bethesda, MD

Cyclin G-associated kinase (GAK), the ubiquitous form of auxilin, is known to be an essential cochaperone for Hsc70 dissociation of clathrin from clathrin-coated vesicles (CCVs). This cochaperone contains a kinase domain, a Pten-like domain, a clathrin-binding domain and a J-domain that binds Hsc70. GAK was knocked out from mouse embryonic fibroblasts (MEFs) derived from GAK-conditional knockout mice by expressing cre recombinase. This caused mislocalization of clathrin adaptors, cargos, and some TGN markers, which was the same phenotype observed in MEFs depleted of clathrin using siRNA, indicating that GAK depletion resulted in loss of clathrin function. While the number of CCPs at the PM and at the TGN was greatly reduced, there was a marked increase in the number of self-assembled clathrin structures devoid of adaptors or cargos in the cytosol of GAK-depleted MEF cells, presumably due to loss of GAK and Hsc70 chaperone function. To test the domains essential for the function of GAK, the
distribution of transferrin receptor (TfR) and cation-independent mannose 6-phosphate receptor (CI-MPR), transferrin (Tf) uptake, and clathrin dynamics were examined in GAK-depleted cells expressing different fragments of GAK. Not only did the full-length and kinase-free GAK give complete rescue, but in addition, there was almost full rescue of TfR and CI-MPR localization, as well as clathrin exchange with a fragment consisting of just the clathrin binding domain and the J-domain of GAK. Therefore, the Pten-like domain, which binds phospholipids, is not essential for recruitment of Hsc70/GAK to CCVs. However, since uncoating is slower without it, it does improve uncoating efficiency. We conclude that the clathrin binding domain along with the J-domain is sufficient for cochaperoning activity of GAK.

Probing Direct Changes in Live Cell Elasticity in Response to Specific Drugs: a Combined Fluorescence/AFM Study.
A. Berquand*2, A. Holloschi3, A. Slade1, P. Kioschis3; 1Veeco Instruments Inc., Santa Barbara, CA, 2Veeco Instruments Inc., Mannheim, Germany, 3Hochschule Mannheim, Mannheim, Germany

In the present study, we show how Atomic Force Microscopy (AFM) and Inverted Optical Microscopy (IOM) can be used as one single tool to probe in situ direct changes in cell elasticity in response to specific agents. We investigated the effect of two drugs, nocodazole and latrunculin, that are known to enable disruption of tubulin and actin networks respectively. We used MIRO (Microscope Image Registration and Overlay), a powerful automated software allowing fast and easy overlay between optical and AFM images, and a combined AFM-IOM system to target locations on the fluorescence image for AFM force measurements. Elasticity measurements were calculated from the extend part of the approach-retract curves performed in single force or force volume modes, on living Hela cells and two CHO specific cell lines that naturally express fluorescent actin and tubulin, respectively. Results show that nocodazole does not significantly affect cell elasticity whereas latrunculin treatment gives rise to a spectacular change in elasticity indicating that actin cytoskeleton plays a much more important role in cell architecture and mechanics than tubulin network. This work opens the way to exciting outlooks in the field of cancer research.

Quantitative and Sensitive Detection of Target DNA Using Nano-Particles as Labels.
H. Kim1, H. Takei1,2, K. Yasuda1,3; 1Kanagawa Academy of Science and Technology, Kanagawa, Japan, 2Department of Life Sciences, Faculty of Life Sciences, Toyo University, Gunma, Japan, 3Department of Biomedical Information, Division of Biosystems, Institute of Biomaterials and Bioengineering, Tokyo Medical and Dental University, Tokyo, Japan

1. Objective Obtaining expression information in a cellular system is essential for understanding the mechanisms of living organisms. The DNA microarray screening has been widely used to obtain such information. The next step in the development of this method is improvement of the detection sensitivity at the single cell level. 2. Methods to improve the detection sensitivity, we tested a method in which gold nano-particles (gold NPs) of several different sizes were to be used as labels. A probe DNA which has a thiol group at the 5’ end was immobilized on surfaces of gold NPs, 10 to 50 nm in diameter. The target DNA was designed so as to be complementary with both probe DNA on the NPs and probe DNA immobilized on a DNA microarray. Hybridization was performed in two steps; first, the target DNA was hybridized with the probe DNA on the microarray, and next the target was reacted with the other probe DNA immobilized on gold NPs. The labeled target DNA was visualized and quantified using a field emission scanning electron microscope (FE-SEM). 3. Results The detection sensitivity was evaluated by using commercially available DNA microarrays with hybridizations of target DNA in the concentration range between 100 aM to 1 μM. Control experiments were performed at other spots on the microarray where non-complementary DNA was immobilized. As results, the detection sensitivity was normally
improved 10 to 100 fold under several different reaction conditions in comparison with conventional fluorescent labeling. The use of NPs of different sizes allowed simultaneous and specific detection of target DNAs having different sequences. 4. Conclusions for assays using DNA microarrays, the use of gold NP labels greatly improved the detection sensitivity toward target DNA. This method is useful for the detection of target molecules at low level expression. on the other hand, relatively long time is required for observation of many spots on a DNA microarray because of the use of an FE-SEM. Therefore, a labeling method should be chosen to suite particular experimental objective. One useful way is reduction of the reaction area on the DNA microarray, which would allow immediate and sensitive detection of target DNA using NP labels.

A Novel Fluorimetric Assay for Detection of Calpain Activity with FRET-Based Substrate.
M. Zhu, F. Li, X. Tong, J. He, A. Hong, V. Rakhmanova; AnaSpec, Inc., Fremont, CA

The calpains are a family of intracellular cysteine proteases. The best-characterized calpains are the isoforms µ- and m-calpain, which are also known as calpain 1 and calpain 2, respectively. Calpains are calcium-dependent and function by modulating the biological activities of many proteins through selective cleavage. Studies have demonstrated that calpains are implicated in a variety of calcium-regulated cellular processes as well as in various pathological phenomena. It has been proposed that calpains represent potential therapeutic targets for drug discovery. Here we report the development of a novel fluorimetric assay for detecting calpain enzyme activity using fluorescence resonance energy transfer (FRET) techniques. We designed and synthesized a new calpain FRET substrate peptide labeled with QXL TM 520 quencher and 5-carboxyfluorescein (5-FAM) fluorophore. Calpain cleaves the FRET substrate into two separate fragments resulting in the release of 5-FAM fluorescence, which can be monitored at excitation/emission= 490 nm/520 nm. Increase in 5-FAM fluorescence is proportional to calpain activity. The assay features a simple "add-mix-measure" protocol and provides a linear range of 0.15 mg/mL- 40.0 mg/mL for calpain 1. The IC50 of two known calpain inhibitors, SJA6017 and B27-WT, is 28.1 nM and 39.6 nM, respectively. The assay can detect both calpain 1 (µ) and 2 (m) activities and is ideal for kinetic study of these enzymes. Moreover, the long wavelength fluorescence of 5-FAM is less interfered by the autofluorescence of components in biological samples and test compounds.

T. Kaneko, F. Nomura, Y. Tomoe, K. Yasuda; Department of Biomedical Information, Institute of Biomaterials and Bioengineering, Tokyo Medical and Dental University, Tokyo, Japan

To understand the community effects in cardiomyocyte networks, we developed the on-chip single-cell measurement system combined with on-chip agarose microchamber and multi-electrode array system. The on-chip agarose microchamber system could construct the arbitrary microstructure with photo-thermal etching of agarose layer on the chip using a focused laser beam. The on-chip multi-electrode array system could measure the field potential of cardiomyocytes on the electrode. Firstly, we measured the stability of fluctuation of cardiomyocyte beat rate dependent of cell number using on-chip agarose microchamber system. The beat rate fluctuation tended to decrease as cell-community size increases, irrespective of cell network pattern. Secondly, we observed the response of cardiomyocyte networks to electrical stimulation using on-chip agarose microchamber and electrical stimulation system. The range of stimulation frequency in cardiomyocyte response to electrical stimulation tended to wide as cell-community size increases. Finally, we measured the single-cell level field potential propagation in cardiomyocyte networks using on-chip single-cell measurement system. Contrary to slow conduction velocity of dispersed cardiomyocytes culture, the conduction velocity measured by the field potential propagation in cardiomyocyte narrow linear networks was similar to the action potential propagation in a whole heart. In conclusion, our findings demonstrate that the
community effects in cardiomyocyte networks improve the beat rate stability, response to stimulation, and signal conduction in networks.

Angiogenesis and Cancer Cell Invasion in Microfluidic Flow Cells Using Real-Time Microscopy.
C. G. Conant, M. Schwartz, C. Schwartz; Fluxion, S. San Francisco, CA

Understanding the molecular and cellular mechanisms of cancer progression from primary malignancy to metastatic disease is critical to development of successful treatments. Cell invasion from the primary tumor and tumor-induced angiogenesis are just two of many phenomena contributing to the pathology of metastatic disease. Both biological processes involve migration and transmigration of cells in response to chemoattractants. In Vitro analysis of these phenomena typically involves deposition of a basement membrane derived matrix (Matrigel) in a transwell plate insert. This allows quantitation of either invasion or angiogenesis, but the inserts can be cumbersome to process. Here, we demonstrate a microfluidic based method to follow angiogenesis or cell invasion in real time. The method enables acquisition of high content data by microscopy using microfluidic flow cells which are optimized for imaging. The channels can be filled with matrix and the device’s fluid exchange capabilities facilitate introduction of cells and compounds. Using this technique, we tested endothelial cell response to bFGF and fumagilin. It was shown that bFGF impregnated in the matrix promoted angiogenesis while fumagilin abrogated the effect. We also investigated invasion of serum starved HT1080 and MCF-7 cells into serum containing matrix and found that as predicted only HT1080 cells successfully invaded the matrix. Using these experimental conditions, the method is amenable to screening many cell-types or many simultaneous conditions or compounds by microscopy in the solid or liquid matrix of a microfluidic channels.

Multiphoton Imaging and Nanoprocessing of Stem Cells.
K. Koenig1, 2, A. Uchugonova1; 1Microsensors, Saarland University, Saarbruecken, Germany, 2JenLab GmbH, Jena, Germany

Objective. Application of multi photon microscopes for safe long-term high-resolution imaging of stem cells during differentiation within 3D microenvironment without the use of exogenous markers as well as for highly-localized nanoprocessing (optical cleaning and targeted transfection). Methods a novel compact nonlinear laser scanning microscope FemtOgen (JenLab GmbH, Germany) with sub-20 femtosecond 75 MHz near infrared laser pulses was employed in addition to a conventional ZEISS LSM510-NLO-Meta system (250 fs at the sample, 80 MHz)). for nanoprocessing, single point illumination of the cell membrane was performed to induce a transient nanopore for the delivery of DNA plasmids vector pEGFP-N1. Animal and human adult pancreatic and salivary gland stem cells were investigated within monolayers as well as spheroids. Results. Near infrared femtosecond laser pulses have been used to realize marker-free two-photon autofluorescence excitation of NAD(P)H and flavoproteins. In addition, second harmonic generation (SHG) was induced within the extracellular matrix structure collagen. Measurements of the same cell spheroids have been performed up to 5 weeks after the incubation with chondrogenic and osteogenic differentiation medium. Differentiated cells exhibited a longer mean fluorescence lifetime and a blue-shifted spectrum. Interestingly, mean powers in the µW range were sufficient to realize non-destructive imaging at GW/cm2 light intensities when using sub-20 fs laser pulses whereas powers of less than 7 mW and low millisecond exposure times were sufficient to realize transient nanoholes at TW/cm2 intensities for transfection. GFP plasmids were optically introduced in stem cells with >70% transfection efficiencies. Furthermore, optical knock-out of single cells of no interest was performed to realize an optical cleaning of stem cell cultures. Conclusion. Ultracompact sub-20 femtosecond laser microscopes may become novel tools for stem cell research. Uchugonova, König, JBO 13(2008)054068 Uchugonova et al. Opt. Exp. 16(2008)9358 Uchugonova et al. J. Probing the Role of Cell-Cell Interactions in Tumor Angiogenesis Using Micropatterned Tumor Cell Arrays.
C. Tan1,2, B. Seo1, D. Brooks1, E. Chandler1, C. Fischbach1, H. Craighead2; 1Biomedical Engineering, Cornell University, Ithaca, NY, 2Applied & Engineering Physics, Cornell University, Ithaca, NY

Microenvironmental conditions contribute to tumor development and progression, however the specific role of cell-cell interactions in tumor angiogenesis remains elusive. To address this question, we have developed a peel-off cell culture array (PeelArray) chip that enables the spatiotemporal control of cell-cell interactions and the unprecedented study of angiogenic factor secretions in response to varying cell-cell interactions. The PeelArray chip consists of a polymer (Parylene) stencil coated on top of a coverslip, which can be easily peeled off to selectively micropattern biomolecules and cells in localized regions. We have used these PeelArrays to create large uniform arrays of fibronectin features of defined surface areas and performed continuous culture of single tumor cells or tumor cell clusters (for OSCC-3 and DU145 cell lines).

A broad assessment of angiogenic factor secretion using cytokine antibody arrays revealed that vascular endothelial growth factor (VEGF) and interleukin-8 (IL-8) were differentially expressed by cells devoid of cell-cell contact and cells located within cell clusters. More extensive analysis by immunocytochemistry and ELISA confirmed that cell-cell interactions play a synergistic role in regulating angiogenic potential of tumor cells. Furthermore, inhibitory studies using neutralizing E-cadherin antibodies indicated that the difference in angiogenic factor secretions were related to alterations in E-cadherin signaling. Our PeelArray technology is easy to use and has broad applicability for quantitative biological studies such as mapping protein expression, single-cell behavior studies and studies of microenvironmental effects on stem cells.

A Setup for Hypoxia Studies in 24-Well Cell Culture Plates.
M. Polinkovsky1, M. Pamenter2, G. Haddad2, A. Groisman1; 1Physics Department, UCSD, La Jolla, CA, 2School of Medicine, UCSD, La Jolla, CA

Hypoxic conditions, with the concentration of oxygen reduced below its normal physiological level, have been shown to significantly affect the expression of numerous genes and influence cellular behavior. However, due to the difficulty of generating well-controlled levels of oxygen in cell culture media, studies of cells under hypoxia are typically limited to a single oxygen concentration at a time. To study cells under multiple levels of hypoxia in parallel, we have built and tested a system to impose precise oxygen concentrations, [O2], in cell culture media in 24-well plates. The system uses a novel, computer controlled, multi-channel gas mixer to generate mixtures of N2 and O2 (with 5% CO2 in all mixtures), in which [O2] is set anywhere between 0 and 21% with 0.1% accuracy. Six different mixtures are supplied to six rows of wells of a 24-well plate using flexible strips with micro-machined gas distribution networks and four silicone plugs in each strip (the plugs are inserted into the wells on the plate). In this fashion, we have the ability to study the response of cells to six different levels of [O2] in parallel, with four separate wells for each [O2]. As a first test of the system, we have measured the mortality rate of mammalian cells exposed to different levels of [O2]. We have found significant differences between cells under hypoxia ([O2] < 4%) and cells in media saturated with air ([O2] = 21%). Specifically, during a period of 15 hours, the mortality rate of hypoxia-treated mouse cortical neurons was a factor of 2 higher than for neurons under control conditions (0.96% dead/hr and 0.52% dead/hr, respectively). In addition, we have used the system with cultures of mouse cortical neurons, fibroblasts, and glial cells to quickly determine the threshold of hypoxic response in different cell lines as well as to study the effect of hypoxia on gene expression. A specific advantage of our system is that standard 24-well plates can be adapted to quantitative studies of hypoxia with cellular responses to six precisely defined oxygen concentrations tested in parallel.

759/B706
High-Throughput Assessment of Cellular Mechanics and Underlying Physiologies.
Cellular mechanics regulates various physiological functions of tissues and organs including their integrity and development. Disturbance of this regulation can result in fatal diseases such as fibrosis and atherosclerosis. To understand how cell mechanics affects tissue functions or vice versa, we developed a three dimensional hydrogel tissue (HT) assay system that simultaneously quantifies the contractility and multiple physiological parameters of cells. Rat embryo fibroblasts (REF52) suspended in a collagen matrix was incubated to form HT membranes around scaffolds in wells that conform to 96-well plate format. To assay cellular mechanics, we used a robotic device, Palpator™, that can automatically measure the mechanical properties of eight HTs in 5 min. To assay cellular physiology, F-actin content and mitochondrial potential (MMP) were monitored using the fluorescent markers Alexa™-conjugated phalloidin and tetramethylrhodamine, ethyl ester. We also assessed cellular viability using 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium. To demonstrate the application of this assay system, we successfully screened for a small molecule that modulates contractility without affecting actin integrity, mitochondria activities or cell viability. Four test compounds were assayed: Rho kinase inhibitor (H1152), cytochalasin D (CD), 2,4-dinitrophenol (DNP), and rotenone (ROT). DNP, CD, and H1152 treatments (3 hr) dose-dependently reduced HT contractility with EC50 of 1300, 0.2, and 0.1 μM respectively. Treating HT with DNP dissipated MMP with EC50 of 340 μM. CD treatment (24hr) reduced F-actin labeling and viability to 75% of non-treated control. Although ROT did not affect contractility, it significantly reduced viability (55% of control). While all four compounds reduced HT force, we found H1152 to have the least negative effects on cellular physiology. To better characterize HT physiology, we are developing assays to measure ATP concentration, O2 metabolism and free radical production. Our HT-based assay system would be useful for revealing underline mechanisms that regulate cell and tissue mechanics. Further, the system can be used for high-throughput compounds screening.

Development of a Novel Screening System for Claudin Binder Using Baculovirus Display.

T. Yamaura1, A. Takahashi1, H. Kakutani1, M. Kondoh1, T. Sakihama2, T. Hamakubo2, K. Yagi1; 1Graduate School of Pharmaceutical Sciences, Osaka University, Osaka, Japan, 2Department of Molecular Biology and Medicine, Research Center for Advanced Science and Technology, The University of Tokyo, Tokyo, Japan

Objective: Claudin (CL), a tetra-transmembrane protein, is a component of tight junction (TJ) in epithelium. CL comprises a family containing 24 members. A CL-4 binder (C-CPE) is a potent mucosal absorption enhancer. Most of malignant tumors are derived from epithelium, and overexpression of CL is frequently observed in the tumors. These findings indicate that CL binder is a promising molecule for pharmaceutical therapy. However, because of the hydrophobicity, it is difficult to prepare CL protein in an intact form on the plate. There is little success of developing CL binder by high-throughput screenings. Recently, a novel type of protein expression system using baculovirus has been developed. Membrane proteins are displayed on the budded baculovirus (BV) in their active form (Sakihama et al., 2008). In the present study, we developed a method to screen for CL binders by using BV display system. Methods: CL-displaying BV (CL-BV) was prepared as described previously (Saeki et al., in press). Interaction of CL-BV with C-CPE was evaluated by enzyme-linked immunoassorbent assay. C-CPE-displaying phage (C-CPE-phage) library was prepared by random mutation in the functional amino acids. Modulation of TJ-barrier was evaluated in Caco-2 monolayer cell sheets. Results: C-CPE bound to CL-4-BV but not to mock-BV. In order to apply the BV display system to screening for CL-4 binders, we constructed a C-CPE-phage, which interacted with CL-4-BV. C-CPE-phages could be successfully selected from a mixture of C-CPE-phage and scFv-phage by using CL-4-BV. Moreover, novel CL-4 binders were also screened in C-CPE phage library. The C-CPE derivatives modulated TJ-barrier. Conclusion: The CL-displaying BV system may be a promising method to produce a novel CL binder and modulator.

Iporation: A Novel Technology for High-Throughput Sirna Delivery in Primary and Hard-To-Transfect Cells.
L. Chitayat, M. Hu, W. Jiang, X. Xi, Y. Huang; Rational Biotechnology Inc., Menlo Park, CA

Effective siRNA delivery in cultured cells has great utility in basic research as well as therapeutic development. Primary cells directly derived from tissues represent superior In Vitro models mimicking In Vivo physiology and pathophysiology. Traditional transfection methods, such as lipofection and electroporation, have limited utility in delivery siRNA in delicate primary cells due to low efficiency and high cellular damage. Also, the chemical reagents used in lipofection and electroporation buffers often cause off-target effects on many genes, obscuring the desired gene silencing effects from specific siRNAs. We have developed a novel iPoration technology in 96/384-well formats to address the unmet needs in high-throughput siRNA delivery in primary cells and hard-to-transfect cell lines. Unlike traditional electroporation that uses high-voltage pulses to treat cells in suspension, iPoration injects precise electrical currents into adherent cells grown on semi-porous membranes, thus induces temporary membrane permeation in the cells. This novel approach consistently produces over 90% siRNA delivery efficiency with virtually no cellular damage in various cell types including differentiated primary endothelial and epithelial cells, stem/precursor cells, and hard-to-transfect cell lines such as Caco-2. Using the iPoration technology, we routinely achieve over 75% gene knockdown effectiveness at siRNA concentrations of 100nM or less, twenty times less than what is needed for a currently available electroporation-based method. In a genome-wide microarray analysis of primary Human Cardiac Microvascular Endothelial Cells (HMVEC-C) treated with iPoration, non-specific effects (log2 ratio >1) are seen only in 0.34% of the nearly 31,000 genes analyzed, which is more than 10-fold less compared to previously reported data from lipofection. These results demonstrate that our novel iPoration technology is an ideal tool for high-throughput siRNA delivery in primary and hard-to-transfect cells, and will have great applications in functional genomics, target identification and validation, and siRNA therapeutic development.

PSI: Biology High-Throughput Enabled Structural Biology.
P. Preusch, R. Basavappa, J. Chin, C. Edmonds, W. Smith, C. Lewis, J. Berg; Cell Biology & Biophysics, NIH-NIGMS, Bethesda, MD

The primary goal of the Protein Structure Initiative:Biology (PSI:Biology) initiative to be funded by the NIGMS is to apply high-throughput structural biology to important biological problems. This will be accomplished by establishing partnerships between centers for structure determination and biologists with interests in particular proteins or collections of proteins. The PSI:Biology network centers will include: 1) Centers for High-Throughput Structure Determination, 2) Centers for Membrane Protein Structure Determination, 3) the PSI:Materials Repository, and 4) the PSI:Biology Knowledgebase. The partnerships, established through Consortia for High-Throughput-Enabled Structural Biology Partnerships, will define targets for structure determination and provide funds for functional studies in the applicants' laboratories and for a portion of the cost for structure determination in the center. In addition to protein structures and models, the PSI:Biology network will generate and make available reagents and plasmids for expressed proteins to support functional studies in the research community. NIGMS encourages Partnership applications from biologists or groups of biologists with biological questions that will benefit from the determination of relevant protein structures. The PSI:Biology high-throughput approach will enable examination of families of proteins related to the target proteins, an approach that has proven highly successful in generating the first structure of a family member and then allowing many other family members to be modeled. Examples of current partnerships include using structural genomics, modeling and systems biology to generate a three-dimensional reconstruction of the central metabolic network of the bacterium, Thermotoga maritima, and the discovery of novel enzymatic mechanisms for the enoylase and amido hydrolase classes of enzymes. Additional opportunities for researchers to join the PSI:Biology network will be provided.
through ongoing and future program announcements. Researchers may also suggest proteins for structure determination through the PSI Community Nomination site at: http://cnt.psi-structuralgenomics.org/CNT/targetlogin.jsp.

Design and Validation of a Multiforce High Throughput System (MHTS) for Measuring Single-Cell Mechanics.
R. C. Spero1, V. Swaminathan1, D. Bober1, E. T. O’Brien1, S. L. Rogers2, R. L. Superfine1;
1Department of Physics and Astronomy, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Department of Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

We report on a Multiforce High Throughput System (MHTS) for high content screening (HCS) of cell mechanics. In the past decade, HCS has changed the way assays, such as binding and motility, are performed. Independently, there is increasing understanding of the role of mechanics in cell sensing, signaling, and differentiation. However, there has been little intersection between these two trends: low throughput techniques dominate mechanical study of biological systems. We present a system that applies forces to microspheres using a magnetic field gradient. The spheres can be adhered to cell membranes to measure cell mechanics or elicit a biochemical response. The MHTS has a wide force range of 1pN - 10 nN, depending on particle size. The system temperature can be controlled in the range 20 - 40°C, and MHTS microplates have been used to grow cell cultures. The MHTS is compatible with high-NA fluorescence microscopy. We have engineered novel magnetic field geometries that increases the usable microplate area for a cell mechanics experiments. We have used the MHTS to explore the role of PTPase, an enzyme known to be involved in force sensing, on the compliance of Drosophila fly cells. Spring constants were $760\pm70$ N/m and $240\pm50$ N/m for normal and PTPase-inhibited cells, respectively. These initial studies show promise for mechanical screening of the RNAi library available for these cells. Finally, we report on our latest results applying the MHTS to measure metastatic potential of cancer cells.

The Split-TRP System: A Versatile Protein Screening Platform for the Identification of Protein-Protein Interactions in All Cellular Compartments.
N. Lentze1, L. Baumann1, M. Rezwan1, K. Kunzelmann3, M. Amaral2, D. Auerbach1;
1Dualsystems Biotech, Schlieren, Switzerland, 2Faculty of Sciences, University of Lisboa, Lisboa, Portugal, 3Department of Physiology, University of Regensburg, Regensburg, Germany

Yeast two-hybrid based systems are powerful tools for the detection and characterization of protein-protein interactions (PPIs). However, some important protein classes, e.g. integral membrane proteins and transcription factors are difficult to investigate using two-hybrid technologies. To overcome these limitations we employed a novel protein complementation screening platform. PPIs are detected by reconstitution of the split-protein sensor TRP1, enabling trp1 cells to grow on medium lacking tryptophan. Since the interaction readout is direct and independent of transcriptional reporter activation the rate of false positives is lowered considerably. Furthermore, the technology allows detection of PPIs in their natural setting, e.g. the cytosol, the nucleus or at cellular or organellar membranes. Several proteins involved in human diseases, including the cell cycle checkpoint protein p53, the amyloid precursor protein APP or the ion channels cystic fibrosis transmembrane conductance regulator and betaENaC were successfully tested in pairwise interaction studies, demonstrating the universal applicability of the system. Screening p53 and APP against human cDNA libraries validated for the isolation of novel binding partners from cDNA expression libraries. This project was funded in part by the European Union Framework 6 Grant “Target Screen 2”, contract number 037365.

Cellular Signaling in Tnfα Stimulated A549 Lung Carcinoma Cells: Phospho-Protein and Cytokine/Chemokine Multiplex Profiling.
Signaling events initiated by extracellular receptor activation lead to the expression and release of cytokines/chemokines. These events are central to cellular and tissue homeostasis, development and functional response. The complexity and number of protein targets involved in such signaling events and cellular responses that cells may undergo require tools that enable multiplex analysis of samples. Here we demonstrate the use of Luminex® technology for the multiplexed analysis of cell signaling and cytokine/chemokine expression following TNFα stimulation of A549 cells. Tissue culture supernatants and cell lysate samples were collected over a 24 hour time course from TNFα stimulated cells. These samples were analyzed using MILLIPLEX® MAP and MILLIPLEX® EpiQuant immunoassays, respectively. Of the 42 cytokines/chemokines investigated, an increased expression level (as compared to vehicle control) was observed for 21 targets in cell culture supernatants. Of the 78 phospho-tyrosine cell signaling targets analyzed, a response was observed in 43 target sites. The magnitude of cytokine/chemokine and phospho-tyrosine response varied significantly between targets. for several phosphorylation sites, a decrease in phosphorylation was observed in response to TNFα treatment. Results were obtained using fewer than 288 microplate wells (three-96 well plates), significantly reducing sample and reagent consumption and laboratory time. This approach clearly demonstrates the applicability and utility of coupling intracellular multiplex screening with the measurement of secreted factors - the end-product of many signaling pathways.

The PSI Structural Genomics Knowledgebase - A One-Stop Shop for Protein Structure, Function, Sequence, Methods, and More.
M. Gabanyi1, J. D. Westbrook1, W. Tao1, A. Kouranov1, R. Shah1, T. Schwede2, L. Bordoli2, K. Arnold2, F. Kiefer2, P. Michael2, J. Kopp2,3, P. D. Adams4, W. Minor5, R. Nair5, J. LaBaer7, H. M. Berman1; 1Chemistry and Chemical Biology, Rutgers University, Piscataway, NJ, 2Swiss Institute of Bioinformatics & Biozentrum, University of Basel, Basel, Switzerland, 3Biochemie-Zentrum, Heidelberg University, Heidelberg, Germany, 4Physical Biosciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, 5Molecular Physiology and Biological Physics, University of Virginia, Charlottesville, VA, 6Biochemistry & Molecular Biophysics, Columbia University, New York, NY, 7Biosdesign Institute, Arizona State University, Tempe, AZ

To enable biological research, the Protein Structure Initiative Structural Genomics Knowledgebase (PSI SGKB) integrates biological and structural data for all protein sequences. Researchers can use the PSI SGKB to jump-start new biological projects or find solutions to laboratory bottlenecks. With a text, PDB ID, or sequence, users can find matching PSI and PDB structures; view related annotations about sequence, structure, and function; interact with computational 3D models; find protein production protocols; purchase available DNA clones and vectors; and discover new technologies developed by the PSI for protein production, structure determination, and analysis. In collaboration with the Nature Publishing Group, the PSI SGKB provides a research library, editorial about new research advances and technologies, news, RSS feeds, and an events calendar to present a broader view of structural biology and structural genomics. A description of how this resource can be used for research will be presented. The PSI SGKB is funded by the NIGMS.

The NCI-Nature Pathway Interaction Database (PID, http://pid.nci.nih.gov; Schaefer et al., 2009) is a freely available collection of professionally curated and expert-reviewed signaling and regulatory pathways composed of human molecular interactions, signaling events and cellular processes extracted from primary literature. Pathways selected for curation are based on potential drug targets, suggestions made by our users and reviewers, and other cell signaling molecules. As of September 2009, the database contains 97 pathways encompassing 5650 interactions or events, 2794 proteins, 138 small molecules, 2219 complexes and 2152 peer-reviewed publications. Created in a collaboration between the U.S. National Cancer Institute and Nature Publishing Group, the PID is aimed at researchers interested in cell signaling pathways, such as molecular cell biologists, and bioinformaticians. The database offers a range of tools to facilitate pathway exploration. Users can browse the pre-defined set of pathways and create network maps centered on a single molecule or biological process of interest. The Batch query tool allows users to upload molecule lists, such as those derived from microarray data, and visualize the resulting molecular connectivity map. In addition, users can download lists of proteins, references used to create the pathway and complete database content in extensible markup language (XML) or Biological Pathways Exchange (BioPAX) format. The database is updated every month and supplemented by a concise editorial section that provides synopses of recent noteworthy papers in cell signaling and specially commissioned articles on the practical uses of other relevant Bioinformatics tools. Users can sign up for email alerts or RSS feeds to receive database updates.

Automated Visualization of Subcellular Environments.
G. Johnson, M. Al-Alusi, D. Goodsell, A. Olson; Molecular Biology, The Scripps Research Institute, La Jolla, CA

The elaborate biological machinery that allows our cells to function properly, or that can cause disease when broken, exists on a scale that is too small to see with a microscope and too large to visualize with nano-inference technologies like x-ray crystallography. This fact makes the fundamental causes of both health and disease difficult to study as it forces expert and student alike to abstract a mental picture of life’s most complex spatiotemporal interactions from countless data that spread across dozens of disciplines. Until science invents more direct methods of observing the mesoscale, we can, at best (and at least), assemble nanoscale structures onto microscale data using distribution functions gleaned from other branches of biology with varying reliability. In an effort to better comprehend cell function, we have begun to contribute a visualization standard that can accept, manipulate, and even assess the data produced across multiple scientific disciplines- to frame the details of molecular biology on a broader cellular map and to extrapolate predictions where reasonable. A computational toolkit we develop aims to provide ease and accessibility to mesoscale content to both the scientific community, by allowing for more efficient and non-redundant hypothesis driven research, and to educators and learners of all levels via the selective filtering and post-processing of complex subcellular data. Our toolkit's algorithm models molecular elements into cellular electron tomograms automatically. By directly accessing raw data inputs, the software can deposit molecular detail across surfaces and throughout volumes to simulate cellular membranes and compartments. Here we show examples of the algorithm in action as it fills both prokaryotic and human whole-cell tomograms with molecular detail. We show options for interactively conveying confidence across the different parameters in the model and explain how ports reaching out to various databases can continuously provide input to each modeling algorithm to alter these confidence values. Finally, we show immediate applications for education and outreach while the algorithms continue to develop towards research standards.

RandTag: Proteome-Wide Study of Protein Subcellular Location in NIH 3T3 Cells.
L. Coelho, M. Fuhrman, E. Osuna-Highley, P. B. Berget, J. W. Jarvik, R. F. Murphy; Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA, "Joint CMU-
The RandTag project is a collaborative effort to image the subcellular distributions of fluorescently tagged proteins in NIH 3T3 cells. The project goal is to obtain a proteome-wide description of the subcellular localization of proteins in this mammalian cell line. CD-tagging is used to obtain clonal cell lines in which a new exon containing eGFP is inserted into the chromosomal copy of a random gene. Tens of thousands of wide-field images of these cell lines are generated each week using automated fluorescence microscopy. Some clones are also selected for confocal imaging using a computer-assisted decision making process. The location of each GFP guest exon is determined by DNA sequencing; and literature-based information about each tagged protein is also collected. For handling this large quantity of heterogeneous data, we use automated, machine-learning based, computational methods. In particular, we employ algorithms previously developed and validated by our group for the image-processing pipeline. We have also developed a graphical model to integrate the various sources of information, taking into account their respective importance (e.g., a literature reference on the same organism is more relevant than one based on homology). Release 1 of information on over 3,000 clones has already been made publicly available through our Protein Subcellular Location Image Database, and new releases are planned every six months. The project is on going, with over one hundred clones being analyzed each week. An upcoming release will contain not only images for all proteins but generative models of subcellular patterns that can be used in systems biology simulations.

A Comprehensive Bioinformatics Analysis of HDAC-Interacting Proteins.
S. Seto, X. Qu; Bioinformatics, Moffitt Research Institute, University of South Florida, Tampa, FL

Histone deacetylases (HDACs) are enzymes that regulate the functions of histone and non-histone proteins by catalyzing the removal of acetyl groups from lysine residues. They control gene expression by altering chromatin organization and dynamics. In addition, HDACs function as key regulators of many cell processes including intracellular trafficking, autophagy and organelle turnover, ciliary disassembly, cell matrix interactions and signaling, cell migration, cell death, and cell-cell Interactions. Many proteins that have previously been described as protein modification enzymes represent only single members of protein complexes and only function properly together with other factors. Increasing evidence suggests that HDACs may also require additional factors for their various functions. Using publicly available databases and bioinformatics tools such as BLAST, we were able to identify putative interacting proteins of eighteen human HDACs by constructing a “round trip” between human HDACs and their interacting proteins through homologues in other species that are experimentally verified to interact. A database was developed by combining many data sources containing protein-protein interaction information, and a fully automatic method was developed to query, annotate and identify potential interacting proteins, which can be applied to any protein of interest. Our findings that HDACs associate with a diverse number of different proteins lead to many questions. For example, do proteins that interact with HDACs stimulate or antagonize HDAC activities? Do HDACs reciprocally alter the functions of these HDAC-binding proteins? Work is now underway to further analyze the proteins that associate with HDACs and to determine how HDACs modulate the functions of these proteins. Knowledge of these interactions will provide a basic understanding of the mechanism of each HDAC and add to our understanding of how HDACs regulate many important biological processes.

The Rational Design of Predicted Neuraminidase Inhibitors for the Treatment of Swine and Avian Influenza.
D. B. Dadon1,3, J. Durrant1, J. McCammon1,2; 1Chemistry and Biochemistry, UCSD, La Jolla, CA, 2HHMI, La Jolla, CA, 3UCSD-IMSD, La Jolla, CA
The World Health Organization warns about the pandemic potential of the H5N1 and H1N1 strains of influenza because of developing drug resistance and human-to-human transmission. In the current study, virtual docking of fragments derived from FDA approved drugs followed by fragment linking within the neuraminidase (N1) enzymatic pocket is used to increase the library of available molecules for virtual screening. Though virtual screening is a well-established technique, it does not typically account for the entire range of receptor flexibility. The Relaxed Complex Scheme (RCS) partially resolves this problem by integrating data from molecular dynamics simulations with computational ligand-receptor docking to get an accurate ensemble binding energy average for each ligand. Here, we generated fifteen novel molecules with better-predicted binding energies than all known neuraminidase inhibitors like oseltamivir, peramivir, and zanamivir. Additionally, our preliminary analysis suggests that these inhibitors have a binding mode distinct from that of oseltamivir and zanamivir. They seem to bind farther from mutations known to confer resistance. Future studies include expanding the list of potential candidate molecules followed by experimentally validating our new library in their ability to inhibit these viruses. The wider implication of this study is to increase the probability of identifying drugs with the ability to fight rare and lethal strains of influenza, especially those with resistance to known drugs.

**Purification and Characterization of a Monocot Lectin Having Anti-Proliferative Effect on Human Cancer Cell Lines.**

V. Dhuna, K. Sharma, J. Singh, S. Kamboj; Molecular Biology and Biochemistry,, Guru Nanak Dev University, Amritsar, India

Objective: Lectins are defined as carbohydrate binding proteins other than enzymes and antibodies. Lectins have emerged as very important macromolecular tools to recognize carbohydrates on cell surfaces. The present work is designed to purify and characterize monocot lectins with interesting biological properties from Indian monocot plants. Methods: on the basis of sugar specificity determined by hemagglutination, asialofetuin-linked affinity was used to purify monocot lectins. Anti-proliferative potential was determined with sulphorhodamine-B assay. Results: Arisaema utile lectin (AUL) gave a single band in SDS-PAGE at pH 8.3 corresponding to subunit Mr 13.5 kDa. The native molecular mass of 54 kDa suggested a homotetrameric structure. Like other monocot lectins, AUL gave multiple bands in isoelectric focusing and in native PAGE at pH 8.3. AUL was inhibited by N-acetyl-D-lactosamine (LacNAc), a disaccharide and asialofetuin, a complex desialylated serum glycoprotein. When treated with denaturing agents, the lectin was stable in the presence of urea (3 M), thiourea (4 M) and guanidine HCl (4 M). The lectin had no requirement for divalent metal ions i.e. Ca2+ and Mn2+ for its activity. Amino acid analysis revealed high content of aspartic acid, glutamic acid, glycine and threonine and a very low amount of methionine but complete absence of cysteine. Amino acid modification studies of AUL revealed the involvement of tryptophan and tyrosine residues involved in lectin-sugar interaction. Using Far UV CD spectra the estimated secondary structure was 37% α-helix, 25% β-sheet and 38% random contributions. In Vitro anti-proliferative activity of AUL was tested on eleven different human cancer cell lines viz. MCF-7 (Breast), SK-N-SH (CNS), 502713 (Colon), Colo-205 (Colon), HCT-15 (Colon), HT-29 (Colon), SW-620 (Colon), Hep-2 (Liver), IMR-32 (Neuroblastoma), DU-145 (Prostate) and PC-3 (Prostate). The concentrations of AUL which produced 50% inhibition (IC50) of cancer cell lines viz. SW-620, HCT-15, SK-N-SH, IMR-32, Colo-205 and HT-29 at 38, 42, 43, 49, 50 and 89 µg/ml, respectively. Conclusion: The purified Arisaema utile lectin was found anti-proliferative towards human cancer cell lines.

**Actin Cytoskeleton and Extracellular Matrix Remodeling during Early Adipocyte Differentiation.**
Adipocyte differentiation at an early stage is directly regulated by gene expression of a master regulator such as peroxisome proliferator-activated receptor-γ2 (PPARγ2). During adipogenesis, extracellular matrix (ECM) remodeling defines important events of the differentiation process. This is characterized by conversion from the fibronectin (FN)-rich stromal matrix of a preadipocyte to the basement membrane of an adipocyte. Adipocyte differentiation has been reported to result in the conversion of filamentous actin from stress fibers and lamellipodia to cortical actin structures. However, the order of the following events has not been clarified: (a) PPARγ2 expression, (b) ECM remodeling, and (c) actin cytoskeleton remodeling. In this study, we aimed to elucidate the remodeling of the actin cytoskeleton and ECM during early adipocyte differentiation. Before adipogenic induction, preadipocytes showed fibroblastic morphology with a well-developed actin stress fiber pattern and formed FN networks in connection with their actin cytoskeletons. After differentiation for 24 h, the actin fibers were disassembled and disorganized, and as a result, the FN networks were also disorganized. After 48 h of differentiation, the fibers disappeared and a cortical actin structure was formed. Coincidentally, the FN networks degraded and disappeared. After 60 h of differentiation, lipid droplets accumulated in the cytoplasm and laminin-8 expression was detected on the plasma membrane. Matrix metalloproteinase (MMP)-2, a catabolic enzyme essential for ECM remodeling, was activated after 48 h of adipocyte differentiation, whereas MMP-9 was not detected. Furthermore, PPARγ2 increased significantly after 48 h of differentiation. These results indicate that remodeling of the actin cytoskeleton and ECM precedes PPARγ2 expression during adipocyte differentiation, and therefore, we suggest that this remodeling acts as a trigger for adipocyte differentiation.

The Nanomechanical Signature of Tumorigenic Transformation.
M. Plodinec1, R. Suetterlin1, R. Zanetti-Daellenbach2, E. C. Obermann3, S. Eppenberger4, U. Aebi1, C. Schoenenberger1; 1M.E.Müller Institute for Structural Biology, Biozentrum, University of Basel, Basel, Switzerland, 2Breast Center, University Women's Hospital Basel, Basel, Switzerland, 3Department of Pathology, University Hospital Basel, Basel, Switzerland, 4Tumorbank Basel Foundation, Basel, Switzerland

Cells within tissues continuously encounter dynamic mechanical challenges to which they respond by remodeling their cytoskeleton. In cancer, these encounters are often altered thereby causing a change in the cellular response. Here we have been employing atomic force microscopy (AFM) which allows for measuring changes in the nanomechanical properties associated with tumorigenic transformation under near-physiological conditions. For example, the local stiffness of a specimen may be determined at high spatial resolution by indenting the specimen surface with the AFM tip and monitoring its deformation. On a nanoscopic level, AFM has been recently used in a clinical setting to probe with high sensitivity cell mechanics. To date, AFM has not yet been applied to three-dimensional (3D) cell culture models or intact cancer tissue, which more appropriately represents the In Vivo characteristics of the disease. Towards this goal, we have grown normal (wt) Rat2 fibroblasts and a tumorigenic derivative (Rat2sm9) in a 3D culture system to yield spheroids. Structural changes in the cytoskeleton of these cells cultured on a flat support or as 3D spheroids were correlated with differences in their nanomechanical properties. In tumor spheroids we measured a gradual centripetal softening from their periphery to the core caused by increasing hypoxia towards the core, whereas wt spheroids exhibited a homogeneous stiffness distribution. Nanomechanical testing of mammary tumors from transgenic mice corroborated these findings. To verify the clinical relevance of our study for human carcinomas, we obtained breast biopsies from 25 patients of different age groups and measured their nanomechanical properties. In malignant tumors the stiffness decreased up to 15-fold from the biopsy’s periphery to its core, whereas in benign lesions the stiffness appeared similar in all regions. The nanomechanical signature of the different carcinomas correlated well with the pathologist’s histological findings. Our long-term goal is to establish nanomechanical

775/B722
Activation of FAK by Integrin β4 in an EGFR/Src Dependent Manner in Tumor Progression.

Y. Tai1, P. Chu1, I. Lai1, T. Shen2, M. Abdel-Ghany2, B. Pauli2, J. Guan3, H. Tseng1; 1National Taiwan University, Taipei, Taiwan, 2Cornell University, Ithaca, NY, 3University of Michigan Medical School, Ann Arbor, MI

Both of integrin β4 and FAK (focal adhesion kinase) have been shown to associate with tumor progression in a variety of cancers. Recent studies showed that clustering of integrin β4 could lead to activation of FAK and its downstream signaling. Here, we further demonstrated a physical and functional association between these two molecules in Vivo and in vitro. An eleven amino-acid motif within the amino-terminus of FAK was identified to be essential for the interaction with the membrane proximal cytodomain of integrin β4. Nevertheless, this interaction occurred in an adhesion-dependent manner, especially adherent onto laminin, which subsequently resulted in the phosphorylation and activation of FAK in both of HCT116 and MDA-MB-231 cells. Moreover, EGF signaling and the activity of Src were crucial for this interaction, whereas PI3 kinase was indispensable. Interestingly, this interaction was not observed in MCF7 and other less-aggressive tumor cells, implicating that the involvement of this interaction in tumor progression. In addition, in HCT116 and MDA-MB-231 cells, disruption of the interaction between integrin β4 and FAK reduced cell proliferation, migration and invasion, in accordance with the roles of phospho-Akt, phospho-Stat3, and phospho-p38 resulted from this interference. Our data resolved for the first time a direct signaling transmission from integrin β4 to FAK through the physical recruitment in regulating cellular functions, thereby strengthening a link between integrin and FAK biochemically and functionally and shedding light on better strategies for cancer therapies. Key words: integrin beta4, FAK, tumorigenesis, metastasis

776/B723
Regulation of Hoxa1 Signaling during the Endodermal Differentiation of Mouse ES Cells.

C. A. Addae, E. Martinez-Ceballos; Environmental Toxicology, Southern University and A&M College, Baton Rouge, LA

Embryonic stem (ES) cells have the ability to differentiate into a wide variety of somatic and extra-embryonic tissues. ES cells can differentiate into all three primary embryonic germ layers (ectoderm, mesoderm, and endoderm). Differentiations of ES cells into embryonic endodermal lineages are poorly understood. The endodermal differentiation of ES is directed by the expression of the master gene Sox17. Previous experiment in our lab indicates Hoxal gene to inhibit the endodermal differentiation in mouse ES cells by repression the expression of Sox17 gene but the exact mechanism is unknown. Thus, the goal of this research is to understand the mechanism by which the Hoxal transcription factor represses the differentiation of ES cells into endodermal precursors and to identify which retinoic acid receptor (RAR α, β, or γ) is involved in the activation of endodermal markers. Investigating the mechanism by which Hoxa1 represses the differentiation cell along the endodermal lineage, was accomplished by examining the role of Hoxa1 protein first as a direct repressor of endodermal gene expression and then as a direct activator of neural gene expression. To examine the role of Hoxal as a direct repressor of endodermal differentiation, the time-dependent expression of both Hoxa1 and Sox17 mRNA expression in Wt embryoid bodies (EBs) was determined by RT-PCR after treatment with various RA doses. To identify which of the RARs is involved in the activation of Sox17 gene expression by RA, we treated EBs produced from Wt and Hoxa1-/- Es cells with various concentrations of selective RAR agonists. The expression levels of Sox17 mRNA were assayed by RT-PCR. The results obtained from this work may help to improve current endodermal differentiation protocols employing ES cells and, therefore, it would impact a number of related research areas including tissue engineering.

Improving Sialylation of Recombinant Glycoproteins in Cultured Mammalian Cells Using a Pathway-Focused Glycogene Toolbox.

P. Zhang, D. L. Tan, D. W. Heng, T. Wang, Z. Song; Expression Engineering I, Bioprocessing Technology Institute, Singapore, Singapore

Sialylation extent of N-glycans critically determines the circulatory half-lives of recombinant glycoprotein drugs. Significant efforts have been made to improve the sialylation of recombinant glycoproteins with the aim of extending their in vivo circulation time, which primarily focus on the glycan terminal modifying enzymes. Here we report a systematic functional analysis of 31 major N-glycosylation-related genes, which form the “glycogene toolbox”, on sialylation of recombinant EPO expressed in six commonly used mammalian cell lines. The sialylation pattern of recombinant EPO was determined by isoelectric focusing/immunoblotting. Among these lines, BHK and CHO cells were found to sialylate recombinant EPO most effectively. HEK293, Cos-7 and 3T3 cells showed intermediate sialylation capabilities, whereas NS0 cells sialylated recombinant EPO poorly. Combinatorial and individual overexpression of the glycogenes showed that none of the 31 genes was able to improve EPO sialylation in BHK cells and CHO cells. In HEK293, Cos-7, 3T3 and NS0 cells, however, two sialyltransferases, namely ST3GalIII and ST3GalIV, significantly enhanced the extent of recombinant EPO sialylation. ST6GalI overexpression was also able to enhance recombinant EPO sialylation in HEK293 and Cos-7 cells, though to a lesser extent. In contrast, overexpression of the upstream glycogenes that synthesize the core structures of N-glycans had no positive impact on EPO sialylation in all six cell lines tested. These upstream genes did not have a synergistic effect when co-transfected with sialyltransferases. Our pathway-focused functional analysis of glycogenes provides systematic insights into impacts of glycogenes on sialylation of recombinant glycoproteins and a general guide for engineering mammalian cells to produce highly sialylated N-glycoproteins.

778/B725
Mutation in Leucine 118 of the LHβ Subunit Reveals a Novel Sorting Signal for the Regulated Secretion of LH from GH3 Cells.

A. Jablonka-Shariff, I. Boime; Dept. of Developmental Biology, Washington University School of Medicine, St. Louis, MO

The pituitary lutropin (LH) and follitropin (FSH) are members of glycoprotein hormone family, which also include thyrotropin. The coordinated secretion and activities of LH and FSH are essential for control of gonadal function. LH dimer is released through the regulated pathway, i.e., it is released by secretagogues, while FSH dimer is secreted constitutively. Defining the sorting signals governing the trafficking of LH and FSH is critical for understanding the link between their secretion and reproductive role. Since LH and FSH are synthesized in the same gonadotrope cell and share an identical α subunit, the β subunit must contain the determinants for sorting. One unique feature of the LHβ subunit is its carboxyl terminal hydrophobic heptapeptide (115-Leu-Ser-Gly-Leu-Leu-Phe-Leu-121). Previously we demonstrated that deleting the heptapeptide from LHβ subunit diverted the truncated LH dimer to the constitutive pathway, resulting in a significant decrease in the accumulated intracellular pool in transfected rat somatotrope-derived GH3 cells. Addition of the heptapeptide to FSHβ resulted in a more regulated secretion of the FSH dimer proving this peptide is a sorting signal for LH dimer. The sequence resembles the XXXLeuLeu motif found in the cytoplasmic domain of transmembrane proteins. To examine the structure-function of the heptapeptide several alanine substitution mutants spanning residues 118-121 were constructed. Stable GH3 cell lines were labeled with [35S]cysteine and proteins from lysates and media were immunoprecipitated with antiserum that reacts with human LHβ. Absence of leu118 or both leu118 and 119 in the heptapeptide not only decreased the accumulated intracellular pool of the mutants, but also dramatically enhanced their secretion compared to the LH dimer. These results suggest that the leucine residues in the heptapeptide of the LHβ subunit, particularly residue 118, are critical determinants for the regulated secretion of LH dimer.

779/B726
Combination of 5-Azacytidine Plus Ascorbic Acid Induces Morphological Features and Molecular Markers Like-Cardiomyocytes in Mesenchymal Stem Cells from Bone Marrow.

J. Salas1, A. Parra1, A. Miliar1, C. Hernandez1, D. Ramos1, E. Mera1, M. Gomez1, M. Valdez1, L. Acevedo1,2, G. Gutierrez1; 1Posgrado, Medicine Highschool, Mexico City, Mexico, 2Posgrado, Biologic Sciences Highschool, Mexico City, Mexico

Cardiovascular diseases are the most frequent cause of death in the industrialized world, with the main contributor being myocardial infarction. Regeneration of the diseased myocardium by cell transplantation is an attractive therapeutic modality. Bone marrow mesenchymal stem cells have been shown to transdifferentiate into cardiomyocytes after 5-azacytidine treatment (5-aza). Nevertheless, an important goal is to develop efficient protocols for directing the cardiomyogenic differentiation In Vitro so many researches look for new suggestions to improve the conditions actually exist. The objective of this work was the isolation and characterization of mesenchymal stem cells from rat bone marrow as well as their differentiation in vitro. We show that exposure of the cells to a combination of two differentiate factors mainly mentioned in literature: 5-azacytidine and ascorbic acid, induce differentiation of cells producing morphology like cardiomyocytes (cells with defined fibers and a more extended shape). Methods. We employed microscopy and RT-PCR to confirm that treatment with 5-aza plus ascorbic acid induces a loss of the morphology and molecular markers of mesenchymal cells, such as CD70 and SH2 (depending of the concentration). This effect was not observed with the factors by separate. We show that the combination of both factors induce the gene expression of markers of cardiomyocytes such as cardiac troponin T (cTnT) as well as Nkx2.5. Conclusions: The capability of differentiation of mesenchymal stem cells from bone marrow into cardiomyocytes using a combination of 5-azacytidine-ascorbic could be approach for cardiac tissue repair and could represent a great promise for clinical application.

780/B727
Effect of Methyl Nutrients on the Growth of Multidrug Resistant MCF-7 Human Breast Cancer Cells.

L. Mabasa, K. Cho, A. W. Fowler, C. Park; Animal Sciences, North Dakota State University, Fargo, ND

Lipotropes (methyl group containing nutrients, including methionine, choline, folate, and vitamin B12) are dietary methyl donors essential for epigenetic changes required for cell proliferation and maintenance of tissue integrity. The objective of this research was to determine the extent to which dietary methyl donors may affect the proliferation and death (caspase-3 enzyme activity) of the multidrug resistant MCF-7 (MCF-7/Adr) and the parent MCF-7 human breast cancer cells. MCF-7 and MCF-7/Adr were allowed to grow in a complete Dulbecco's Modified Eagle Medium in a tissue culture flask. Upon reaching confluence, cells were seeded in four 96-well flat-bottom tissue culture plates and treatment cells exposed to 2.5, 5, 7.5, 10, or 20 times the level of each lipotrope contained in the basal culture medium (control) and then incubated for 24, 48, 72, or 96 hours. Cell proliferation was measured using colorimetric CellTiter 96 Aqueous One Solution Assay. Cells were also seeded on a 24-well tissue plate, treated with or without the 20 times lipotrope level, and cell lysates collected after 120 hours. The activity of caspase-3 enzyme was measured by the colorimetric assay with CaspACE assay system. After 96 hours of incubation, lipotropes reduced the proliferation of MCF-7/Adr and MCF-7 by 17% and 5%, respectively, as compared to the control. Lipotropes also slightly increased the activity of caspase-3 in both cell lines as compared to the control. These results suggest that dietary methyl nutrients may alter the expression of genes conferring multidrug resistance in human breast cancer cells, thereby rendering the cells susceptible to apoptosis. Further studies on the effect of lipotropes on the expression of genes responsible for multidrug resistance (e.g., MDR1) and the synergistic effect of lipotropes with cancer drugs on resistant cells are warranted.

781/B728
A Quantification of Resting Membrane Potential Changes in E. coli and HEK293-Herg Cells by Dielectric Spectroscopy.
We present a method to obtain the resting membrane potential ($\Delta \Psi$) from the dielectric behavior of a suspension of living cells by the use of dielectric spectroscopy (DS). The presence of membrane potential has a specific effect on the dielectric behavior of cell suspensions and it can be extracted from the low frequency dielectric dispersion curves. Therefore, we use DS to monitor low frequency dielectric permittivity changes of E. coli and mammalian cell suspensions from HEK293-hERG line. E. coli cells are harvested from three regions of the exponential growth stage: early, mid and late phase. For all DS recordings, cells were measured at the same concentration, but were harvested in different growth stages and resuspended in water with glucose. From the dielectric curves, the average $\Delta \Psi$ of E. coli is extracted by means of a theoretical model. Membrane potential values resulting from fittings with the theoretical model indicate that membranes depolarize from -220 mV (early exponential phase) to -140 mV (late exponential phase). For mammalian cells, $\Delta \Psi$ changes are triggered by the use of various pharmaceutical compounds that act as HERG K+ channel blockers and IC50 values are computed for each compound.

782/B729
A Novel Marker of Undifferentiated Liver Progenitor Cells.
R. Y. Huang1,2, C. Chiu3, L. Chiou4, G. Huang5, H. Lee1,4; 1Institute of Biotechnology, College of Bio-Resources and Agriculture, National Taiwan University, Taipei 106, Taiwan, 2Bureau of Pharmaceutical Affairs, Department of Health, Taipei 104, Taiwan, 3The Graduate Institute of Applied Science and Engineering, Department of Life Science, Fu-Jen Catholic University, Taipei County, Taiwan, 4Department of Internal Medicine, National Taiwan University Hospital and National Taiwan University College of Medicine, Taipei 100, Taiwan

Objective: Although some of hepatic progenitor cells have been characterized, up to now, neither liver stem cells nor universal liver stem cell markers have been identified. An adult rat liver stem cell line, Lig-8, has been derived from non-parenchymal fraction of F344 rats. This study is to identify and characterize interest rat stem cell marker, LigAg, which is specifically express in Lig-8 cells and recognized by our derived monoclonal antibody, named Ligab. Methods: to generate monoclonal antibody Ligab, we subcutaneously injected whole Lig-8 cells into mice. The Ligab specifically recognizes its target antigen (LigAg) with native form expressed by Lig-8 cells. for knowing the presence of LigAg in Lig-8 cells and the localization of LigAg-bearing cells in rat liver, we indirectly conjugated Ligab with FITC to perform immunofluorescent stain. for In Vitro differentiation, sodium butyrate (SB) was used to induce Lig-8 cells differentiation, and differentiated properties of expression of cytokeratin (CK)-19 and albumin were detected by PCR and immunocytostaining. To identify LigAg, we extracted different fractions of proteins from Lig-8 cells followed by immunoprecipitation and analyzed with SDS-PAGE. The identified bands in SDS-PAGE will be excised for peptide sequencing. Results: The yielded Ligab belongs to IgG subclass G1. LigAg is expressed on membrane and in cytoplasm of Lig-8 cells. Ligab could detect its antigen only by native PAGE-based immunoblotting. Indirect immunohistochemical staining in rat normal liver sections distinguishes LigAg bearing cells from currently known hepatic progenitor cells. In the induction with SB in vitro, Lig-8 cells were shown able to differentiate into both hepatocytes and bile duct cells with prospective markers expression. More interestingly, LigAg was decreasingly expressed along with Lig-8 cells differentiation. Conclusions: Inasmuch as our results showed LigAg was specifically expressed in hepatic progenitor cells, and its expression in a decreasing trend with Lig-8 cells differentiation. LigAg can be a differentiation-related marker for these cells and Ligab may help study the molecular mechanisms of liver progenitor cell differentiation.

Silencing TIEG1 Expression Promotes Myotube Formation through Regulation of Apoptosis.
M. Miyake, S. Iwasaki, C. Guozheng, H. Takahashi, K. Watanabe, S. Ohwada, H. Aso, T. Yamaguti; Animal Biology, tohoku university, Sendai, Japan
TGF-β inducible early gene 1 (TIEG1), also called KLF10, is a zinc-finger transcription factor and regulates cell proliferation, differentiation and apoptosis in osteoblasts and leukocytes. It has been reported that TIEG1 expresses highly in skeletal muscle and the expression was induced by TGF-β, one of myogenic inhibitor. However, there are no any studies on the role for TIEG1 in skeletal muscle. Therefore, we attempted to define the expression and function of TIEG1 during myogenesis using C2C12 myoblasts. The expression of TIEG1 mRNA was significantly up-regulated in the early period and the increased expression maintained during myogenic differentiation. TGF-β and myostatin, an inhibitor against myogenesis, induced the TIEG1 mRNA expression at the early stage of proliferation. When TIEG1 expression was silenced using siRNA, TIEG1 mRNA substantially declined. Silencing TIEG1 expression did not affect the cell number and the cell proliferation by BrdU incorporation assay. on the other hand, TIEG1 silencing cells significantly augmented myotube formation (fusion index) and nuclear number per field compared with control cells. These findings indicate that myogenic differentiation may be promoted by TIEG1. However, no differences detected on the mRNA expressions of myogenin, myogenic differentiation marker, between TIEG1 silencing and control C2C12. In contrast, vital cell number in TIEG1 silencing cell cultures predominated over control cell cultures in the early stage of differentiation. Since myoblasts undergo apoptosis during myogenic differentiation, apoptotic cells were determined in TIEG1 silencing cell cultures using TUNEL staining. The proportion of apoptotic TIEG1 silencing cells was less than that of control cells. However, caspase-3 activity was expressed in TIEG1 silencing cells higher than control cells. The results indicate that TIEG1 regulates myoblast apoptosis during myogenic differentiation independently of caspase pathway, resulting in inhibiting myotube formation.

Study of Cytotoxic Effect of Photodynamic Active Drugs on NIH3T3 Cell Line Morphology.
K. Tomankova¹, H. Kolarova¹, P. Kolar², D. Jirova², K. Kejlova², H. Bendova²; ¹Medical Biophysics, Faculty of Medicine, Palacky University, Olomouc, Czech Republic, ²National Institute of Public Health, Prague, Czech Republic

In presence of molecular oxygen, light-activation of the photosensitizer, which accumulates in cancer cells, leads to the local production of reactive oxygen species (ROS). This is one of the several reasons leading to cell death and in some cases we could observe signs of apoptosis. We study changes in the morphology of non-cancer mouse fibroblast cell (NIH3T3) before-after photodynamic therapy (PDT) by atomic force microscopy (AFM), scanning electron microscopy (SEM), fluorescent microscopy and cytotoxic influence determined by measuring of reactive oxygen species production (ROS). We use the CAlIPcS2 an ZnTPPS4 as photodynamically active components. PDT was induced by efficient LED source (670 nm and 417 nm, 12 mW.cm-2) with light dose up to 15 J.cm-2. The kinetic production of ROS was study by molecular probe CM-H2DCFDA and fluororeader Biotech. Fluorescent microscopy was undergoing by Annexin/propidium measuring. Samples for AFM and SEM were prepared using glutaraldehyde fixation and scanned in air. The results show ROS kinetic production during PDT and modification of morphological features investigated by AFM. The combination of a sensitizer and the specific light source can lead to the loss of surface rigidity and eventually to dramatic changes of the cell shape, which we can study by different microscopic methods with high resolution. Our result indicate that non-cancer NIH3T3 cell line, are not so sensitive to PDT as cancer cells. This work was supported by the Ministry of Health NS9648-4/2008 and Ministry of Education of the Czech Republic MSM 6198959216.

JNK and ERK Regulate TGF-β1 and FGF2-Induced Downregulation of Lumican and Keratocan Expression in Corneal Keratocytes.
N. SundarRaj, J. Chen, E. Guerriero; Ophthalmology Department, University of Pittsburgh School of Medicine, Pittsburgh, PA
Corneal stroma cells (keratocytes) are quiescent in the normal adult cornea. However, they are activated to fibroblast or myofibroblast phenotypes in response to a stromal injury. Downregulation of the expression of keratan sulfate proteoglycans (KSPGs), lumican and keratocan, is one of the phenotypic changes associated with activation of keratocytes. TGF-β1 or FGF-2 induces downregulation of lumican and keratocan In Vitro in cultured corneal stromal keratocytes. The present study evaluated whether MAPKs regulate TGF-β1 or FGF2-induced downregulation of KSPGs. Keratocytes isolated from rabbit corneal stroma, plated in a serum free medium, were activated with FGF2/heparin or TGF-β1 in the presence or absence of inhibitors of MAPKs, JNK, ERK, or p38. Immunocytochemical analysis of the cells and western blot analysis of secreted proteoglycans indicated that the inhibition of JNK with SP600125 or ERK with PD98059 during keratocyte activation prevented TGF-β1 or FGF2-induced downregulation of KSPGs. Similar analyses of the core proteins derived by keratanase digestion of the KSPGs secreted in the culture supernatants indicated that both lumican and keratocan were downregulated in the activated keratocytes. JNK or ERK inhibition blocked downregulation of both lumican and keratocan. Real-time RT-PCR analysis of mRNAs indicated that the levels of lumican and keratocan mRNAs were significantly reduced in TGF-β1 and FGF2 activated keratocytes. JNK and ERK inhibition during the activation prevented the loss in the levels of lumican and keratocan mRNAs. In conclusion, activation of JNK and ERK signaling pathways may be responsible for downregulation of the transcription of lumican and keratocan mRNAs and thus the diminished expression of these KSPGs during corneal wound healing. (Supported by NIH grants EY03263(NS), EY08098 (core grant), Research to Prevent Blindness, and Eye and Ear Foundation of Pittsburgh, PA.)

Study of Photodynamic Effect on MCF7 Cell Lines by Fluorescence Methods.
H. Kolarova1, K. Tomankova1, P. Kolar1, D. Jirova2, K. Kejlova2, H. Bendova2; 1Medical Biophysics, Faculty of Medicine, Palacky University, Olomouc, Czech Republic, 2National Institute of Public Health, Prague, Czech Republic

Photodynamic therapy (PDT) utilizes a combination of a photosensitizing chemical and visible light for the treatment of solid malignancies and is also showing promise as a treatment modality for many nonmalignant diseases including atherosclerosis deposits inside arteries. The photochemical interactions of sensitizer, light, and molecular oxygen produce singlet oxygen and other forms of active oxygen, such as peroxide, hydroxyl radical and superoxid ion. The tumour is destroyed either by reactive singlet oxygen species (ROS), type II mechanism, and radical products, type I mechanism, generated in an energy transfer reaction. Phthalocyanine CIAIPcS2, belonging among the promising second generation of sensitizers, was evaluated as an inducer of photodamage and apoptosis on MCF7 (human breast adenocarcinoma) cell line. The light emitting diodes (LEDs 670 nm, FWHM 15 nm, 10 mW.cm-2) for identification of apoptosis the Vybrant apoptosis Assay Kit (annexin V conjugated to fluorescein and propidium iodide) was used. Morphological changes in cells have been evaluated using fluorescent microscope. The production of ROS was investigated by molecular probe CM-H2DCFDA. Cell damage was evaluated using fluorescence microscope. The quantitative ROS production changes in relation to sensitizer concentration were proved by fluororeader. Efficiency of photodynamic therapy is affected by a number of factors including absorption spectrum of the photosensitizer, wavelength of the activation light, depth of the light in the biological tissue, tissue answer on singlet oxygen. The ability of PDT to produce a rapid apoptot ic response may be an important element of successful photodynamic therapy. MCF7 cells are sensitive to photodynamic damage. Phthalocyanine CIAIPcS2 represents efficient sensitizer with high phototoxicity to MCF7 cells. This work was supported by the Ministry of Health NS9648-4/2008 and Ministry of Education of the Czech Republic MSM 6198959216.

Effect of Co-Culture with Chondrocytes on Adipose Tissue-Derived Mesenchymal Stem Cells.
L. JaiSun; Orthopedics, Hospital, Siksa-Dong, Korea, South
INTRODUCTION Adipose tissue-derived mesenchymal stem cells (ATMSCs) obtained from lipoaspirates have the multi-lineage potential to differentiate into adipogenic, chondrogenic, myogenic, and osteogenic cells. However, several studies indicated that ATMSCs have lower chondrogenic potential compared with MSCs from bone marrow. The aim of this study was to test the hypothesis that co-culture of ATMSCs with chondrocyte or culturing ATMSCS under conditioned medium from chondrocytes might promote chondrogenesis from ATMSCs.

METHODS To examine cell-cell interactions in co-culture, in-vitro pellet cultures were carried out by mixing 1.25 x 10^5 ATMSCs (P3) and 1.25 x 10^5 chondrocytes (P3) in the same pellet, and compared with the pellets from 2.5 x 10^5 ATMSCs or from 2.5 x 10^5 chondrocytes. These were cultured in chondrogenic medium that did not contain growth factors. In order to effect of conditioned media from chondrocytes culture on ATMSCs, 2.5 x 10^5 ATMSCs were cultured in soups (soup: conditioned medium from chondrocytes culture). RESULTS The pellets were digested after 3 weeks of culture, and the DNA contents and GAG were measured. GAG contents increased from ATMSCS either by co-culturing with chondrocytes (10.7%, p<0.05) or by culturing under conditioned medium from chondrocytes culture (9.6%, p<0.05). Real-time PCR analysis showed that COL2A1 slightly increased by 20% when ATMSCs were treated with conditioned medium from chondrocytes culture. COL1A1 gene expression was stationary and COL10A1 gene expression slight increased in the conditioned medium. Although SOX-9 and COL2A1gene expression was several times greater in the ATMSCs-chondrocytes co-culture than in ATMSCs only, these gene expressions were still several times lower than those in chondrocytes only. Interestingly, COL1A1 and COL10A1 gene expressions were greater in ATMSCs-chondrocytes co-culture than in ATMSCs only. The results from Safranin-O staining generally paralleled those from GAG analyses: greater metachromatic staining when treated with conditioned media or in ATMSCs-chondrocytes co-culture.

Analyzing the Evolution of the Melanocortin Receptor Accessory Protein Gene Family.

R. M. Dores¹, J. A. Sebag², P. M. Hinkle²; ¹Biological Sciences, University of Denver, Denver, CO, ²Pharmacology and Physiology, University of Rochester, Rochester, NY

The human melanocortin 2 receptor (MC2R), unlike the other human melanocortin receptors (MC1R, MC3R, MC4R, MC5R), requires the melanocortin receptor accessory protein (MRAP) for proper routing from the ER to the plasma membrane. There also is evidence that MRAP plays a role in the signal transduction process when ACTH binds to mammalian MC2Rs. MRAP is single chain polypeptide with a single transmembrane spanning domain. In the human genome there are two mrap-related genes (mrap and mrap2) which are located on different chromosomes. Working on the assumption that all vertebrate MC2Rs require an “MRAP” for translocation and activation, genomes from several vertebrates were screened for the presence of MRAP-related genes using the tblastn program. The MRAP gene was detected in all of the mammalian genomes that were analyzed and in the genome of the chicken (Gallus gallus). However, this gene was not detected in genomes of a reptile, an amphibian, two bony fish or a cartilaginous fish. By contrast the MRAP2 gene was detected in all vertebrate genomes analyzed. Following alignment of the MRAP-related and MRAP2-related proteins, Maximum Parsimony analysis (PAUP) indicated that the MRAP-related and MRAP2-related proteins formed two distinct clades. Collectively, these data suggest that MRAP2 was the original melanocortin accessory protein gene, and that the divergence of the MRAP gene from the MRAP2 gene occurred during the radiation of the reptiles. To test the functional role of MRAPs for non-mammalian MC2Rs, the MC2R gene of the frog, Xenopus tropicalis, was transfected into CHO cells in the presence or absence of either mouse MRAP or mouse MRAP2. The frog MC2R only translocated to the plasma membrane when the mammalian MRAPs were co-transfected with the frog MC2R. It appears then that the evolution of a functionally distinct vertebrate MC2R gene has been dependent on the co-evolution of the MRAP genes.

Collagen Based 3-D Tissue Culture Models.
A. A. Sule¹, A. Nana², S. Dimitrijevich¹; ¹Integrative Physiology, UNTHSC, Fort Worth, TX, ²Department of Orthopaedic Surgery, TCOM, Fort Worth, TX

Introduction Three-dimensional (3-D) tissue models are best suited for In Vitro studies of cellular responses that represent In Vivo relevance. Particularly important is their suitability for studying processes that In Vivo involve the preparation of tissue for mechanical challenges such as ossification and mechano-transduction. Purpose to demonstrate that impregnation with collagen type I gel containing mesenchymal stem cells ("coll-gel"), of porous scaffolds of differing stiffness serves as appropriate 3-D model for studies of bone maturation and characteristics. Methods Collagen type I foam and βTCP Preforms®, were impregnated with "coll gel" containing fluorescently labeled human dermal fibroblasts or human mesenchymal stem cells (hMSC). The cells were visualized using confocal microscopy. Treatment of the matrices with collagenase released the cells and allowed determination cell viability and proliferation using MTT. Response of cells to mechanical forces was also studied. Ossification of impregnated scaffolds by hMSC after osteogenic differentiation was demonstrated by von Kossa stain. Results Impregnation of collagen foam and βTCP showed 50% and 50% absorption of their weight in collagen solution (gel) respectively. Cy5 labeled collagen type I occupied the pores throughout the two scaffolds. Long-term viability (30 days), migration of dermal fibroblast into and out of the impregnated collagen foam, and response of cells to stretching were demonstrated. Matrices containing collagen gel populated with hMSC supported were von Kossa stain positive (ossification) and contained deposited glycosaminoglycans. Conclusions The scaffolds retain collagen type I as a fibrillar hydro-gel and contained randomly distributed cells throughout. Long-term cell survival allowed differentiation in situ. The model was cytocompatible as demonstrated by proliferation and migration of the cells into and out of the matrix. Alignment of the cells in response to applied forces suggested mechanoresponsiveness, and ossification indicated In Vivo relevance. Taken together these observations suggest that the proposed strategy to be appropriate for studying bone morphogenesis and mechano-responses in vitro.

Non-Viral Transfer of Sox-Trio Gene to Adipose Stem Cells Using a Microporator.
L. JaiSun; orthopedics, hospital, Siksa-Dong, Korea, South

INTRODUCTION : It has been reported that adipose tissue-derived mesenchymal stem cells (ASCs) obtained from lipoaspirates have the multilineage potential to differentiate into adipogenic, chondrogenic, myogenic and osteogenic cells. However, several studies including one from the authors’ group demonstrated that chondrogenic differentiation comparable to that from MSCs was not achieved from ASCs. This study tested the hypothesis that Sox-trios(Sox-5,6,9) enhance chondrogenesis and suppress hypertrophic changes during chondrogenesis from ASCs (adipose tissue stem cells). METHODS : to create non-viral expressing Sox5, Sox6, and Sox9, full-length human Sox5, Sox6, and Sox9, full-length human Sox5, Sox6, and Sox9 complementary DNA (cDNA) was amplified by polymerase chain reaction (PCR) and cloned into pEGFPC1 mammalian expression vector. The microporatorTM and the buffer system were utilized for gene delivery. After microporation, in-vitro pellet cultures were carried out using 2.5 x 10⁵ ASCs in chondrogenic medium. Flow cytometry revealed that 85~98% of cells were infected with Sox-trio genes. After three weeks, cells were analyzed for DNA contents, GAG amount, real time PCR, western blotting and Safranin-O staining. RESULTS : GAG contents increased 3-folds when Sox-trio was transferred. Real-time PCR analysis showed that the mRNA levels of COL2A1 increased 8-folds in ASCs to which Sox-trio genes were transferred. COL1A1 or COL10A1 mRNA did not change, in contrast to ASCs in which TGF-β2 was treated. Safranin-O staining demonstrated that ASCs to which the sox-trio genes were transferred exhibited greater accumulation of proteoglycan-rich matrix than ASCs treated with TGF-β2. Western blotting showed that ASCs to which the sox-trio genes were transferred exhibited greater level of type II collagen than ASCs treated with TGF-β2. DISCUSSION : This system of nonviral Sox-trio gene transfer, with high efficiency for transfection and great potential for the inductions of chondrogenic differentiation from MSCs, offers a powerful means for cartilage tissue engineering from ASCs.
Polyphenolic Stilbenes Suppress TPA/VD3-Induced Osteoclastic Changes of Monocytic Cells through NF-κB Inhibition.

K. Matuoka¹, K. Sasaki¹, K. Aeba¹, A. Gosslau², K. Y. Chen²; ¹Pharmacy, Chiba Institute of Science, Choshi, Chiba-ken, Japan, ²Chemistry and Chemical Biology, Rutgers University, Piscataway, NJ

Osteoclasts, resorbing bone and thus playing an essential role in bone remodeling and the pathology of osteoporosis, originate from monocyte-macrophage lineage, where NF-κB signaling is critical. As a polyphenolic stilbene resveratrol suppresses the NF-κB function, it is conceivable that it suppresses osteoclastic differentiation. In this study, we have examined effects of resveratrol and its analogs by using THP-1 monocytic cells as an osteoclastic model system. Exposure of the cells to 12-O-tetradecanoylphorbol-13-acetate (TPA) and 1α,25-dihydroxyvitamin D3 (VD3) for 3 - 5 days induced osteoclast-related phenotypes: attachment to the substrate and flattened, enlarged and/or multinucleated morphology. Phagocytic and tartrate-resistant acid phosphatase activities are also induced. for examination cells were treated with chemicals 4 - 5 h prior to TPA/VD3 and cultured in the presence of both reagents. Although resveratrol at 12.5 - 50 μM was not apparently effective, its analogs MR-4 (2.5 - 10 μM) and MC-4 (100 - 400 nM) [A.Gosslau et al., Eur J Pharmacol, 2008] substantially suppressed the osteoclastic changes: the flattened/enlarged cell population was reduced and there was a relative increase in small cells resembling untreated/induced cells. An NF-κB inhibitor BAY 11-7085 (5 - 10 μM) caused a similar change, suggesting that the effects of MR-4 and MC-4 are ascribable to NF-κB inhibition.

In addition, a Sirt1 inhibitor nicotinamide appears to be supportive for the osteoclastic changes. on the other hand, we have observed that heparin, a glycosaminoglycan species known to cause osteoporosis upon long-term clinical administration, augments the TPA/VD3-induced changes, where MEK/ERK and PI3K/AKT systems may be important. When cells were co-treated with heparin and MR-4 or MC-4, the stilbenes could not completely abolish the effect of heparin, and vice versa. The same results were obtained with a combination of heparin and BAY 11-7085. Therefore, the actions of heparin and the stilbenes may employ different cellular signaling. These observations together imply that the polyphenolic stilbenes MR-4 and MC-4 have ability to reduce osteoclasts through NF-κB inhibition.

Raman Spectroscopic Analysis of Rat Pancreatic Islets.

K. A. Hobbs¹, E. Waddell², J. U. Johnson³, A. D. Johnson¹; ¹Biological Sciences, University of Alabama in Huntsville, Huntsville, AL, ²Chemistry, University of Alabama in Huntsville, Huntsville, AL, ³Food and Animal Science, Alabama a & M University, Normal, AL

Raman spectroscopy is an established technique that is now being innovatively used as a method for characterizing chemical properties of tissues and cells. Thus in these preliminary studies we explore the feasibility for the use of Raman spectroscopy in differentiation and functional studies of pancreatic islet cells. In addition, procedures involving pancreatic islet cells will be examined using the RDABS® Muscarinic M₃ Receptor IFA kit for indirect immunofluorescence. In these studies, alloxan monohydrate (C₄H₂N₂O₄ • H₂O) was used to induce the hyperglycemic condition in Sprague Dawley rats. Islets were isolated using a liberase enzyme solution prepared in Hank’s Balanced Salt Solution buffer which was injected into the common bile duct to distend the pancreas. The distended pancreas was digested with liberase enzyme and islet cells were purified using a Ficoll gradient. Islets were then handpicked using an inverted surgical microscope and plated in Dulbecco’s modified Eagle’s medium without sodium pyruvate. Cultures were supplemented with 10% heat-inactivated, fetal calf serum and 1% gentamicin and were incubated at 37°C in a 5% CO₂ environment. Islet specificity was determined by the use of dithizone (DTZ) stain which binds to the Zn²⁺ molecule of insulin revealing a red color. Photomicrographs were taken of freshly isolated, alloxan treated, and the DTZ stained islets using a Nikon Eclipse E600 Biomedical Microscope. Also, isolated islets were placed on an excimer laser optic chip, examined using a Horiba Jobin Yvon HR 800 Confocal Raman Spectrometer, and scanned using a He-Ne 635 nm laser. Preliminary results using Raman
spectroscopy revealed a significant peak analysis at a Raman shift of approximately 3000 cm\(^{-1}\). To our knowledge, Raman spectroscopy has never been used to examine rat pancreatic islets under these conditions and it is our goal to continue with these studies which may lead to the discovery of novel information about pancreatic function and a better understanding of conditions such as diabetes.

**A New Cellular Delivery System QD/Sr9: Exploration of the Efficiency, Uptake Mechanism, and Intracellular Localization.**  
Y. Huang\(^1\), H. Lee\(^2\), K. B. Shannon\(^1\), Y. Xu\(^1\); \(^1\)Biological Sciences, Missouri University of Science and Technology, Rolla, MO, \(^2\)Natural Resources and Environmental Studies, National Dong Hwa University, Hulien, Taiwan

Recently luminescent semiconductor quantum dots (QDs) have begun to be used for delivering and monitoring biomolecules, such as drugs and proteins. The high quantum yield and photostability of QDs allows long term monitoring. However, we found that QDs alone had a very low efficiency to transport across cytoplasm membrane. In order to increase the delivery efficiency, we used nona-arginine (sR9), a cell penetrating peptides, to facilitate QDs' uptake. We found that sR9 could significantly increase the cellular uptake of QDs by non-covalent binding between QDs and sR9. Further, we explored the mechanisms of QD/sR9 internalization. Low temperature and metabolic inhibitors markedly influenced on the uptake of QD/sR9, indicating an energy-dependent process. Several pathway inhibitors and RNAi technique were used to analyze the transduction pathways. Epifluorescence imaging studies indicated that QD/sR9 were internalized by macropinocytosis, which was energy and lipid-raft dependent endocytosis process. According to results of RNAi, transduction was independent of clathrin- and caveolin-mediated endocytosis. Contrarily, data from inhibitors are not conclusive. Subsequently we explored the subcellular localization of QD/sR9, and found that the majority of QD/sR9 was localized in lysosomes, but not in mitochondria and nuclei. A pH sensitive, fusogenic HA2 sequence has been incorporated to liberate the delivery system from vesicle entrapment. These results demonstrated a new cellular delivery system. (Supported by M S&T cDNA Resource Center and NIH R15EB009530).

**Osteopontin Protein Expression and Secretion Patterns in HFOB 1.19 Cells Treated with Carbon Nanotubes and Chitosan-3-Trimethoxysilylpropyl Methacrylate.**  
J. Stone\(^1\), C. Durand-Rougely\(^1\), R. Ibraheem\(^1\), R. Chapa\(^1\), W. Jones\(^1\), P. Traisawatwong\(^2\), C. Kelly-Brown\(^2\), M. Stewart\(^2\), T. Fisher\(^2\), K. Hibbert\(^2\), L. Carson\(^2\), A. Oki\(^2\), G. Regisford\(^1\); \(^1\)Biology, Prairie View A&M University, Prairie View, TX, \(^2\)Cooperative Agricultural Research Center, Prairie View A&M University, Prairie View, TX

Biomaterials such as carbon nanotubes (CNT) and chitosan exhibit the characteristics necessary for successful bone regeneration. Osteopontin (OPN), a protein secreted by osteoblast cells, is a good indicator of normal bone cell growth. Therefore, our objective was to determine the expression and secretion patterns of OPN when human fetal osteoblastic cells (hFOB 1.19) were cultured with hybrid composite bone materials made from CNT and Chitosan-3-trimethoxysilylpropyl methacrylate (CTS-3-TMSPM). We believed that the aforementioned hybrid composite bone materials would increase the secretion and expression of OPN in the osteoblast cell line, hFOB 1.19. These osteoblast cells were treated with CNT or CTS-3-TMSPM (0, 250, 500 and 1000ng/mL) for 24, 48, and 72 hours. Media was collected daily and subjected to an enzyme linked immunosorbent assay (ELISA) to determine OPN secretion. Following 72 hours of treatment, cells were harvested and protein isolated for use in western blot analysis. Cells were also cultured on two chamber slides in the presence of CNT or CTS-3-TMSPM (0, 250, 500 and 1000ng/mL) for 24 hours and then subjected to immunocytochemistry (ICC) to localize OPN. The secretion of OPN by hFOB 1.19 cells was not significantly affected by CNTs or CTS-3-TMSPM. The expression of OPN protein tended to increase in a dose-dependent manner in cells that were grown in the presence of CTS-3-TMSPM. Alternatively, OPN protein expression tended to
decrease in a dose-dependent manner in CNT-treated cells. Osteopontin protein was localized in all cells, but there was a higher expression in cells that were grown in the presence of 500ng/mL of CNT compared to controls and CTS-3-TMSPM. Bone regeneration and repair may thus be aided by the use of CNT and CTS-3-TMSPM. Future work will be performed to determine the application of these biomaterials, CNT and CTS-3-TMSPM, for bone repair and regeneration.
Minisymposium 9: Cellular Basis of Morphogenesis (795 – 800)

A Molecular Clutch Linking Actomyosin Contractility to Cell Movements.
M. Roh, G. Shemer, J. McClellan, B. Goldstein; University of North Carolina - Chapel Hill, Chapel Hill, NC

How embryonic cells transition from spatial patterning to morphogenesis is a fascinating and incompletely understood topic. In C. elegans, the first morphogenetic movement is the internalization of two endodermal precursor cells (E cells). The current model for how these cells become internalized is that an apically-enriched population of activated non-muscle Myosin II motors drives apical constriction, and this may pull a ring of six neighboring cells together to cover the free surfaces of the E cells. We have examined non-muscle Myosin II dynamics with diffraction-limited fluorescence imaging to follow movements of myosin foci with respect to the zones where E cells contact their neighboring cells. We expected to observe narrowing of the contact zones in concert with contraction of the actomyosin network. We were surprised to find instead that centripetal myosin movements preceded narrowing of contact zones, contracting the apical actomyosin network multiple times over before significant neighboring cell movements. Later, myosin foci continued to coalesce centripetally and contact zones narrowed in concert. This suggests that a regulatable link (a clutch) may connect cortical actomyosin contraction to neighboring cell movements. To test this hypothesis, first, we tracked cell surface movements using fluorescent quantum dots. Our results suggest that free surfaces of E cells move together with cortical actomyosin contraction before neighboring cells move in concert, suggesting that the regulatable link lies between the E cell apical cytoskeleton and neighboring cells, and hence may be comprised of cell-cell adhesion complex proteins or proteins that link the adhesion complex to the cytoskeleton. Second, we analyzed adhesion-defective embryos and found coupling of myosin and contact zone dynamics fails. Together with the finding that similar centripetal myosin movements move polarity proteins toward the center of the apical surface at earlier embryonic stages (Munro et al., 2004), our results suggest that the transition from apicobasal cell polarization to cell internalization is governed by a molecular clutch.

Sensory Dendrites Extend by ‘Dropping Anchor’ Prior to Cell Migration.
M. G. Heiman, S. Shaham; Rockefeller University, New York, NY

One of the greatest unsolved problems in biology is how groups of cells self-assemble into highly ordered structures. Nowhere is this problem more astounding than in the nervous system, where neurons and glia assume exquisitely precise shapes that must be intimately coordinated for the nervous system to function. Amazingly, the C. elegans nervous system develops almost identically in each individual, implying that a map of every cell contact is encoded in the single-cell embryo. To decipher this map, we turned to the amphid, the major sense organ of C. elegans, composed of 12 neurons that extend unbranched sensory dendrites to the tip of the nose, and are ensheathed there by two glia. To learn how these cells attain their shapes, we isolated mutants in which sensory dendrites fail to reach the nose tip. These mutants defined two genes, dex-1 and dyf-7. Using single-cell tracking with a photoconvertible fluorescent protein, we found that sensory neurons born near the nose anchor dendritic tips there and then crawl away, stretching dendrites out behind them as they migrate; in dyf-7 mutants, the dendrites fail to anchor and are dragged along with the migrating cells. DEX-1 and DYF-7 are secreted and act during anchoring, with DYF-7 expressed by the neurons and localizing to dendrite tips, and DEX-1 expressed by neighboring cells. DYF-7 contains a zona pellucida (ZP) domain and forms multimers of dimers, likely assembling a matrix to which dendrites anchor. DEX-1 and DYF-7 resemble tectorins, matrix-forming proteins of the vertebrate inner ear that anchor the tips of sensory hair cells. We recently isolated a mutant in FBN-1, a fibrillin homolog with a ZP domain, which is also required for amphid dendrite anchoring, DEX-1, DYF-7 and FBN-1 are strongly required for the amphid but not other sense organs; likewise, we have found mutants that affect other sense organs but not
the amphid, suggesting each sense organ recognizes a discrete anchor site at the nose. As ZPs are found in diverse sense organs across species, and as the *C. elegans* genome encodes 40 ZP proteins, an intriguing hypothesis is that combinations of multimerized ZPs in the early embryo encode discrete anchor sites for different sensory dendrites.

*Drosophila* Cytonemes Are Ligand-Specific Cell Extensions That Ferry Signaling Molecules Over Long Distance.

S. Roy, F. Hsiung, T. B. Kornberg; Cardio Vascular Research Institute, University of California San Francisco, San Francisco, CA

Cytonemes are types of filopodia first identified in the Drosophila wing imaginal disc that were proposed to be involved in long distance signaling during development. The present work reports presence of several novel types of cytonemes and shows that the sizes and orientations of each cytoneme type depend on a specific ligand protein. Receptors for ligands had punctal distributions that were motile and localized specifically in responding cytonemes and they appear to be localize only to responsive cytonemes. Vesicular puncta containing both co-localized ligand and receptor were found in cytonemes that appeared to touch ligand-expressing cells, providing direct evidence that cytonemes transporting signaling ligands. Thus, cytonemes are diverse in composition and function, can ferry signaling proteins, and exhibit specificity for stimulating ligands and as well as dynamic plasticity. These findings strongly support cytoneme-based movement of signaling proteins as a mechanism for cell-cell communication in which controlled amounts of signaling protein can be targeted to a specific recipient cell.

798

Planar Cell Polarity, Ciliogenesis, and Neural Tube Closure.

J. Wallingford; ¹Howard Hughes Medical Institute, Austin, TX, ²Section of Molecular Cell and Developmental Biology, University of Texas, Austin, Austin, TX

The planar cell polarity (PCP) pathway controls a wide variety of polarized cellular processes during development. In vertebrate embryos, PCP proteins are essential for neural tube closure, acting to control both cell movements and ciliogenesis. Despite these important roles, the downstream mechanisms by which the PCP cascade directs the execution of discrete cell behaviors remains poorly understood. We have focused recent efforts on the PCP effector proteins, Fuz and Fritz. We show that Fuz acts at the level of vesicle trafficking during ciliogenesis, directing the transport of proteins to the basal body and along the axoneme. By contrast, Fritz interacts with cytosolic chaperones and controls microtubule assembly during ciliogenesis. Interesting, Fritz also acts to control plasma membrane stability during convergent extension. Understanding how Fuz and Fritz interact with the core PCP proteins such as Dishevelled is an active area of study in our lab. These data should shed light on the etiology of human neural tube defects. More generally, these results provide new insights into the mechanisms by which developmental regulatory systems interface with fundamental cellular machinery to drive morphogenesis.

799

Regulated Cell Polarity Defines Long Bone Morphology.

A. T. Dudley, M. J. Ahrens, Y. Li, H. Jiang; BMBCB, Northwestern University, Evanston, IL

A central question in developmental biology is how morphologically distinct structures are generated from similar cell types. The skeleton provides a good model system to answer this question due to the highly diverse and complex morphological differences displayed by the individual elements. Analysis of the growth plate cartilage by Dodds suggested that longitudinal growth of long bones might result from the specific arrangement of chondrocytes. In the proliferative zone, chondrocytes become discoid and arrange in columns, like stacks of coins, which are parallel to the long axis of the cartilage. Although well-organized chondrocytes derive
from a relatively unstructured pool of progenitor cells, it is not known whether this arrangement of cells is the result of a regulated process or is in response to physical constraints of the cartilage matrix. Here we test Dodds’ model that individual chondrocyte columns form from single progenitor cells by a process in which cells divide orthogonal to the stack then intercalate into columns. Here we show that discoid proliferative chondrocytes orient the division plane to generate daughter cells that are initially aligned orthogonal to the column and then intercalate. Downregulation of Frizzled (Fzd) signaling in chick long bones produces cell autonomous changes in proliferative chondrocyte organization characterized by arbitrary division planes and altered cell stacking. By contrast, in Piga mutant mice, chondrocytes display normal planes of cell division but fail to intercalate into columns. Thus, orientation of cell division and cell intercalation are mechanistically separable events. In all cases, defects in column formation lead to shorter wider bones, consistent with a model in which cell arrangement defines vectors of growth in developing cartilage. Collectively, our findings demonstrate that signaling pathways regulate cell polarity and cell arrangement in the cartilage growth plate and suggest important roles for polarized cell behaviors in generating the unique morphological characteristics that shape individual cartilage elements that compose the articulated skeleton.

800
Regulation of Oriented Cell Division by Receptor Tyrosine Kinase Signaling in Airway Morphogenesis.
G. Martin, N. Tang, R. Metzger; Department of Anatomy, University of California, San Francisco, San Francisco, CA

We have been studying the consequences of altering Receptor Tyrosine Kinase (RTK) signaling in the developing mouse lung by inactivating Sprouty genes, which encode negative feedback inhibitors of FGF receptor and other RTK signaling pathways. Our data show that the combined loss of sprouty1 and sprouty2 in lung epithelium at an early stage of development results in an increase in RAS/MAP Kinase (MAPK) signaling downstream of FGF10 and its cognate receptor, which causes widening and shortening of the primary airway branches. We present evidence that such alterations in airway size and shape are due to a change in oriented cell division within the lung epithelium resulting from the increase in RAS/MAPK signaling. These data thus support the idea that regulating airway morphogenesis depends on precise control of oriented cell division.

Minisymposium 10: Cilia and Centrosomes (801 – 806)

801
Evolution of Centriole Assembly Mechanisms.
Z. Carvalho-Santos1, F. Cadete2, P. Machado1, P. Branco1, A. Rodrigues-Martins1, J. Borrego-Pinto1, N. Matias1, J. Pereira-Leal2, M. Bettencourt-Dias1; 1Cell Cycle Regulation Lab, Instituto Gulbenkian de Ciência, Oeiras, Portugal, 2Computational Genomics Lab, Instituto Gulbenkian de Ciência, Oeiras, Portugal

The centriole Basal body (CBB) nucleates cilia and flagella and is an essential component of the centrosome, underlying eukaryotic microtubule-based motility, cell division and polarity. In recent years, components of the CBB assembly machinery have been identified, but little is known about the regulation and conservation of this important process. Given the diversity in cellular contexts encountered in eukaryotes, but remarkable conservation of CBB morphology, we asked whether we could obtain general mechanistic principles that explain CBB assembly. We profiled each component of the human CBB assembly machinery across eukaryotes. We found a universal module of three components (UNIMOD: SAS6, SAS4/CPAP and BLD10/CEP135) that correlates with the occurrence of CBBs and propose they define the CBB conserved morphological structure. Surprisingly, other players (SAK/PLK4, SPD2/CEP192 and CP110) emerged in a taxon-specific manner. Moreover, we often observed extreme protein divergence amongst CBB components and show that divergence amongst SAK/PLK4 family members leads
to loss of cross-species complementation, suggesting species-specific adaptations in CBB assembly. Our work defines universal predictors for the presence of CBBS, which we used to follow their evolution. We propose that the UNIMOD explains the conservation of CBB architecture and that taxon and tissue-specific molecular innovations play a role in coordinating CBBO biogenesis and function to different cellular contexts. In order to further understand the evolution of CBBS we have created a bioinformatics tool that allows integrating morphological information (annotated light and electron microscopy images) and molecular information (phylogenetic distributions of CBB components). By bridging the gap between morphological and molecular information and becoming a community built tool, CentrioleDB will enable a more general understanding of CBB assembly mechanisms.

802

**Poc1 Is Required for Basal Body Stabilization.**

C. G. Pearson¹, D. P. Osborne², T. H. Giddings¹, P. L. Beales², M. Winey¹; ¹MCD Biology, University of Colorado, Boulder, CO, ²Molecular Medicine Unit, University College London, London, United Kingdom

Basal bodies are responsible for the nucleation and anchoring of both motile and immotile cilia. Defects in basal bodies and cilia result in a class of human diseases known as ciliopathies. The biogenesis of basal bodies is facilitated by the step-wise addition of ultra-structural domains. Cartwheels, composed of nine-radiating spokes extending from a central hub, are formed early during basal body assembly. Triplet microtubules are then nucleated from the ends of each spoke to build the cylinder shaped structure. Using a proteomics strategy, we identified novel components of basal bodies, including the cartwheel protein, Poc1. Poc1 is a conserved WD40 repeat containing protein that is required for the structural maintenance of basal bodies in Tetrahymena. The two human Poc1-like proteins localize to the proximal end of centrioles and basal bodies and HsPoc1B knockdown decreases primary cilia formation. Poc1B knockdown in Zebrafish results in defects commonly associated with ciliopathies. To understand how Poc1 assembles into the basal body structure for stability, the incorporation of Poc1 protein during new basal body assembly was quantified. Proteins were found to localize at basal bodies by distinct mechanisms ranging from α-tubulin that is stably incorporated only during new assembly to those, such as Spag6, that dynamically exchange at basal bodies throughout the cell cycle. These patterns of incorporation reflect the diversity of ultra-structural domains that each component localizes. Poc1, among other core components that are responsible for basal body assembly and maintenance, stably incorporates during new basal body assembly. Finally, the timing of Poc1 incorporation relative to other basal body proteins was measured. These studies illuminate the molecular pathways for basal body assembly in the context of the basal body ultra-structure.

**Novel Features in Formation and Function of the “9+2” Axoneme Revealed by a Basal Body-Deficient Mutant of Chlamydomonas.**

M. Hirono, Y. Nakazawa, R. Kamiya; Department of Biological Sciences, University of Tokyo, Tokyo, Japan

Axonemes of eukaryotic cilia and flagella have the “9+2” structure consisting of the nine outer doublet microtubules and the central pair microtubules (CP), with various projections periodically arranged on the microtubules. How this elaborate structure assembles and functions is poorly understood. To address this question, we investigated the effects of the change in the number of the outer doublets by observing axonemes produced by a Chlamydomonas mutant, bld12. This mutant has defects in stabilizing the 9-fold symmetry of the basal body structure, and thus produces axonemes with 8, 9, 10, or 11 doublets. Most of the 8-doublet axonemes contained no CP, but those of a double mutant with pf14, a mutant lacking the radial spokes, contained CPs. Thus the CP formation apparently depends on the space limited by the outer doublets and the radial spokes. In 10- or 11-doublet axonemes, 4 to 6 radial spokes were detached from the CP, resulting in a distorted arrangement of the doublets. The detachments were found predominantly
on the C2 side of the two CP microtubules, named C1 and C2. However, in double mutants with
pf6 or pf16, which lack a prominent projection on C1 or the entire C1 microtubule, radial spokes
frequently attached to a projection on C2. From these observations, we conclude that 1) the radial
spokes actually bind to the CP and pull the doublets toward the center, and 2) the projections on
C1 bind to the radial spoke more strongly than those on C2, while multiple projections on CP
interact with the radial spoke. These results thus provide invaluable insights into how the central
pair microtubules are formed and how they interact with radial spokes.

804
Cell Shape and Stiffness Regulate Ciliogenesis in Cell Cycle Arrested Cells.
A. Pitaval1, Q. Tseng1, M. Bornens2, M. Théry1; 1DSV/iRTSV, CEA, Grenoble, France, 2UMR144,
Institut Curie, Paris, France

Background Regulation of the balance between cell growth and quiescence is fundamental to
embryogenesis and tissue renewal. Induction of cell quiescence is regulated by numerous factors
and coincides with dramatic cell reorganisation, including the growth of a primary cilium. The
relationship between cell cycle exit and primary cilium growth is poorly understood, though it is
believed that the two processes are tightly coupled. Results We analysed cell cycle exit and
ciliogenesis in human epithelial cells and found that all cells exiting the cycle do not generate a
primary cilium. Low incidences of primary cilia were observed in sparse cell cultures after cell
cycle arrest compared to confluent cultures. Using adhesive micro-patterns of various sizes, we
showed that the probability of generating a cilium was inversely correlated to the cell spreading
area. The growth of a primary cilium in sparse cell culture or in over-spread cells on micro-
patterns could be promoted by inhibition of Rho kinase suggesting that high level of acto-myosin
contraction prevents ciliogenesis. Consistent with this interpretation, most cells in sparse cultures
on soft, deformable surfaces had primary clia contrary to cultures on rigid substrates where few
cells were ciliated. In addition, cilia were longer in culture conditions reducing the level of cell
tension. Conclusions These results indicate that cell cycle exit is not sufficient to induce
ciliogenesis. External physical parameters affecting myosin phosphorylation and the level of cell
tension such as microenvironement geometry and rigidity regulate the growth and extension of
primary cilia in cell cycle arrested cells.

805
The BBSome Functions as a Coat Complex for Ciliary Membrane Trafficking.
H. Jin1, S. Roehl White1, N. Shida1, J. Bazan2, M. Nachury1; 1Department of Molecular and
Cellular Physiology, Stanford University School of Medicine, Stanford, CA, 2Department of
Protein Engineering, Genentech, South San Francisco, CA

The primary cilium, a “signaling antenna” projecting at the surface of the cell, is required for the
transduction of Hedgehog and planar cell polarity signals and concentrates many signaling
receptors on its surface. Moreover, ciliary dysfunction leads to obesity, retinal degeneration and
kidney cysts in the inherited disorder Bardet-Biedl Syndrome (BBS). Although fourteen BBS
genes have now been identified, the molecular pathway of BBS has remained elusive. Our recent
discovery of a stable complex of seven highly conserved BBS proteins, the BBSome,
considerably simplifies the apparent molecular complexity of BBS. At the functional level, we have
implicated the BBSome in vesicular trafficking to the cilium based on its functional interaction with
Rab8, a trafficking GTPase required for cilium growth. However, a clear understanding of the
molecular activity of the BBSome is currently lacking. We have now initiated an in-depth
biochemical characterization of the BBSome and of the only other BBS protein that is universally
conserved in ciliated organisms, the Arf-like GTPase ARL6 BBS3. Using affinity
chromatography, structural modeling, gene replacement, and biochemical reconstitution from
pure components, we arrive at the conclusion that the BBSome functions as a vesicular sorting
complex that follows the paradigms established by clathrin, COPI and COPII coats.
Bardet-Biedl Syndrome (BBS) is a cilia-related disorder characterized predominantly by obesity and retinopathy. In humans, 12 genes causing BBS have been identified; 8 of these are conserved in Chlamydomonas. To learn more about the function of these genes, we identified Chlamydomonas insertional mutants defective in BBS1, BBS4, and BBS7. The mutants assemble motile, full-length flagella but lack the ability to phototax. In wild-type flagella, BBS4 is present in a ~12S complex (the BBSome) containing at least four other BBS proteins (BBS1, 5, 7, and 8) and undergoes intraflagellar transport (IFT). However, both immunofluorescence microscopy and double total internal reflection fluorescence microscopy using BBS4-GFP plus IFT20-mCherry (in a BBS4- and IFT20-null background) indicate that the BBSome is associated with only a subset of IFT particles. Absolute quantitation of IFT-particle proteins and BBSome proteins by mass spectrometry using an AQUA peptide strategy shows that the BBSome proteins are at least 5x less abundant than IFT-particle proteins in the wild-type flagellar membrane plus matrix fraction. In the bbs4 mutant, assembly and transport of IFT particles is unaffected and IFT complex a and complex B co-localize normally. 1D- and 2D-PAGE indicate that the mutant flagella contain normal amounts of most proteins but abnormally accumulate several signaling proteins, including a phospholipase. Consistent with this, the lipid composition of the membrane is altered in bbs4 flagella. We conclude that an evolutionarily conserved BBSome is carried by IFT but is not an integral component of the IFT machinery. Chlamydomonas BBS4 may be required for flagellar signaling and/or the removal of certain proteins from the flagellum via IFT.

Molecular Mechanisms Underlying Pathogen Recognition in Plants.

R. Innes, B. DeYoung, R. Bhat, D. Qi, N. Rodibaugh; Department of Biology, Indiana University, Bloomington, IN

Plant disease resistance proteins belonging to the nucleotide binding-leucine rich repeat (NB-LRR) class often detect pathogen effector proteins indirectly, via sensing modification of effector targets. We are studying this process using the RPS5 protein from Arabidopsis. RPS5 detects the cysteine protease AvrPphB of Pseudomonas syringae, and this detection requires a second Arabidopsis protein, PBS1. Cleavage of PBS1 by AvrPphB is required to activate RPS5. Current work is focused on defining what parts of PBS1 are required for interaction with RPS5, what parts of RPS5 are required for downstream signaling, what other proteins are part of the RPS5 complex prior to activation, and whether subcellular relocalization of RPS5 occurs upon activation. Preliminary data indicate that RPS5 and PBS1 initially localize to the plasma membrane, but upon activation RPS5 relocates to the nucleus and to the chloroplast. We are currently evaluating the functional relevance of this relocalization. Our work has broad implications regarding activation of NB-LRR proteins in general, including human homologues belonging to the NOD family, which function in the human innate immune system, and which are implicated in several autoimmune diseases.
808
Exosomes as Regulators of the Immune Response against Mycobacterial Infections.
J. Schorey; Biological Sciences, University of Notre Dame, Notre Dame, IN

*Mycobacterium tuberculosis*, the causative agent of tuberculosis, is a major human pathogen and is responsible for approximately 1.7 million deaths annually. It is estimated that over 2 billion people are infected with *M. tuberculosis* but the vast majority maintain a latent infection. Controlling an *M. tuberculosis* infection requires a robust innate and acquired immune response. However, *M. tuberculosis* is an intra-macrophage pathogen and it is unclear how antigens and pathogen associated molecular patterns (PAMPs) expressed by the bacteria gain access to the immune system to promote this robust response. We have found that macrophages infected *in vitro* and *in vivo* release exosomes containing mycobacterial components including lipoarabinomannan and the 19 kDa lipoprotein. Exosomes released from infected cells stimulate macrophage and dendritic cell activation in a TLR/MyD88 dependent manner. Moreover, exosomes isolated from *M. bovis* BCG infected macrophages when administered intra-nasally into uninfected mice stimulated antigen specific CD4+ and CD8+ T cells indicating that they have mycobacterial antigens. This T cell activation did not require co-administration of adjuvant suggesting that exosomes have both antigenic and adjuvant properties. Proteomic analysis showed that these exosomes contain over 50 mycobacterial proteins including a number of immuno-dominant antigens such as Ag85 complex, MPT-64, MPT-63 and GroES. Studies are ongoing to define the mechanism by which exosomes may function to regulate an immune response against a *M. tuberculosis* infection and whether exosomes can be developed into a TB vaccine and used in TB diagnostics.

A. E. Palmer, S. B. VanEngelenburg; Chemistry & Biochemistry, University of Colorado, Boulder, CO

The Type-III Secretion System (T3SS) is a sophisticated macromolecular machine enabling gram-negative pathogenic bacteria to inject proteins into eukaryotic host cells. Upon protein entry, T3SS effectors work cooperatively to hijack cellular signaling pathways and reprogram the host cell to enable bacterial survival. Progress in understanding when effectors are injected and where they localize within the host cell has been hindered by the lack of adequate tools to directly study these proteins in the native cellular environment. Moreover, studying the coordinated action of effectors has been hampered by the dearth of appropriate tools to track specific effectors within the context of infection. We have developed two approaches for lighting up and imaging bacterial effector proteins during the infection cycle, allowing us to dissect their secretion kinetics, localization, and dynamics within the host cell. We have applied these tools to Salmonella enterica Typhimurium. Salmonella enterica species encode two T3SSs and translocate over 60 individual proteins into host cells. Using an in situ chemical labeling system, we were able to quantify the rates of effector secretion into host cells using live-cell fluorescence microscopy, and demonstrated differential secretion for antagonistic effectors. In a complementary approach, to address the “where” of bacterial protein localization post-injection, we adapted a split GFP system which allows for live-cell monitoring of effector protein dynamics. Using these approaches we have defined the localization and dynamics of multiple Salmonella effectors during the course of an infection cycle. In particular we identified effectors that localize to distinct populations of Salmonella-induced filaments, which derive from different host-cell membranes.

810
Evolutionary Arms Races Involving the Innate Immunity Factor Protein Kinase R.
N. Eldes, S. Child, A. Geballe, H. Malik; Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA,
Protein surfaces involved in host-pathogen interactions can evolve in a manner resembling molecular arms races where each side gains fleeting advantages in ongoing genetic conflicts. Signatures of these arms races can be discerned phylogenetically by calculating rates of non-synonymous codon substitutions (dN) - that alter amino acid sequences - compared to rates of synonymous, silent changes (dS). A dN to dS ratio exceeding one indicates positive selection, which can reflect rapid evolution in these antagonistic settings. We found that Protein kinase R (PKR), an important component of innate immunity in primates and other mammals, evolves under extreme positive selection in primates. This rapid evolution likely reflects conflicts with a diversity of viral factors that directly interact with PKR to disable it. For example, some viruses encode factors that alter the cellular distribution of PKR from cytoplasm to nucleus. Redistribution of PKR may be an effective means of blocking the activation of this antiviral kinase, which is triggered by the recognition of cytoplasmic nucleic acids produced by viruses. We examined PKR evolution at single codon resolution and discovered strong positive selection in an otherwise conserved helix, which makes direct contact with the substrate of PKR. Several viruses encode mimics of PKR’s substrate, so we tested the possibility that variation in PKR might affect vulnerability to such mimics. Performing infection studies in primate cell lines and using a yeast growth assay that recapitulates PKR activity, we tested a panel of primate variants of PKR against K3L, a substrate mimic from vaccinia virus. Some variants of PKR resist K3L due to positive selection in sites involved in substrate recognition. Surprisingly, variation in another surface of PKR also affects discrimination of substrate mimics, revealing that adaptive changes on multiple surfaces produces combinations of changes that increase the odds of defeating mimicry. Our study reveals exceptional evolutionary flexibility at a host-pathogen interface and provides a framework for examining other nucleic acid sensors and additional host factors that might evolve in molecular arms races with pathogens.

The Influenza Virus M2 Ion Channel Protein Mediates the ESCRT-Independent Budding of Filamentous Virions.
J. Rossman1, X. Jing1, G. Leser1, R. A. Lamb1,2; 1Biochemistry, Molecular Biology and Cell Biology, Northwestern University, Evanston, IL, 2Howard Hughes Medical Institute, Chevy Chase, MD

Influenza a virus buds from cells as spherical (~100 nm diameter) and filamentous (~100 nm x 2-20 μm) virions that are thought to be equally infectious. Filamentous virions appear to be the predominant form isolated from the human upper respiratory tract and are seen in the recent 2009 H1N1 pandemic virus. While many of the interactions required for influenza virus assembly have been determined, the molecular machinery needed to complete the budding process for filamentous, as well as for spherical virions is not known. Many viruses utilize the host endosomal sorting complex required for transport (ESCRT) machinery to mediate membrane scission and virion release. Binding of late domain sequences in many viral matrix proteins mediates recruitment into the ESCRT pathway, enabling the virus to utilize host proteins involved in the budding and release of endosomal vesicles into multi-vesicular bodies, for their own budding. However, the available data for influenza virus indicates that the virus may bud independently of ESCRT proteins, with the mechanism of virion release unknown. While investigating the mechanism of filamentous virion budding, we have found a new role for the influenza virus M2 protein that is independent from its previously determined ion channel activity. Utilizing recombinant viruses and fluorescence microscopy, we show that multiple domains within the M2 protein are required for the formation of filamentous virions. We observed that the cytoplasmic tail of M2 is involved in localization of M2 to sites of virus budding. Through a variety of molecular and biochemical approaches, we find that the M2 protein’s amphipathic helix, located within the cytoplasmic tail, mediates a cholesterol-dependent alteration in membrane curvature. This alteration of membrane curvature is seen to facilitate filamentous virion formation and viral
budding. We suggest that M2 may mediate the final step of budding for all influenza a viruses, serving as a virus-encoded ESCRT substitute.

812
A. K. Neumann, K. Jacobson; Cell & Developmental Biology, University of North Carolina, Chapel Hill, NC

Fungal pathologies are seen in immunocompromised and healthy humans. C-type lectins expressed on immature dendritic cells (DC) recognize fungi. We report a novel dorsal pseudopodial protrusion, the “fungipod”, formed by DC after contact with yeast cell walls. These structures have a convoluted cell-proximal end and a smooth distal end. They persist for hours, exhibit noticeable growth and total 13.7±5.6 μm long and 1.8±0.67 μm wide at the contact. Fungipods contain clathrin and an actin core surrounded by a sheath of cortactin. The actin cytoskeleton, but not microtubules, is required for fungipod integrity and growth. An apparent rearward flow (225±55 nm/sec) exists from the zymosan contact site into the distal fungipod. The phagocytic receptor Dectin-1 is not required for fungipod formation, but CD206 (Mannose Receptor) is the generative receptor for these protrusions. These novel pseudopodial structures may be involved in yeast retention on the DC, promoting phagocytosis and engulfment responses to larger microorganisms.

Minisymposium 12: Lipid Dynamics (813 – 818)

813
Dynamics of Plasma Membrane Reorganization Induced by Equinatoxin II.
A. J. García-Sáez1, S. Buschhorn2, H. Keller1, G. Anderluh3, K. Simons2, P. Schwille1; 1Biophysics- Schwille Lab, Biotechnology Center (BIOTEC), TU Dresden, Dresden, Germany, 2MPI for Cell Biology and Genetics, Dresden, Germany, 3University of Ljubljana, Ljubljana, Slovenia

Equinatoxin II is a pore forming toxin from sea anemone Equinia actinia that efficiently lyses several cell types and shows permeabilizing activity in model membranes. Equinatoxin II activity depends on the presence of sphingomyelin in the target membrane, which has been proposed to act as a specific receptor for the toxin and as a promoter of the membrane organization necessary for toxin activity. In this work, we investigated the mechanism of action of the toxin and the role of sphingomyelin in living cells. We found that fluorescently-labeled Equinatoxin II shows a higher binding to the apical membrane of polarized MDCK cells, which is enriched in sphingomyelin when compared to the basolateral membrane. Using 5D microscopy on living COS-7 cells, we followed the reorganization of the plasma membrane that we found to happen shortly after toxin binding. This redistribution affects raft and non-raft proteins labeled with GFP and leads to the formation of immobile protein domains. Interestingly, Equinatoxin II seems to colocalize with clustered GPI-GFP, a typical raft marker. Our fluorescence cross-correlation spectroscopy and FRET studies indicate that membrane reorganization is accompanied by Equinatoxin II oligomerization. at longer times, Equinatoxin II causes to the growth of non-retracting, plasma membrane blebs that correlate with calcium entry into the cytosol and PIP(4,5)P2 degradation at the plasma membrane. Finally, cells collapse after osmotic swelling. Altogether, our results suggest that alteration of the plasma membrane organization is part of the deadly strategy of Equinatoxin II and highlight the essential role of membrane structure for life progression.
Cell fusion is essential for organ development and sexual reproduction. Molecular genetic studies of cell fusion in *C. elegans* have led to the discovery of the FF family of fusogens. EFF-1 and AFF-1, are type I membrane glycoproteins that are essential for cell fusion. FF proteins can fuse cells when ectopically expressed on the plasma membranes of nematode, insect and mammalian cells. One third of all somatic cells in *C. elegans* fuse homotypically and specifically either via EFF-1 or AFF-1. Cells can change shape by fusing with themselves through a process of autacellular fusion. We will discuss how the FF proteins fuse cells via an universal intermediate in which the outer leaflets of the plasma membranes merge before the inner leaflets (hemifusion). The FF proteins are genuine cell fusogens because they are: (1) Essential for ectodermal and mesodermal cell fusion. (2) Expressed specifically on the surface of both fusing plasma membranes at the time of fusion. (3) Sufficient to fuse cells that normally do not fuse *In Vivo* and in tissue culture cells. We will also describe how these fusogens sculpt epithelial toroidal cells, muscular rings, long tubes, and complex neuronal trees containing repetitive menorah units. Understanding the mechanisms of cell fusion and membrane sculpting by EFF-1 and AFF-1 may facilitate the identification of other fusogens required for fertilization and somatic fusion in different organisms.

Clathrin-mediated endocytosis (CME) is the major mechanism of cargo internalization from the plasma membrane (PM). CME initiates as a result of recruitment of adaptors and clathrin to create a small invaginating region of the PM termed a clathrin-coated pit (CCP). Following a maturation process involving recruitment of other endocytic accessory factors, CCPs pinch off and form clathrin-coated vesicles. The spatial and temporal hierarchy of molecular events governing CCP maturation is not yet fully defined. Several CCP factors bind phosphatidylinositol-(4,5)-bisphosphate (PIP2) and PIP2 is required for CCP initiation. However, whether PIP2 is synthesized or enriched within CCPs, and how this might participate in CCP maturation remains unknown. To determine how PIP2 dynamics may control CCP maturation we have applied a combination of time-lapse TIRF microscopy of cells expressing fluorescently-labeled clathrin with computational analysis of CCP dynamics. Monitoring lifetimes allows identification of 3 distinct subpopulations of CCPs: 2 short-lived abortive and a long-lived productive subpopulations; we previously proposed that progression to the productive CCP stage is gated by an endocytosis restriction/checkpoint. Using this method in combination with siRNA silencing and overexpression, we find that PIP2 synthesis by phosphatidylinositol-5-kinase type I (PI5K1) positively controls CCP initiation and aids in the efficiency of productive CCP maturation. PIP2 degradation by the phosphatases OCRL1 and synaptojanin1 (SJ1) negatively regulates the efficiency of progression of CCPs to the productive stage and also increase the rate of turnover of abortive CCPs. In contrast, synaptojanin2 (SJ2) is required for efficient progression past the endocytic restriction/checkpoint to the productive CCP stage. SJ1,SJ2 and OCRL, but not PI5K, localize to CCPs. Taken together, these results suggest a model in which PIP2 is produced in the bulk PM and aids in recruitment of endocytic proteins. SJ2 acts early in CCP maturation, likely aiding CCP growth by ensuring dynamic turnover of PIP2 within nascent CCPs. SJ1 and OCRL negatively regulate CCP maturation and may provide input into the endocytic restriction/checkpoint machinery.
Regulation of Phosphoinositide Dynamics at Endocytic Clathrin-Coated Pits by the Inositol 5-Phosphatase Ship2.

F. Nakatsu, R. Perera, L. Lucast, R. Zoncu, F. Gertler, D. Toomre, P. De Camilli; 1Department of Cell Biology, Yale University School of Medicine, New Haven, CT, 2Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT, 3Department of Biology, Massachusetts Institute of Technology, Cambridge, MA

Phosphatidylinositol 4,5-bisphosphate [PI(4,5)P2] and its phosphorylated product phosphatidylinositol 3,4,5-triphosphate [PI(3,4,5)P3] are two major phosphoinositides (PIs) primarily concentrated at the plasma membrane where their levels are tightly controlled in space and time by kinases, phospholipases and phosphatases. Endocytosis is tightly coupled to the dephosphorylation of these PIs and we have previously identified three inositol 5-phosphatases involved in such dephosphorylation: synaptojanin 1 and 2 as well as OCRL. Here we show that the inositol 5-phosphatase SHIP2, a negative regulator of PI(3,4,5)P3-dependent insulin signaling, is also concentrated at clathrin-coated pits (CCPs) and regulates their dynamics. As shown by TIRF microscopy, SHIP2 is recruited to early stage CCPs and disappears from them before fission. Recruitment of SHIP2 to CCPs is mediated by intersectin 1. SHIP2 knockdown and the acute inducible recruitment to the plasma membrane of a PI 3-kinase, i.e. two conditions expected to increase PI(3,4,5)P3 levels, shorten CCP lifetime. Both localization at CCPs and phosphatase activity of SHIP2 are required for efficient negative regulation of insulin signaling. These findings corroborate the concept that phosphoinositide metabolism plays a key role both in endocytosis and in signaling at endocytic CCPs.

Characterization of Atlastin-Mediated Membrane Fusion In Vitro.

T. J. Moss, J. A. McNew; Biochemistry and Cell Biology, Rice University, Houston, TX

Homotypic membrane fusion is essential for the formation and maintenance of the dynamic structure of the endoplasmic reticulum (ER). The large GTPase atlastin has recently been shown to be important in ER formation and maintenance and is able to promote the tethering and homotypic fusion of liposomes in vitro. Atlastin, along with mitofusins, represents a novel class of fusogens distinct from SNARE's and viral fusogens. Our current studies are aimed at determining the mechanism by which Drosophila atlastin tethers distinct membranes and drives the merging of lipid bilayers. We are conducting a structure-function analysis of atlastin domains required for membrane fusion and oligomerization. We have found that carboxy-terminal truncations result in an impaired ability to fuse membranes. Additionally, mutations designed to disrupt a predicted juxtamembrane coiled-coil domain reduce GTPase activity and prevent the ability of atlastin to fuse liposomes. Furthermore, acute addition of the amino-terminal cytoplasmic domain of atlastin inhibits the fusion of atlastin proteoliposomes while the cytoplasmic domain lacking the predicted coiled-coil domain has no effect. These results suggest that the carboxy-terminal 70 residues are important for atlastin function and that atlastin may form homo-oligomers through a juxtamembrane coiled-coil to promote homotypic membrane fusion.

A Combined Genetics and Lipidomics Approach to Explore Metabolism and Functions of Membrane Lipids.

X. Guan, C. M. Souza, H. Pichler, M. Wenk, H. Riezman; 1Biochemistry and Biological Sciences, National University of Singapore, Singapore, Singapore, 2Biochemistry, University of Geneva, Geneva, Switzerland, 3Graz University of Technology, Graz, Austria

With the burgeoning appreciation of the critical functions of lipids in biological processes, and aided by advances in technologies that afford an '-omic-centric' view of the lipid inventory of biological systems, the field of lipidomics has emerged over the last 5 to 10 years. In particular, the development of electrospray ionisation (ESI) and matrix-assisted laser desorption/ionisation
(MALDI) mass spectrometry (MS) has led to the realisation of a new level of sensitivity, resolution and throughput for simultaneous analysis of multicomponent lipid mixtures, generating a metabolic fingerprint containing quantitative as well as qualitative information on the system investigated. We previously developed a novel label-free approach, based on ESI-MS and chemometry, to detect changes in the metabolic fingerprint during a cellular perturbation. Without the need for prior knowledge of the chemistry of the analytes, the tool is particularly powerful in detecting changes that cannot be easily anticipated. The availability of a wide range of genetic and chemogenetic libraries for various model organisms, including the budding yeast Saccharomyces cerevisiae and the fruit fly Drosophila melanogaster, offers unparalleled opportunities for genome-wide screens to discover and/or characterise mutants involved in lipid metabolism, transport and turnover, as well as the revelation of novel lipid functions. For the first time, we combined lipidomics with yeast and fly genetics to probe for novel enzymatic activities and modulators of known ones, with a focus on sphingolipids. We further provided evidence of an exquisite specificity of interactions between lipids in living cells that is critical for cellular functions.

**819**

**Nuclear Body Crosstalk.**

*K. Praveen, T. K. Rajendra, A. Matera; Department of Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Cajal bodies (CBs) are conserved nuclear subdomains that are present in both animal and plant cells. CBs contain high concentrations of the marker proteins coilin and SMN, as well as the spliceosomal small nuclear ribonucleoproteins (snRNPs) U1, U2, U4 and U5. In metazoa, related structures known as histone locus bodies (HLBs) are found located adjacent to the replication-dependent histone gene cluster. HLBs are critical for efficient histone mRNA formation *in vivo*, and contain factors required for histone gene transcription and pre-mRNA 3’ end formation, including NPAT, FLASH and the U7 snRNP. HLBs and CBs are often found in close proximity to each other in human cancer cell lines and *Drosophila* nurse cells, but whether this represents a functional association is not known. Here we present a study of the interconnectivity of *Drosophila* CBs and HLBs by utilizing mutants in the snRNP and histone mRNA biogenesis pathways. Intriguingly, in a variety of both snRNP and histone biogenesis mutants, CBs are disrupted and coilin is delocalized, forming a kind of ‘cloud’ around the nurse cell HLBs. This phenotype was extremely penetrant. Notably, HLBs remained largely unaffected in the majority of these backgrounds. The strikingly similar phenotypes in each of these classes of mutation suggest that CB integrity is dependent on ongoing histone pre-mRNA processing. Other examples of molecular crosstalk between CBs and HLBs in both wildtype and mutant backgrounds will be discussed.

**Nuclear Protein and Cajal Body-Associated Coilin Modulates the Mitochondrial Apoptotic Pathway Following UV-C-Induced Chromatin Damage.**

*P. Texier, M. Sabra, B. Gibert, N. Vey, J. El Maalouf, P. Lomonte; Center for Molecular and Cellular Genetic, CNRS, Villeurbanne, France*

Coilin is a nucleoplasmic protein and a major component of the nuclear domains called Cajal bodies (CBs). Since its description in the early 1990s no clear biological activity has been assigned to the protein. Coilin is highly dynamic and its nuclear distribution changes dramatically following various stressful stimuli such as irradiations, drugs, and even viral infection. We recently described the accumulation of coilin at, and its association with centromeres following centromeric chromatin damage induced by the ICP0 protein of herpes simplex virus type 1 or by siRNA depletion of centromere protein CENP-B. We hypothesized that coilin might participate in a cell response dedicated to sense and signal aberrant chromatin structures. We also assumed
that any stress that would abruptly affect chromatin might involve coilin in a signalling pathway whatever the chromatin is centromeric or not. UV-C are known to profoundly modify the chromatin structure and to induce apoptosis in a p53-independent manner. We therefore tested the contribution of coilin in UV-C-induced apoptosis. Coilin was depleted using siRNAs in various cell lines before they were stressed with UV-C. The degree of susceptibility to apoptosis was dose- and cell-type dependent but the lack of coilin systematically reduced apoptotic marks such as chromatin condensation, phosphatidylserine externalisation, activation of effector caspases and inactivation of PARP-1. We showed using various apoptosis-inducing stress, including UV-C, etoposide and TRAIL ligand, that the mitochondrial-controlled pathway was suppressed in coilin-depleted HeLa cells. This lack of susceptibility to apoptosis was correlated with a defect in cytochrome c release out of the mitochondria without significantly affecting the amount of pro- and anti-apoptotic proteins. We then found that Bax oligomer formation was dramatically reduced. Altogether, this study describes the role of coilin as a protein that acts as a modulator of the apoptotic intrinsic pathway following a stress that affects the chromatin structure.

A. Sharma1,3, H. Takata2, K. Shibahara4, A. Bubulya5, P. Bubulya5; 1Biomedical Sciences Program, Wright State University, Dayton, OH, 2Integrated Genetics, National Institute of Genetics, Shizuoka, Japan, 3Biological Sciences, Wright State University, Dayton, OH

Nuclear speckles provide important spatial organization and dynamic regulation for pre-mRNA processing factors in mammalian cells. While the nuclear speckle proteome is complex, little is known at the molecular level about how these factors are organized into nuclear speckles or how alterations in the organization of these factors impacts gene expression. We have discovered a new function for a large (2564 amino acid) nuclear speckle protein called Son in maintaining the organization of pre-mRNA processing factors in nuclear speckles. Depletion of Son by RNAi causes snRNP and serine-arginine rich (SR protein) splicing factors to undergo dramatic disorganization into doughnut-shaped nuclear speckles. Rescue of the disorganized nuclear speckle phenotype requires a region of Son with multiple tandem repeat motifs that are unique to Son. This demonstrates that the tandem repeats of Son are necessary for appropriate localization of pre-mRNA processing factors, and it suggests a potential role for Son as a nuclear speckle scaffold. Son depletion does not alter protein levels of other splicing factors, and it does not reduce global transcription or constitutive splicing. However, Son depletion can affect alternative splice site selection. Surprisingly, in addition to its nuclear functions, Son depletion also results in decreased cell proliferation due to growth arrest in mitosis. Son is critical for promoting the transition from metaphase to anaphase. Son is therefore essential for nuclear organization and function, as well as for normal cell cycle progression.

822
An Atypical Progeria Mutation Alters Lamin Polymerization, Nuclear Assembly and Chromosome Organization.
P. Taimen1, K. Pfleghaar2, T. Shimi3, D. Möller2, K. Ben-Harush3, M. R. Erdos4, S. A. Adam1, H. Herrmann5, O. Medalia6, F. S. Collins4, A. Goldman1, R. Goldman1; 1Cell and Molecular Biology, Northwestern University Medical School, Chicago, IL, 2Division of Molecular Genetics, German Cancer Research Center, Heidelberg, Germany, 3Department of Life Sciences, Ben Gurion University and the NIBN, Beer-Sheva, Israel, 4Genome Technology Branch, National Human Genome Research Institute, Bethesda, MD

Numerous mutations in the human nuclear lamin a gene (LMNA) cause the premature aging disease, progeria. The most common form of progeria produces LAΔ50/progerin, a truncation near the C-terminus of lamin a (LA) leading to its permanent farnesylation and abnormal nuclear membrane association. There are also several mutations located in the α-helical central rod domain of LA which would not impact its state of farnesylation. However, this domain is required for the normal polymerization of LA into higher order structures. We studied cells from a patient...
with one of these mutations, E145K, in which the nuclei are severely lobulated with abnormal A- and B-type lamin networks, clustered centromeres, mislocalized telomeres and disorganized pericentric heterochromatin. Expression of FLAG-E145K-LA induces similar changes in HeLa cells. Live cell imaging of these transfected cells shows that lobulation originates as nuclei assemble in daughter cells and that the clustered centromeres normally seen in early G1 are abnormally retained throughout interphase. This abnormal positioning of chromosomes results in the mislocalization of DNA replication factories which is correlated with premature replicative senescence in patient cells. In Vitro analyses of E145K-LA polymerization by ultracentrifugation, negative staining and cryo-electron tomography show severe defects in the assembly of lamins into higher order structures. Similar assays of LAΔ50/progerin show that all steps in the polymerization process are normal. The results demonstrate that the E145K mutation impacts lamin assembly and nuclear architecture differently than the LAΔ50/progerin mutation. The results also shed new light on the wide array of lamin functions in the nucleus. Supported by NIA and a Ellison Medical Foundation Senior Scholar Award (RDG), EURO-Laminopathies project of the European Commission (HH), German-Israel Foundation (HH and OM), Fritz-Thysen Stiftung (OM), Sigrid Juselius Foundation (PT) and Deutsche Forschungsgemeinschaft (KP).

Integrity of the Nuclear Lamina Is Required for Germline Stem Cell Homoestasis.
P. Geyer, B. Pinto, L. Wallrath; University of Iowa, Iowa City, IA

The nuclear lamina is a filamentous network that underlines the nuclear envelope. Lamina components include lamins, as well as the LEM domain (LEM-D) proteins, named for LAP2, emerin and MAN1. LEM-D proteins establish a bridge between the nuclear lamina and chromatin through the ~40 amino acid LEM domain (LEM-D) that binds Barrier-to-Autointegration Factor (BAF), a DNA and histone binding protein. Mutations in genes encoding LEM-D proteins cause tissue-restricted human disease, such as Emery-Dreifuss muscular dystrophy, even though these genes are globally expressed. We are studying a Drosophila emerin homologue called Otefin. Genetic analyses demonstrate that loss of Otefin causes tissue-restricted defects that are limited to female sterility. Mutant females contain rudimentary ovaries indicative of an early block in oogenesis. In a wild type ovary, germline stem cells (GSCs) divide asymmetrically to form cystoblasts that differentiate into oocytes. BMP signaling plays a central role in controlling GSC self-renewal, establishing a limiting signal that represses expression of differentiation genes in GSCs, but not in the daughter cystoblasts. BMP signals emanate from the adjacent somatic cap cells that comprise the instructive cells of the specialized GSC niche. Immunohistochemical analyses show that loss of Otefin causes excessive BMP signaling. We find that terminal filament cells lacking Otefin adopt a cell fate similar to the instructive cap cells, which may account for the elevated BMP response. These effects result in changes of expression in BMP responsive genes, thereby blocking cystoblast differentiation. In addition, otefin defective germ cells display lobulated and thickened nuclear lamina, which may contribute to altered nuclear functions. Within ten days, otefin females show loss of cells in the somatic GSC niche, as well as of germ cells, representing an accelerated aging phenotype. These data demonstrate that Otefin plays an essential role in GSC maintenance through regulation of differentiation of the somatic cells of the niche and BMP signaling. Our findings support models suggesting that laminopathies arise from dysfunction of the homeostasis in stem cell populations.

Distinct Clustering of Active and Repressed Genes at the Nuclear Periphery of Mouse Embryonic Stem Cells.
L. Luo, L. Shopland; Institute for Molecular Biophysics, The Jackson Laboratory, Bar Harbor, ME

A gene’s location in the nucleus can impact its expression. A gene can be influenced by another nearby gene and by association with a sub-nuclear compartment, such as the nuclear periphery. However, the mechanisms mediating gene 3D clustering or associations with nuclear compartments are poorly understood. We previously discovered that the set of genes across a 5
Mb region of mouse chromosome 14 cluster together in the nucleus to form 3D gene hubs. These hubs form at or near the nuclear periphery in multiple cell types, including mouse embryonic stem cells (ESCs). To determine mechanisms mediating this 3D gene clustering, we investigated the relative locations of these genes based on their activity and epigenetic state. In ESCs, four of the genes are in a repressed and epigenetically “bivalent” state. Bivalent genes are marked by covalent histone modifications indicative of both transcriptionally active (histone H3 K4-trimethyl) and repressed (histone H3 K27-trimethyl) chromatin. The locations of the repressed genes in ESCs were compared to four active genes in the same chromosomal region. We found that the repressed genes form homotypic clusters within the nucleus, as do the active genes. These two types of genes clusters are adjacent to each other but non-intermingling. In addition, the repressed genes on average localize closer to the nuclear periphery than the active genes, although active genes do co-localize with the lamina in some cells. Interestingly, loss of the histone H3 K27-trimethyl mark from the repressed genes due to mutation of the Polycomb group gene Eed does not alter gene association with the nuclear periphery. However, the 3D organization of these normally repressed genes is altered relative to the active gene set. Together, our findings suggest that gene 3D clustering is related to transcriptional activity and epigenetic state. Furthermore, these data indicate that trimethylation of H3K27 is not required for localization to the nuclear periphery, but rather that this epigenetic mark plays a role in the relative arrangement of genes at the nuclear periphery.

Minisymposium 14: Organization and Dynamics of the Cytoskeleton (825 – 830)

825 Intermediate Filaments Bind Tubulin and Function as a Local Tubulin Reservoir to Modulate the Assembly of Microtubules.

J. Eyer1,2, A. Bocquet2,3, R. Berges2, R. Frank4, P. Robert2, A. C. Peterson5; 1Neurobiology & Transgenesis, INSERM, Angers, France, 2Neurobiology & transgenesis, Université, Angers, France, 3Centre de Recherche Pierre Fabre, Castres, France, 4Department of Chemical Biology, Helmholtz Centre for Infection Research, Braunschweig, Germany, 5Laboratory of Developmental Biology, McGill University, Montreal, QC, Canada

Neurofilaments (NF) assemble from three intermediate-filament proteins, are exceptionally stable and contribute to the radial growth of axons. Microtubules (MT) are dynamic structures that assemble from tubulin dimers to support intracellular transport of molecules and organelles. Here we show that intermediate filament proteins, including NF, desmin, GFAP, keratin, and vimentin, contain motifs in their N-terminal domains that bind unassembled tubulin. Peptides corresponding to these Tubulin-Binding-Sites inhibit MT polymerization in vitro. Some are taken up by cultured cells where they disrupt MT and cause an arrest of cell division. In transgenic mice in which NF are aggregated in cell bodies and thus withheld from the axonal compartment, the levels of tubulin accumulated in both cell bodies and axons is normal. However, in their cell bodies, MT are not detectable while they assemble in excessive numbers in axons. These observations indicate that NF and other intermediate filaments can function as a dynamic tubulin reservoir modulating local MT assembly. This property places them in a unique position to contribute to a wide array of MT-dependent cell functions. Eyer, the German National Genome Research Net to R. Frank and the Canadian Institutes of Health Research to A. Peterson. A. Bocquet and R. Berges were supported by Angers Agglomeration and ARC.

826 Acetylation of Microtubules Is a Regulator of Their Sensitivity to Severing by Katanin in Neurons and Fibroblasts.

H. Sudo, P. W. Baas; Drexel University College of Medicine, Philadelphia, PA
Here we investigated whether the sensitivity of microtubules to severing by katanin is regulated by acetylation of the microtubules. During interphase, fibroblasts display long microtubules with discrete regions rich in acetylated tubulin. Overexpression of katanin for short periods of time produced breaks preferentially in these regions. In fibroblasts with experimentally enhanced or diminished microtubule acetylation, the sensitivity of the microtubules to severing by katanin was increased or decreased respectively. In neurons, microtubules are notably more acetylated in axons than in dendrites. Experimental manipulation of microtubule acetylation in neurons yielded similar results on dendrites as observed on fibroblasts. However, under these experimental conditions, axonal microtubules were not appreciably altered with regard to their sensitivity to katanin. We hypothesized that this may be due to the effects of tau on the axonal microtubules, and this was validated by studies in which overexpression of tau caused microtubules in dendrites and fibroblasts to be more resistant to severing by katanin in a manner that was not dependent upon the acetylation state of the microtubules. Interestingly, none of these various findings apply to spastin, as the severing of microtubules by spastin does not appear to be strongly influenced either by the acetylation state of the microtubules or by tau. We conclude that sensitivity to microtubule-severing by katanin is regulated by a balance of factors including the acetylation state of the microtubules and the binding of tau to the microtubules. In the neuron, this contributes to regional differences in the microtubule arrays of axons and dendrites.

827
Microtubule Organization and Motor Co-Operation in Long-Range Endosomes Motility.
G. Steinberg1, M. Schuster1, G. Fink2, J. Collemare1; 1University of Exeter, Exeter, United Kingdom, 2MPI-CBG, Dresden, Germany

In elongated cells of the model fungus Ustilago maydis microtubules serve as tracks for long-range motility of membranous cargo. The plus-ends of microtubules are directed towards the growth region, whereas the minus-ends are located at mobile and bi-polar nucleation sites. The position of these microtubule organisation centres depends on the activity of cytoplasmic dynein, which results in a complex anti-polar microtubule array. Early endosomes utilise this array for long-range motility, which is mediated by kinesin-3 and dynein. Both motors move their cargo in opposite direction, and their activity is therefore determined by the polarisation of the microtubule array. Live cell imaging of photo-activated early endosomes and the respective motors suggest a cooperative mechanism by which counteracting motors cope with the anti-polar microtubule orientation in order to govern long-range motility of early endosomes.

828
A Network of Formin Inhibitors Required for Actin Assembly and Architecture.
M. A. Chesarone, C. J. Gould, B. Goode; Biology, Brandeis University, Waltham, MA

Formins are a conserved family of actin nucleation- and elongation-promoting factors with essential roles in governing eukaryotic cell shape and behavior. In vivo, the potent activities of formins must be tightly controlled in a temporal manner to yield actin filaments of the appropriate length and thereby maintain actin network architecture and function. In many cases, the timing of formin activation appears to be under the control of Rho proteins; however, mechanisms for inhibiting and/or inactivating formins are only just beginning to emerge. Recently, we identified Bud14 as a strong inhibitor of the yeast formin Bnr1 that can displace the Bnr1 FH2 domain from rapidly growing barbed ends of filaments (Chesarone et al., 2009). Further, deletion of BUD14 led to abnormalities in actin cable architecture and secretory vesicle transport. Here, we identify the orphan kinesin Smy1 (suppressor of myo2) as a novel direct inhibitor of Bnr1. Like Bud14, purified Smy1 binds to the FH2 domain and potently suppresses the actin assembly activity of Bnr1. A specific region of Smy1 outside of its putative motor domain mediates these effects. Further, smy1Δ and bud14Δ show synthetic defects in cell growth and compounded defects in actin cable assembly, suggesting that they coordinate the timing of Bnr1 activity in vivo. Both Smy1 and Bud14 depend on Myo2-dependent transport on actin cables for their delivery to polarity sites where formins localize, suggesting a possible negative feedback loop that
attenuates Bnr1 activity. Interestingly however, Smy1 did not displace Bnr1 from growing barbed ends, suggesting that it has a mechanistically distinct role from Bud14 in inhibiting Bnr1. Together, this work demonstrates that even a relatively simple eukaryote like budding yeast requires multiple formin binding partners to regulate the precise timing and duration of formin activity, and thus maintain proper actin network organization and function.

829
Regulation of Rho Proteins Homeostasis by RhoGDI1.
E. Boulter¹, R. Garcia-Mata¹, C. Guilluy¹, A. D. Dubash¹, G. Rossi¹, P. J. Brennwald¹, K. Burrridge¹,²; ¹Cell and Developmental Biology, UNC-Chapel Hill, Chapel Hill, NC, ²Lineberger Comprehensive Cancer Center, UNC-Chapel Hill, Chapel Hill, NC

Rho GTPases are molecular switches that regulate many cellular functions including cell migration, organization of the actin cytoskeleton and adhesion dynamics. At steady state, most Rho proteins are bound in the cytosol to Rho Guanine nucleotide Dissociation Inhibitors (RhoGDI). The major GDI in mammalian cells, RhoGDI1 binds to RhoA, Rac1 and Cdc42 and is expressed at a level approximately equal to the sum of these Rho family members. RhoGDI1 has generally been considered to passively hold Rho proteins in an inactive state within the cytoplasm. However, the precise biological function of RhoGDIs has remained elusive. Here we show that RhoGDI1 controls the homeostasis of Rho proteins in eukaryotic cells. We found that RhoGDI1 depletion in mammalian cells, as well as in S. cerevisiae, triggers an almost complete degradation of the major Rho GTPases. In the absence of RhoGDI1, cytosolic Rho GTPases that have been geranyl-geranylated are cleared from the cytosol by the proteasome. Since the level of RhoGDI1 is limiting, there is competition between different Rho proteins for binding to RhoGDI1. We show that overexpression of an exogenous Rho GTPase leads to the displacement of endogenous Rho proteins from RhoGDI1 and their subsequent degradation. These results demonstrate an unanticipated crosstalk between Rho GTPases mediated by binding to RhoGDI1. The competition of Rho proteins for binding to RhoGDI1 raises important questions about some of the conclusions drawn from studies that manipulate Rho protein levels. In many cases the responses of cells may arise not simply from the overexpression or knockdown per se, but from additional effects on the levels of other Rho GTPases due to competition for binding to RhoGDI1.

830
The Arp2/3 Activator WASH Controls the Fission of Endosomes through a Large Multiprotein Complex.
E. Derivery¹,², C. Sousa², J. J. Gautier², B. Lombard⁴, D. Loew¹, A. Gautreau¹,²; ¹CNRS, UMR144, Institut Curie, Paris, France, ²Lab Enzymologie et Biochimie Structurales, CNRS, Gif-sur-Yvette, France

The Arp2/3 complex is an actin nucleator that generates branched actin networks. It is activated by Nucleation Promoting Factors (NPFs) such as N-WASP, Scar/WAVE, WHAMM or JMY. Recently, the WASH family of NPFs has been identified but its cellular role is unclear. Here we show that endogenous WASH localizes to a microdomain of sorting and recycling endosomes. Accordingly, WASH is required to generate actin networks associated with these endosomes. NPF regulation is provided by multiprotein complexes, as exemplified by Scar/WAVE. We purified a novel stable multiprotein complex containing seven subunits, including WASH and the heterodimer of capping protein (CP). In agreement with cellular observations, the purified WASH complex activates Arp2/3 mediated actin nucleation and binds directly to liposomes. Interestingly, the WASH complex also has a low capping activity, suggesting a tight control of CP within the complex. Specific inhibition of WASH mediated actin polymerization, obtained by microinjection of blocking antibodies or through siRNA mediated depletion, induces the formation of long membrane tubules pulled out from endosomes along microtubules, suggesting a role of WASH in the fission of transport intermediates. Indeed, we found that WASH interacts with dynamin and that inhibition of dynamin phenocopies WASH depletion. In line with such a role in endosome fission, WASH is required for efficient transferrin recycling. Together these data suggest that the
WASH molecular machine, integrating CP with a NPF in an unprecedented manner, controls the fission of endosomes through an interplay between the forces generated by microtubule motors and actin polymerization.

Minisymposium 15: Systems Biology (831 – 836)

Sake to Chocolate: Systems Genetics and Natural Variation in Yeast.
V. L. Ahyong¹, C. Ludlow¹, A. C. Scott¹, P. Ruusuvuori¹,², U. Lao¹, L. A. Baumgardner¹, D. B. Martin¹, I. Shmulevich¹, A. M. Dudley¹; ¹Institute for Systems Biology, Seattle, WA, ²Department of Signal Processsing, Tampere University of Technology, Tempere, Finland

Leveraging the information in individual genome sequences is of increasing relevance to understanding human health and is essential to the development of predictive, preventive, and personalized medicine. Common diseases such as asthma, diabetes, heart disease are complex traits, with interactions that can range from simple binary relationships to many genes with complicated interdependencies. Genetics, the study of how differences in DNA sequence affect the observable characteristics of an individual, is fundamentally a systems science. Systems genetics uses large-scale, high-throughput methods to decipher the network of gene functions and interactions in an organism. This network, in which genes interact with each other and with the environment in complex ways, provides the framework through which biological information is transmitted, integrated, and ultimately used by the downstream networks of proteins, RNAs, and small molecules. Here we present an example of how systems level approaches can be used to dissect a complex quantitative trait, the “fluffy” colony morphology phenotype. We start with a collection of natural isolates of Saccharomyces cerevisiae from diverse sources (e.g. laboratory strains, clinical isolates, sake brewing, soil samples) and geographic locations (six continents) as a rich source of naturally occurring genetic polymorphisms. We mate these parental strains, isolate large numbers of recombinant progeny, assay their phenotypes across numerous conditions, and genotype them by multiplexed, next generation DNA sequencing. Our results demonstrate the power of integrating automated image analysis, comprehensive molecular network data (including RNA expression and mass spec based proteomics), spatial and temporal information, and large-scale genetic analysis. We believe such approaches will increase our understanding of the underlying structure of complex traits and lead to methods for predicting phenotypes in more complex systems, such as humans.

832
A High-Content Screen to Functionally Classify Proteins Required for Cell Viability and Division.
R. Green¹, A. Audhya², A. Desai¹, K. F. Oegema¹; ¹Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, UCSD, La Jolla, CA, ²Department of Biomolecular Chemistry, University of Wisconsin-Madison Medical School, Madison, WI

Systems biology analyzes molecular assemblies within functional networks. The success of this approach relies upon available systematic and functional information for the components of these molecular assemblies. RNA-mediated interference (RNAi) is a key method for linking genes to their cellular functions. In addition to relatively ‘low content’ single reporter assays, RNAi has been used to perform high-content microscopy-based assays, integrating spatial and/or temporal information. This approach has been used to characterize the set of genes required for cell viability and division in C. elegans, a model system for molecular analysis of animal cell division. Of the 20,000 genes, 10% are required for embryo production or viability; these genes were previously screened by filming the first two embryonic divisions following RNAi depletion. This screen allowed for the functional classification of ~400 genes, however it did not provide high quality functional information on the ~560 genes whose inhibition blocks embryo production (the sterile collection). Here, we functionally characterize the sterile collection by performing a second
high-content screen, using two-color fluorescence confocal microscopy to examine gonad structure, in living worms, after individual depletion of the 560 sterile gene products. Gonad-morphology data was analyzed by binary scoring for 94 potential defects, and a clustering algorithm was used to group genes with similar phenotypic profiles. The clusters were then re-examined by eye for accuracy. Our analysis placed genes into ~20 broad groups that could be partitioned into ~100 different phenotypic classes, which typically corresponded to subunits of specific protein complexes. As a result, we have classified the ~170 previously "unknown" genes into functional groups and have provided additional data on the ~390 "known" genes. Upon publication, our data will be pooled with the previous high-content screen data and collectively housed in the PhenoBank online database, creating a valuable resource for the scientific community. This work provides an important platform for systems biology based analysis of the pathways contributing to embryo production, cell division, and development.

833 Mitochondrial Network Morphology: Control of Abundance and Topology in Budding Yeast.
S. M. Rafelski1, M. P. Viana2, K. S. Thorn1, L. F. Costa2, W. Marshall1; 1Biochemistry & Biophysics, UCSF, San Francisco, CA, 2Inst. de Fisica de Sao Carlos, Universidad de Sao Paulo, Sao Carlos, Brazil

We want to understand the fundamental unsolved questions of how the 3-dimensional geometry of cellular structures is generated and how this geometry contributes to cellular functions. An ideal system to approach this question is the dynamic, physical network of interconnected tubules that makes up mitochondria. In budding yeast the mitochondrial network localizes at the cell periphery, undergoes constant fusion and fission dynamics that remodel the network, and exhibits consistent changes in morphology under different physiological conditions. We have developed a method to quantify the 3D mitochondrial morphology by considering the mitochondria as a network of edges (the tubules) and nodes (the branch points where tubules connect). Live mitochondria are rapidly imaged in 3D at high resolution using Spinning-disk Confocal microscopy. Specialized segmentation and 3D skeletonization methods are applied to the image stacks to extract the mathematical graph of the mitochondrial network. for validation and testing the limits imposed by microscopy imaging, we create theoretical microscope images from predetermined skeletonized structures and compare these to the 3D skeletons obtained by our methodology. We then apply concepts and methods from complex networks and shape analysis research to obtain measurements of the total amount, arc lengths, density, and connectivity of mitochondrial tubules in the cell. Using our methodology, we investigate mechanisms of mitochondrial abundance control during cell cycle progression. During budding, we find that mitochondria accumulate in the bud at a constant rate independent of the volume or density of mitochondria in the mother. Differences in mitochondrial density between individual cells or different growth conditions can be explained by differences in the cell growth rate and the duration of the cell cycle. We also analyze how topological network properties depend on tubule density at the cell surface and on fusion and fission dynamics. We find that the frequency of fusion/fission events is directly correlated with, and may be regulated by, the amount of mitochondria in the cell.

834 Quantitative Output of a Signaling Pathway Is Controlled by Microtubule-Mediated Repositioning of the Nucleus.
G. Pesce1, R. C. Yu1, A. A. Colman-Lerner1,3, D. Rockwell1, S. Berrios1, R. Brent1,2; 1Molecular Sciences Institute, Berkeley, CA, 2Fred Hutchinson Cancer Research Center, Seattle, WA, 3Laboratorio de Fisiologia y Biologia Molecular, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Buenos Aires, Argentina

Genetically identical cells differ from each other in size, shape and other aspects. Such heterogeneity can affect the quantitative outputs of cell signaling systems; thus, mechanisms that
adjust transmitted signal to account for individual variability could be advantageous. We showed earlier that the mating pheromone response system of S. cerevisiae compensates for cell-to-cell variation by scaling the amplitude of the transmitted signal (Nature, 2005. 437 (7059) 699). Here, we designed a genetic screen to identify components responsible for controlling cell-to-cell variation in transmitted signal amplitude. We found that deletion of a class of genes increased variability in pheromone-responsive gene induction assayed at the single cell level, but did not affect the population’s average pathway output. This class included BIM1 and KAR3, whose products attach to and control the length of microtubule-mediated links between the nucleus and the specialized plasma membrane site where pheromone receptors cluster. We therefore examined the sub-cellular position of the nucleus in these mutants. In time course experiments, the position of the nucleus in wild-type cells exposed to pheromone was stable and pheromone-dependent: the higher the dose, the further the nucleus was from the signaling site. By contrast, in both mutants, the nucleus moved randomly within the cell and its average distance to the signaling site did not correlate with pheromone dose. Thus, mutations that increased cell-to-cell variation in transmitted signal amplitude also increased variability in the position of the nucleus. Perturbing the connection between the nucleus and the signaling site impaired the ability of cells to select the mating partner producing the most pheromone. Thus, our results revealed that a mechanism that controls the position of the nucleus enhances the precision of a signaling system, perhaps by enabling the cell to adjust the amplitude of the transmitted signal to that cell’s shape and size. This mechanism might be operational during response to developmental cues, when cells of diverse size and shape must manifest a uniform output to a level of signal presented to them at a specific position within a gradient.

Reconstructing the EGFR Autocrine Signaling Network by Integrating Proteomic and Genomic Data.
H. Shankarin3, M. Singhal3, T. H. Heibeck2, V. A. Petyuk2, W. Qian2, H. Wiley1; 1EMSL, Pacific Northwest National Laboratory, Richland, WA, 2Biological Sciences, Pacific Northwest National Laboratory, Richland, WA, 3Computational Biology and Bioinformatics, Pacific Northwest National Laboratory, Richland, WA

Many types of cells integrate information from multiple signaling pathways by modulating EGFR autocrine signaling - a process known as EGF receptor transactivation. To better understand the mechanism(s) by which signals from different receptors are integrated by cells, we created a multi-tier model of the major signaling pathways in human mammary epithelial cells. We first defined the topology of these pathways by using a combination of quantitative MS-based proteomics data and gene expression profiles together with curated protein interaction data. We then experimentally treated the cells with a variety of growth factors followed by global phosphoproteomics analyses. The pattern of protein phosphorylation was then overlaid on the reconstructed network topology to generate hypotheses regarding how different pathways interact to generate a particular response, such as ERK phosphorylation. Some of these hypotheses were then tested by targeted experiments and by steady-state perturbation of the autocrine signaling network. This combined “top-down” and “bottom-up” approach for reconstructing signaling networks generated some intriguing findings regarding their architecture. First, there are numerous feedback loops, both positive and negative, that operate over a wide range of different temporal scales and respond to different levels of stimulation. Second, many different adaptor proteins are shared between multiple signaling pathways, but are expressed at low levels relative to receptors. Modeling suggests that this differential expression can give rise to a signaling hierarchy between different pathways based on both receptor-ligand abundance and affinity for adaptor proteins. Finally, we found that signal integration occurs separately at the level of individual pathway activation and at the level of gene transcription. Our results suggest that both quantitative proteomics and gene expression data can greatly facilitate the reconstruction of signaling networks by imposing realistic constraints on mathematical models of these networks and by revealing multiple levels of regulation.

Cell to Cell Variability in the Responses of Mammalian Cells to Death Ligands.
P. Sorger, S. Spencer, B. Aldridge, J. Albeck, S. Gaudet, D. Flusberg, J. Burke, W. Chen; Department of Systems Biology, Harvard Medical School, Boston, MA

Cell to cell variability in phenotype and fate is important for tissue homeostasis, the emergence of drug resistance and the evolution of tumors. I will discuss cell to cell variability in the responses of clonal populations of human cells to TRAIL, a prototypical inducer of receptor-mediated (extrinsic) apoptosis and an investigational therapeutic. Some TRAIL-treated human cells die within ~40 min, others only after 12 hr and some live indefinitely. During this variable delay initiator caspases (ICs) are active in processing substrates such as Bid but mitochondrial membrane permeabilization (MOMP) does not occur and downstream effector caspases (ECs) are catalytically inactive. We have tested three possibilities to explain why some cells in a notionally uniform population die rapidly and others slowly or not at all (i) cell to cell genetic or epigenetic variation (ii) the involvement of one or more involving biochemical processes subject to stochastic fluctuation (iii) difference in cell state such as. position in the cell cycle or protein concentrations. To distinguish these three possibilities we compared the fates of sister cells exposed to TRAIL using live-cell microscopy. Genetic and epigenetic factors are transmitted with near-perfect fidelity; reaction rates dominated by stochastic fluctuations are more similar in sisters than in any two cells chosen at random and variability arising from differences in mRNA or protein levels should be transiently heritable (because division is a binomial process in which sister cells inherit roughly equal numbers of abundant cytosolic and nuclear factors but drift towards the population average over time). The later explanation is correct - natural fluctuations in protein levels dominate phenotypic heterogeneity in extrinsic apoptosis and cause transient phenotypic heritability. Variability can be manipulated by protein over-expression and drugs and I will describe analytic methods for modeling these perturbations. Finally, I will show that natural variation can be sufficient to cause some cells to follow one biochemical pathway to death and another set of genetically identical cells to follow a fundamentally different pathway.

Epigenetic Regulation of Stem Cell Fate in Plants.

Plant stem cells are located in specialized niches, termed meristems, at the growing tips of the plant. Stem cell fate within the shoot apical meristem (SAM) is specified in part by the KNOX homeobox genes. Down-regulation of KNOX expression is a key factor that distinguishes stem cells and their immediate indeterminate derivatives in the SAM from lateral organ initials. Moreover, normal leaf development requires the continued silencing of these stem cell regulators. We have shown that this process is mediated by the DNA-binding proteins ASYMMETRIC LEAVES1 (AS1) and AS2, which target the chromatin-remodeling factor HIRA to the KNOX loci in differentiating lateral organs. More recently we have shown that HIRA facilitates the recruitment of Polycomb Repressive Complex2 to the KNOX loci, which catalyses the establishment of the H3K27me3 repressive mark. This mark is recognized by LIKE-HETEROCHROMATIN PROTEIN1, which through a currently unknown mechanism, leads to a stable repressive chromatin state at the KNOX loci that allows cellular differentiation. Our research has shown that cellular differentiation is achieved via an epigenetic mechanism in which HIRA serves as an intermediary factor that recruits PRCs to pluripotency determinants. A role for HIRA and PRC2 in regulating stem cell homeostasis is conserved in animals, presenting the possibility that our results in plants uncover a highly conserved epigenetic mechanism that allows cellular differentiation.

**Regulation of Stem Cell Function in Aging Organisms.**

A. Wagers\(^1,2,3\), S. R. Mayack\(^1,2,3\), J. L. Shadrach\(^1,2,3\), F. S. Kim\(^1,2,3\), \(^1\)Dept Developmental & Stem Cell Biology, Joslin Diabetes Center and Harvard Stem Cell Institute, Boston, MA, \(^2\)Stem Cell and Regenerative Biology, Harvard University, Cambridge, MA, \(^3\)Harvard Stem Cell Institute, Cambridge, MA

Aging of multicellular organisms typically involves a progressive decline in normal cell replacement and repair processes, resulting in a number of physiologic deficiencies, including inefficient muscle repair, reduced bone mass, and dysregulation of blood formation (hematopoiesis). While defects in tissue-resident stem cells clearly contribute to these phenotypes of aging, it has been unclear to what extent these defects arise from stem cell intrinsic alterations versus age-related changes in the stem cell supportive microenvironment, or niche. To address this important question, we have established complementary In Vivo and In Vitro heterochronic models to assess stem cell and niche cell activity with age. Our data indicate that stem cell-supportive niche cells become deregulated with age, and this deregulation contributes directly to hematopoietic stem cell (HSC) dysfunction. Furthermore, we find that age-dependent defects in both niche cells and HSCs are controlled systemically, and can be reversed by exposure to a young circulation. These studies reveal a novel and critical role for both local and systemic factors in signaling age-related changes in HSC engraftment activity and lineage potential, and highlight a new paradigm in which blood-borne factors in aged animals act via local niche cells to induce age-dependent disruption of stem cell function. Modulation of stem cell interactions with the niche thus represents a promising avenue for restoring youthful function in aging tissues.

**Germ Cells Are Forever.**

R. Lehmann; HHMI and Skirball Institute, Langone Medical Center, New York, NY

From generation to generation, germcells provide the continuity of life. Despite their critical role, we still know little about how germcells are initially specified and what allows germcells to evade the deadly fate of the soma. Germcells are highly specialized; their role is to produce gametes and to escape somatic differentiation. But, in contrast to somatic cell fates, no master-regulator transcription factor has been identified that specifies germcell fate. from studies in flies, worms, and mice, three general features have emerged: 1) Transcriptional silencing coincides with germcells specification. 2) Conserved, germcell-specific translational regulators are active throughout the germcell life cycle. 3) Germ-line soma interactions are critical for different aspects of germcell behavior such as germcell migration, stem cell establishment and maintenance, protection of the germ line genome and differentiation of germcells into egg or sperm. We study germcell biology in Drosophila. We use genetic, biochemical and structural approaches to characterize critical germ plasm components essential for germcell fate specification. We find that germcells form by a specialized budding process, which is remarkably different from the process of somatic cell formation. Combining genetics with In Vivo imaging we have developed a dynamic picture of the migratory path of Drosophila germcells. Initiation of migration requires the Tre1 GPCR. GPCR activation mediates polarization, individualization and transepithelial migration of germcells. The lipid phosphate phosphatases (LPP) Wunen and Wunen 2, homologs of mammalian LPP3, guide germcells from the midgut to the somatic gonad and are also required in germcells for their survival and migration. Final, at the end of the migratory route germcells associate with the somatic gonad, HMGCoA reductase activity is required for the geranylation of a germcell attractant produced by the somatic gonad and exported by an unconventional secretory pathway.

**Feedback Control of Mitosis.**

A. Musacchio; Department of Experimental Oncology, European Institute of Oncology, IFOM-IEO Campus, Milan (Italy), Milan, Italy

Kinetochores (KTs) are proteinaceous structures implicated in the formation of load-bearing chromosome-microtubule attachments in mitosis. We are interested in the organization of KTs and in the feedback control mechanisms operating at the KT-microtubule interface. Two such control mechanisms exist: 1) An error correction mechanism protecting from incorrect KT-microtubule attachments. It allows the selective stabilization of correct attachments and the destabilization of incorrect attachments, thus promoting bi-orientation. 2) The spindle assembly checkpoint (SAC). It is required to synchronize the metaphase-anaphase transition with the completion of KT-microtubule attachment for all sister chromatid pairs in a cell. The relationship between error correction and the SAC is our main focus. To tackle this problem, we are taking an approach of biochemical reconstitution, structural analysis, and cellular studies. Both feedback control mechanisms operate near a large protein assembly, the Knl1-Mis12 complex-Ndc80 complex (KMN) network. The KMN network contains the main microtubule-binding activity of KTs. It is also crucial for recruiting the SAC components to KTs. Finally, it is a target of enzymes, such as the Aurora B and Mps1 kinases, that are essential for error correction. Thus, the KMN network may integrate adequate physical responses to the state of KT-microtubule attachment. I will present structural data on the KMN network, revealing the overall shape of the complex, as well as the molecular details of inter-subunit interactions that support complex oligomerization. I will also present our approach towards reconstitution of the reactions responsible for the recruitment of the SAC proteins to KTs and for error correction. Our efforts are based on a paradigm, strongly supported by studies with specific small-molecule inhibitors, that the Aurora B kinase is the upstream kinase in a hierarchical kinase cascade that controls error correction as well as the SAC response. Our working model is that the interaction of the Aurora B kinase with the KMN network is the crucial mechanism regulating the feedback mechanisms acting at KTs. A molecular model for how this might occur will be discussed.

**Structure of a Bacterial Dynamin-Like Protein Lipid Tube Provides a Mechanism for Self-Assembly and Membrane Curving.**

H. Low, C. Sachse, L. Amos, J. Lowe; Structural Studies, MRC Laboratory of Molecular Biology, Cambridge, United Kingdom

Proteins of the dynamin superfamily mediate membrane fission, fusion and restructuring events by polymerising upon lipid bilayers and forcing regions of high curvature. In this work, we show the electron cryomicroscopy reconstruction of a bacterial dynamin-like protein (BDLP) helical filament decorating a lipid tube at ~11 Å resolution. We fitted the BDLP crystal structure and produced a molecular model for the entire filament. The BDLP GTPase domain dimerises and forms the tube surface, the GTPase effector domain (GED) mediates self-assembly, whilst the paddle region contacts the lipids and promotes curvature. Association of BDLP with GMPPNP and lipid induces radical large-scale conformational changes effecting polymerisation. Nucleotide hydrolysis seems therefore to be coupled to lipid dissociation and polymer disassembly rather than membrane restructuring. Observed structural similarities with rat dynamin 1 suggest our results have broad implication for other dynamin family members.
Finding and Recognizing the Right Partner during Meiosis.

A. Sato¹², D. J. Wynne¹², C. M. Phillips², R. A. Kasad¹², R. Rillo¹², P. M. Carlton⁴, J. H. Chretien¹,², A. Dernburg¹,²,³; ¹Howard Hughes Medical Institute, Chevy Chase, MD, ²Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, ³Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, ⁴Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

Sexual reproduction requires the unique cell division process known as meiosis, the goal of which is to produce haploid cells containing exactly one set of chromosomes. This requires that homologous chromosomes - pairs of chromosomes inherited from each parent - separate from each other after undergoing an intricate process of pairing, synapsis, and recombination. The primary questions we have investigated are what forces bring chromosomes together, and how each chromosome recognizes its true homologous partner among the chromosomes in the nucleus. We have explored these questions in the nematode C. elegans, which combines powerful molecular genetics with outstanding opportunities to directly image meiosis in both fixed and living animals. Our work has shown that special regions on each chromosome are required for both pairing and synapsis. These regions, known as "Homolog Recognition Regions" or "Pairing Centers," contain a high density of short, repetitive sequences, which recruit a family of zinc finger proteins known as HIM-8 and ZIM-1, -2, and -3. During early meiotic prophase, the binding of these proteins promotes interaction of chromosomes with the microtubule cytoskeleton, through a bridge of SUN and KASH domain proteins that spans the nuclear envelope. Disruption of microtubules sharply reduces chromosome dynamics and inhibits pairing between homologs. The cytoplasmic dynein motor complex is dispensable for pairing, but is required for chromosomes to "recognize" their partners and initiate formation of the synaptonemal complex, which stabilizes the relationship between homologs and enables them to undergo reciprocal recombination. Together these discoveries have shed light on longstanding mysteries about chromosome dynamics involved in reproduction.

Bioengineering (843 – 862)

Visualizing the Dynamics of Immunological Synapse Formation.

M. J. Biggs¹², L. C. Santos³, M. P. Sheetz², S. Wind¹; ¹APAM, Columbia University, New York, NY, ²Biological Sciences, Columbia University, New York, NY

Antigen-specific T lymphocyte activation, expansion, and acquisition of effector functions are critical components of an adaptive immune response. T-cells engage antigen presenting cell (APC) in a long lasting interaction that results in the formation of a structure known as the immunologic synapse (IS), a precursor to T-cell activation and proliferation. Here we describe a novel system to observe the modulation of protein organization and clustering which occurs at the is during the process of antigen recognition. at present, the most studied method for obtaining high-resolution images of the is in viable cells relies on the use of planar lipid bilayers [1], which can only provide a limited understanding of supramolecular clustering during is formation. Studies with these bilayers have revealed the is to consist of a central cluster of T-cell receptors (central supramolecular activation clusters [cSMAC]) surrounded by a ring of adhesion molecules (peripheral SMAC [pSMAC]). In parallel, large molecules like CD43 and CD45 are excluded from the is and migrate centrifugally to the distal supramolecular activation cluster (dSMAC) [2]. K562 cells modified to act as artificial APCs were used to study the formation of the is in T-cell populations. Cells were immobilized by micropit arrays which were functionalized to promote K562 cell adhesion. Human T-lymphocytes were purified from whole blood samples by negative selection and incubated with the sequestered K562 cells. Quantitative imaging of fluorescent TCR microclusters at the T-cell/APC interface has revealed assembly of microclusters at the pSMAC followed by transport towards the cSMAC. Simultaneously, LFA-1/ICAM-1 complex is assembled at the dSMAC, and transported to the pSMAC. This suggests that a modulation in the distribution

S. Chirasatitsin1, M. Flores-Merino2, G. Reilly?, G. Battaglia?, A. J. Engler1; 1Bioengineering, University of California, San Diego, La Jolla, CA, 2The Kroto Research Institute, The University of Sheffield, Broad Lane, United Kingdom

The cell microenvironment is composed of an extracellular matrix (ECM) with specific mechanoechemical properties that can direct cell behavior. Current hydrogels display a variety of these parameters, but they typically lack the ability to display these properties, such as adhesivity, in small, discrete "sticky" patches, such as the RGD binding site of fibronectin does in the context of an assembled matrix. Moreover, our ability to detect these regions by conventional light microscopy techniques is likely limited. Using a unique application of force spectroscopy on an atomic force microscope (AFM), we demonstrate here the ability to determine local changes in the 1) adhesive or 2) elastic properties of a material down to the resolution of the tip diameter, ~50 nm. Ligand-coated polyacrylamide (PA) hydrogels were interrogated with antibody-coated AFM tips to measure and map adhesion forces as a means of identifying these "sticky" patches. Fibronectin as a positive result is compared with albumin as a negative one. Micropatterned ligand study also verifies the specificity of this interaction. For elasticity, PA and polyvinyl pyrrolidinone (PVP) hydrogels were mapped, and while PA gels displayed a relatively uniform elasticity, PVP gels showed small regions where elasticity varied up to 50% from Eaverage. Domain area was found to be 0.2 - 0.6 μm2 in size. Though a sharp transition between 1 and 1.5% crosslinking was observed, indicating unique transition state in the PVP gel, it did not correlate with changes in surface roughness, pointing to a fundamental difference in the network structure of PVP versus PA gels. We feel that both applications demonstrate the resolution and versatility of this unique AFM application, which will enable detection of mechanical features well below the resolution limit of conventional light microscopy.

Thermoplasmonic Nanoarrays to Manipulate Cell Adhesion.
J. Polleux; New Materials & Biosystems, Max Planck Institute of Metals Research, Stuttgart, Germany

The cell, the most fascinating entity due to its complex and hierarchical micro-nanomachinery, uses specific transmembrane receptors, the integrins, to bind extracellular matrices (ECM) and to trigger subsequently its activity. Towards the development of lab-on-chip systems, control over these binding-sites would offer a unique way to organize, guide and release the entire cell or only part of it. Other than micropatterning and stimulus-responsive surface chemistries, only a limited number of technologies have been developed to culture cells in an effort to manipulate and investigate dynamic adhesive processes in more details. Our overall objective intends to develop a new generation of culture substrates engineered for cell manipulation with the abilities to interface specifically integrins and to generate heat nano-locally for the dissociation of the {integrin-ECM} bounds. The present paper describes our work on the design, characterization and effect of thermoplasmonic gold nanopatterned surfaces on cell adhesion. We find that gold nanoarrays, when made of 40 nm-particles functionalized with ECM-ligands (like the GRGDS peptide), are multifunctional because they support in-vitro cell growth, generate heat while excited by a green laser, and thus, change the state of adhered fibroblasts or melanoma from rounded to apoptotic. By simply adjusting the laser power, the released thermal energy can either be lethal for cells, or functional to release their focal adhesions from the array. When lethal (laser power >30 mW/cm2), the heat induces the fixation of the cells, which remain intact or detach within few
minutes, while a power of 20 mW/cm² causes the detachment of filopodes and the retraction of lamellipodia, which lead the cells to round up and to re-spread instantly after laser exposure. Our set up can easily reach the single cell resolution, offering a promising platform for microfluidic systems and new experiments in cell biology and nanophysics.

Human Donor Variability and Dose-Dependant Effect of BMP4 on the Osteogenic Capacity of Human Umbilical Cord Stem Cells.
A. Witt¹,², J. Nance¹,², S. James¹,², K. Wescoe¹,², A. Usas³, B. Deasy¹,³,⁴; ¹Bioengineering, University of Pittsburgh, Pittsburgh, PA, ²Stem Cell Research Center, Children's Hospital of Pittsburgh, Pittsburgh, PA, ³Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, ⁴McGowan Institute of Regenerative Medicine, University of Pittsburgh Medical Center, Pittsburgh, PA

Human umbilical cord stem cells (UCSCs) may be beneficial for use in cell therapy. Isolation of these cells from the umbilical cord results in a high harvest yield, and high expandability with stem cell phenotype stability. In this study, we examined human donor variability and dose-dependant effects of BMP4 on osteogenic capacity of UCSCs. Human UCSCs (n=8 donor populations) were stimulated with osteogenic media containing 0.1, 1, 10 and 100 ng/mL bone morphogenic protein 4 for 5-7 days and percent alkaline phosphatase (ALP) was examined. We subsequently prepared UCSC for the classic pellet assay (2.5E5 cells/pellet) for growth in control media, DMEM, or osteogenic media with 10ng/mL dose of (BMP4) for 10 and 28 days. Pellets were examined by micro-CT for matrix mineralization and were fixed in formalin for histological analysis. We observed that the most effective dose of BMP4 to increase ALP positivity varied with the donor population. In the pellet assay, we observed a larger amount of bone volume present in certain populations (UC80, UC82, UC84 and UC86). By day 28, we observed that these same populations did not continue to represent the most osteogenic cells, rather populations (UC79, UC81, UC83 and UC85) showed larger amount of bone volume present. To date, we have not detected any correlation between cell markers or ALP expression and mineralized matrix formation. Investigation shows that while all UCSC populations were capable of osteogenic differentiation, there was variability among populations. While previous studies showed remarkable phenotype consistency in the isolation of mesenchymal stem cells from the umbilical cord, UCSCs showed dose-dependant effects related to BMP4 concentration and length of stimulation. Findings have implications for individualized therapeutic approaches using mesenchymal stem cells. Whether autologous cells or allogeneic cells may be used in cell therapies, it will be important to examine the specific responsiveness of a given stem cell populations. Future studies are ongoing to examine the molecular differences among the populations with disparate osteogenic responses.

Biophysical Cues Modulate Redox Potential in Cells.
P. Russell, C. J. Murphy; Surgical and Radiological Sciences, University of California at Davis, Davis, CA

Objective: to determine if biophysical cues influence redox potential in cells involved with the drainage of aqueous humor from the eye. Methods: Human trabecular meshwork cells, TM-1, were plated onto hydrogels with Young’s moduli of 3, 30 and 100 kiloPascals (kPa) as well as on standard tissue culture plastic. The amount of reduced glutathione (GSH) in the TM-1 cells was measured using Ellman’s reagent. Cells were also plated onto fabricated polyurethane substrates that were either flat, or had a repeating pitch structures (equal sized grooves and ridges) of 400, 1400 or 4000 nm. After five days in culture, the cells were challenged with 0.5 mM H2O2 for two hours and then were harvested to measure GSH. Results: Cells grown on all compliant substrates had markedly elevated GSH. Preliminary data indicate cellular GSH was 5-30 fold higher on the hydrogels than on the plastic surfaces. The GSH was highest on the 30 kPa hydrogel and decreased somewhat as compliance decreased or increased around this value.
After the oxidative stress, cells grown on the 400 and 1400 nm pitch patterned substrates had significantly more GSH than those cells grown on the chemically identical flat surfaces or the cells on the 4000 nm pitch substrates. Conclusions: Our lab and others have previously shown that biophysical cues influence a wide menu of fundamental cell behaviors including orientation, cell proliferation, and gene expression. These data show that substrates that possess biophysical attributes (compliance and topography) that more closely approximates those observed In Vivo influence the redox potential of the cell. These results again demonstrate the importance of the biophysical environment on cell behaviors and composition. Cells In Vivo never perceive the hard flat surfaces that are typically used to culture them in vitro.

Laminin Active Peptides Conjugated on Chitosan Membrane as a Cell Adhesive Matrix.
K. Hozumi, A. Sasaki, D. Otagiri, Y. Yamada, Y. Kikkawa, F. Katagiri, M. Nomizu; School of Pharmacy, Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan

Laminins are multifunctional heterotrimeric glycoproteins. at present, five α (α1-α5), three β (β1-β3), and three γ (γ1-γ3) chains have been identified and 16 isoforms can be formed by various combinations of each subunit. Laminins show tissue- and/or developmental stage-specific expression. Laminins-111, consisting of laminin α1, β1, and γ1 chain, plays a critical role during embryonic development and in maintaining the many biological functions of basement membrane. We previously identified about 50 active sequences from laminin-111 through the peptide screening method using over 673 peptides covering the entire sequence of laminin-111. Further, some biological active peptides from laminin-111 had been used to develop the artificial cell sheet by conjugated on chitosan membrane and found that cell-peptide-chitosan sheet accelerate the wound healing. Here, we conjugated 33 cell adhesive peptides from laminin-111 on chitosan membranes and assessed their biological functions to analyze the peptide specific functions. 24 cell adhesive peptide-conjugated chitosan membranes promoted human dermal fibroblasts (HDFs) attachment and 12 peptide-chitosan membranes showed cell spreading. HDF attachment to 9 peptide-chitosan membranes was inhibited by heparin and to 12 peptide-chitosan membranes was inhibited by EDTA. Additionally, HDF attachment to several peptide-chitosan membranes were inhibited by anti-β1 integrin antibodies. Further, 17 peptide-chitosan membranes promoted neurite outgrowth with PC12 cells. These results suggest that peptide-chitosan membranes interact with different cell surface receptors in a peptide dependent manner. These cell adhesive peptide-chitosan membranes could use to analyze the cellular functions mediated by specific cell surface receptors and have a potential to use as a biomedical material.

Laminin B133 (Dsitkyfqmsle) Peptide Forms Amyloid-Like Fibrils and Interact with Integrin A2β1 and Syndecan.
F. Katagiri1, T. Kazuki1, Y. Ohga1, K. Hozumi1, Y. Kikkawa1, Y. Kadoya2, M. Nomizu1; 1School of Pharmacy, Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan, 2Department of Anatomy, Kitasato University School of Allied Health Sciences, Sagamihara, Japan

B133 peptide (DSITKYFQMSL, mouse laminin β1 chain 1298 - 1309) promotes cell attachment, neurite outgrowth, and amyloid-like fibril formation. Cell attachment to B133 is inhibited by both heparin and EDTA. We evaluated the essential residues for the B133 activities using various deletion peptides and sets of alanine substituted peptides. The N-terminus deletion peptide B133a (SITKYFQMSL) promoted cell attachment with well-organized actin stress fibers, although the amyloid-like fibril formation and neurite outgrowth activity were eliminated. Cell attachment to B133a was inhibited by EDTA and anti-integrin α2 and β1 antibody. The shortest peptide maintained the characteristics was B133d (KYFQMSL). In contrast, the C-terminus deletion peptide B133g (DSITKYFQMSL) showed cell attachment with membrane ruffling. Additionally, B133g promoted amyloid-like fibril formation and neurite outgrowth activity. B133g
promoted heparin dependent cell attachment and significantly stimulated attachment to syndecan over-expressed cells, suggesting that B133g promotes syndecan-mediated cell attachment. The Congo red analysis, which evaluated amyloid-like fibrils forming ability, indicated that amyloid-like fibril formation of B133g was stronger than that of B133. The shortest peptide maintained the activities was B133i (DSITKYFQM). Further, alanine substituted analyses of B133a and B133g suggest that the important residues for the integrin α2β1 mediated cell attachment are I, T, Y, F, M, and E, and for the syndecan mediated cell attachment are D and I. The N-terminus D residue was required for neurite outgrowth. Furthermore, amyloid-like fibril formation required D and I residues. These data suggest that the integrin α2β1 mediated cell attachment of B133 is critical for the B133i sequence, especially C-terminus E, and the syndecan-mediated cell attachment of B133 is required for the amyloid-like fibril formation and the N-terminal amino acid residues. In summary, the B133 peptide is bifunctional, and the integrin α2β1 and syndecan bindings are sequence and conformation dependent. These findings were useful to clarify the mechanism of amyloid-like fibril formation and create artificial materials with various biological functions.

Hard Tissue Generation on Dental Implant Surfaces by 3-D Culture of Bone Marrow-Derived Cells with a Collagen Scaffold In Vitro.
S. Kumabe, M. Nakatsuka, T. Mikami, H. Mikami, Y. Iwai; Department of Oral Anatomy, Osaka Dental University, Hirakata-shi, Japan

[Objective] We studied a host microenvironment, which regulated mouse osteoblasts to osseointegrate the implant by generation of mineralized matrix in a biocompatible and osteoconductive collagen scaffold onto the dental implant surfaces. [Materials and Methods] KUSA/A1 cells (JCRB1119; mouse osteoblastic cell line, bone marrow-derived mesenchymal cells) were used. The immature cells were seeded in Dulbecco’s Modified Eagle Medium (DMEM) supplemented with 10% FBS, penicillin (125 μg/ml)/streptomycin (200 μg/ml) in a humid 5% CO₂/air at 37°C. In order to induce differentiation in vitro, the KUSA/A1 cells were exposed to 50 μg/ml ascorbic acid (AA)+10mM β-GP (induction condition). Titanium alloy implants (Anodic Oxidized, HA-coated and 99% Ti) were used in the study. Collagen scaffold was used for 3-D culture of the mature KUSA/A1 osteoblasts. Step 1: the cells were monolayer-cultured in the DMEM+AA+β-GP (8.0×10⁴ cells/ml, 12-well). Step 2: the cell/collagen scaffold clusters were 3-D cultured in the DMEM+AA+β-GP (8.0×10⁴ cells/ml, 12-well). Step 3: subsequently, the cells embedded in the scaffold were cultured on the 3 types of implant surfaces (Anodic Oxidized, HA-coated and 99% Ti) (1×10⁵ cells/ml, 10cm dishes; DMEM+AA+β-GP). Light/phase-contrast microscopy, proliferation rate, ALPase activity, osteocalcin and calcium amount, and mineralization examinations for bone-like tissue formation were performed in attempts to study the histology and characteristics of the hard tissue generation. [Results & Conclusions] The KUSA/A1 osteoblasts, being 3-D cultured under induction condition in collagen type I scaffold having low antigenecity, actively proliferated and differentiated to deposit hard tissue in the scaffold in vitro. This study suggested that GTR concept tissue engineering of mesenchyme-derived cells obtained osseointegration on the implant surfaces in vitro, which would serve as a biocompatible and temporary 3-D framework followed by biodegradation and bone remodeling to optimize an implant-tissue interface -osseointegration- in vivo.

Claudin as a Target Molecule for Mucosal Absorption of Peptide Drug.
M. Kondoh₁, H. Uchida², T. Hanada², K. Yagi₁; ¹Graduate School of Pharmaceutical Sciences, Osaka University, Osaka, Japan, ²Department of Biopharmaceuticals Research, Biopharma Center, Asubio Pharma Co., Ltd., Gunma, Japan

Objective: Recent progress in genomic and proteomic research provides us biologics (peptides, proteins and nucleic acids) as pharmaceuticals. Biologics is hydrophilic and poor in absorption. Paracellular pathway is an ideal route for absorption of biologics; however, epithelium functions as a barrier separating intra and outer body. Tight junctions (TJs) seal intercellular spaces in
epithelium and prevent free movement of solutes across epithelium through the paracellular route. Claudin, a four-transmembrane protein, comprises a protein family consisting of more than 20 members and is a key component in TJs-barrier. We previously found that a claudin-4 modulator, C-terminal fragment of Clostridium perfringens enterotoxin corresponding to 184-319 amino acids (C-CPE), enhanced jejunal absorption of dextran. In the present study, we investigated whether a claudin-4 modulator is a potent mucosal absorption-enhancer of a peptide drug.

**Methods:** Human parathyroid hormone derivative hPTH(1-34) was used as a peptide drug. Mucosal absorption was evaluated by rat jejunal, pulmonary and nasal administration of hPTH(1-34) and C-CPEs. Plasma hPTH(1-34) levels were measured by radioimmunoassay. Binding of C-CPEs to claudin-4 was assayed in enzyme-linked immunosorbent assay and Biacore assay. Modulation of TJ-barrier was evaluated using Caco-2 monolayer cell sheets. **Results:** C-CPE enhanced nasal absorption of hPTH(1-34) but did not jejunal and pulmonary absorption. C-CPE enhanced jejunal and pulmonary absorption when hPTH(1-34) was administered 4 h after C-CPE-treatment. C-CPE has poor solubility (0.3 mg/ml). Previous report indicated that N-terminal partly truncated C-CPE is a claudin binder with high solubility (10 mg/ml). We found that the truncated C-CPE bound to claudin-4, modulated TJ-barrier and enhanced jejunal absorption of dextran. The truncated C-CPE enhanced jejunal and nasal absorption of hPTH(1-34).

**Conclusion:** Claudin is a potent target molecule for development of mucosal absorption of peptide drug.

Notch Ligand Endocytosis and Force Generation Measured by Optical Laser Tweezers.
B. S. Shergill\textsuperscript{1,2}, L. Meloty-Kapella\textsuperscript{2}; \textsuperscript{1}Biomedical Engineering, University of California, Irvine, Stockton, CA, \textsuperscript{2}Biological Chemistry, UCLA, Los Angeles, CA

The Notch pathway is an evolutionary conserved signaling system used extensively throughout embryonic development and continues to function in the maintenance of tissues and stem cells in adults. Notch signaling requires a series of proteolytic cleavage events to release the Notch intracellular domain that functions directly in signal transduction. The Notch receptor is locked-down in a protease resistant state by a negative regulatory region (NRR) that protects an ADAM (A Disintegrin And Metalloprotease) cleavage site. Engagement with ligand-bearing cells is proposed to induce global conformational movements in Notch that unfold the NRR structure to expose the ADAM cleavage site and initiate proteolytic activation. Since endocytosis is critical for Notch signaling we are using optical tweezers to determine if ligand cells exert a pulling force on bound Notch and if this is dependent on ligand endocytosis. Specifically, we trap and place Notch-coated polystyrene beads next to cells expressing the Notch ligand Delta-like 1 (Dll1) and record the displacement of the Notch-bead as measured on a quadrant photodiode (QPD). Our preliminary findings identify a significant displacement of Notch-beads, indicating a force generated by the Dll1 cells on beads, and furthermore, the ability of our system to detect nanometer displacement. Importantly, Dll1 cells defective in endocytosis bind trapped Notch-beads but do not significantly displace them, suggesting that bead displacements by wild-type Dll1 are related to ligand endocytosis. To identify the specific endocytic pathway and characterize ligand cell endocytic forces measured with optical tweezers, we are using Dll1 endocytic mutants and RNA interference to deplete various endocytic proteins. Together our data provide support for the idea that endocytosis of ligand bound Notch exerts a force on Notch to facilitate proteolytic activation for downstream signaling.

Optimal formulation and route of delivery enhance cancer drug efficacy. In this study, a novel water dispersible oleic acid (OA)-triton X-100-coated Fe3O4 nanoparticles loaded with 10-Hydroxycamptothecin (HCPT) was developed to induce apoptosis in human lung cancer HCC827 cell line. HCPT partitions into the OA shell surrounding Fe3O4 nanoparticles and Triton X-100 that anchors at the OA-water interface confer the aqueous dispersion to the formulation. HCPT-loaded Fe3O4 nanoparticles were characterized by transmission electron microscopy (TEM), X-ray Diffraction (XRD), Fourier Transform Infrared (FT-IR) Spectroscopy, as well as High Performance Liquid Chromatography (HPLC) analysis. The HCPT-loaded Fe3O4 nanoparticles displayed excellent water dispersion, narrow size distribution, and were readily loaded with high doses of water-insoluble anti-cancer drug (HCPT). Our results demonstrated that HCPT-loaded Fe3O4 nanoparticles elicited an anti-proliferative effect in a dose-dependent manner in several cancer cell lines using MTT cell viability and flow cytometry assays. Apoptotic DNA ladder bands were clearly detected in human lung cancer HCC827 cells when treated with HCPT-loaded Fe3O4 nanoparticles. Furthermore, we found that compared with void Fe3O4 nanoparticles alone, HCPT-loaded Fe3O4 nanoparticles evoked synergistic effects by increasing cell apoptosis. Western blot analysis revealed an enhanced activation of caspase-8, 9, and 3 as well as an increased cleavage of poly (ADP-ribose) polymerase (PARP). Combined with annexin V-FITC apoptosis detection, our data suggests that HCPT-loaded Fe3O4 nanoparticles could be developed as a chemotherapeutic agent for increasing anti-cancer drug efficacy.

Distinct Changes in Cell Proliferation within the Dentate Gyrus and Medulla Follow Spinal Cord Injury.
M. Carmichael1,2, N. L. Hayes1, R. S. Nowakowski1,2; 1Neuroscience & Cell Biology, UMDNJ at RWJMS, Piscataway, NJ, 2Biomedical Engineering, UMDNJ at RWJMS / Rutgers University, Piscataway, NJ

Cell proliferation within the spinal cord is a well known concomitant of the inflammatory and degenerative events following spinal cord injury (SCI). Despite recent studies, much remains unknown regarding the role(s) and diversity of cell proliferation after injury, including whether it occurs in supraspinal regions distant from the lesion site. We sought to elucidate whether SCI elicits a proliferative response in the brain stem and/or forebrain, with the hypothesis that there is such a response within these regions. The rationale for this hypothesis is twofold: 1) axon degeneration, particularly anterograde degeneration, should stimulate glial cell proliferation associated with reorganization, and 2) many of the axons damaged by SCI are long motor pathways from brain stem nuclei and the cortex. To characterize the changes in cell proliferation within the medulla and dentate gyrus (DG) of adult, male C57BL/6J mice 96 hrs after SCI, we used a single injection of bromodeoxyuridine (BrdU) 30 minutes before sacrifice to label cells within S-phase. In the medulla, there is an 80% increase in the number of S-phase cells (p<0.05) predominantly in white matter tracts, suggesting that this response is glial. Double-labeling confirmed this to be a glial response, with GFAP+ and NG-2+ cells predominantly accounting for the S-phase cells (BrdU+). Moreover, this response is within regions that correlate with motor pathways damaged in the spinal cord. Interestingly, there is a 20 - 30% decrease (p<0.01) in the number of S-phase cells within the DG, a structure with no direct connections to the spinal cord. These data suggest that in response to SCI: 1) cell proliferation occurs in the brain, i.e., distant from a spinal cord lesion, 2) the increase in cell proliferation in the medulla is secondary to axonal degeneration, and 3) the decrease in cell proliferation within the DG is precipitated by a systemic signal elicited after SCI. Taken together, these results indicate that after SCI there are changes in cell proliferation within regions of the CNS distant from the site of SCI and these changes differ quantitatively and qualitatively in the areas studied.

Furfural Prevents Growth and Induces Cellular Damage That Is Suppressed by the Overexpression of OYE2 in Saccharomyces Cerevisiae.
R. E. McRae, S. W. Gorsich; Biology, Central Michigan University, Mt. Pleasant, MI
A renewable fuel source is necessary to combat the rising economical and environmental concerns currently associated with fossil fuels. One possible renewable fuel is bio-ethanol from lignocellulosic biomass. However, there are many problems that need to be addressed before this alternative fuel can be realized. One major problem is the existence of multiple inhibitors found in a typical lignocellulosic hydrolysate. Some of the predominant inhibitors include furfural, hydroxymethylfurfural (HMF), and vanillin. These chemicals inhibit the growth and fermentation of the budding yeast, Saccharomyces cerevisiae. In order to fight the effects of fermentation inhibitors the stress protective gene, OYE2, was subcloned into the pRS425-MET25 expression vector. The enzyme encoded by OYE2 is a NADPH specific oxidoreductase linked to stress tolerance. To determine whether or not OYE2 overexpression increased furfural tolerance, we took exponentially growing yeast with either pRS425-MET25 or pRS425-MET25-OYE2 and exposed them to furfural. Aliquots of cells were removed at set time points to assay growth, reactive oxygen species (ROS) accumulation (dihydroethidium stain), membrane damage (mitochondrial targeted-GFP and FM 4-64), and chromatin damage (DAPI stain). Furfural induced the accumulation of ROS and cause cellular damage to membranes and nuclear chromatin. Yeast overexpressing OYE2 grew better in medium containing low and high amounts of furfural (25 mM and 50 mM, respectively). We predict overexpressing OYE2 will subsequently cause reduced damage to membranes and chromatin. These data demonstrate that overexpressing OYE2 provides protection to yeast against the industrial inhibitor furfural. This strategy indicates that genetically engineered yeast strains may prove valuable in improving the technology needed for lignocellulose to be converted into an efficient supply of bio-ethanol.

Probing Cellular Mechanobiology in Three-Dimensional Culture with Collagen-Agarose Matrices.

T. A. Ulrich1,2, A. Jain2, K. Tanner2, J. L. MacKay2,3, S. Kumar1,2; 1UCSF/UC Berkeley Joint Graduate Group in Bioengineering, University of California, Berkeley and University of California, San Francisco, Berkeley, CA, 2Department of Bioengineering, University of California, Berkeley, Berkeley, CA, 3Department of Chemical Engineering, University of California, Berkeley, Berkeley, CA

Cellular mechanobiology studies are currently limited by the lack of three-dimensional (3D) scaffolds that combine the biofunctionality of native extracellular matrix (ECM) proteins with the tunability of synthetic materials. Here, we introduce a novel biomaterial platform in which the biophysical properties of collagen I matrices are progressively altered by adding agarose. We find that agarose increases the bulk elasticity of 3D collagen ECMs over two orders of magnitude by forming a dense meshwork that intercalates between the entangled collagen fibers. Embedded glioma cells exhibit a pronounced transition to amoeboid motility accompanied by severe limitation of cellular invasion from multicellular spheroids as the agarose content of the hydrogels is increased from 0-1% w/v. Our results are consistent with a model in which agarose structurally couples and reinforces individual collagen fibers, simultaneously introducing steric barriers to cell motility while shifting ECM dissipation of cell-induced stresses from the non-affine deformation of individual collagen fibers to the bulk-affine deformation of a continuum network.

N. Cawley1, A. Voutetakis2, A. Cotrim2, A. Rowzee2, T. Rathod1, C. Zheng2, Y. Loh1, B. Baum2; 1NICHD, NIH, Bethesda, MD, 2NIDCR, NIH, Bethesda, MD

An adenoviral vector (Ad-GLP-1) was constructed that expresses bioactive glucagon-like peptide 1 (GLP-1) in the salivary glands of mice and its effectiveness at modulating glucose homeostasis was evaluated. The construct was engineered with the signal sequence of mouse growth hormone, to direct it into the secretory pathway, followed by a furin cleavage site and GLP-1(7-37) encoding an Ala to Gly substitution at position 8 to achieve resistance to degradation and
therefore increase its In Vivo half-life. When expressed in Neuro2A and COS7 cells, the active form of GLP-1 was detected specifically in the conditioned medium of the transduced cells by RIA; showed resistance to degradation by dipeptidyl-aminopeptidase IV; and induced the secretion of insulin from NIT1 pancreatic β-cells in vitro. In Vivo studies demonstrated that mice transduced with the Ad-GLP-1 in the submandibular gland had serum GLP-1 levels ~3-times higher than mice treated with the control Ad-Luciferase (Ad-Luc) vector. In fasted animals, glucose levels were similar between Ad-GLP-1 and Ad-Luc treated mice in keeping with GLP-1’s glucose dependent action. However, when challenged with glucose, Ad-GLP-1 treated mice cleared the glucose significantly faster than control mice. These studies demonstrate that the bioactive peptide hormone, GLP-1, normally secreted from endocrine cells in the gut through the regulated secretory pathway, can be engineered to be secreted into the circulatory system from exocrine cells of the salivary gland to affect glucose homeostasis.

Kinesin-Calmodulin Fusion Protein as a Molecular Shuttle.
H. Shishido1, K. Nakazato1, E. Katayama2, S. Chaen3, S. Maruta1; 1Div. of Bioinfo., Grad. Sch. of Eng., Soka University, Tokyo, Japan, 2Div. of Biomolecular Imaging, Inst. of Med. Sci., University of Tokyo, Tokyo, Japan, 3Dept. of Int. Sci. in Phys. and Biol., Coll. of Humanity and Science., Nihon University., Tokyo, Japan

Recently attention is focused on the application of molecular shuttles based on the kinesin and microtubule to the bionanotechnology such as nano-electro-mechanical systems (NEMS) or lab-on-a-chip. Previously biotin-avidin and antigen-antibody system have been used to attach target cargoes on kinesin. Although the systems are highly specific and tight, these are flawed as irreversible binding. In this study, we have developed molecular shuttle, which has reversible cargo loading system using calmodulin (CaM) and M13 peptide. We have designed kinesin K560 chimera protein fused with CaM at the C-terminal tail region of kinesin (K560-CaM). K560-CaM was expressed by E. coli. expression system and purified. The ATPase activity and the microtubules gliding activity of K560-CaM were almost in the normal range of the kinesin wild type. The Ca²⁺ dependent reversible binding of K560-CaM to the M13 peptide was monitored with HPLC using size-exclusion column (SEC-HPLC). Rotary-shadowing electron microscopy demonstrated that K560-CaM was observed as tetrameric configuration in the absence of Ca²⁺. on the other hand, in the presence of Ca²⁺, K560-CaM was observed as dimeric and tetrameric configuration. The Ca²⁺-dependent configurationally change of K560-CaM was also monitored by SEC-HPLC and analytical ultracentrifugation. Finally, we successfully observed that K560-CaM transports M13 peptide coupled with quantum dot along the rhodamine labeled microtubule in the presence of Ca²⁺ using TIRF-Microscopy. The transport velocity and run length of K560-CaM-Qdot are 305 ± 0.025 nm/s (mean± SE, N=48) and 5.19 ± 0.78 mm (mean± SE, N=48), respectively. on the other hand, in the absence of Ca²⁺, it is not observed K560-CaM-Qdot moving along rhodamine labeled microtubule.

Flagellar Regeneration after Laser Severing.
W. B. Ludington1, L. Z. Shi2, M. S. Harsono3, Q. Zhu2, M. W. Berns2,3, W. Marshall1; 1Biochemistry and Biophysics, UCSF, San Francisco, CA, 2Beckman Laser Institute, UCI, Irvine, CA, 3Bioengineering, UCSD, San Diego, CA

BACKGROUND: We study the control systems that determine eukaryotic flagellar length. Chlamydomonas reinhardtii cells construct two structurally identical flagella that are equivalent to mammalian cilia. By severing one of the two flagella, we perturb the system and measure the recovery kinetics in what Rosenbaum et al (1969) first described as the long-zero response. APPROACH: We use a tunable IR femtosecond laser to induce single deflagellation in microfluidically trapped cells. By time-lapse imaging, we track the length kinetics of the response. We then use the length kinetics to fit parameters of a simple 4-parameter ODE model of the system. METHODS: The microscope system is comprised of an inverted microscope, external
optics to direct the laser beams into the microscope, a CCD digital camera, and hardware-software for control of laser power, specimen stage and microscope stand focus and illumination. The ablation laser used in this system is femto-second Ti:Sapphire laser, which is tunable from 710 - 990 nm. Software for computer control of all hardware and image acquisition is custom coded in the Labview programming language. FINDINGS/CONCLUSIONS: Considerable cell-cell variation exists in the long-zero response. Some cells completely recover to initial flagellar lengths with the classical deceleratory kinetics described by Rosenbaum et al (1969). However, we also observe other distinct recovery responses, including recovery by deceleratory kinetics to a shorter flagellar length, the classic overshoot described by Rosenbaum et al (1969), complete resorption of flagella with no regrowth, partial resorption followed by recovery to a shorter length, and oscillating recovery where the flagella recover to the initial length but then shorten and later lengthen. From analyzing our results we can determine the parameter ranges in our ODE model that can account for the kinetics data. Overall, we note that cell-cell variation cannot account for all of the variation we see because some temporal variation exists within individual cells. In order to minimize such variation as a result of cell cycle or growth conditions, we conducted our experiments in light-dark synchronized cells as well as in gametes.

Lipid Bodies in Chlamydomonas Reinhardtii.
N. Ullrich², Z. Wang¹, S. Joo¹, S. Waffenschmidt², U. Goodenough¹; ¹Biology, Washington University, St. Louis, MO, ²Biochemistry, University of Cologne, Cologne, Germany

Given current interest in the development of technologies that harvest lipids from microalgae and convert them into diesel biofuel, we have initiated analysis of lipid-body (LB) biosynthesis in the unicellular green soil alga Chlamydomonas reinhardtii. When deprived of nitrogen after entering stationary phase in liquid culture, C. reinhardtii cells proceed to produce abundant cytoplasmic LBs, as well as abundant starch, via a pathway that entails a regulated autophagy program. After 48 hr of N-starvation, LB content in the wild-type strain has increased 15-fold. When starch biosynthesis is blocked in the sta6 mutant, LB content increases 30-fold, documenting that genetic manipulation can enhance algal LB production. Use of cell-wall-less strains permitted development of a rapid “popped-cell” microscopic assay to quantitate LB content per cell, and permitted gentle cell breakage and LB isolation. The highly purified LBs contain 90% triacylglycerol (TAG) and 10% free fatty acids (FFA). The fatty acids associated with the TAGs are roughly 50% saturated (C:16 and C:18) and 50% unsaturated, half of which is oleic acid (C:18:1). The FFA are roughly 50% C:16 and 50% C:18. The LB fraction also contains a minor amount of phospholipid, with the same phospholipid profile as whole-cell extracts, but lacks any chloroplast-specific galactolipids, attesting to the purity of the preparation; the phospholipids presumably form bilayers or monolayers around the LBs. Low levels of protein are also present; SDS-PAGE resolves 3 polypeptides migrating as 68K, 55K, and 27K species. Nitrogen-stress-induced LB production in C. reinhardtii has the hallmarks of a discrete pathway that should be amenable to genetic manipulation and additional enhancement.

Overexpression of ZWF1 and YDR049W Protect Yeast from Oxidative Damage Caused by the Fermentation Inhibitor Furfural.
S. Allen, S. W. Gorsich; Biology, Central Michigan University, Mt. Pleasant, MI

Currently our nation is facing many environmental and economical concerns, raising the need for an alternative and renewable fuel source. One such fuel source that has been proposed and tested is bio-ethanol. Unfortunately before an ethanol-based fuel industry can be achieved, several complications must be addressed. While the current process of producing bio-ethanol using Saccharomyces cerevisiae (baker’s yeast) using corn starch is quite efficient, our nation lacks the amount of corn needed to produce the desired amount of bio-ethanol for fuel. However, alternative substrates that would replace cornstarch substrates, such as lignocellulosic biomass waste, produce multiple inhibitors during the fermentation process. These inhibitors prevents
yeast from efficiently producing ethanol. These inhibitors include furfural, hydroxymethylfurfural, and vanillin. In order to overcome this problem, robust yeast strains are needed that can survive the stresses present during the industrial fermentation process. Our objective is to genetically engineer a more robust yeast strain using genes we have previously identified as functioning in furfural tolerance. Two of these genes are ZWF1 and YDR049W which were both subcloned into the pRS425-MET25 expression vector. These subclones were used to see if their overexpression would increase growth and decrease cellular damage to membranes, actin cables, and chromatin as assayed using fluorescence markers in the presence of furfural. When ZWF1, a pentose phosphate pathway gene, was overexpressed yeast grew better in the presence of furfural and furfural induced damage to membranes, actin cables, and chromatin was less severe. The overexpression of YDR049W was less effective at reducing furfural sensitivity compared to ZWF1 overexpression. Overexpressing ZWF1 and possibly other genes will lead to more robust yeast that are capable of surviving the stresses associated with the industrial fermentation of lignocellulosic biomass waste.

Engineering of Fatty Acid Production and Secretion in Saccharomyces cerevisiae. G. Ribeiro, M. Côrte-Real, B. Johansson; Departamento de Biologia, Universidade do Minho, Braga, Portugal

Production of renewable liquid biofuels that can substitute fossil fuel, has emerged as a major challenge for applied biology. Biodiesel, in the form of fatty acid esters, produced by oleaginous microorganisms could be an attractive alternative, since the utilization of diesel fuel is more efficient than for example ethanol. Oleaginous yeasts may accumulate very high (60%) levels of intracellular lipids but two drawbacks are the relatively complicated extraction process and the subsequent transesterification with the accompanying glycerol by-product formation. The objective of this work is to apply metabolic engineering of fatty acid synthesis and secretion in the model yeast S. cerevisiae in order to create a microorganism able to produce and secrete free fatty acids or fatty acid esters. S. cerevisiae is a proper model, since lipid metabolism has been studied extensively and all genes encoding enzymes directly involved in lipid synthesis are known. This organism has also been reported to acquire oleaginous properties by no more than three genetic modifications(1). In the yeast S. cerevisiae, activation of exogenous long-chain fatty acids to coenzyme a derivatives, prior to metabolic utilization, is mediated by the fatty acyl-CoA synthetases Faa1p and Faa4p. It has been shown that free fatty acids are secreted from a FAA1,4 double mutant(2). This modification will be combined with modifications of core fatty acid elongation, such as overexpression of acetyl-CoA synthetase (Acs1p), in an attempt to improve fatty acid production rate. Essential for this work is to facilitate a biological platform for efficient fatty acid or lipid production. In this work, the “delitto perfetto” method (3) was applied to delete these two fatty acyl-CoA synthetases generating genetically clean strains without markers or bacterial DNA. Results show that this technique can be used to generate multiple knockouts by recycling the marker gene. 1.Kamisaka Y, Tomita N, Kimura K, Kainou K, Uemura H. Beta-Arrestin1 as the Pivotal of Multiple Signals Promotes Leukemia Progression. H. Liu, J. Long, P. Zhang, Z. Tu, L. Zou; ^1Center for Clinical Molecular Medicine, Children's Hospital, Chongqing Medical University, Chongqing, China, ^2Department of Clinical Biochemistry in Laboratory Faculty, and the Key Laboratory of Laboratory Medical Diagnostics in the Ministry of Education, Chongqing Medical University, Chongqing, China
Arrestins (Arrs) are scaffold proteins consisting of four members: β-arrestin1 (β-Arr1), β-arrestin2 (β-Arr2), α-arrestin, and s-arrestin. Only β-Arr1 and β-Arr2 are ubiquitously expressed, and mediate desensitization, sequestration, and recycling of G protein-coupled receptors (GPCRs). Recent studies showed that β-arrestins also serve as modulators of intracellular signals, including ERK, JNK3, ASK1, IGF-1 and PI3K-Akt, through which regulate various cellular functions in both normal and malignant cells. β-Arrs are found to be associated with tumor signaling pathways such as TGF-β1, P53/MDM2 and NF-κB. Our previous data have disclosed that β-Arr1 promotes MMP9 activity and tumor angiogenesis through PI3K signals by providing a suitable microenvironment for tumor progression. However, little is known about β-Arrs function in leukemia. Here we collected the bone marrow (BM) and periphery blood (PB) samples from 95 patients with newly diagnosed leukemia, 36 volunteers without malignant hematological diseases as the control, to investigate the expression of β-Arrs. The results showed that all the mRNA and protein levels of β-Arr1 and β-Arr2 increased significantly in both BM and PB samples of leukemia patients (P<0.05 or P<0.01) comparing with controls. However, there was no significant difference of β-Arr expressions among the diverse subtypes of leukemia (AML, ALL and CML) samples (P>0.05), but the relative expression of β-Arr1 was always higher than β-Arr2 in the same patient. We further found that over-expression of β-Arr1 could promote leukemia cells to proliferate and vice versa. Interestingly, PI3K/Akt, JNK/STAT, NF-κB and Wnt/β-catenin pathways were all activated in the leukemia cells, and could be reduced by knocking down β-Arr1. In addition, the expressions of downstream genes of these signals including cyclin-D1, c-fos and c-myc were increased too. Furthermore, the expressions of cyclin-D1, c-fos and c-myc could be suppressed by blocking β-Arr1. Our data firstly reveal a pivotal role for β-arrestin1 in leukemia cells, in which β-Arr1 plays the hinge of multiple signals by promoting cell proliferation for the pathogenesis and progression of leukemia.

A Novel Mechanism for Chemo-Immune Modulation: Cancer Chemotherapy-Induced Elevation of MHC I and ISG15 Expression.
S. Wan, Y. Tsai, L. F. Liu; University of Medicine and Dentistry of New Jersey, Piscataway, NJ

It has long been recognized that some chemotherapeutic agents, including cyclophosphamide, gemcitabine, cisplatin, and 5-flourouracil, have immuno-modulating functions, and can be used in combination with immunotherapy for better tumor killing efficacy. A number of mechanisms have been proposed including the suppression of regulatory T cells. However, the underlying mechanism for the chemo-immune modulation remains largely unclear. In this study, we showed that topotecan (TPT), as well as other chemotherapeutic agents (etoposide, taxol, vinblastine, and cisplatin), can upregulate the expression of Major Histocompatibility Complex Class I (MHC I) and Interferon-Stimulated Gene 15 (ISG15) in tumor cells, through induction of interferon-beta (IFN-b). Elevated MHC I on tumor cell surface sensitizes the cell to antigen-specific cytotoxic T lymphocyte killing. ISG15, an interferon-inducible cytokine, is known to stimulate T cell and induce natural killer cell proliferation. Here, we showed that conditioned media from TPT-treated ZR-75-1 cells induced elevation of MHC I and ISG15 expression in untreated cells, indicating the secretion of a transmissible factor(s) that is (are) responsible for the induction. Furthermore, we demonstrated that IFN-b was responsible for the TPT effect on MHC I and ISG15, as interferon receptor 1 subunit (IFNAR1) siRNA knockdown diminished the induction, and neutralizing antibody against IFN-b, but not IFN-a, blocked the induction. Finally, we found that NF-kB activation inhibitors block the MHC I and ISG15 induction by TPT, suggesting a pivotal role of NF-kB in mediating the TPT effect on MHC I and ISG15. In conclusion, we propose that induction of MHC I upregulation by chemotherapeutic agents such as TPT may be responsible for at least in part the immuno-modulatory effect of cancer chemotherapy. This chemo-immune modulation is likely to be through a series of events involving chemo-induced NF-kB activation, IFN-b secretion, and elevated expression of MHC I and ISG15.

Water Soluble Wolfberry Phytochemicals Induce Cell Cycle Arrest and Apoptosis in Cancer Cells.
Y. Jiang, D. Lin; Kansas State University, Manhattan, KS

Objective: The objective of the current study is to determine the effect of water soluble phytochemicals of Lycium barbarum (wolfberry), a common Chinese herbal medicine, on cell viability and induction of apoptosis in cancer cell lines. Methods: Three cancer cell lines, including human colon cancer SW480, human leukemia Jurkat, and feline lymphoma F1B cells, were used in this study. Wolfberry fruits were purchased from the local grocery store. The water soluble wolfberry extracts (i.e., wolfberry phytochemicals) were isolated, freeze dried, and re-dissolved in cell culture media. Total polyphenols were analyzed by Folin-Ciocalteu method. Antioxidant activity was determined by ferric-reducing antioxidant power (FRAP) assay. Cell cycle arrest was determined by flow cytometry. Western blotting was used to monitor alteration of protein expression. Results: Total polyphenols in water soluble wolfberry extracts was 1873 mg gallic acid / 100 g dry weight, and antioxidant activity of the extracts was 7771.2 micromol Trolox/ 100 g dry weight. Water soluble wolfberry extracts inhibited growth of SW480, Jurkat, and F1B cells in a dose dependent manner. The growth inhibition effects were found to be 1mg/ml at 48 hours after treatments in SW480 and Jurkat cells. Flow cytometry results indicated that the treatments of wolfberry extracts induced cell cycle arrest in G2M phase and consequent apoptosis at 48 hours after treatments. Protein levels of cyclin B1, cleaved caspase-3, and cleaved poly(ADP-ribose) polymerase (PARP) were significantly increased by the treatments as determined by Western blotting. Conclusions: Water soluble wolfberry phytochemicals were effective in inhibiting cell growth and inducing apoptosis in cancer cells in culture. Further studies on identification of major active components and potential synergy of the wolfberry phytochemicals may help to develop novel complementary therapeutic agents and/or dietary regimens for cancer prevention and treatment.

Controlling Tumor Inflammation: Role of Integrin \(\alpha_4\beta_1\) in M1-M2 Macrophage Polarization.
L. Nguyen, P. Foubert, J. A. Varner; Medicine, UCSD Moores Cancer Center, San Diego, CA

Two types of macrophages linked to cancer, M1 and M2, secrete cytokines and immune response factors that inhibit or stimulate tumor progression, respectively. By increasing the M1 to M2 ratio in the tumor microenvironment, the fate of the tumor can be controlled. Previous research has shown that the accumulation of macrophages in tumors is regulated by the integrin \(\alpha_4\beta_1\). Blocking the function of this integrin can reduce tumor growth, inflammation, and metastasis. Therefore, we investigated the role of \(\alpha_4\beta_1\) in controlling the M1/M2 macrophage ratio. Our experiment used a mouse model with subcutaneous injection of Lewis Lung Carcinoma (LLC) tumor cells in wild type (WT) and mutant mice (Y991A or YA), which express a non-functional \(\alpha_4\) subunit in the cytoplasmic region of the tail. First, we isolated tumor infiltrating macrophages using magnetic-activated cell sorting (MACS). Then, we performed quantitative PCR for different cytokines to distinguish M1 and M2 macrophages. We observed a downregulation of immunosuppressive M2 cytokines (TGF-\(\beta_1\), but non-significant reduction in IL-10. However, there was an upregulation of immunostimulatory M1 cytokines (IL-12, IFN-\(\gamma\), TNF-\(\alpha\)) in the Y991A mice. This may indicate a general reduction in tumor inflammation, angiogenesis, lymphangiogenesis, and metastasis, as well as increased anti-tumor immunity. The ability to manipulate the M1/M2 ratio may lead to better prognosis and novel treatments for future cancer therapy.

Different Induction of Granulocytic Differentiation by HDAC Inhibitors and All-Trans Retinoic Acid in Human Acute Promyelocytic Leukemia HL-60 and NB4 Cells Is Associated with the Involvement of C/EBP\(\alpha\), PU.1 and G-CSF Receptor Signals.
CCAAT/enhancer-binding protein-alpha (C/EBPα) and PU.1 are the basic transcription factors that control differentiation-related genes, including G-CSFR and human neutrophil elastase (HNE). Here, we analyzed a role of C/EBPα and PU.1 in the human acute leukemia HL-60 and NB4 cells in association with a modified chromatin structure by histone deacetylase (HDAC) inhibitors. We demonstrated that diverse HDAC inhibitors - FK228, sodium phenyl butyrate and vitamin B3 in combinations with all trans-retinoic acid (RA) effectively accelerated and enhanced HL-60 but not NB4 cell granulocytic differentiation detected by NBT test and CD11b or CD34 expression by flow cytometric analysis. HDAC inhibitors induced a time- and dose-dependent accumulation of hyper-acetylated histone H4 in both cell lines with the delay in NB4 cells. Chromatin immunoprecipitation analysis revealed that 6 h-pretreatment with sodium phenyl butyrate before the combined treatment with RA and vitamin B3 caused histone H4 acetylation in the G-CSF and the G-CSF receptor promoter regions in HL-60 cells. The time-dependent different induction of HL-60 and NB4 cell differentiation was coincident with different activation of C/EBPα and PU.1 binding activity to the G-CSFR and the HNE promoters in electrophoretic mobility shift assay. The results indicate that epigenetic events, such as histone acetylation, might be involved in the activity modulation of the key transcription factors responsible for the induction of leukemia cell granulocytic differentiation.

B-Catenin Mediates FGF-7-Induced Ocular Surface Squamous Neoplasia in the Transgenic Mice.
C. Liu1, Y. Zhang1, M. Call1, M. M. Taketo2, W. W. Kao1; 1Ophthalmology, university of cincinnati, Cincinnati, OH, 2Pharmacology, Kyoto University, Kyoto, Japan

We have recently reported that excess fibroblast growth factor-7 (FGF-7) in Krt12rtTA/rtTA/tetO-FGF-7 double transgenic mice induced by doxycycline (Dox) resulted in a corneal epithelial tumor resembling human ocular surface squamous neoplasia (OSSN). In this study, we further investigate the role of β-catenin in mediating FGF-7 induced corneal tumorigenesis. We examined the role of FGF-7/β-catenin signaling in OSSN. Pannus surgically removed from patients exhibited excess FGF-7 and nuclear β-catenin. In vitro, FGF-7 induces stabilization and nuclear translocation of β-catenin in human corneal epithelial cells. Conditional Ctnnb1 loss- and gain-of-function mutants were expressed in tet-On Krt12rtTA/rtTA/tetO-FGF-7 mice that manifested OSSN upon Dox induction. Loss of Ctnnb1 from the corneal epithelium did not have significant effects on corneal homeostasis, but abolished OSSN caused by FGF-7 in Dox-treated Krt12rtTA/rtTA/tetO-FGF-7/tetO-Cre/Ctnnb1lox(E2-6)/lox(E2-6) mice. In contrast, in Dox-treated Krt12rtTA/rtTA/tetO-Cre/Ctnnb1floxed E3/Wt mice, expression of constitutive active β-catenin in differentiated (Keratin 12-positive) corneal epithelial cells trigger de-differentiation of corneal epithelial cells into more primitive progenitor cell phenotype expressing p63, and suppression of K12 keratin and Pax-6. The results suggest that β-catenin plays a pivotal role in mediating the formation of OSSN. Thus, the administration of inhibitor(s) that prevents activation of β-catenin may be beneficial for treating OSSN. β-catenin in human corneal epithelial cells.

A Critical Concentration of CD8+ T Cells Is Required to Block Growth of B16 Murine Melanoma Cells.
S. Budhu1, A. Pandolfi2, S. Han3, A. Constantinescu4, G. Catalano5, J. Loike1, R. Clynes4, S. Silverstein1,4, 1Physiology and Cellular Biophysics, Columbia University, New York, NY, 2MD/PhD Program, Albert Einstein College of Medicine, Bronx, NY, 3Columbia College, New York, NY, 4Department of Medicine,, Columbia University, New York, NY, 5Microbiology, Columbia University, New York, NY
Li et al (PNAS 99:8289-94, 2002) derived an equation that can be used to calculate the critical neutrophil concentration, the concentration of neutrophils required to hold bacterial growth constant. We report here that this equation can be used to calculate the critical concentration of CD8+ OT-1 cells (CTC) required to control growth of SIINFEKL peptide-pulsed B16 melanoma cells and of SIINFEKL-B16 cells in spheroids in three-dimensional collagen-fibrin gels. Combined with clonogenic assays for B16 cells, the collagen-fibrin gel system employed in these studies are 3,500 to 4,000-fold more sensitive than the packed-cell-pellet type assays generally used to measure CD8+T-cell cytolytic activity. We report that the CTC is 3.9 x 10^7 OT-1 cells/ml collagen-fibrin gel, and that ≥10^7 OT-1 cells/ml gel kill 100% of 2 x 10^7/ml SIINFEKL-B16 cells in these gels in 7 days. The efficiency of T-cell killing (as measured by the killing constant, k, for OT-1 cell-mediated cytolysis of SIINFEKL-B16 cells [~8 x 10^-10 ml/OT-1 cell/min]) is comparable to that calculated for LCMV-specific CD8+T-cell-mediated cytolysis of LCMV-peptide-pulsed splenocytes in mouse spleen in vivo, and ~7 fold greater than for OT-1 cell killing of ova peptide-expressing B16 cells in B16 melanomas in vivo. Accordingly, the CTC for OT-1 cell killing of ova-B16 cells in ova-B16 melanomas In Vitro is ~9 fold lower in collagen-fibrin gels than OT-1 killing of ova peptide-expressing B16 cells in B16 melanomas in vivo. Thus collagen-fibrin gels provide a useful system with which to explore kinetic and functional relationships between CD8+T-cell effector functions In Vitro and in vivo. Supported by NIAID grant AI20516.

A Role for CtIP in DNA Interstrand Cross-Link Repair.
M. Duquette1,2, Q. Zhu3, M. W. Berns3, C. McGowan1,2; 1Department of Molecular Biology, The Scripps Research Institute, La Jolla, CA, 2Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, 3Department of Bioengineering, University of California, San Diego, La Jolla, CA

A DNA interstrand cross-link (ICL) is a highly toxic form of DNA damage that consists of a covalent bridge between complementary strands of the DNA double helix. An ICL provides a physical barrier that prevents DNA strand separation during replication and transcription, thus causing cell death if not properly repaired. In order to characterize which factors are required for initiating the repair of ICLs in human cells during S-phase, we employed a novel laser scissor assay that allows us to generate ICLs in specific regions of the cell nucleus by activating psoralen by irradiation with laser light at the effective wavelength of 365 nm. We found that CtIP, a conserved protein that acts cooperatively with the Mre11-Rad50-Nbs1 (MRN) complex in double strand break repair, is required for ICL repair. We found that enrichment of the repair proteins γH2AX, ATM, FANCD2 and Rad51 at nuclear regions containing ICLs is reduced in CtIP siRNA depleted cells compared to control siRNA treated cells. In contrast, depletion of the nucleases Mus81 or Xpf, which have been proposed to act early in ICL repair, had no effect on γH2AX levels at laser activated ICLs. We propose that CtIP acts in concert with MRN to initiate repair at replication forks stalled at ICLs enabling recombination mediated repair to proceed.

Independent, Stochastic Competition between Mitotic Slippage and Death Activation Governs Live-Or-Die Decisions in Response to Kinesin-5 Inhibitors.
H. Huang, J. Shi, T. J. Mitchison; Department of Systems Biology, Harvard Medical School, Boston, MA

After a prolonged treatment of Kinesin-5 inhibitors (K5Is), a class of anti-mitotic drugs now in phase I clinical trial, cancer cells display large intra- and interline variation in their live-or-die decisions. It has been proposed that cell fates are dictated by two competing pathways, one involving death activation, the other protecting cyclin B1 degradation/mitotic slippage (Gascoigne and Taylor, 2008). This model has not been rigorously tested both experimentally and computationally: for example, it is unclear whether these two pathways are mechanistically coupled, or independent. In this study, we present evidence supporting that they are independent pathways, and the stochastic, kinetic competition between the two determines cell fates. We
developed methods to separate the two pathways experimentally in four human cancer cell lines with different degrees of death sensitivity. This allowed us to measure kinetics that are normally hidden in drug treatment alone, i.e. cyclin B1 degradation kinetics in death-sensitive cell lines, and death kinetics during mitotic arrest in death-resistant lines that tend to slip out of mitosis before they die. We then used Monte-Carlo methods to randomly select events from these two experimentally measured probability distributions, and showed that for all four lines, the simulated behavior matched the observed behavior when both processes occur together in K5I treatment. We further showed experimentally, that cyclin B1 degradation kinetics is unaffected when death kinetics is stimulated by co-treatment with TRAIL, and death kinetics is unaffected when cyclin B1 degradation is prevented by Cdc20 knockdown. This again argues the two pathways are independent. Taken together, our results reveal that intra- and interline variation of cell fate in response to K5I originates from independent, stochastic competition between death activation and cyclin B1 degradation.

Expression of βig-H3 in Cancer Stroma Derived from Mesenchymal Stem Cells in the Lung Adenocarcinoma.
S. Shin, E. Jeon, S. Heo, J. Kim; School of Medicine, Pusan National University, Gyeongsangnam-do, Korea, South

βig-h3 plays a pivotal role in tumorigenesis and metastasis as an extracellular adhesion molecule. However, the molecular mechanisms involved in the expression of periostin in tumor tissues are largely elusive. Lysophosphatidic acid (LPA) is a bioactive lipid that promotes cancer cell adhesion and motility through activation of G protein-coupled receptors. In the present study, we demonstrate for the first time that LPA stimulates the expression of βig-h3 in human adipose tissue-derived mesenchymal stem cells (hASCs). The LPA-induced expression of βig-h3 was abrogated by pretreatment of the cell with Ki16425, an antagonist of LPA receptors, or by depletion of LPA receptor 1 expression with small interfering RNA (siRNA) or small hairpin RNA (shRNA). Furthermore, conditioned media from A549 human lung adenocarcinoma cells induced expression of βig-h3 and the expression of big-h3 was completely abrogated by treatment with Ki16425 or silencing of LPA receptor 1, suggesting that LPA is involved in the cancer conditioned media-induced βig-h3 expression. In addition, treatment of A549 cells with recombinant βig-h3 protein enhanced proliferation, adhesion, and invasion of A549 in vitro. Taken together, these results suggest that cancer-derived LPA stimulates secretion of βig-h3 from hASCs and βig-h3 play a key role in tumorigenesis as a paracrine factor.

Differential Effects of Hypoxia and Actin-Sequestering Protein, Thymosin Beta-4 on HeLa Cell Survival and Death through ROS-Mediated HIF-1α Stabilization.
J. Oh, Y. Ryu, E. Moon; Bioscience and Biotechnology, Sejong University, Seoul, Korea, South

Here, we investigated the effect of actin-sequestering protein, thymosin beta-4 (TB4)-induced hypoxia on tumor cell survival and death. The increased TB4 level was detected in human gastric and colon cancer mass. Hypoxia inducible transcription factor (HIF)-1α was stabilized by TB4 in HeLa cervical tumor cells. When cells were treated with TB4 protein (TB4P), a significant increase in intracellular ROS level was detected. The increased level of HIF-1α by TB4P was reduced by the treatment with N-acetylcysteine (NAC), a well-known ROS scavenger. A basal level of tumor cell death was reduced by TB4. In contrast, hypoxia increased ROS and the basal level of tumor cell death. While HIF-1α stabilization was independent of the relative intracellular ROS level, the effect of exogenous H2O2 on cell density was different. While 10nM H2O2 increased cell density, more than 10mM H2O2 reduced it. NAC treatment attenuated TB4-increased cell density. Paclitaxel-induced tumor cell death was reduced under all hypoxia conditions but no decrease by TB4 was detected when cells were transfected with HIF-1α-siRNA. Paclitaxel-induced B16F10
mouse melanoma regression was physiologically inhibited in TB4-transgenic mice compared to wildtype mice. Taken together, these findings demonstrate that TB4 could play a role in tumor cell resistance to anticancer agents through ROS-mediated HIF-1α stabilization. Our data also show that the effect of TB4-induced hypoxia on enhancing cell survival is different from the effects of oxygen-deficient hypoxia on increasing cell death. These results suggest that TB4 could be a novel modulator to control tumor cell survival and death through the regulation of ROS production.

Photodynamic Therapy in an HCT116 Human Colon Cancer Xenograft Model Using a Chlorine-Based Photosensitizer DH-II-24.
Y. Lim, J. Yoo, D. Park, Y. Kim, K. Ha; Molecular and Cellular Biochemistry and Vascular System Research Center, Kangwon National University School of Medicine, Chun-Cheon, Korea, South

While photodynamic therapy (PDT) has been recognized as a promising therapeutic modality for the treatment of various cancers and diseases, developments of effective photosensitizers are highly desired to improve the prospect for the use of PDT. In this study, we evaluated DH-II-24, a new photosensitizer, for antitumor PDT In Vitro and in vivo. Loaded into human colorectal carcinoma cells (HCT116), DH-II-24 was primarily accumulated in mitochondria, lysosomes and endoplasmic reticula. Administration of DH-II-24 followed by light exposure induced necrotic cell death in a dose-dependent manner, whereas DH-II-24 in the absence of light displayed a minimal cell death. In order to investigate the distribution and pharmacokinetics of the photosensitizer in vivo, DH-II-24 was intravenously injected to female BALB/c nude mice. Fluorescence imaging In Vivo showed that DH-II-24 was rapidly distributed across the entire body and then mostly eliminated at 24 h. Next, effectiveness of DH-II-24-mediated PDT was examined on colorectal carcinoma xenografts established subcutaneously in BALB/c nude mice. DH-II-24 (1 mg/kg, i.v. administration) followed by light exposure significantly suppressed growth of xenograft tumors, compared to light exposure or DH-II-24 alone. Histological examination revealed necrotic damage in PDT-treated tumors, concomitantly with severe damage of tumor vasculature. These results suggest that DH-II-24 is a potential photosensitizer of photodynamic therapy for cancer.

Functional Analysis of Glucocorticoid-Regulated Genes in Childhood Acute Lymphoblastic Leukemia.
M. Carlet1, M. Wasim2, G. Gruber1, J. Rainer2,1, C. Ploner1, R. Kofler1,2; 1Department of Molecular Pathophysiology, Biocenter, Innsbruck Medical University, Innsbruck, Austria, 2Tyrolean Cancer Research Institute, Innsbruck, Austria

Glucocorticoids (GC) have pronounced effects on metabolism, differentiation, proliferation and cell survival. In certain lymphocytes and lymphocyte-related malignancies, GCs inhibit proliferation and induce apoptosis. This has led to their therapeutic use in malignant lymphoproliferative disorders. Our lab addressed the molecular basis of the anti-leukemic GC effects by comparative gene expression profiling using acute lymphoblastic leukemia (ALL)-children and related experimental systems. This provided a list of candidate genes for the anti-leukemic GC effects. Two interesting members of this list are SIK1 and PFKFB2 that have both been implicated in energy metabolism and survival. The former exerts pro- and anti-apoptotic functions in various biological systems, the latter is a regulator of glucose metabolism, a phenomenon that plays a crucial role in lymphoid cell death decisions. A third candidate, ZBTB16 is a transcriptional repressor involved in differentiation of myeloid cells and translocated to the RAR-alpha receptor in acute promyelocytic leukemia. To test their possible involvement in GC-induced cell death and/or cell-cycle arrest, we generated lentiviral constructs for conditional expression of SIK1, ZBTB16 and the 2 major PFKFB2 splice variants. Using these constructs, we established several stable transfected subclones of the human ALL cell line CCRF-CEM with tetracycline-regulated expression of our genes. Functional analyses showed a different role of the two isoforms of PFKFB2 in modulating GC-induced cell death. While PFKFB2-15A was without
effect, overexpression of PFKFB2-15B entailed accelerated GC-induced apoptosis suggesting that deregulation of glucose metabolism by GC may contribute to GC-induced cell death in ALL cells. on the other hand, overexpression of ZBTB16 resulted in pro-survival effects, explained by its inhibitory role on GC-dependent transcription. Overexpression of SIK1 in CCRF-CEM subclones had no detectable effect on survival or cell cycle progression, neither alone nor in combination with GC. It may, however, contribute to other effects of GC on innate and adapted immunity. To address this further, we are currently investigating the role of this gene in SIK1-KO mice.

**Elevated IFIT2 Expression Promotes Oral Squamous Cell Carcinoma Differentiation.**  
*K. Lai, T. Lee; IBMS, Taipei, Taiwan*

Interferon-induced protein with tetratricopeptide repeats 2 (IFIT2) is one of most responsive interferon-stimulated genes to interferons, viruses, and a variety of agents. However, the biological functions of IFIT2 are poorly understood. Our previous studies have shown that elevated IFIT2 protein expression was positively associated with tumor differentiation status and better prognosis in patient with oral squamous cell carcinoma (OSCC). However, whether IFIT2 plays any role in OSCC differentiation is currently unknown. To this end, confluence-induced differentiation model was established and several well-known differentiation marker proteins, such as Cytokeratin10/Cytokeratin 13 (CK10/13) and involucrin were used to define distinct stages of OSCC differentiation. We found that IFIT2 expression was increased in early differentiation and sustained higher in terminal differentiation. We observed that IFIT2 expression was higher in superficial cell layer as compared with basal cell layer by using immunostaining assay. These results confirmed that IFIT2 expression was positive associated with OSCC differentiation status. Furthermore, we overexpressed IFIT2 protein in OSCC cells, and select two stable clones to study whether IFIT2 could regulate OSCC differentiation. Under pre-confluence condition, CK10/13 and involucrin levels were increased by 12.8 and 1.8-fold, respectively, in IFIT2-overexpressed cells as compared with cells transfected with control plasmid. Similarly, involucrin level was increased by 5.8-fold in IFIT2-overexpressed cells as compared with cells transfected with control plasmid under post-confluence condition. These results indicate that elevated IFIT2 expression may regulate OSCC differentiation. Moreover, Immunoprecipitation-western and confocal image analysis showed that IFIT2 interacted with CK10/13. Thus, elevated IFIT2 expression may be a pre-requisite of OSCC differentiation through binding of CK10/13.

**STIM1 Remodels Calcium Signaling for Cancer Cell Proliferation and Metastasis.**  
*P. Lin1, M. Shen1,2; 1Department of Pharmacology, National Cheng Kung University, Tainan City, Taiwan, 2Department of Obstetrics and Gynecology, National Cheng Kung University, Tainan City, Taiwan*

Store-operated calcium entry (SOCE) is the predominant Ca2+ entry mechanism in nonexcitable cells. Recent studies have identified two genes, STIM1 (stromal interaction molecule 1) and Orai1 (also named CRACM1), that are responsible for SOCE activation. Here we demonstrate the important role of STIM1 in promoting cancer cell proliferation and metastasis. Overexpression of STIM1 enhanced the invasive migration of cervical cancer cells, whereas knockdown of endogenous STIM1 significantly inhibited that of cervical cancer cells. The molecular mechanisms by which STIM1 regulated the invasive migration involved the modulation of focal adhesion turnover and subsequently cellular contraction force. Knockdown of STIM1 inhibited cervical cancer cell proliferation and caused cell cycle arrest at S and G2/M phase by p21 upregulation and Cdc25C downregulation. In severe combined immune deficiency mice model, we subcutaneously injected the clones of cervical cancer cells with differential STIM1 expression. STIM1 overexpression enhanced tumor formation and increased tumor vessel density. In contrast, STIM1 knockdown retarded tumor growth and decreased vessel density. Treatment with
SOC channel inhibitors, SKF96365 and 2-aminoethoxydiphenyl borate (2-APB), also inhibited tumor formation and angiogenesis. In 75% of surgical specimens we examined (n=30), STIM1 was overexpressed in cervical cancer tissues. In addition, the expression level of STIM1 in tumor tissues was closely correlated with tumor size and pelvic lymph node metastasis, which are two major poor prognostic factors for early-stage cervical cancer. Thus, the processes of proliferation and metastasis remodeled by STIM1 overexpression may provide the therapeutic intervention.

Inhibitory Effects of miR-200a on Nasopharyngeal Carcinoma Cell Growth, Migration and Invasion Are Mediated by Different Targets.
H. Xia¹, S. Ng¹, H. Kung², M. Lin³; ¹Integrative Chemical Biology Laboratory, Department of Chemistry, The University of Hong Kong, Hong Kong, China, ²State Key Laboratory in Oncology in South China, The Chinese University of Hong Kong, Hong Kong, China

Abstract: Nasopharyngeal carcinoma (NPC) is a cancer originating in the nasopharynx with viral, dietary, and genetic factors implicated in its causation. The molecular basis of NPC pathogenesis has not been well defined. Recently studies have shown that miR-200a was downregulated in NPC by microRNA microarray analysis. To further investigate the function of miR-200a in NPC carcinogenesis, we analysed miR-200a expression in a panel of different differentiated NPC cell lines, including C666-1 (un-differentiation), CNE-1 (high differentiation), CNE-2 and HNE1 (low differentiation). We found that miR-200a expression was relatively lower in un-differentiated C666-1 than in highly differentiated CNE-1 cells. By loss-of-function and gain-of-function studies, we observed that over-expression of miR-200a inhibited C666-1 cell growth, migration and invasion, while knock-down of miR-200a enhanced growth, migration and invasion in CNE-1 cells. To understand the molecular mechanisms, we further identified ZEB2 and CTNNB1 as the functional downstream targets of miR-200a to mediate these effects. Interestingly, we found that siRNA suppression CTNNB1 mainly affect cell growth while siRNA suppression ZEB2 mainly affect cell migration and invasion in NPC cells. These data suggest that inhibitory effects of miR-200a on NPC cell growth, migration and invasion are mediated by different targets and pathways. Hence, miR-200a might serve as a regulatory factor of NPC carcinogenesis as well as a potential therapeutic candidate for miRNA-based cancer gene therapy. Keywords: microRNA, Nasopharyngeal Carcinoma, migration, invasion, CTNNB1, ZEB2

An Activator of PHD2, KRH 102140, Down-Regulates HIF-1α in Human Cancer Cells.
Y. Soh, Y. Park, S. Kim, M. Nepal; Dental Pharmacology, Chonbuk National University, Jeonju, Korea, South

Hypoxia-inducible factor-1 (HIF-1) is a transcriptional activator that functions as a master regulator of cellular and systemic oxygen homeostasis. HIFs are negatively regulated by a family of prolyl hydroxylases (PHD1-3). The PHD2 isofrom is the main down-regulator of HIFs in normoxia and mild hypoxia, but chemical activators of PHD2 are relatively unknown. Thus, the present study was undertaken to find new activator of PHD2 and to investigate the potential of the compound as a regulator of HIF-1α. Previously, we reported a PHD2 activator, KRH102053 which decreased the protein level of HIF-1α and inhibited angiogenesis. Among derivatives of KRH102053, KRH102140 was found to have more potent than KRH102053 in attenuating HIF-1α. The effects of KRH102140 on controlling HIF were examined in human HOS osteosarcoma, and human HepG2 hepatoma cells. Under our experimental conditions, KRH102140 decreased the protein level of HIF-1α and the mRNA levels of HIF-regulated downstream target genes, which are related to angiogenesis and energy metabolism. Consistent with these results, KRH102140 also significantly inhibited the degree of tube formation in human umbilical vein endothelium cells. These results suggest that KRH102140 have the potential for use as therapeutic agents against various diseases associated with HIF.
HSP70 & HSP90 Promote HSP60 Migration from Cytosol to Mitochondria in Human Colon Cancer.

H. Choi, Y. Hwang, S. Hong, D. Kwak, Y. Jeung, Y. Choi, D. Kim, B. Kim, S. Kim, J. Yang; Gachon University of Medicine and Science, Incheon, Korea, South

Heat Shock Proteins (HSPs), which act as chaperone to refold denatured protein by stress, have been studied to understand cell protection mechanism of various stress responses: Reductive Oxidant Species (ROS), Heat shock, virus infection, cancer and so on. In these conditions, expression of HSPs is remarkably increased. Specially, HSP60 is most abundant protein not only in mitochondria (mtHSP60), but also in cytosol (cyHSP60). While both cyHSP60 and mtHSP60 in normal cells reveal almost equal amount, in stress situation, mtHSP60 is extremely accumulated to protect in mitochondrial matrix and most of cytosol HSP60 quickly immigrates into mitochondria. We found same phenomenon in human cervix, breast and colon cancer in our previous study. Solving to understand these result, we analyzed mitochondrial import system or Transporter Outer Membrane (TOM) complex's mechanism. We obtained normal and colon cancer tissues from four colon cancer patients. We performed co-IP, using non-denature lysis buffer, IgG-A agarose bid, and HSP60 primary antibody and carried out western blot analysis. In results, expressions of cyHSP60-attached HSP70 and HSP90 more increased in colon cancer than normal tissues. The western blot result suggests that cancer cell's cyHSP60 transfer to mitochondria utilizing HSP70 and HSP90. Recently studies have demonstrated that high accumulation of mtHSP60 stabilizes survivin protein which kind of cancer specific gene involved in anti-apoptosis.

Activation of Ras Activity by Grb7 in Cell Migration and Cancer Progression.

P. Chu, T. Shen; Department of Plant Pathology and Microbiology, National Taiwan University, Taipei, Taiwan

We have previously reported that growth factor receptor-bound protein 7 (Grb7) enable phosphorylated by FAK to facilitate cell migration. More recently, in our laboratory a novel pathway via FAK-Grb7-ERK signaling axis was proposed in cell migration in response to integrin activation. Here, we further demonstrated that Grb7’s RA domain presents a high affinity in association with K-Ras and N-Ras. Moreover, overexpression of wild-type Grb7 was able to promote K-Ras activity but not Y338F mutant, implying that FAK could relay to MAPK cascade via phosphorylating Grb7 and promoting Ras activation in the regulation of cell migration. Consistently, we also found that, under EGF stimulation, wild-type Grb7 can be phosphorylated, enhance cell migration, protect cells from UV-induced apoptosis, and enhance Ras activity. Further studies will elucidate the molecular mechanisms by which Grb7 enables Ras activation and the significance and importance of this novel signaling event in cancer development.

Coronin-1C Expression in Metastatic Melanoma Controls Actin-Dependent Invasive Motility.

D. Roadcap1, P. A. Groben2, N. E. Thomas2, J. Bear1; 1Lineberger Cancer Center, UNC-Chapel Hill, Chapel Hill, NC, 2Dermatology, UNC-Chapel Hill, Chapel Hill, NC

Mammalian Coronin proteins play an important role in regulating F-actin dynamics and cell migration. Based on previous work, type I Coronins (1A, 1B, and 1C) remodel Arp2/3-containing branched actin networks and contribute to disassembly. In addition to interaction with Arp2/3, Coronin 1B is also required for proper targeting of Slingshot-1L, an activating phosphatase for the ADF/cofilin family of actin-binding proteins, to the rear of lamellipodia. Coronin-1C, a closely related isoform, is upregulated in multiple tumor types, and we have identified Coronin-1C as an ERK responsive target that is specifically upregulated in metastatic melanoma. Advanced melanoma is one of the most feared human cancers, and is noteworthy for its therapeutic
resistance, aggressive clinical behavior, and proclivity for early metastasis. Tumor invasion and metastasis utilize multiple actin-dependent processes, including cell migration and invasion, vesicle trafficking, and matrix degradation. Immunofluorescence staining of melanoma cells for Coronin-1C demonstrated that it localizes to structures important for all of these functions: the leading edge of migrating cells, motile cytoplasmic puncta thought to be vesicles, and to invadopodia. To test for functional significance to these processes, we modulated Coronin-1C expression in melanoma cells by overexpression or shRNA-mediated knockdown. We found that shRNA mediated knockdown of Coronin-1C expression in highly aggressive melanoma cells led to decreased cell migration speeds. Furthermore, loss of Coronin-1C decreased invadopodia formation in invasive cells while Coronin-1C overexpression increased invadopodia formation in melanoma cells that initially had low Coronin-1C levels. These data suggest that Coronin-1C promotes the rapid turnover of actin filaments in melanoma cells and increases their capacity to perform actin dependent processes during tumor metastasis. Coronin-1C is therefore at minimum a good biomarker for aggressive melanomas, and potentially of significance when considering the methodology of treatments for these advanced tumors.

884/B42
High Resolution Intravital Imaging Reveals Distinct Tumor Cell Extravasation Pathways Induced by VEGF and Twist Metastatic Genes.
K. Stoletov, H. Kato, E. Zardouzian, J. A. Kelber, J. Yang, S. J. Shattil, R. Klemke; UCSD, La Jolla, CA

Metastatic tumor cells invade into the vascular system where they are transported to distant tissues via normal blood circulation until they finally lodge in small capillaries. These cells then extravasate out of the vessel lumen through the endothelium into the surrounding tissues, where they form new tumors. It is controversial, however, as to whether cell extravasation is a regulated and a rate-limiting step during metastasis. Previous work indicated that normal and transformed cells can extravasate equally well independently of their metastatic ability, whereas other data indicates that this process is regulated by specific metastatic gene signatures. Here, we show that cancer cell extravasation is a highly dynamic and complex process regulated by pro-metastatic genes. High resolution time-lapse imaging of vessel-arrested tumor cells revealed that they are not passively immobilized in the lumen as previously believed, but instead display dynamic amoeboid-like movement along the endothelial surface. Surprisingly, cell locomotion can be against or with the blood flow and requires integrin-mediated tumor cell adhesion to the blood vessel wall. Extravasating cells can use para- or trans-cellular modes of emigration and do not damage the vessel wall causing leakage as previously suggested, but rather induce local vessel remodeling characterized by altered endothelial cell-cell junctions and endothelial cell clustering around the invading tumor cell. Tumor cell secretion of pro-angiogenic factor VEGF promoted tumor cell extravasation by increasing vascular wall remodeling in an integrin dependent manner. In contrast, induction of the pro-metastatic gene, twist, caused tumor cells to switch from integrin dependent to an integrin independent mode of extravasation that required ROCK-mediated formation of dynamic membrane blebs and protrusions that penetrated the vascular wall. Our results show that oncogenic gene expression can promote distinct tumor cell extravasation pathways and challenge the current view that extravasation is an unregulated, passive process. These data are vital for establishing tumor cell extravasation as a central target for novel anti-metastatic therapies.

MicroRNA-132 Functions as a Novel Angiogenic Switch by Targeting P120RasGAP.
S. Anand, B. Majeti, L. M. Acevedo, E. Murphy, R. Mukthavaram, L. Scheppke, L. Barnes, E. Goka, J. Lindquist, S. M. Weis, D. Shields, D. A. Cheresh; Moores Cancer Center, University of California, San Diego, La Jolla, CA

Activation of the angiogenic program in quiescent endothelial cells is a complex, tightly regulated process during development and disease. We show here that a microRNA, miR-132, functions as
a novel angiogenic switch by targeting p120RasGAP in quiescent endothelium and thereby facilitates angiogenesis. We identified miR-132 during a screen of human microRNAs that were upregulated in HUVECs during growth factor treatment and in a human ES cell model of vasculogenesis. Importantly, miR-132 was also expressed in a majority of human hemangiomas and tumor vasculature but not in normal blood vessels. Transfection of miR-132 decreased endothelial proliferation and tube formation in vitro. Strikingly, injection of anti miR-132 decreased FGF induced angiogenesis in matrigel plugs and developmental angiogenesis in retinas in neonatal mice. Multiple prediction programs identified p120RasGAP as a primary target of miR-132. Expression of miR-132 on HUVECs significantly decreased p120RasGAP levels and Ras activity. p120RasGAP, while highly expressed in normal endothelium, was lost in tumor endothelium in both human and mouse tissues. Moreover, using αVβ3 targeting nanoparticles to deliver anti miR-132 to tumor endothelium, we were able to restore p120RasGAP, suppress tumor angiogenesis and growth in melanoma and breast cancer models. Taken together, we show that miR-132 and p120RasGAP function as a unique angiogenic switch to maintain endothelial quiescence and perturbation of this switch during tumorigenesis is critical for neovascularization.

Evaluating the Contribution of 14-3-3 Proteins to Colon Cancer Progression.
K. J. Gordon, R. A. Feldman, J. D. Martinez; Arizona Cancer Center, University of Arizona, Tucson, AZ

The 14-3-3 class of proteins are a highly conserved family of phospho-threonine-serine binding proteins that contribute to multiple vital cellular functions, including cell cycle regulation, growth, and metabolism. There are seven human isoforms: beta, gamma, epsilon, zeta, eta, theta, and sigma. Previous studies from our laboratory have demonstrated that 14-3-3 proteins affect the cell cycle progression of lung cancer cells and their sensitivity to ionizing radiation. However, only a few reports suggest that 14-3-3 protein expression may be altered in colon cancer, and the majority of these studies used cell culture models. To our knowledge there have been no studies that have assessed the expression of 14-3-3 proteins in the intact colonic epithelium. Therefore, the objective of this study was to determine whether 14-3-3 proteins were expressed in normal mouse colonic epithelium and whether there were any alterations in 14-3-3 protein expression in colon cancer induced by azoxymethane. Using immunohistochemistry with a pan-specific antibody, we determined that 14-3-3 proteins are predominantly expressed in the upper half of the crypt in mouse colonic epithelium. Using antibodies specific to the sigma and gamma isoforms, we determined that 14-3-3 sigma and gamma were also expressed predominantly in the fully-differentiated cells at the top of the crypt. In azoxymethane-induced colon tumors, there was increased and more widespread expression of 14-3-3 proteins. These observations suggest that increased expression of 14-3-3 proteins may contribute to colon cancer progression. Further studies are warranted to determine the specific effects of increased 14-3-3 expression in colon epithelial cells.

Genomic Models of Functional Embryomas within Adult Neoplastic Cells.
J. A. Hovsepian, J. H. Frenster; Medicine, Stanford University, Stanford, CA, ^2^Radiology, Stanford University, Stanford, CA

Genomic analysis of vertebrate neoplasms often reveals the re-expression of exclusively-embryonic genes within neoplastic adult cells. Exclusively-embryonic genes are normally expressed during embryogenesis, but not again within normal adult cells. Other lifetime-embryonic genes are less constrained, and are co-expressed with adult genes within normal adult cells. The re-expression of one exclusively-embryonic gene within one normal adult cell is sufficient to initiate an adult neoplasm: Okito K, et al, “Generation of germline-competent induced pluripotent stem cells”, Nature 448: 313-317 (July19, 2007). Large embryonic gene networks are often re-expressed intact, as in the epithelial-mesenchymal transition (EMT) mediating

Novel Signaling Pathways Linking ErbB2-Mediated Malignancy with Cysteine Cathepsin Activity.

T. Kallunki1, B. Rafn1, P. Szyniarowski1, E. Corcelle1, N. Fehrenbacher1, P. Kohonen2, C. Olsen3,4, H. Edgren2, O. P. Kallioniemi2,5, J. Nylandsted1, J. Moreira3, M. Jäättelä1; 1Apoptosis Department, Institute of Cancer Biology and Centre for Genotoxic Stress Research, Danish Cancer Society, Copenhagen, Denmark, 2Medical Biotechnology Department, VTT Technical Research Centre of Finland and University of Turku, Turku, Finland, 3Department of Proteomics in Cancer, Institute of Cancer Biology and Danish Centre for Translational Breast Cancer Research, Danish Cancer Society, Copenhagen, Denmark, 4Department of Molecular Cancer Biology, Institute of Cancer Biology, Danish Cancer Society, Copenhagen, Denmark, 5Institute of Molecular Medicine Finland (FIMM), EMBL Molecular Medicine Partnership, Helsinki, Finland

Almost 1/3 of breast cancer overexpress ErbB2 receptor tyrosine kinase, which is associated with an aggressive disease. Although many of the signaling pathways activated by ErbB2 are well characterized, its downstream effectors that drive breast malignancy are largely unknown. We have analyzed 487 primary breast cancer samples with tissue microarrays or mRNA expression arrays for the expression of ErbB2 and cathepsins B and L and found out that ErbB2 expression correlates with the expression of lysosomal cysteine cathepsins B and L. We show that these two cysteine cathepsins are essential for the ErbB2-induced invasion and aggressive phenotype of breast cancer cells and that their activity can be inhibited by Herceptin treatment. Employing a kinase siRNA screen, we have identified four known mediators of ErbB2 signaling and six previously unknown kinases as crucial regulators of ErbB2-induced cathepsin expression and malignancy and explored their function, hierarchy and their mode of regulation of the malignant cysteine cathepsin activity. Our study indicates that cysteine cathepsins B and L are important mediators of the invasive ErbB2 signaling. Therapeutic interventions targeting the kinases and signaling pathways that ErbB2 utilizes to regulate cathepsin B and L activity may confer clinical benefit in ErbB2-driven malignancies.

Human Endothelial Progenitor Cells (EPCs) Role in Tumor Angiogenesis.

Human Endothelial progenitor cells (EPCs) isolated from peripheral blood have the following CD34, VEGFR-2, or AC 133 (CD133) and Aldehyde dehydrogenase antigen-positive cells, which may home to site of neo-vascularization and differentiate into endothelial cells. Endothelial cells contribute to tumor angiogenesis, and can originate from sprouting from neighboring pre-existing vessels. The bone marrow-derived circulating EPCs can contribute to tumor angiogenesis and
growth of certain tumors. In this study we observed EPCs labeled with GFP contribute to breast, brain and prostate cancer tumor angiogenesis in mouse tumor explants. This study confirms the EPCs play a major role in tumor angiogenesis in breast, brain and prostate cancers as indicated in the tumor explants.

Human Liver Cancer Stem Cells as a Potential Target for Novel Drug Therapy and Drug Discovery.
J. Sharma, C. DiMaggio, N. Taw, M. Majdoub, N. Liles, G. Velazquez, N. Amezcua, C. Sharma, M. Sharma; Stem Cell Biology, Celprogen, San Pedro, CA

Hepatocellular carcinoma (HCC) is an aggressive tumor with a poor prognosis. Current therapeutic strategies against this disease target mostly rapidly growing differentiated tumor cells. In the present study we have isolated liver cancer stem cells for screening novel drug candidates for the treatment of patients with liver cancer. The metastatic spread of liver cancer cells from the primary tumors to major vital organs, such as lung, colon, brain, and bone, is responsible for the majority of cancer-related deaths. Liver Cancer stem cells are likely to play essential roles in the metastatic spread of primary liver tumors because of their self-renewal capability and their potential to give rise to differentiated progenies that can adapt to different target organ microenvironments. In the present study we have developed a high throughput cell based assay system with human liver cancer stem cells. This assay system has enabled us to identify 300 novel drug candidates for liver cancer patients. The gene expression and protein expression profiles enable one to constructively conclude the novel drugs safety and efficacy. The current cell based assay system enables one to perform novel drug candidates screening with human Liver parental and cancer stem cells simultaneously.

Neuromedin-B, Gastrin Releasing Peptide and Bombesin S-3 Receptors in SW-13 and H-295r Human Adrenal Carcinoma Cell Lines.
J. W. Brown 1,2, A. Treszl 3, A. V. Schally 1,3,4, L. Young 1,2, L. M. Fishman 1,2; 1Division of Endocrinology, Diabetes & Metabolism, Department of Medicine, University of Miami Miller School of Medicine, Miami, FL, 2Adrenal Research Laboratory, Research (151), VA Medical Center, Miami, FL, 3Endocrine, Polypeptide & Cancer Research Institute, VA Medical Center, Miami, FL, 4Departments of Pathology and Urology, University of Miami Miller School of Medicine, Miami, FL

Neuromedin-B, gastrin releasing peptide and bombesin S-3 receptors are a closely related seven-transmembrane, G-protein coupled family of receptors which have been strongly conserved during evolution. They are expressed in normal GI and CNS target tissues in humans and have also been shown to be present at high levels in many types of aggressive human malignancies - including cancers of the lung, liver, pancreas, thyroid, and intestine, as well as in neuroectodermal paragangliomas (Bostwick and Bensch, 1985; Price et al., 1985; Schally and Nagy, 2004). There is substantial evidence in the literature showing that antagonists to all three peptide receptors are capable of suppressing the otherwise rapid growth of many of these tumors (Schally and Nagy, 2004). Furthermore, alterations in G-protein coupled receptor genes are believed not only to contribute to the growth of a number of malignancies but also, in some cases, to cell transformation itself and to the induction of a malignant phenotype (Burger et al, 1999). Our objective in this study was to determine whether the bombesin family of receptors exists in human adrenal carcinoma cells. Our results indicate strong transcriptional expression of gastrin-releasing peptide and bombesin S-3 receptor mRNAs using RT-PCR analyses in steroid-producing H-295r human adrenal cortical carcinoma cells cultured in Dulbecco’s Modified Eagles Medium with 10 % fetal calf serum, but very little transcriptional expression of these two peptide receptors in the less differentiated (i.e., mostly non-steroid producing) SW-13 human adrenal cortical carcinoma cell-line. Our studies also indicate that the neuromedin-B receptor is significantly expressed in the SW-13 human adrenal cortical carcinoma cell-line, while being only
weakly expressed in the H-295r cell-line. In conclusion, we see significant but differential expression of the bombesin family of receptors in the SW-13 and H-295r human adrenal carcinoma cell-lines. This work was supported by the U.S. Department of Veterans Affairs and the South Florida Veterans Affairs Foundation for Research & Education. We thank Dr. Jozsef Varga for helpful comments and suggestions.

Increased Expression of Human Peptide Deformylase in Certain Cancers.
K. M. Reindl, K. Sorensen; Biological Sciences, North Dakota State University, Fargo, ND

Peptide deformylase (PDF) removes the N-formyl group from the initiator methionine in newly synthesized polypeptides in prokaryotes. A human PDF isoform (hsPDF) has been recently discovered that localizes to the mitochondrion, but it is unclear if it plays a role in deformylation of mitochondrial polypeptides. Interestingly, inhibitors of PDF are more cytotoxic toward cancer cells than non-cancer cells, and also display anti-tumor effects in vivo. The objective of this study was to quantify human peptide deformylase in cancerous and non-cancerous tissues. Quantitative real time PCR was used to measure hsPDF mRNA expression in cancerous and non-cancerous tissues of eight different types (breast, colon, kidney, liver, lung, ovary, prostate, and thyroid). HsPDF levels increased in all tumor tissues compared to normal tissues, but increases were most dramatic in breast, colon, and lung tissues where levels were over 3-fold higher in cancer samples. These results suggest that hsPDF is up-regulated in certain cancers, and that hsPDF may play an active role in human cells.

DNA Damage after Exposure to Prosthetic Metal Wear Particles.
L. Lacharme-Lora¹, C. Brown², E. Ingham², C. Case¹; ¹University of Bristol, Bristol, United Kingdom, ²University of Leeds, Leeds, United Kingdom

The use of Metal on Metal (cobalt-chromium alloy) orthopaedic implants has increased considerably in recent years. It has been shown that as these implants wear away, they generate high quantities of cobalt-chromium particles and ions, which can disseminate to the rest of the body. Exposure to these metal particles has been associated with cytotoxic and genotoxic effects on cells in vitro. To understand better the biological consequences of exposure to prosthetic metal wear particles a mouse model of this exposure has been developed in our laboratory. This model was used to investigate whether exposure to these metal particles causes DNA damage in the bone marrow and brain of treated mice. C3H mice were exposed to metal wear particles (1.2 x 106 µm3/25g mouse; 3µm; approx 4.5 x104). The 2.9 micron cobalt-chromium particles were injected peri-articularly into the right knee of C3H mice at times 0, 6, 12 and 18 weeks. DNA damage 1 week and 1 month after last exposure was determined by comet assay and tail moment was used to evaluate DNA damage. When comparing the tail moment of exposed animals with controls, it was found that exposure to metal particles induced DNA damage in bone marrow 1 week and 1 month after exposure, and no damage was present in brain at any time point. Tail moments in bone marrow cells of the control group after 1 week and 1 month were 1.46 ± 0.12 and 1.98 ± 0.25 respectively, while in the exposed group they were 3.13 ± 0.28 and 4.46 ± 0.68 respectively. Two plausible explanations for these results are i) that ions corroded from the particles may gain access to the bone marrow but not a cross the blood brain barrier; ii) DNA damage by metal In Vivo may depend on rate of cell division. Further studies will be carried out to test these two hypotheses.

The Influence of Vanadium Compounds on Human Lung Cancer Cells Line A549.
W. A. Dabros¹, A. M. Kordowiak²; ¹Dept.of Pathomorphology, Jagiellonian University Medical College, Krakow, Poland, ²Dept of Biochemistry, Biophysics and Biotechnology., Jagiellonian University, Krakow, Poland
In our study we used the cells line A549 obtained from the bank. This is the continuation of the investigation of the vanadium compounds having some ability to normalize the morphological features of neoplastic cells. Control cells. There were mostly cells with lobulated nuclei and highly scant cytoplasm. Sometimes nucleolus undergoing segregation was seen. Pleomorphic mitochondria and scarce rough endoplasmic reticulum canals were observed. The cell membrane was often folded and demonstrated cytoplasmic processes. In general, the cytoplasm did not abounded in organelles. Experimental groups. The cells exposed for 48 hours to the effect of three vanadium compounds: Na3VO4 20mM, NaVO3 20mM and BMOV 40mM - such concentration values were selected, at which approximately 50% cell growth inhibition was determined by biochemical methods MTT and CV. Generally, all the presented cells line A549 from various experimental groups demonstrate changes with a similar character. Only the group BMOV 60 mM of our experiment shows more advanced ultrastructural changes, most likely in consequence of increasing the vanadium dose. This is an effect observed in our previous experiments. on the other hand, metavanadate results in the most severe damage to the cells. The activity of orthovanadate is clearly less effective as compared to metavanadate, however, orthovanadate is less toxic. The observed damage represents typical cytotoxic changes. No such changes have been seen in the controls; dead cells were seen there indeed, but in some percentage of cases, this is a common phenomenon, especially in cell lines cultured in vitro. In the experiment no normalizing effect of vanadium could be detected, neither in particular cell groups nor in the intergroup comparison of vanadium-treated and control cells. These conclusion was based on both biochemical and morphological studies. In all groups it was possible to observe more or less damaged cells under electron microscopy.

LKB1 Facilitates Activation of the Unfolded Protein Response in NSCLC Cells.
L. J. Inge, K. Swetel, K. Coon, R. Bremner; Center for Thoracic Disease, St. Joseph’s Hospital and Medical Center, Phoenix, AZ

Increasing evidence suggests that somatic mutations to the LKB1 tumor suppressor are a common event in the progression of non-small cell lung cancer (NSCLC). LKB1 plays an important role in the regulation of cell metabolism, serving as the primary activator of the metabolic sensor, AMPK. In response to decreases in available ATP, due to nutrient deprivation and/or hypoxia, LKB1-AMPK signaling alters cellular functions in order to restore homeostasis. Loss of LKB1 function and the subsequent failure to activate AMPK during energetic stress conditions, results in cell death. This phenomenon is of clinical interest, as it suggests that induction of energetic stress through pharmacological means might provide significant clinical benefits for patients with LKB1 null NSCLC. We have found that pharmacological induction of energetic stress, using the glucose analog, 2-deoxyglucose (2DG), results in increased toxicity in LKB1 null NSCLC cells. In investigating the mechanisms for 2DG-induced toxicity, we show that LKB1 facilitates activation of the Unfolded Protein Response (UPR), a stress response of the Endoplasmic Reticulum. Microarray analysis revealed that LKB1 expressing NSCLC cells dramatically increased expression of UPR related genes compared to LKB1 null NSCLC cells with 2DG treatment. We provide additional evidence that this novel function is due to LKB1 activity, as re-expression of LKB1 in a LKB1 null NSCLC cells induced expression of UPR markers (CHOP, BiP) in response to 2DG. In conclusion, our study suggests a novel regulatory function of LKB1 and provides insight into the design of therapeutic strategies for LKB1 null NSCLC.

Therapeutic Effects of Targeting Integrin A4B1 and Its Mechanism of Action.
C. N. Felsen1, C. Avraamides2, B. Garmy-Susini2, J. A. Varner1,2; 1Department of Medicine, University of California San Diego, La Jolla, CA, 2Moores Cancer Center, University of California San Diego, La Jolla, CA
Angiogenesis, the development of new blood vessels, promotes tumor growth and is regulated by integrins, including integrin α4β1. To determine if targeting integrin α4 in tumor models has therapeutic effects, we treated mice bearing subcutaneously injected Lewis lung carcinoma (LLC) tumors and mice that spontaneously develop breast cancer (PyMT model) with a small molecule inhibitor of integrin α4. Mice treated with this inhibitor have significantly decreased tumor volume and weight in the LLC model and decreased tumor burden in the spontaneous breast cancer model. Examination of tumors in the PyMT model shows a significant decrease in both blood vessel and macrophage infiltrates in the treated group compared to the control group. Therefore, targeting integrin α4 has potential for therapeutic value in cancer treatment. To understand the mechanism of how integrin α4β1 is activated we are exploring the role of PI3-kinase α in lymphatic endothelial cells (LECs). We recently found that integrin α4β1 is involved in lymph node lymphangiogenesis, or the development of new lymphatic vessels, of which LEC migration is an essential step. Previous work in our lab showed that PI3-kinase γ activates integrin α4β1 in myeloid cells. However, chemical inhibitors to PI3-kinase α, but not to PI3-kinase γ, block VEGF-C stimulated LEC migration and inhibit In Vivo lymph node lymphangiogenesis. These data suggest that PI3-kinase α regulates LEC migration and potentially activates integrin α4β1 in LECs.

Discovering New Biomarkers for Liver Injury.
E. Gonzalez1, J. Conde-Vancells1, E. Rodriguez-Suárez2, C. Alonso3, R. Suero3, A. Castro3, A. Berisa4, Z. Luká5, C. Wagner5,6, S. Lu7, F. Elortza2, J. Barr3, J. M. Mato1, J. M. Falcon1; 1Metabolomic Unit, CIC-bioGUNE, CIBERehd, Derio, Spain, 2Proteomics Unit, CIC-bioGUNE, ProteoRed, Derio, Spain, 3Proteomics Unit, CIC-bioGUNE, ProteoRed, Derio, Spain, 4R&D and Innovation Department, FAES Farma SA, Leioa, Spain, 5Department of Biochemistry, Vanderbilt University, Nashville, TN, 6Tennessee Valley Department of Medical Affairs, Medical Center, Nashville, TN, 7Division of Gastrointestinal and Liver Diseases, Keck School of Medicine, University Southern California, Los Angeles, CA

Liver disorders are a serious worldwide health issue, but currently liver biopsy remains the main approach for diagnosis, providing information only once the disease is manifested. So, in liver pathology does exist the urgent need of identifying early, sensitive and specific biomarkers detectable by non-invasive techniques that permit us diagnosis, prognosis and monitoring treatments. In this line, our laboratory followed two different approaches, one based on metabolomics and other on proteomics. Firstly, we have conducted a metabolic profile analysis of serum samples from rats treated with D-galactosamine (GalN), a well-established hepatotoxin that causes acute liver damage resembling viral hepatitis. Interestingly, we have found a small subset of metabolites showing strong correlation with the hepatic damage determined by histological analysis of liver sections and by alanine transaminase activity in serum. on the other hand, we have chosen a special kind of extracellular vesicles named exosomes as biological source for biomarker discovery. These vesicles are considered a mirror of the cellular state and constitute a subcellular proteome that can be suitable to identify clinically relevant under-represented proteins. According to that, our group has detected difference in the protein content of hepatocyte-derived exosomes from wild-type and knockout mouse models for chronic hepatic injury, reflecting the changes found in the cell surface of these cells. We have also detected differences in the protein content of exosomes purified from the urine of both chronic (knockout mice) and severe (GalN-treated rats) models regarding the corresponding control animals, pointing out to several putative early and disease progression indicators. Finally, a proteomic analysis of these urinary vesicles in normal conditions revealed the presence of proteins that have been associated to diseases and could be candidate to biomarkers. All these results strongly support the metabolic profiles and exosome proteomics as experimental approaches to identify new specific biomarkers for liver diseases.

Potential Novel Treatment for Second-Hand Cigarette Smoke-Induced Liver Steatosis.

H. Yuan, M. Martins-Green; Department of Cell Biology and Neuroscience, University of California, Riverside, Riverside, CA

Nonalcoholic fatty liver disease (NAFLD) is the single most common liver problem in the United States. It appears to be linked directly to the growing epidemic of obesity in adults as well as in children. Fatty liver or hepatic steatosis has been classified as the first stage of NAFLD. However, the underlying mechanisms of hepatic steatosis remain unclear. Previously we showed that mice exposed to second-hand smoke, which contains more than 4000 compounds, have lipid accumulation in the liver tissue. This lipid accumulation is caused by modulating the activity of 5'-AMP-activated protein kinase (AMPK) and sterol response element binding protein-1 (SREBP-1), two critical molecules involved in lipid synthesis. We hypothesize that the drug AICAR (5-Aminoimidazole-4-carboxamide ribonucleoside), an AMPK activator, can reverse, at least in part, the lipid accumulation caused by second hand smoke. To test this possibility, we used the ApoB100 transgenic mice fed on high fat diet, exposed them to sidestream whole (SSW) smoke (a major component of “second-hand” smoke), with or without administration of AICAR. We found that in the response to stimulation of SSW for only 5 days, the activity of AMP kinase in the liver was recovered by AICAR, with subsequent inactivation of SREBPs leading to decline in accumulation of fat in the liver. We are currently investigating whether AICAR affects the fatty acid influx, another possible way of accumulation of fat in the liver. This latter process reflects predisposition of individuals to the development of insulin resistance when exposed to smoke. Understanding the regulatory mechanisms of AICAR on the effects of cigarette-smoke-induced steatosis may provide insight into diabetic conditions related to NAFLD and points to possible treatment of these conditions.

The Use of Anti-Sense Oligonucleotides to Rescue a Common Mutation in Hermansky-Pudlak Syndrome Type 1.

L. Vincent, W. Westbroek, R. Hess, M. Huizing, W. Gahl; MGB, NIH NHGRI, Bethesda, MD

Hermansky-Pudlak syndrome (HPS) is due to defects in the biogenesis of lysosome-related organelles, such as melanosomes in melanocytes and delta granules in platelets. As a result, clinical features of HPS patients include ocuocutaneous albinism, a bleeding diathesis, and other sporadic complications, such as granulomatous colitis or a fatal pulmonary fibrosis. The most common subtype, HPS-1, occurs primarily among Puerto-Ricans and results from a 16-bp duplication founder mutation in exon 15 of the HPS1 gene. Little is known about the function and structure of HPS1, making directed therapy difficult. In view of successful advances in therapeutic exon skipping (e.g., for Duchene Muscular Dystrophy), we introduced anti-sense morpholino oligonucleotides (MOs) to HPS patients’ cultured melanocytes to induce skipping of in-frame exons carrying deleterious HPS1 mutations. The effects and efficacy of each MO on the HPS1 mRNA transcript were validated using RT-PCR analysis. Furthermore, we completed immunofluorescence (IF) staining against the melanosome-specific protein TYRP1 to detect the correction of abnormal melanosome trafficking patterns defects (i.e. lack of accumulation in dendritic tips) that are typical for HPS-1. Exon 12, exon 13, and exon 15 MOs effectively removed ~75%, 95%, and 60%, respectively, of their targeted exon in HPS1 transcripts. IF analysis of patients’ melanocytes transfected with exon 12 MO and exon 13 MO did not rescue the lack of melanosomal accumulation at the dendritic tips; however, this staining appeared to be increased in patients’ melanocytes transfected with the exon 15 MO. Ongoing immunoblot assays against HPS1 and HPS4, which interact in the Biogenesis of Lysosome-related Organelles Complex (BLOC)-3, will further verify cellular functionality of these exon-skipped HPS1 isoforms. Further investigations into targeted exon skipping could result in clinical applications for the treatment of systemic complications associated with HPS-1. More specifically, the promising results of skipping of exon 15 may prove to be extremely beneficial for the large group of Puerto-Rican HPS-1 patients with the 16-bp duplication founder mutation.
900/B58
Divalent Interaction between HPS1 and HPS4 to Form the Biogenesis of Lysosome-Related Organelles 3 (BLOC-3).
C. Carmona-Rivera¹, J. S. Bonifacino², C. L. Cadilla³, W. A. Gahl¹; ¹National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, ²National Institute of Child and Human Development, National Institutes of Health, Bethesda, MD, ³Biochemistry, University of Puerto Rico, School of Medicine, San Juan, PR

Hermansky-Pudlak Syndrome (HPS) [MIM#203300] is a rare autosomal recessive disorder characterized by oculocutaneous albinism, a bleeding tendency, and sporadic pulmonary fibrosis, granulomatous colitis or infections. HPS is a heterogeneous disorder; eight HPS-causing genes have been identified in humans. HPS type 1 is the most severe subtype with a prevalence of ~1/1800 in Northwest Puerto Rico. Mutations in HPS genes affect the biogenesis of lysosome-related organelles such as melanosomes and platelet dense granules. The products of the HPS type 1 and 4 genes (i.e., HPS1 and HPS4) assemble to form a complex known as Biogenesis of Lysosome-related Organelle Complex 3 (BLOC-3). Here, we report the identification of two interacting regions in each HPS protein required to form the BLOC-3. We found that HPS1 interacts with HPS4 in two regions, spanning amino acids 1-197 and 506-700 but not with the middle portion of HPS1 (250-505). In addition, HPS4 displays dual binding sites to HPS1, comprised by its N-terminus (1-230) and a distinct region between residues 340-399. Further interaction studies showed that the N- termini of HPS1 and HPS4 interact with each other and that a discrete region of HPS4 (340-708) showed interactions with both the N- and C- termini of HPS1 protein. However, the C- terminus of HPS4 (528-708) by itself did not show any interaction with HPS1, suggesting no participation in the formation of the HPS1-HPS4 complex. In Vitro assays with truncated HPS1, mimicking mutations found in HPS1 patients, showed retention of some interaction with HPS4, suggesting the possibility to generate (a truncated form of) BLOC-3 in these patients that could retain partial function and could possibly explain the variable progression of the pulmonary fibrosis in BLOC-3 deficient patients. These observations not only extend our understanding of BLOC-3 assembly, but also represents an important first step in the mapping of the domains that may sense regulatory signals responsible for the biogenesis of lysosome-related organelles. This work was partially supported by the IRTA-NIH Program and grants R25GM81838 and RCMI G12RR03051.

G. S. Dhaunsi; Pediatrics, Kuwait University, Kuwait

Congenital disorders of glycosylation (CDG) are a rare group of inherited metabolic disorders caused by defective glycosylation of proteins. Though CDG patients present variable clinical phenotypes, however they show a common feature of deglycosylation of proteins. Recent studies have provided some insight into the basic mechanisms associated with pathogenesis of CDG. We have investigated the mitogenic activity of Insulin (Insulin-Transferrin-Selenium, ITS) and Insulin-like growth factor-1 (IGF-1) in peripheral blood lymphocytes isolated from CDG patients. Cultures of lymphocytes were established from blood samples of six confirmed patients of CDG and twelve age and gender matched healthy controls. Cells were serum-starved for 36 hrs before treatment with varying concentrations of insulin and IGF-1. Mitogenic activity of growth factors was determined by measuring the DNA synthesis in cell cultures in the presence / absence of ITS/IGF-1. We observed that lymphocytes isolated from CDG patients had significantly (p< 0.001) reduced DNA synthesis in response to a 24 hr treatment with IGF-1 (50ng/ml) as compared to IGF-1-induced DNA synthesis in lymphocytes isolated from controls. Interestingly, lymphocytes from CDG patients and normal subjects did not show marked difference in their DNA synthesis following treatment with Insulin. In conclusion, our results show that CDG patients have impaired mitogenic response to IGF-1, however insulin-mediated DNA synthesis remains unaffected by deglycosylation of proteins in these patients. ( Funded by research grant MK 01 /05).

Mechanical Stretch Enhances MMP-2 Production in Vascular Smooth Muscle via Activation of Akt Pathway.
K. Seo, S. Lee, C. Kim, H. Park, J. Yun, J. Bae, J. Park, M. Yun, S. Bae, C. Kim; MRC for Ischemic Tissue Regeneration and Medical Research Institute, Pusan National University, YangSan, Korea, South

Increased biomechanical stresses in the fibrous cap of atherosclerotic plaques contribute to plaque rupture, and increased risk of symptomatic plaque rupture seems to be partially mediated by matrix metalloproteinases (MMP). However, the role of mechanical strain on MMP production in vascular smooth muscle is still unclear. Therefore, this study determined the role of mechanical stretch on MMP production, and signal pathways involved in mechanical stretch-induced MMP production in VSMC. When VSMC was stimulated with cyclic stretch (0-10% strain, 60 cycles/min, 0-24 hrs, sine waveform) using Flexcell Tension Plus FX-4000T system, both the production and gelatinolytic activity of MMP-2, but not MMP-9, were increased in a frequency- and time-dependent manner. Among the possible VSMC signaling pathways modulated by stretch, phosphorylation of Akt and ERK, but not p38MAPK and JNK was increased by 10% stretch in a time-dependent manner to 240 min. Stretch-induced MMP-2 production with increased activity was exclusively decreased by inhibition of PI3K/Akt pathway, but not by inhibition of other MAPK pathways including ERK pathway. Collectively, our data indicate that mechanical stretch induces MMP-2 production in VSMC, and it is mediated at least partly by activation of the PI3K/Akt pathways, consequently leading to atherosclerotic plaque instability. (this study will be included the effect of signal specific isoform for Akt by short hairpin RNA knockdown approach.)

Acrolein Enhances 5-Lipoxygenase Expression and Activity on Murine Macrophages via EGF-Receptor and ERK Pathways.
C. Kim, S. Lee, K. Seo, M. Yun, C. Kim; Pusan National University, Yangsan, Korea, South

Oxidation of lipids is considered a key feature of atherogenesis. Acrolein, a major component of lipid peroxidation product, has been implicated in the development of atherosclerosis. 5-lipoxygenase (5-LO) in atherosclerosis lesions was mainly localized in macrophages. However, the pathogenic role of acrolein in macrophages responses has not yet been elucidated. Therefore, we investigated the role of acrolein on 5-LO expression and activity in murine macrophages. Stimulation of J774A.1 cells with acrolein led to 5-LO mRNA and protein expression in association with 5-LO activity, as measured by leukotriene B4 (LTB4) production in a concentration- and time- dependent manners. Among the mitogen-activated protein kinase (MAPK) pathways, acrolein increased phosphorylation of ERK, but not JNK and p38 MAPK up to 120 min. Linked to these results, the increased 5-LO expression and activity by Acrolein were significantly attenuated by PD98059, an ERK inhibitor, suggest a role of ERK signaling on 5-LO expression and activity by acrolein. Moreover, Acrolein-induced 5-LO expression was blunted by AG1478, an epidermal growth factor receptor (EGFR) inhibitor, but not by AG1295, a platelet derived growth factor receptor (PDGFR) inhibitor, confirming that AG1478, a EGFR inhibitor prevented increased phosphorylation ERK by acrolein. Collectively, these data suggest that Acrolein-induced 5-LO expression and activation is activation of EGFR mediated ERK pathways, consequently leading to development and progression of atherosclerosis.

904/B62
NF-xB and Sp1 Contributes 4-Hydroxynonenal-Mediated Up-Regulation of 5-Lipoxygenase Expression in J774A.1 Cells.
S. Lee, C. Kim, K. Seo, M. Yun, C. Kim; Pusan National University, Yangsan, Korea, South

Increased levels of 4-hydroxynonenal (HNE) and 5-lipoxygenase (5-LO) co-exist in macrophages in atherosclerotic lesions. While 5-LO has been suggested as a modulator of atherosclerotic
plaque instability, it remains unclear on the mechanism by which it is regulated. To gain insights of transcriptional regulation of 5-LO gene, we examined the promoter activity of 5-LO. We have amplified a genomic sequence of promoter 2.0 kb upstream of the transcription initiation site of mouse genomic DNA by PCR. A series of sequentially deleted fragments were fused to pGL3 vector containing a luciferase reporter gene. Luciferase assay was performed by transfecting the constructs into a murine macrophages cell line, J774A.1. The assay resulted in the identification of promoter region 50-213 bp upstream of transcription start site, which is responsible for a remarkable enhancement of transcriptional by HNE. A site-directed mutagenesis of this region revealed that transcriptional factors including Sp1 and NF-κB were associated with up-regulation of HNE-induced 5-LO expression. The role of Sp1 and NF-κB in 5-LO expression was further confirmed by siRNA knockdown of Sp1 and NF-κB. Importantly, among the MAPK pathways, ERK inhibitors, PD98059 and p38 MAPK inhibitors, SB203580 were attenuated HNE-induced NF-κB and Sp1 activity. Collectively, these data suggest a differential requirement that ERK/NF-κB and p38 MAPK/Sp1 pathway were up-regulated 5-LO expression by HNE, consequently provide novel options for therapeutic interventions to regulate 5-LO expression in atherosclerosis.

Functional Significance of a Single Nucleotide Polymorphism in Neuropeptide Y Receptor 2 Gene Candidate Gene for Hypertension.
E. Albino1, K. Sugimoto2, T. Katsuya3, A. Y. Deng3, J. Dutil1; 1Dept. Biochemistry, Ponce School of Medicine, Ponce, PR, 2Dpt. Geriatric Medicine, Osaka University Graduate School of Medicine, Suita, Japan, 3Molecular Genetics Laboratory, University of Montreal Research Center CHUM, Montreal, QC, Canada

Hypertension (HTN), or high blood pressure, affects 1 in 3 adults in the US and is an important risk factor for cardiovascular and kidney diseases. Multiple genes as well as environment and lifestyle factors influence the risk of developing high blood pressure. Our previous work in animal models and human populations identified Neuropeptide Y receptor 2 (NPY2R) as a candidate gene for hypertension. In two independent Japanese populations, bearing the GG genotype at a single nucleotide polymorphism (SNP) located 224 bp upstream of the transcription start site of NPY2R (-224 A>G) was associated with a protective effect against HTN. However, the functional significance of the NPY2R -224 A>G SNP and its potential role in the HTN at the molecular level remains unknown. Our objective was to assess the effect of the a to G substitution in the promoter of NPY2R on the expression levels of this gene. Human Embryonic Kidney (HEK) 293 cells were transfected with pGL4.10 DNA constructs containing the promoter of NPY2R and each nucleotide a or G at the -224 position upstream of the luciferase reporter gene. Interestingly, the luciferase activity induced by the NPY2R promoter with the G allele in position -224 was reduced by 34% compared to that induced by the promoter bearing an A. The different levels of relative Luciferase activity between a and G constructs were statistically significant (p < 0.01). Together, our data provide strong evidence for a functional role of NPY2R in genetic predisposition to hypertension.

Anti-Hypertensive Effect of Gomisin a in Angiotensin II-Induced Hypertensive Mice.
J. Yun, J. Bae, J. Park, K. Seo, C. Kim, H. Park, S. Lee, M. Yun, S. Bae, C. Kim; Pusan National University, Yangsan, Korea, South

Gomisin a (GA) is a small molecular weight lignan contained in Fructus Schisandrae, the dried seed of schisandra chinensis which is widely used as a tonic in traditional Korean medicine. Previously, we demonstrated that GA induced vascular relaxation through partially activation of endothelium-dependent nitric oxide pathway, and partially dephosphorylation of myosin light chain. In this study, we examined the anti-hypertensive effects of GA in angiotensin II(AngII)-induced hypertensive mice. C57BL6 mice infused subcutaneously with AngII (2μg/kg/min, osmotic mini-pump) showed an increase in blood pressure. To determine the single-dose effect, GA was infused into femoral vein, and then blood pressure was monitored via carotid artery. at
concentrations of 10 μg/kg - 100 μg/kg, blood pressure in hypertensive mice, but not in control mice, decreased by GA in a concentration-dependent manner. In the continuous-dose test, GA (2 and 10 μg/kg/min) was infused subcutaneously for 2 weeks using osmotic pump. The increase in blood pressure in AngII-infused mice was significantly attenuated by infusion of GA in a dose-dependent manner, while GA had no effect on blood pressure in control mice. Based on these results with our previous study in which GA directly induced vasorelaxation, it is suggested that GA has anti-hypertensive effects via its direct effects on hypertensive vasculature. However, further experiments are needed to determine the signal pathways involved in GA-mediated anti-hypertensive effects.

Expression of Usher Syndrome Type 3 -Gene (CLRN1) in Zebrafish Sensory Cells.
H. Vastinsalo1,2, J. B. Phillips3, E. Sankila1,4, M. Westerfield2; 1Folkhalsan Institute of Genetics, Helsinki, Finland, 2Department of Medical Genetics, University of Helsinki, Helsinki, Finland, 3Institute of Neuroscience, University of Oregon, Eugene, OR, 4Helsinki University Eye Hospital, Helsinki, Finland

Objective: Usher syndrome (USH) is the most common form of combined blindness and deafness. Usher syndrome type 3 (USH3) is the rarest subtype caused by mutations in Clarin 1 -gene (CLRN1). CLRN1 protein has four predicted transmembrane regions and is known to localize in the plasma membrane when expressed in cell cultures. The function of CLRN1 in the retina and the cochlea remains unknown. In this study, we investigate the expression and localization of clrn1 in zebrafish in order to enlighten the function of clrn1 in hearing, balance and sight. Methods: The main zebrafish clrn1 variant expression was studied from sectioned zebrafish adult and larvae eyes and ears with in situ hybridization. The Clrn1 protein localization was studied with antibody specific to zebrafish Clrn1. Morpholino oligonucleotide (MO) specific to clrn1 was used to inhibit clrn1 expression and the functional and morphological effects of Clrn1 absence were studied with behavioural tests and histological studies. Results: The in situ hybridization studies showed zebrafish clrn1 expression in hair cells of the larvae ear and neuromasts. In larval retina the in situ expression was concentrated in the inner nuclear layer (INL), in adult retina clrn1 expression was also found in the photoreceptors. The Clrn1 antibody studies showed similar localization dynamics with the Clrn1 first appearing in the INL in larval retina and in adult also in the photoreceptors. When Clrn1 production was inhibited with a clrn1 translation blocking morpholino, the injected larvae showed reduced levels of protein in the retina, exhibited slower optokinetic responses (OKR) and had obvious balance problems. Conclusions: Zebrafish clrn1 expression and protein localization in ear hair cells was consistent with the reported findings of Clrn1 expression in mouse cochlea. In the retina, it seems Clrn1 is present both in the adult INL and photoreceptors. Our studies showed that both clrn1 RNA and protein are present in the zebrafish larval ear and eye, and blocking clrn1 translation and thus presence of Clrn1 protein produces defects in vision, hearing, and balance.

Modified Mild Heat Shock with Electrical Stimulation Ameliorates Progressive Proteinuria in Mouse Model of Alport Syndrome.
T. Koga1,2, Y. Kai1,2, T. Komune1,2, T. Shuto1,2, M. Suico1,2, H. Kai1,2; 1Department of Molecular Medicine, Kumamoto University, Kumamoto, Japan, 2G-COE, Kumamoto University, Kumamoto, Japan

Alport Syndrome (AS) is a hereditary nephritis caused by defects in the genes encoding alpha-3, alpha-4, or alpha-5 chains of type IV collagen (COL4A3, COL4A4, COL4A5, respectively) in the glomerular basement membrane. The estimated gene frequency ratio of AS is 1:5000. Among AS patients, X-linked AS (XLAS) is the most common disease, which is caused by mutations in COL4A5 gene in the X chromosome and accounts for 85% of the cases. Approximately 90% of patients with AS develop end-stage renal disease (ESRD) by age 40 years. Despite the importance of AS, no effective treatment yet exists for AS patients. Novel therapeutic strategies
are thus urgently needed for progressive proteinuria and nephritis in AS patients. In the present study, we show that combination treatment with mild electrical stimulation (MES) and heat shock (HS) ameliorates progressive proteinuria and albuminuria in XLAS mouse model. We also demonstrate that MES with HS prevents the progressive nephritis in Alport mice. Interestingly, the activation of 5'-AMP activated protein kinase (AMPK), a crucial factor for regulating proteinuria, was seen in the kidneys of mice treated with MES+HS. Although the molecular mechanisms of how MES with HS ameliorates proteinuria and activates AMPK need to be further elucidated, our study provides a novel therapeutic strategy for Alport syndrome.

Diabetes Induced Glomerular Filtration Barrier Damage Is Ameliorated by Podocyte Targeted Metallothionein Overexpression in OVE26 Mice.
E. Carlson1, J. Teiken1, D. Laturnus1, S. Zheng2, P. Epstein2; 1Anatomy & Cell Biology Room 1701, University of North Dakota, Grand Forks, ND, 2Pediatrics, University of Louisville, Louisville, KY

The OVE26 transgenic diabetic mouse exhibits several characteristics of human diabetic nephropathy (DN), including glomerular and mesangial hypertrophy, increased glomerular apoptosis, increased tubular albumin and severe albuminuria. To test our hypothesis that diabetic renal injury may be the result of oxidative insult in the glomerular filtration barrier, Nmt transgenic mice that overexpress the antioxidant protein metallothionein (MT) specifically in podocytes were crossed with OVE26 diabetic mice. The effects of podocyte MT overexpression on glomerular basement membrane (GBM) thickness, glomerular volume, glomerular cell density and number, podocyte effacement, and endothelial cell fenestration were analyzed by TEM morphometry in 150 day-old OVE26, Nmt, OVE26/Nmt, and FVB (control) mice. Urinary albumin excretion (UAE) was measured by ELISA. Compared to normoglycemic Nmt and FVB controls, OVE26 diabetic mice showed significantly increased GBM thickness, glomerular volume, mesangial and endothelial cell proliferation, total glomerular cell number, and UAE. Podocyte density was decreased, though absolute numbers were similar in diabetics and controls. Importantly, OVE26/Nmt mice exhibited significant protection against diabetes-induced increased GBM thickening, glomerular hypertrophy, mesangial and endothelial cell proliferation and UAE. While podocyte numbers remained unchanged, podocyte damage (effacement) and endothelial cell injury (substantial fenestration loss) were significantly attenuated in OVE26/Nmt mice. These results provide evidence for a direct role of oxidative damage to the podocyte in diabetic glomerular filtration barrier dysfunction, and show that podocyte specific MT overexpression can reduce or delay several primary complications of DN. Funded in part by NIH Grant DK072032.

HIBM is an adult-onset, progressive neuromuscular disorder, caused by GNE mutations. GNE encodes the ubiquitously expressed, key enzyme in sialic acid (SA) synthesis, UDP-GlcNAc 2-epimerase/ManNAc kinase. We created an HIBM mouse model, mimicking the Persian-Jewish founder mutation M712T. Mutant mice unexpectedly died before day 3 of life (P3) from severe glomerulopathy due to hyposialylation, but survive with treatment if fed the SA precursor ManNAc. In addition to administering precursors in the SA pathway, we sought to deliver an intact GNE gene as a feasible treatment option. We created a human non-viral GNE-plasmid embedded in cationic liposomes (hGNE-lipoplex), which was administered via intramuscular injection (biceps and extensor carpi radialis longus) to one HIBM patient. The patient showed no adverse effects and her arm muscle strength improved moderately. To proceed with hGNE-
lipoplex intravenous (IV) or intrahepatic (the major organ of SA synthesis) injections in patients, we tested these treatments in our HIBM mice. hGNE-lipoplex was injected IV (retro-orbitally) and intra-hepatically in litters at age P1. Survival beyond P3 was the initial outcome parameter. The major tissues of treated mice were assessed at P5 for hGNE expression, glomerular disease, sialylation, and histology. Intrahepatic treatment yielded survival of all wild type (+/+) and heterozygous (+/-) pups, but just one of 8 mutants survived beyond P3; that pup had increased sialylation of the glomerular glycoprotein podoclyxin at P5. IV injections resulted in no surviving mutants beyond P3; however, some +/- pups died as well, indicating possible lethality of the injection method. Surviving +/+ showed hGNE expression in liver and kidney at P5, indicating no toxicity of hGNE-lipoplex and effective gene delivery to these tissues. It is possible that hGNE-lipoplex treatment at P1 (untreated mice die at P3) may not allow enough time for hGNE protein to be expressed and to produce enough SA, whereas the ManNAc treatment immediately delivers the substrate, bypassing the critical GNE processing step, allowing for faster production of SA. Further animal studies are planned to elucidate the timing and efficacy of GNE-lipoplex therapy.

Sialic Acids Prevent the Myopathic Phenotype in the DMRV/hIBM Mouse Model.
M. V. Malicdan, S. Noguchi, Y. K. Hayashi, I. Nonaka, I. Nishino; National Institute of Neuroscience, NCNP, Tokyo, Japan

Distal myopathy with rimmed vacuoles (DMRV) or hereditary inclusion body myopathy (hIBM) is a progressive autosomal recessive myopathy affecting adult patients. This debilitating myopathy, for which up to this time has no cure, renders patients non-ambulatory about 12 years after the disease onset. Characteristic findings include skeletal muscle atrophy and weakness, and accumulation of autophagic vacuoles in myofibers, scattered atrophic fibers, and intracellular accumulation of amyloid and other proteins. The development of therapy for DMRV/hIBM has primarily been hampered by the lack of understanding of disease pathomechanism. Although this myopathy is secondary to mutations in the UDP-N-acetylglucosamine 2-epimerase/N-acetylmannosamine kinase (GNE) gene that is crucial in the synthesis of sialic acid, it has been controversial whether hyposialylation contributes to the pathogenesis of DMRV/hIBM. Nevertheless we recently shown that DMRV/hIBM mouse model, a Gne deficient mouse that expressed the human GNE p.D176V mutation, hyposialylation was documented in serum and various organs, in addition to the characteristic features found in the human disease. Here, we evaluated the effect of sialic acid metabolites in the DMRV/hIBM mice. After determining the efficient route and dose of administering these metabolites, we gave three types of agents (20 mg/kg/day): ManNAc, the physiologic sialic acid precursor; NeuAc, the most abundant sialic acid; or sialyllactose, a sialic acid conjugate. All agents were continuously given from 10-20 weeks of age until the mice reached 55-57 weeks. Analysis of motor performance and ex vivo muscle contractile properties showed a remarkable improvement in all parameters tested. Muscle atrophy and myofiber degeneration were remarkably reduced. These findings were accompanied by an increase in sialic acid levels in the muscle, serum, and other organs. These data provide evidence that hyposialylation plays a major role in disease pathomechanism. Moreover, our results demonstrate a promising strategy that can potentially be used in the treatment of DMRV/hIBM.

912/B70
Muscle Atrophy in the DMRV/hIBM Mouse Model.
S. Noguchi, M. V. Malicdan, Y. K. Hayashi, I. Nonaka, I. Nishino; Dept. of Neuromuscular Research, National Institute of Neuroscience, NCNP, Tokyo, Japan

Distal myopathy with rimmed vacuoles (DMRV), also called hereditary inclusion body myopathy (hIBM), is an autosomal recessive debilitating disorder affecting young adults with the age of onset ranging from 15 years to late thirties. The disease is characterized clinically by preferential involvement of tibialis anterior and hamstring muscles and relative sparing of quadriceps, and
monday

pathologically by the presence of rimmed vacuoles, which are seen on electron microscopy as clusters of autophagic vacuoles, in addition to scattered atrophic fibers and muscle degeneration. Up to this time, treatment for this myopathy remains elusive. DMRV/hIBM is caused by missense mutations in GNE gene that encodes the essential enzyme in sialic acid biosynthesis. We recently generated a model mouse for DMRV/hIBM that expressed human GNE with the missense mutation D176V, but lacks the endogenous mouse GNE. This DMRV/hIBM model exhibited hyposialylation in serum and various organs which predated the skeletal muscle weakness, atrophy, rimmed vacuole formation, and deposition of amyloid and various proteins within the myofibers, supporting the theory of hyposialylation in the pathomechanism of DMRV/hIBM. In this study, we analyzed chronological changes in muscle size, myofiber cross-section area and pathological alteration of the gastrocnemius muscles of the DMRV/hIBM mice. Myofiber atrophy was noted in all fiber-types from 20 weeks of age, which preceded and was independent from the characteristic hallmarks on pathology, including amyloid deposition and rimmed vacuoles at 50 weeks of age. In addition, muscle atrophy was accompanied by upregulation in the expression of autophagy-related genes and atrogenes that encode ubiquitin ligases. These data suggest that the activation of lysosomal and proteosomal degradation pathways in muscles may contribute to myofiber atrophy in the DMRV/hIBM mouse model.

913/B71
Locally Acting IGF-1 Isoform (mIGF-1) Protects Cardiomyocytes from Hypertrophic and Oxidative Stresses via SirT1 Activity.
M. Vinciguerra¹ ² ³ ⁴, M. Santini², P. Kratsios¹, W. Claycomb³, A. Ladurner⁴, N. Rosenthal² ³; ¹Mouse Biology Unit, European Molecular Biology Laboratory (EMBL), Monterotondo, Italy, ²Harefield Heart Science Centre, Harefield, United Kingdom, ³Dept. of Biochemistry and Molecular Biology, Louisiana State Univ. Health Sciences Center, New Orleans, LA, ⁴Genome Biology Unit, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

Oxidative and hypertrophic stresses contribute to the pathogenesis of heart failure. Insulin growth factor-1 (IGF-1) is a peptide hormone with a complex post-transcriptional regulation, generating distinct isoforms. We have previously shown that a locally acting IGF-1 isoform (mIGF-1) helps the heart to recover from toxic injury and from infarct. Sirtuin 1 (SirT1) belongs to the sirtuin family of NAD+-dependent protein deacetylases, whose activation lengthens life span and could prove beneficial for human health. In the murine heart, moderate SirT1 overexpression was reported to mitigate oxidative stress. Circulating IGF-1 isoform and SirT1 play antagonizing roles in life span determination and share molecular downstream targets in the heart, in turn affecting cardiomyocyte physiology. However, how different IGF-1 isoforms may impact SirT1 and affect cardiomyocyte function is unknown. Here we show that, unlike circulating IGF-1 isoform, locally acting mIGF-1 increases SirT1 expression/activity in cultured HL-1 and in neonatal mouse cardiomyocytes. mIGF-1-induced SirT1 activity exerts protection against angiotensin II (Ang II) -triggered hypertrophy. Moreover, we found that SirT1 is required for mIGF-1-mediated protection against paraquat (PQ) and Ang II-induced oxidative stress, while circulating IGF-1 isoform was unable to do so. Interestingly, potent cardio-protective genes (adiponectin, UCP-1 and MT-2) were increased in mIGF-1-overexpressing cardiomyocytes, in a SirT1-dependent fashion. Conversely, circulating IGF-1 isoform did not affect adiponectin, UCP-1 and MT-2 mRNA levels. Thus, mIGF-1 protects cardiomyocytes from oxidative and hypertrophic stresses via SirT1 activity, and may represent a promising therapeutic target to fight heart diseases.

914/B72
O-Glcnacylation Regulates Hyperglycemia-Induced GPX1 Activation.
S. Park¹, W. Yang¹, S. Ji¹, J. Kang², J. Kim³, H. Song³, I. Mook-Jung³, J. Cho³; ¹Biology, Yonsei university, Seoul, Korea, South, ²Biochemistry and Biomedical Sciences, Seoul National University, Seoul, Korea, South

The antioxidant enzyme glutathione peroxidase 1 (GPX1) has an important role in cell survivals in response to oxidative stress. It is well known that oxidative stress-induced phosphorylation of
GPX1 regulates its activity. Also, hyperglycemia-induced GPX1 activation has been reported, but the exact mechanism has not been established yet. In this study, we show that posttranslational modification of GPX1 by O-linked N-acetylglucosamine (O-GlcNAc) increases under hyperglycemic conditions and the modification occurs at the C-terminus of GPX1. And we investigate that O-GlcNAcylation of GPX1 increases its binding to the c-Abl/Arg tyrosine kinases, which are important for oxidative stress-induced GPX1 activation, resulting in increased GPX1 activity. Furthermore, we demonstrate that NAG-thiazoline (NTZ), O-GlcNAcase inhibitor, treatment can induce GPX1 activation in the mice tissue. Our findings suggest that O-GlcNAcylation has an important role in GPX1 activation under hyperglycemic conditions due to diabetes.

915/B73
Creation of a Mouse Model for Lowe Syndrome.
S. P. Bothwell, E. K. Chan, R. L. Nussbaum; Institute for Human Genetics, University of California at San Francisco, San Francisco, CA

Lowe syndrome is an X-linked disorder characterized by congenital cataracts, intellectual deficits, and renal tubular dysfunction characterized by low molecular weight (LMW) proteinuria, renal tubular acidosis, aminoaciduria, phosphaturia, and inability to concentrate urine. It is caused by loss-of-function mutations in the OCRL1 gene, a PIP2 5-phosphatase. Mutations in OCRL1 are also responsible for a subset of Dent disease, a renal disorder characterized by LMW proteinuria, hyperphosphatemia, and hypercalciuria. To date, a mouse model of Lowe syndrome has not been available, as mice deficient in either Ocr1 or Inpp5b, an autosomal paralog of Ocr1, do not recapitulate the disease. Mice deficient in both Ocr1 and Inpp5b die prior to implantation, indicating functional overlap. We hypothesize that Inpp5b may compensate completely for the loss of Ocr1 in mice, while INPP5B may only partially compensate in humans, leading to Lowe syndrome. To develop a model of Lowe syndrome, we set out to replace mouse Inpp5b with human INPP5B in Ocr1 knockout mice. First, we established transgenic mouse lines expressing human INPP5B from a bacterial artificial chromosome. We crossed these lines with Inpp5b-/- mice and subsequently with Ocr1-/- or Ocr1-/-Y mice. Double knockout mice expressing one copy of human INPP5B (Inpp5b-/-; Ocr1-Y; BAC-Tg-) showed reduced post-natal growth and substantial LMW proteinuria. A subset of these mice was severely runted, died prematurely, and had larger amounts of LMW proteinuria. Double knockout mice expressing two copies of human INPP5B (Inpp5b-/-; Ocr1-Y; BAC-Tg+) also have reduced post-natal growth, but only small, variable amounts of LMW proteinuria, and no severe runting. Mice with one or two copies of mouse Inpp5b who are deficient in Ocr1 and do not express human INPP5B have normal growth and no LMW proteinuria. We conclude that mouse Inpp5b prevents the tubular abnormalities caused by the loss of Ocr1 whereas human INPP5B does not, and that there is a gene dosage effect in the degree of compensation by human INPP5B.

916/B74
Defining the Role of OCRL1 in Endocytic Trafficking in the Search for Drug Targets in Lowe Syndrome.
A. M. De Matteis¹, M. Vicinanza¹, A. Di Campli¹, E. Polishchuk¹, M. Santoro⁴,¹, G. Di Tullio¹, E. Levchenko², R. Polishchuk², M. Marzolo³,¹ Department of Cell Biology and Oncology, Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy, ²Department of Paediatrics, Ghent University Hospital Leuven, Leuven, Belgium, ³Facultad de Ciencias Biológicas Pontificia Universidad Católica de Chile, Departamento de Biología Celular y Molecular, FONDAP Centro de Regulación Celular y Patología (CRCP), Santiago, Chile, ⁴Telethon Institute of Genetic and Medicine, Naples, Italy

OCRL1 is a phosphatidylinositol-4,5-bisphosphate 5-phosphatase (PI5P5ase) that cycles between the endosomal compartments and the Golgi complex. Mutations in the ocr1 gene cause Lowe syndrome, a rare X-linked disease that is characterised by congenital cataracts, central hypotonia and renal Fanconi’s syndrome (low molecular weight proteinuria, tubular acidosis). OCRL1 is a multidomain protein with a split N-terminal PH domain, a central 5-phosphatase catalytic domain,
an ASH domain, a C-terminal catalytically inactive Rho GAP domain, multiple clathrin binding motifs, and Rab binding regions. Through these domains and motifs, OCRL1 interacts with key components of the membrane trafficking machineries, such as AP2, clathrin, Rab5, Rab6, Rab14, Arf6 and APPL1. Rather surprisingly, our knowledge of the actual functional role of OCRL1 lags well behind that of its molecular structure and interactors. To gain insight into this and into its PI5Ptase activity in membrane trafficking and in the pathogenetic mechanisms of Lowe syndrome, we undertook two independent approaches: analysis of the endocytic compartments in kidney proximal tubular cells obtained from Lowe syndrome patients; and study of the multiple endocytic pathways and the functional and ultrastructural consequences of the knock-down of OCRL-1 (by RNA interference). Our results indicate that through its PI5Ptase activity, OCRL maintains the identity and function of the early endosomes (through control of their lipid and protein compositions), the structure of the early endosomes as a compartment, and the efficiency of the trafficking pathways that traverse this compartment. This includes megalin, the multiligand receptor that drives the uptake and absorption of proteins in proximal tubular cells, and that undergoes mistrafficking in cells devoid of functional OCRL-1. We have exploited the endocytic defects of cells deprived of OCRL-1 to set up robust and reproducible assays to be used in high-content screening of siRNA libraries or small molecule libraries to identify drug targets and hit compounds for drug development.

Lowe Syndrome Patient Fibroblasts Display OCRL1-Specific Cell Migration Defects That Cannot Be Rescued by the Homologous Inpp5b Phosphatase.
B. G. Coon1,2, D. Mukherjee1,2, C. B. Hanna1,2, D. J. Riese II2, M. Lowe3, R. Aguilar1,2; 1Biological Sciences, Purdue University, West Lafayette, IN, 2Purdue Center for Cancer Research, West Lafayette, IN, 3Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom

The Lowe syndrome is an X-linked, life-threatening, developmental disease characterized by mental retardation, cataracts and renal failure. Although this human illness has been linked to defective function of the phosphatidylinositol 5-phosphatase, Ocr1 (Oculo-Cerebro-Renal syndrome of Lowe protein 1), the mechanism by which this enzyme deficiency triggers the disease is not clear. Ocr1 is known to localize mainly to the Golgi apparatus and endosomes, however it translocates to plasma membrane ruffles upon cell stimulation with growth factors. The functional implications of this inducible translocation to the plasma membrane are presently unknown. Here we show that Ocr1 is required for proper cell migration, spreading and fluid-phase uptake in both established cell lines and human dermal fibroblasts. In agreement with these results, we found that primary fibroblasts from two patients diagnosed with Lowe syndrome displayed similar cellular defects. Importantly, these abnormalities were suppressed by expressing wild-type Ocr1 but not by a phosphatase-deficient mutant. Interestingly, the homologous human PI-5-phosphatase, Inpp5b, was unable to complement the Ocr1-dependent cell migration defect. Further, Ocr1 variants that cannot bind the endocytic adaptor AP2 or clathrin, like Inpp5b, were less apt to rescue the migration phenotype. However, no defect in membrane recruitment of AP2/clathrin or in transferrin endocytosis by patient cells was detected. Collectively, our results suggest that Ocr1, but not Inpp5b, is involved in ruffle-mediated membrane remodeling. Our results provide new elements for understanding how Ocr1 deficiency lead to the abnormalities associated with the Lowe syndrome.

918/B76

Role of OCRL1 in Renal Epithelial Membrane Traffic.
S. Cui, C. Guerriero, C. Szalinski, C. Truschel, R. Hughey, O. A. Weisz; University of Pittsburgh, Pittsburgh, PA

Lowe Syndrome is an X-linked disease resulting from mutations in OCRL1, an enzyme that hydrolyzes the 5’-phosphate from phosphatidylinositol 4,5-bisphosphate (PIP2). Lowe Syndrome patients develop Fanconi syndrome, a renal disorder characterized by urinary loss of excess amounts of low molecular weight proteins, amino acids, bicarbonate, minerals, and phosphate.
Proteinuria is thought to result from impaired function of the multiligand receptor megalin in the kidney proximal tubule. Because PIP2 modulates numerous steps in endocytosis, it has been suggested that OCRL1 deficiency causes impaired megalin trafficking resulting in proteinuria. To test this hypothesis, we knocked down OCRL1 in canine and human renal epithelial cells using siRNA. Cellular PIP2 levels were slightly elevated in cells depleted of OCRL1, and we measured an increase in actin comet frequency in these cells, consistent with previous observations in primary fibroblasts cultured from Lowe Syndrome patients. Apical biosynthetic delivery kinetics were unaffected by OCRL1 knockdown, indicating that the population of PIP2 modulated by OCRL1 is likely not involved in the trafficking of newly synthesized proteins. We did not observe defects in megalin endocytosis or in the fate of megalin ligands in cells lacking OCRL1. Delivery of newly synthesized lysosomal hydrolases, however, was impaired in these cells, suggesting that OCRL1 plays a role in membrane trafficking between the TGN and endosomes. Together, our studies indicate that OCRL1 is not directly involved in receptor mediated endocytosis and megalin ligand uptake. Rather, the renal symptoms observed in Lowe Syndrome patients are likely to result from downstream effects due to loss of OCRL1 function.

Generation of Transgenic Zebrafish Expressing Cytotoxic Beta-Amyloid (Aβ42) Peptides as a Novel Alzheimer's Disease Model.
C. Bodkin-Clarke¹,², G. J. Cole¹,², J. Lee¹,², Biomedical Biotechnology Research Institute, North Carolina Central University, Durham, NC, ²Biology, North Carolina Central University, Durham, NC

Beta-amyloid peptide (Aβ42) is a proteolytically generated short peptide from amyloid precursor protein (APP), and plays a vital role in the pathogenesis of Alzheimer’s disease (AD) due to cytotoxicity stemming from its oligomerization. In contrast to previously established AD animal models where the uncleaved mutant APP from human AD patients is expressed, our approach takes advantage of the direct expression of the toxic human Aβ42 (hAβ42) peptides using transgenesis. Our DNA constructs contain different temporally and spatially specific promoters, and hAβ42 linked to green fluorescent protein (GFP) by the viral 2A peptide. Importantly, Aβ42 is preceded by a zebrafish erythropoietin signal peptide (EpoSP) to ensure the cleavage and secretion of Aβ42, thereby mimicking the natural processing of Aβ42. The combination of highly efficient Tol2 transposon-based transgenesis, the ‘self-cleaving’ viral 2A peptide, and the numerous advantages of transparent zebrafish embryos provide a powerful technology by which the effects of hAβ42 can be continuously analyzed in living animals. We observed GFP expression in the injected embryos as early as 1 day post-fertilization. Immunohistochemistry of the injected embryos confirmed the expression of hAβ42 in and around GFP-positive cells, while acridine-orange staining of living embryos suggests increased cell death in proximity to the expressed hAβ42. Newly established transgenic lines with a heat-shock promoter and EpoSP-EGFP-V2A-hAβ42 are currently analyzed. Further confirmation of the validity of our zebrafish AD models, by detailed cellular and behavioral assays, is underway with an aim to develop these models for chemical modifier screening to identify potential drug candidates for AD treatment. Supported by NIH grant NS33981 and the North Carolina Biotechnology Center

Prevalence of Brain-Reactive Autoantibodies in Human Sera and Their Cellular Targets in the Alzheimer's Disease Brain.
E. Levin¹, N. Acharya², P. Clifford¹, M. Han¹, S. Zavareh¹, N. Coretti¹, V. Venkataraman², R. Nagele¹; ¹NJ ISA, UMDNJ, Stratford, NJ, ²Cell Biology, UMDNJ, Stratford, NJ

Previous studies have reported immunoglobulin (Ig)-positive cells in post-mortem Alzheimer’s disease (AD) brains, which are only rarely observed in healthy, age-matched control brains. This
implies that brain-specific Igs exist in the sera of AD individuals and gain access to the brain interstitium. To investigate this possibility, we determined the prevalence of neuron-binding Igs in sera from AD patients, age-matched controls, and healthy younger individuals via immunohistochemistry and western blot analysis. Whole sera or its purified Ig fraction were applied as primary antibody to histological sections of human AD and age-matched control brains as well as adult mouse brains. Neuron-binding Igs were common in sera from AD and control individuals, with dramatic individual differences in the intensity and cell type specificity of neuronal immunolabeling. Interestingly, neurons in brain regions showing pathology were more reactive to serum Igs than the same neurons in comparable regions devoid of pathology. When sera or their Ig fractions were used to probe western blots of human, rat or mouse brain membrane proteins, a number of different protein targets were detected. Additionally, the relative number and intensity of bands in western blots tended to match the intensity of immunostaining of neurons in sections of human brain. Western analyses also suggested the presence of age- and disease-specific antibodies in some sera. Lastly, human serum Igs were found to immunolabel comparable neurons in histological sections of adult mouse brain cortical and hippocampal neurons and vice versa, suggesting cross-species reactivity. Results suggest a prevalence of neuron-binding Igs in human sera, a finding that leads us to propose that these Igs may be involved in the pathogenesis of AD and other neurodegenerative diseases that include BBB compromise. Supported by the National Institute of Aging (AG00925), the Alzheimer’s Association, and the New Jersey Governor’s Council on Autism.

Neuron-Binding Autoantibodies in Human Sera Enhance Amyloid Beta\textsubscript{1-42} Accumulation in Adult Mouse Brain Neurons.
N. Acharya\textsuperscript{1}, E. Levin\textsuperscript{1}, P. Clifford\textsuperscript{1}, G. Su\textsuperscript{1}, M. Han\textsuperscript{1}, V. Venkataraman\textsuperscript{2}, R. G. Nagele\textsuperscript{1}; \textsuperscript{1}NJ ISA, UMDNJ, Stratford, NJ, \textsuperscript{2}Cell Biology, UMDNJ, Stratford, NJ

A major feature of Alzheimer’s disease (AD) is widespread deposition of amyloid-beta peptides, especially amyloid-beta\textsubscript{1-42} (a\textbeta\textsubscript{42}), in neurons and amyloid plaques. Mechanisms for a\textbeta deposition in the brain and its association with aging remain to be elucidated. Previous studies have reported immunoglobulin (Ig)-positive neurons in post-mortem AD brains, suggesting that the blood-brain barrier (BBB) is permeable to Igs. We have observed a prevalence of immunopositive neurons in plaque- and neurofibrillary tangle-forming regions of AD brains that also exhibit substantial intraneuronal a\textbeta deposition. We hypothesize that chronic binding of Igs to neurons and Ig clearance via endocytosis enhance intraneuronal deposition of exogenous, soluble a\textbeta peptides in neurons. To investigate this, we examined the effects of human and mouse neuron-binding Igs on intraneuronal a\textbeta\textsubscript{42} deposition in adult mouse brain neurons In Vitro (organotypic brain slice cultures) and In Vivo (direct stereotoxic intracranial injection). Results revealed a dramatic enhancement in the rate and extent of exogenous a\textbeta\textsubscript{42} accumulation in mouse cortical and hippocampal neurons upon binding of human or mouse Igs to neurons. Moreover, Igs from individual sera that immunolabeled neurons most intensely in sections of human brain tissue were the most potent at enhancing intraneuronal accumulation of exogenous a\textbeta\textsubscript{42} peptide. Lastly, replacing whole serum or purified Ig fraction with purified antibodies directed against abundant neuronal surface proteins resulted in comparable enhancement of a\textbeta\textsubscript{42} accumulation in mouse brains both In Vivo and In vitro. Results suggest that neuron-binding Igs commonly present in human serum can gain access to neurons through defective BBB and enhance soluble a\textbeta\textsubscript{42} peptide deposition within neurons in AD brains via enhanced endocytosis. Therefore, brain reactive autoantibodies in human sera may be a significant risk factor for AD as well as other neurodegenerative diseases that have BBB compromise. Supported by the Alzheimer’s Association and the New Jersey Governor’s Council on Autism.

Autophagic Regulation of Alpha-Synuclein Pathotoxicity Properties in Budding Yeast Reveals Unexpected Complexities.
Parkinson's disease (PD) is an incurable neurodegenerative disease characterized by the selective loss of dopaminergic neurons in the midbrain. This cell death is likely due to misfolding and aggregation of the protein alpha-synuclein. A prevalent hypothesis is that accelerating the degradation of alpha-synuclein can decrease cellular toxicity. Autophagy is a highly evolutionary conserved catabolic mechanism in eukaryotes used to recycle cell's own components such as damaged proteins. Pharmacological research implicates autophagy-based lysosomal degradation of alpha-synuclein, but genetic evidence is still lacking. We hypothesized that basal autophagy protects cells from alpha-synuclein toxicity and tested it in a budding yeast model in strains deleted for individual genes that control the three steps of autophagy: nucleation, expansion, or fusion. Thus far, we have examined four nucleation genes (Atg11, Atg17, Atg13, and Atg1), four expansion genes (Atg18, Atg4, Atg3, and Atg2), and two fusion genes (Vam3 and Vam7). We predicted accumulation of alpha-synuclein, its altered cellular localization, and increased cellular toxicity, in at least some of these strains. In fact, none of the gene deletions induced alpha-synuclein dependent cellular toxicity. However, alpha-synuclein localization showed subtle yet consistent changes when some Atg genes were absent. Specifically, in the absence of Atg11 and Atg2, alpha-synuclein aggregated and did not maintain plasma membrane localization. Without Atg17, alpha-synuclein became more cytoplasmically diffuse and less plasma membrane localized. To further our understanding of autophagy-mediated alpha-synuclein degradation, we will continue analyzing knockout strains for the remaining genes that compromise autophagy. **Amyloid Beta Mediated Alterations to the Microtubule Associated Protein Tau.**

J. R. Reifert¹,², D. Hartung¹,², S. Feinstein¹,², ¹Neuroscience Research Institute, UCSB, Santa Barbara, CA, ²Molecular, Cellular and Developmental Biology, UCSB, Santa Barbara, CA

Distinguishing hallmarks of Alzheimer's Disease include the accumulation of both amyloid beta (Aβ) plaques and neurofibrillary tangles (NFT's) in specific regions of affected brains. The aggregation of Aβ peptides into insoluble fibrils, the principal components of plaques, involves the production of Aβ soluble oligomer intermediates. NFT's are composed of insoluble aggregates of the microtubule associated protein tau. The amyloid cascade hypothesis suggests that Aβ soluble oligomers alter neuronal metabolism resulting in aberrant tau phosphorylation and truncation, ultimately leading to the production of NFT's and eventual neuronal death. In order to investigate specific effects of Aβ oligomers on tau, cultured rat hippocampal neurons were treated with oligomerized Aβ and a timecourse of biochemical samples were harvested prior to, and during, the period of cell death. Multiple phosphorylation epitopes on tau were analyzed for altered abundance via western blotting using site and phospho-specific antibodies. Surprisingly, none of the 8 phospho epitopes analyzed revealed altered levels within the timecourse of Aβ treatment relative to controls even though altered signaling pathways suggest elevated cdk5 and GSK3β activity within the neurons. on the other hand, a prominent alteration to tau observed throughout the timecourse of Aβ treatment was fragmentation, as seen by the loss of the full-length tau and accumulation of lower molecular weight fragments. These fragments remained stable in the later time points when significant levels of neuronal cell death was observed as assayed by both metabolic function and membrane integrity. Fragmentation of tau was preceded by increased calpain and caspase protease activity consistent with proteolytic action on tau. Taken together, these data indicate that an increase of phosphorylation at the sites we analyzed does not correlate with neuronal cell death whereas there is good temporal correlation between the generation of tau fragments and decreased neuronal viability. Overall, tau proteolysis may be a key functional step in Aβ mediated cell death.

**Feed-Forward Mechanisms of Aβ Production and Secretion in Cortical Neurons.**
Sub-micromolar concentrations of dimeric/trimeric species of Aβ perturb synaptic plasticity in vitro and disrupt cognitive function in vivo. However, even in healthy individuals, Aβ is normally secreted but maintained at sub-toxic levels by various clearance mechanisms. Therefore, non-hereditary mechanisms that facilitate the sustained secretion of Aβ are of great interest for understanding the etiology of sporadic Alzheimer disease (AD). Based upon our findings that in neurons Aβ can induce cofilin-actin rods (rods), which block amyloid precursor protein (APP)-vesicle transport, we proposed a feed-forward mechanism by which neurodegenerative stimuli implicated in Alzheimer disease induce rods, block transport, and enhance Aβ secretion. Here, we report the development of a sandwich ELISA that quantitatively measures endogenous total rodent Aβ (Aβ1-40 + Aβ1-42) at levels down to 10 pg/ml. Using this ELISA and normalizing results to cell density by means of DNA assays, we demonstrate that levels of Aβ increase in response to treatments that generate rods, but only when neuronal ATP-levels remain high enough to promote the accumulation of APP-vesicles at rods. Peroxide (20 μM) treatment, which induces rods in 80% of the neurons and allows APP-vesicle accumulation, gives a 2.5 fold increase in secreted Aβ. Neither ATP depletion nor AMPA-treatment increases Aβ secretion or causes APP-vesicle accumulation, although both treatments induce abundant rods. No significant changes in intracellular Aβ occur under any treatment conditions. (Supported by NIH grant NS40371 to JRB).

Glutamate Induced Cofilin/Actin Rods and Oxidation.
B. W. Bernstein, A. E. Shaw, J. Bamburg; Biochemistry/Molecular Biology, Colorado State University, Fort Collins, CO

Cofilin/actin rods are cigar-shaped actin aggregates that appear in neurites following a wide variety of stress that includes chemical ischemia, anoxia, cofilin over expression, or exposure to excess glutamate, peroxide, or amyloid beta 1-42 oligomers. Rod obstruction of neurite transport and synaptic function results in process degeneration distal to the rod. These rods are abundant in brain of Alzheimer disease (AD) patients but not in non-AD brain. To understand how stress involved in sporadic AD might generate the same pathology seen in familial AD, we are studying factors promoting rod generation. Herein we report that glutamate-induced rod formation likely requires inter-molecular cofilin disulfide bonds. Oxidized glutathione previously was shown in vitro to oligomerize cofilin through inter-molecular disulfide bonds generated between C39 and C147 by oxidation. Dimerized and oligomerized cofilin dramatically bundles actin into rod-like structures in vitro and has no disassembly activity. We adenovirally infected rat E18 hippocampal neurons to express a double cofilin mutant (CC39,147AA-mRFP) and exposed the neurons to excitotoxic levels of glutamate. Correlation coefficient analysis of neuronal confocal images showed that the double mutant had ~50% less tendency to incorporate into rods than wt cofilin-mRFP. In contrast to the double mutant, we found that single cofilin C/A mutants, which are still capable of inter-molecular disulfide bond formation, incorporate into rods as efficiently as wt cofilin-mRFP. It is important to note that the double mutant binds F-actin normally in sedimentation assays. Rods formed through cofilin over expression appear in unusually highly oxidized regions of neurites and are reversed by 15 min exposure to 4 μM β-mercaptoethanol.

Y. Chi, Y. Xiang, D. Tang, Y. Wang; Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI

The accumulation of amyloid beta (Aβ) peptides and formation of beta-amyloid plaques are central events in the development of Alzheimer’s disease (AD). Aβ is produced by the proteolysis
of amyloid precursor protein (APP). APP cleavage by different secretases and Aβ generation occur during APP intracellular trafficking. The Golgi apparatus, the central organelle for intracellular trafficking, however, has been observed fragmented in neurons of human AD patients. The molecular mechanism leading to Golgi fragmentation in AD and its effects on disease development remain elusive. In this study, we demonstrate that the Golgi is fragmented in the brain of APPswe/PS1dE9 double transgenic mice and in Chinese Hamster Ovary (CHO) cells stably transfected with APPswe/PS1dE9. Further experiments provided evidence that the Golgi fragmentation in AD is due to APP proteolysis and subsequent Aβ accumulation, which induces the phosphorylation of Golgi structural proteins and causes Golgi fragmentation. Expression of the N-terminal GRASP-Domain of the Golgi stacking factor GRASP65 rescued the Golgi structure and significantly reduced Aβ40 and especially Aβ42 production. Our results indicate that Golgi fragmentation in AD is caused by Aβ accumulation, which in turn affects APP trafficking and enhances Aβ production. Significantly, improving Golgi structure may alleviate the production of Aβ and decelerate the disease progress.

Investigating the Contribution of Serine Phosphorylation, Alanine-76, and Familial Mutant E46k to A-Synuclein Pathotoxicity in Two Yeast Models.
M. Fiske, K. Solvang, S. Valtierra, S. Herrera, M. Zomiak, A. Konnikova, S. K. DebBurman; Lake Forest College, Lake Forest, IL

Parkinson disease (PD) is a devastating and incurable neurodegenerative disorder that affects over one million Americans. The universal PD pathology is the presence of aggregated α-synuclein within dying midbrain substantia nigra neurons. The role these α-synuclein aggregates play in cell death is unclear, and whether these aggregates are neuroprotective or harmful to cells is still being debated. Here, we first tested the hypothesis that serine phosphorylation promotes α-synuclein aggregation and toxicity by studying two phosphorylation-deficient (S87A & S129A) and two phosphorylation mimic (S87D & S129D) α-synuclein mutants in budding and fission yeast models. In budding yeast, we found that both S87A & S129A altered α-synuclein localization within cells and, surprisingly, increased cellular toxicity, but to differing extents in different strains. In fission yeast, both S87A & S129A redistributed α-synuclein within the cytoplasm, and increased toxicity to a mild extent. Secondly, we tested the hypothesis that alanine-76 (a key residue within the middle hydrophobic domain of α-synuclein) contributes to its aggregation and plasma membrane phospholipid association, by characterizing an A76E and A76R mutant in both yeasts. In support of this hypothesis, in budding yeast, significantly less A76E localized to the plasma membrane. Furthermore, in fission yeast, less A76E was aggregated in live cells. In both yeasts, A76E was found more cytoplasmically diffuse than wildtype α-synuclein. Finally, we examined the properties of E46K, the most recently discovered familial PD mutant. E46K bound to the plasma membrane in budding yeast and formed aggregates in fission yeast. Our data support the notion that serine-87 and serine-129 phosphorylation may make α-synuclein cytoprotective and alanine-76 aids in α-synuclein aggregation and membrane phospholipid binding. E46K had little influence on α-synuclein properties. E46K properties are more similar to wildtype α-synuclein and the A53T familial mutant than to the A30P familial mutant. Mutant Huntingtin Mediates Neuronal Injury by Mitochondrial Fission.
V. de ASSIS, A. Petrilli, W. Song, G. Liot, S. Lubitz, J. Johnson, M. Pouladi, M. Hayden, E. Masliah, M. Ellisman, B. Bossy, I. Rouiller, G. Perkins, E. Bossy-Wetzel; 'Burnett School of Biomedical Sciences, College of Medicine, University of Central Florida, Orlando, FL, 2NCMIR, University of California, San Diego, CA, 3CMMT, University of British Columbia, Vancouver, BC, Canada, 4University of California, San Diego, CA, 5McGill University, Montreal, QC, Canada

It is becoming increasingly clear that mitochondrial dysfunction is an early and central part of Huntington’s disease (HD) pathogenesis. The precise mechanism causing this defect is still
unknown. We therefore investigated whether mutant huntingtin (htt) alters the mitochondrial fission/fusion balance and thereby mediates neuronal injury and cell death. We find that mutant htt triggers polyQ length-dependent mitochondrial fission. EM tomography illustrates mitochondrial and cristae fragmentation in brain sections of mutant htt transgenic mice in vivo. Additionally, mutant htt interacts with the mitochondrial fission factor Dynamin related protein 1 (Drp1) in brain tissue of transgenic mice and post-mortem HD patients, and HD patient lymphoblasts in vivo. Furthermore, mutant htt accelerates Drp1 GTPase activity and modifies its oligomeric ring structure in vitro. Finally, mitochondrial fragmentation, arrest in anterograde and retrograde axonal transport of mitochondria, synaptic spine loss and neuronal cell death are all rescued by expression of Mitofusin 2 (Mfn2) and a dominant-negative Drp1 mutant. Thus, components of the mitochondrial fission and fusion machinery might be new therapeutic targets to combat neuronal injury in HD and perhaps other neurodegenerative disorders. Supported by: R01 NS047456, R01 EY016164, R01 NS055193, Hereditary Disease Foundation (to EBW) P41RR04050, R01 NS14718 (to MHE).

Aberrant Membrane Trafficking from the Recycling Endosome in Huntington's Disease.
X. Li, E. Sapp, A. Valencia, C. Standley, J. Alexander, N. Masso, K. B. Kegel, K. E. Fogarty, N. Aronin, M. DiFiglia; 1Neurology, Massachusetts General Hospital and Harvard Medical School, Charlestown, MA, 2Biomedical Imaging Group, Department of Physiology, University of Massachusetts Medical School, Worcester, MA, 3Department of Medicine and Cell Biology, University of Massachusetts Medical School, Worcester, MA

Huntington's disease (HD) is a neurodegenerative disease caused by CAG repeat expansion (>37) in exon 1 of the gene encoding huntingtin. Whole brain atrophy and loss of neurons in the striatum and the cerebral cortex are hallmarks of HD pathology. There is no treatment to halt disease progression. Most studies to understand HD pathogenesis have focused on N-terminal fragments carrying the expanded polyglutamine tract. Analysis of the effects of the HD mutation on cell functions in the context of endogenous mutant huntingtin is more difficult because phenotypes are less robust and slower to develop than with the use of N-terminal fragments. However, detection and treatment of early phenotypes that precede onset of symptoms in HD patients may be valuable for slowing disease progression. Huntingtin associates with clathrin coated vesicles and interacts with proteins involved in vesicle budding and fusion. In this study, we used primary skin fibroblasts established from HD patients and primary cortical neurons of CAG140 knock-in HD mice as our models to investigate effects of mutant huntingtin on membrane trafficking in the endocytic pathway. We found that primary human HD fibroblasts and primary cortical neurons from homozygous CAG140 knock-in HD mouse embryos were normal in clathrin-dependent endocytosis of transferrin, but had deficits in post-endocytic recycling. Total Internal Fluorescence Reflection (TIRF) live cell imaging was used to track recycling vesicles with labeled transferrin. We found a redistribution of transport intermediates from small to large vesicles and from short to long tubules in primary HD fibroblasts, suggesting a deficit in vesicle budding at recycling endosomes. Biochemical assays showed that mutant huntingtin interfered with the nucleotide exchange on Rab11. Expression of dominant active Rab11 (Rab11Q70L) improved recycling of transferrin receptor in primary HD fibroblasts and increased survival of primary HD cortical neurons. Our study defines a novel mechanism for HD pathogenesis arising from defective Rab11-dependent membrane dynamics at the recycling endosome. Thus, approaches that increase Rab11 activity may be effective for treatment of HD.

Aberrant Proteolysis of Polyglutamine-Expanded Androgen Receptor and Dynamics of Aggregation in SBMA.
E. Heine, C. Orr, D. Merry; Biochemistry and Molecular Biology, Thomas Jefferson University, Philadelphia, PA
The aggregation of mutant and misfolded proteins is a common feature of many polyglutamine (polyQ) repeat disorders; the process by which these inclusions form is an important and unanswered question. Evidence from models of SBMA showing that nuclear inclusions (NI) lack C-terminal AR epitopes support the hypothesis that aberrant proteolysis of the expanded polyQ androgen receptor (AR) leads to accumulation of N-terminal AR fragments, a central process to SBMA pathogenesis. The protease and the circumstances of cleavage are currently unknown. In order to identify the AR proteolytic cleavage site, we immunoprecipitated AR aggregates from an inducible PC12 cell model exhibiting DHT- and polyQ length-dependent nuclear cleavage and aggregation of the expanded AR. Dissolution of NI with organic solvents resulted in the release of a 45 kDa N-terminal AR fragment that was analyzed by mass spectrometry for C-terminal residue identification. Preliminary results suggest that the cleavage point is at either amino acid D152 or L163. Precise identification and confirmation of the residue is ongoing. Studies are under way to identify the protease responsible for the aberrant AR cleavage; initial data suggest that the proteasome plays a role in AR aggregation. To examine the aberrant cleavage and aggregation event in SBMA, we created a PC12 cell line in which expanded AR is fused with CFP and YFP at the N- and C- termini, respectively. We noted that a proportion of cells contain AR aggregates that maintain the C-terminus, leading to the hypothesis that full-length AR is recruited to aggregates and subsequently cleaved. Stages of aggregation were classified based on aggregate size and C-terminus content, and live-cell fluorescent imaging was used to observe the aggregation process after DHT addition. From this we conclude that the aggregation stages represent a continuum of inclusion formation; moreover, that full-length AR aggregates prior to cleavage. A provisional rate of inclusion formation and maturation was determined and showed that inclusions form in 4-12 hours. These studies lay the groundwork for defining the role of AR proteolysis in SBMA pathogenesis as well as identifying the protease responsible for AR cleavage.

C. Droppelmann², K. Volkening², C. Leystra-Lantz², M. J. Strong¹,²; ¹Clinical Neurological Sciences, The University of Western Ontario, London, ON, Canada, ²Molecular Brain Research Group, Robarts Research Institute, The University of Western Ontario, London, ON, Canada

The disruption of the stoichiometry of neurofilament subunits (NFL, NFM and NFH for low, middle and high molecular weight neurofilaments respectively) can lead to the development of aggregates of these proteins, a hallmark of ALS. p190RhoGEF, a guanine nucleotide exchange factor found in mice, has been described that interacts with a small destabilizing region of NFL mRNA and imparts stability to the transcripts. p190RhoGEF is a critical determinant of murine NFL mRNA stability and alteration in its binding contributes to the formation of NF aggregates in mice. However, the function of this protein in humans, and its contribution to ALS pathology is unknown. Previously, we described the interaction of NFL mRNA with RGNEF, the human homologue of p190RhoGEF. This specific interaction was only observed in lysates from ALS affected spinal cords. In this study we have identified 4 distinct isoforms of RGNEF that we called A, B, C and D: the isoform a with 4956 bp; the isoform B with 5118 bp and an additional sequence in 3'; the isoform C with 5196 bp and an insertion before the additional sequence in 3' and the isoform D with 5061 bp similar to the isoform C but with a shorter RNA binding domain sequence than the others isoforms (917 against 1049 bp). We also show that at least two of these isoforms are expressed at mRNA level in the human nervous system with changes in the expression between control and ALS patient spinal cord tissues. These results suggest that the levels of the different RGNEF isoforms may play a role in the development of the ALS pathology, perhaps through distinctive patterns of interaction with NFL mRNA.

Motor Neuron Degeneration Linked with Mitochondrial Fission in Amyotrophic Lateral Sclerosis.
Mitochondrial dysfunction is an early event in motor neuron degeneration during Amyotrophic Lateral Sclerosis (ALS). However, the precise cause of these mitochondrial deficits remains unclear. Mitochondria are dynamic organelles and cycles of mitochondrial fission and fusion ensure equal energy distribution across long axons, effective Ca2+ buffering, bio-energetic functionality, and translocation of the organelle to regions of high energy demands like the synapses. While mitochondrial fragmentation, or fission, contributes to neurodegenerative disorders and affects neurons with long axons such as motor neurons, its potential implication in ALS has never been explored. Therefore we tested whether mitochondrial fragmentation, or fission, by mutant SOD1 (mSOD1) contributes to motor neuron degeneration. To investigate this problem we co-cultured spinal cord motor neurons with astrocytes and used live cell imaging to track mitochondrial dynamics. Among the genes that cause familial ALS is sod1 which encodes Cu/Zn superoxide dismutase (SOD1). We find that mitochondrial length is decreased in motor neurons expressing mSOD1G93A suggesting that mitochondrial fragmentation may occur. In addition, axonal sprouting is decreased and correlates with an accumulation of small rounded mitochondria in the nerve terminal. Furthermore, both anterograde and retrograde transport of mitochondria is defective in mSOD1G93A motor neurons. Motor neurons expressing mSOD1G93A undergo rapid mitochondrial fragmentation in response to glutamate exposure and die faster. These data suggest that defects in mitochondrial dynamics may participate in ALS pathogenesis. Supported by: R01 NS047456, R01 EY016164, R01 NS055193 Timeliness: This study implicates for the first time mitochondrial fragmentation in ALS.

The Effect of Ciprofloxacin on Toll-Like Receptor-4 Expression and Apoptosis Inducing Factor in Murine Microglial.
S. D. Crockett1,2, B. Sims2, 1Human Anatomy and Cell Biology, Univ. of CA Davis, Sacramento, CA, 2Pediatrics, University of Alabama at Birmingham, Birmingham, AL

Objective: to determine if AIF is modulated by a known therapeutic modulator of microglia activation. Mammalian Apoptosis-Inducing Factor (AIF) is a 67-kDa flavoprotein with a dual function of caspase independent cell death and a lesser studied mitochondrial oxidoreductase function in normal physiological conditions. Previous studies have shown that cells with reduced levels of AIF are resistant to PARP-1-dependent cell death. Other studies have linked AIF as a protein that can protect against oxidative stress via a type of antioxidant function. However, there are no known mechanistic strategies whereby the protective characteristics of this protein can be up-regulated without causing indirect cellular death. The aim of our study is to show that under LPS induced microglia stimulation a possible mechanism to reduce AIF’s translocation and possible enhance its protective mitochondrial oxidoreductase properties is through the use of a known toll-like receptor 4 inhibitor such as ciprofloxacin (CIP). Ciprofloxacin, a fluorinated 4-quinolone antibiotic, has modulatory actions as an anti-microbial and anti-inflammatory. Methods: Preliminary results were obtained by exposing lipopolysaccharides (LPS)-challenged BV2 murine microglial cells to various dose concentrations of ciprofloxacin. Samples were collected for analysis using standard western blot, immunocytochemistry, siRNA, In situ cell death detection, GSH depletion assay for AIF expression and translocation. Expression levels were determined for inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2) for microglia activation. Results: LPS causes an increase in AIF, iNOS, and COX-2 expression levels in activated BV-2 cells. AIF expression and translocation correlated to a dose dependent response after exposure to 0, 10, 25, 50, 100mg/L concentrations of ciprofloxacin. No significant increase in cell death or changes in glutathione levels were detected. Conclusion: Ciprofloxacin, in a concentration-dependent manner, decreases AIF expression in activated BV-2 by attenuating the expression of toll-like receptor 4.

Mysterious Growth and Locomotion of C. elegans.
The Huntington Associated Protein -1, HAP-1 (which is classified as T27A3.1 in C. elegans) is the first protein that is known to resemble the diseased protein Huntington. C. elegans is a model organism that can be used to study the binding protein T27A3.1. Because C. elegans contain the T27A3.1 protein in great abundance it was found to be useful when studying growth and locomotion of nematodes. An experiment was designed to determine if the T27A3.1 gene was knocked out of the nematodes, would the locomotion and growth be affected. The first assay was designed to study the movement of the nematodes. Four groups were used were used in this study. In one group T27A3.1 was present while in the other three groups, the gene was knocked out. The assay was performed by placing one L4 hermaphrodite on a NGM agar plate, which consisted of an E. coli bacteria lawn. The behavior of the nematodes was observed under a microscope for 3 minutes and the body bends of the worms were recorded and calculated. The same worms were then utilized for determining the effect that the gene had on the growth of the nematode. The worms remained on the plate at room temperature for 3 days and on the third day the number of offspring from the hermaphrodite was counted and recorded. The data collected proved that T27A3.1 had a significant effect on locomotion and growth. Data collected from the locomotion assay, indicated that the wild type nematodes did exhibit more body bends than the knock out nematodes. An ANOVA test proved a statistical difference between the groups containing the gene and the groups that were lacking the gene. In addition, the growth assay also showed a significant difference between those with the gene and those lacking the gene.

Statins Differentiate Adult Rat Bone Marrow Stromal Cells into Neurons.
H. Kondo1, H. Fujino2; 1Nagoya Women’s University, Nagoya, Japan, 2Kobe University, Kobe, Japan

PURPOSE: Neurons are obtained from differentiation of neural stem cells (NSCs). However, there are not so many NSCs in adult brains. Therefore, it is necessary to develop the method how to proliferate and differentiate endogenous NSCs or to find source of neurons other than NSCs. It has been known that bone marrow stromal cells (BMSC) are able to differentiate towards a neuronal phenotype. Statins, inhibitors of 3-hydroxy-3-methylglutaryl coenzyme a reductase, induce neurite-like outgrowth in PC12 cells and neurogenesis of NSCs after stroke. Therefore, the aim of the present study was to determine the effects of simvastatin, one of statins, on BMSC differentiation in vitro. METHODS: BMSC were collected from femurs and tibias of female Sprague-Dawley rats aged in 8 to 12 weeks. The cells were cultured in Dulbecco’s modified Eagle’s medium (low glucose). Subconfluent cultures of rat BMSC were plated to poly-D-lysine coated. Experiments were initiated by addition of 10 µM or 5 µM active form of simvastatin observing the effect on 24 hrs, 48 hrs, 72 hrs with Fluorescence-Activated Cell Sorting and RT-PCR. The expression of mRNAs encoding the neural markers NSE, β-tubulin III, NF68, and tau, encoding the neural markers, were determined by RT-PCR. RESULTS: BMSC isolated from the femurs of adult rats and propagated In Vitro were negative for CD11b, CD34 and CD45. The levels of expression of β-tubulin III, NF-68 and tau mRNAs were not detectable in uncommitted BMSC, however, were detectable after 24 hrs of neuronal induction. The levels of expression of NSE mRNA exhibited extremely low, however, incubation with the simvastatin for 24 hrs, the levels of expression of NSE mRNA greatly enhanced. CONCLUSION: These data indicate that simvastatin differentiated BMSC into neuron-like cells for 24 hours to be confirmed by the expression of mRNAs encoding the neural markers, NSE, β-tubulin III, NF68, and tau.

Neuroprotective Effects of Cerium Oxide Nanoparticles Are Mediated by Scavenging of Nitric Oxide/Peroxynitrite.
J. M. Dowding1, W. Song1, E. Bossy-Wetzel1, A. Karakoti2, S. Lubitz1, S. Seal2, A. Kim3, G. Perkins4, M. Ellisman5, K. Bossy1; 1Burnett School of Biomedical Sciences, University Central
Florida, Winter Garden, FL, T Nanoscience and Technology Center, University Central Florida, Orlando, FL, $^3$ National Center for Microscopy and Imaging Research, University of California, San Diego, La Jolla, CA

An increase in Nitric Oxide/Peroxynitrite (NO/ONOO-) in the nervous system triggers neuronal injury and cell death and plays a central role in the pathogenesis of acute and chronic neurodegenerative disorders. Thus alleviating NO/ONOO- stress may delay or even prevent neurodegeneration. Here, we explored the ability of cerium oxide nanoparticles (CeO$_2$ NPs) to scavenge NO/ONOO- in cell free systems In Vitro and in intact cortical neurons. Cerium oxide nanoparticles (CeO$_2$ NPs) are distinct from other rare earth metals in that they can alternate between the +3 and +4 state via redox/oxidation reactions at the particle surface and thus may act as autocatalytic antioxidants. Indeed we recently demonstrated that NPs with a high +3/+4 ratio are able to scavenge superoxide anions (O$_2^-$). Redox-cycling manganese-salen complexes that are effective Superoxide Dismutase (SOD) mimetics can also react with peroxynitrite (ONOO-). We therefore were wondering whether the CeO$_2$ NPs similar to SOD mimetics may scavenge NO/ONOO-. Here, we provide evidence that CeO$_2$ NPs interact with ONOO- in vitro. Interestingly, CeO$_2$ NPs provided neuroprotection of cortical neurons exposed to an exogenous NO donor. To test further whether the NP would also be able to scavenge intracellular NO/ONOO- we exposed neurons to toxic levels of glutamate. Glutamate activates the neuronal glutamate receptors and triggers a rapid rise in Ca$^{2+}$, which in turn activates Nitric Oxide Synthase, leading to NO/ONOO- production. Interestingly, the NP provided significant neuroprotection against glutamate-induced excitotoxicity. Furthermore, we show that the CeO$_2$ NPs indeed entered the neurons and were often found in association with mitochondria using EM microscopy. Since CeO$_2$ NPs react with ONOO- in vitro, these results point to an In Vivo scavenging activity of ONOO- by CeO$_2$ NPs. Thus, the radical scavenging properties of CeO$_2$ NPs may offer new opportunities to combat neurodegenerative disorders. Supported by NIH grants R01NS047456, R01 EY016164, R01 NS055193 (to EBW). Effects of Lysosomal-Mediated Regulation of Autophagy Pathway on Neuronal Mitophagy.
A. Simone, Q. Cai, Z. Sheng; Synaptic Function Section, NINDS, NIH, Bethesda, MD

Autophagy is a lysosome-dependent cellular degradation and homeostasis pathway, which, along with proper mitochondria quality control and turnover, has been implicated in the pathologic processes of neurodegenerative diseases. In non-neuronal cells, mitophagy has been shown to be responsible for mitochondrial turnover (Narendra et al., 2008), however, significance of macroautophagy in neuronal mitochondria quality control is not yet well characterized. Here, using both cellular and biochemical approaches on cultured neurons, we establish that proper lysosomal function is necessary for autophagosome clearance in neurons and implicate a critical role of this pathway in mitochondria quality control. First, we observe autophagy upregulation after application of lysosome enzyme inhibitors in neurons. Second, we show that mitochondria turnover is mediated by macroautophagy. Third, through the use of CCCP, a mitochondria decoupler, we demonstrate that damaged or depolarized mitochondria are specifically targeted through the autophagy pathway for clearance. Because impaired autophagy and mitochondria dysfunction have been implicated in a number of neurodegenerative diseases, our study provides a cellular clue for further investigation into the relative contribution of the autophagy pathway to pathology or pathogenesis of relevant neurodegenerative mouse models, such as those for ALS and Alzheimer’s Disease. (Supported by the Intramural Research Program of NINDS, NIH)

938/B96
Contribution of the NR2B Subunit of the NMDA Receptor to Neuronal Calpain and Caspase-3 Activation Following Mechanical Injury In Vitro.
Neuronal cell death following traumatic brain injury (TBI) is associated with the stimulation of the N-methyl-D-aspartate receptor (NMDAR), leading to subsequent activation of calpains and caspases. In the present study, the effect of NMDAR antagonists on protease activation following excitotoxic or mechanical injury In Vitro was evaluated. Cortical neurons at 18 days In Vitro were treated with either vehicle (salt solution), the competitive NMDAR antagonist APV, or the non-competitive, NR2B subunit-selective antagonists (ifenprodil or Ro-25,6981) and were then subjected to either excitotoxic (NMDA) or mechanical (stretch) injury. Neurons exhibited protease activation between 30min and 24h following exposure to 100μM NMDA with caspase-3 activation predominating at 30min and calpain activation predominating at 24h. Both ifenprodil and Ro-25,6981 (1-100μM) significantly reduced caspase-3 activation at 30min (p<0.05) while APV (25μM) was effective at 4h (p<0.05). Calpain activation was inhibited by APV (10-25μM) at 4h (p<0.001) and 24h (p<0.001) and ifenprodil (10μM) at 30min (p<0.05) and 24h (p<0.005), whereas Ro-25,6981 had no effect. Interestingly, ifenprodil at 100μM exacerbated activation of both caspase-3 and calpain at 24h (p<0.001). Following either moderate or severe stretch injury, activation of both calpain and caspase-3 was observed at 30min and 4h but not at 24h. In contrast, mild stretch only activated caspase-3 at 24h. Moderate, but not severe, stretch injury in the presence of either competitive or non-competitive NMDAR antagonists (10μM) significantly inhibited calpain activation (p<0.05) as compared to vehicle treatment. Caspase-3 activation post stretch was not affected. Collectively, these data suggest that NMDARs, including NR2B-containing NMDARs, may mediate calpain activation following mechanical trauma, albeit in a severity-dependent manner. Conversely, caspase-3 activation following stretch injury appears to be independent of NMDAR stimulation. These findings underscore the complexities of neuronal responses to traumatic brain injury.

Expression of PTEN Induced Putative Kinase 1 (Pink1) Alters the Effects of Foxo Overexpression in Drosophila.
A. M. Todd, B. E. Staveley; Biology, Memorial University of Newfoundland, St. John’s, NF, Canada

PTEN induced putative kinase 1 (PINK1) has been shown to play a key role in preventing mitochondrial dysfunction during cellular stress. PINK1 has been demonstrated to act upstream of parkin and interact with several mitochondrial proteins, but its involvement with the insulin receptor (INR) pathway has been largely overlooked. Clues to this interaction include its activation through the dual role of PTEN, an indirect interaction with AKT through parkin, and transactivation by Forkhead box O (Foxo) transcription factors. To further investigate the influence of Pink1 on the INR pathway, we examined the directed expression of Pink1, Pink1 mutants, and Pink1 interfering RNAs (RNAi) with the overexpression of Foxo in the developing eye of Drosophila. Overexpression of Foxo in the Drosophila eye leads to a characteristic phenotype of reductions in cell size and cell number, and can be rescued by co-expression of upstream insulin signaling components. As a protective protein, we looked at the ability of Pink1 to rescue this phenotype. Interestingly, co-overexpression of Foxo and Pink1 showed an increase in the severity of the phenotype, with decreased cell size and number. A partial rescue was observed only with the Pink1 RNAi, suggesting that Pink1 is able to increase the pro-apoptotic effects of Foxo. This is contrary to the view that PINK1 acts exclusively as a protective protein in the cell. It is likely that PINK1 is involved in aspects of cell fate decisions other than mitochondrial protection. Support contributed by: Memorial University School of Graduate Studies Fellowship to A.M. Fluid Shear Stress Modulates Macrophage-Induced Urokinase Plasminogen Activator Expression in Osteoarthritic Chondrocytes.
Y. Wu, C. Chen; Department of Biochemical Science and Technology, National Chiayi University, Chiayi City, Taiwan

Mechanical stress initiates the cartilage lesion by altering chondrocyte-matrix interactions and inducing synthesis of matrix-degrading proteinases by chondrocytes. In addition, macrophage-like cells of the synovium release proinflammatory factors which are responsible for the upregulation of cartilage breakdown proteinases in chondrocytes, and play a critical role in cartilage degradation during osteoarthritis (OA). However, the interplays among macrophages, chondrocytes and shear stress in regulating cartilage function are not clearly understood. In this study, we investigated the mechanisms underlying the modulations of human OA chondrocyte uPA expression by macrophages and shear stress. Stimulation of OA chondrocytes with macrophage-conditioned medium induced time-dependent uPA expression and phosphorylation of ERK, JNK, p38, and Akt. By using specific inhibitors, we demonstrated that activation of JNK and Akt pathways are critical for the macrophage-induced uPA expression. Transcription factor ELISA assay showed that macrophage-conditioned medium increased nuclear factor (NF)-κB-DNA binding activity in OA chondrocytes. Inhibition of NF-κB activation by specific inhibitor blocked the macrophage-induced uPA promoter activity and expression. In addition, Shear stress was applied to human OA chondrocytes following the stimulation of macrophage-conditioned medium. Shearing of OA chondrocytes at 5 and 10 dyn/cm2 inhibited the macrophage-induced JNK, Akt phosphorylation, NF-κB activation, and uPA expression. Our findings serve to elucidate the molecular mechanisms underlying the macrophage induction of uPA expression in human OA chondrocytes and the shear stress protection against this induction.

Homocysteine Induces Cell Proliferation through Up-Regulation of Cyclin D1 Expression via B1 Integrin/Akt/P70s6k Signaling Pathway in Human Vascular Smooth Muscle Cells.
Y. Yang, C. Chen; Department of Biochemical Science and Technology, National Chiayi University, Chiayi City, Taiwan

The molecular basis of homocysteine-induced cell proliferation in human vascular smooth muscle cells (SMCs) remains unclear. We investigated the mechanism by which homocysteine affects the cyclin D1 expression in human umbilical artery smooth muscle cells (HUASMCs). Homocysteine treatment for 24 and 48 h induced proliferation of cells. Homocysteine increased the protein level and promoter activity of cyclin D1. We further examined the mechanism for the regulation of cyclin D1 expression and cell proliferation. Akt and p70S6K signaling pathway was investigated on the responses of cyclin D1 to homocysteine. Homocysteine induced the transient phosphorylation of Akt and p70S6K, and treatment with phosphatidylinositol 3-kinase (PI3K) inhibitor (LY294002) and mammalian target of rapamycin (mTOR) inhibitor (rapamycin) attenuated the homocysteine-induced up-regulation of cyclin D1 expression and cell proliferation. The integrin antagonist RGD peptide and β1 integrin small interfering RNA (siRNA) blocked cell proliferation and cyclin D1 expression as well as Akt and p70S6K phosphorylation. This homocysteine-induced β1 integrin/Akt/p70S6K signaling pathway and expression of cyclin D1 may accelerate progression of atherosclerotic lesions by promoting proliferation of vascular smooth muscle cells.

The Effect of Bevacizumab and Other Growth Factors on the Damage of Corneal Cells.
T. Kim, K. Min, E. Kim; Ophthalmology, Severance Hospital, Yonsei University, Seoul, Korea, South
Purpose: to evaluate apoptosis induced by bevacizumab and protective effect of other growth factors on bevacizumab induced cellular damage in corneal cells Methods: to evaluate induction of apoptosis in corneal epithelial cells and fibroblast by application of bevacizumab, LDH, FACS analysis, annexin V stain, and analysis of expression of apoptosis related markers such as bax, bcl-2, and bcl-xl were done. To reveal the mechanism of bevacizumab induced cellular toxicity and to suggest regulator of the toxicity, after co- treatment of bevacizumab and fetal bovine serum (FBS), EGF, FGF, or TGF-β to epithelial cells and fibroblast, LDH, FACS analysis, annexin V stain, analysis of expression of apoptosis related markers repeated. Results: The apoptotic change of corneal epithelial cells and fibroblasts cells were increased after application of bevacizumab with concentration dependent manner. The expression of bax, bcl-2, and bcl-xl also changed compatible to apoptotic condition. After co- treatment of bevacizumab and FBS or EGF, the level of LDH, Annexin V stain, and FACS analysis showed their inhibitory affect on apoptotic change and cellular damage. Conclusions: Bevacizumab has not only vascular suppression effect but induces apoptosis and cellular damage in corneal epithelial cells and fibroblasts. This toxicity of bevacizumab was inhibited by application of FBS or other known growths factors.

Human Lactoferrin Down-Regulates Tnf-α-Induced Intercellular Adhesion Molecule-1 Gene Expression via NF-κB Inhibition in Endothelial Cells.
C. Kim1, K. Park1, T. Lee1, S. Choi2, J. Kim1; 1Kyung Hee University, Yongin-Si, Korea, South, 2Korea University, Seoul, Korea, South

Intercellular adhesion molecule-1 (ICAM-1) is up-regulated on numerous cell types in response to a variety of inflammatory mediators. TNF-α stimulates the ICAM-1 gene transcription mainly via a variant NF-κB site located from -187 to -178 bp upstream of the transcription start site. In the present study, we provide biochemical and functional evidence that lactoferrin (Lf), a DNA binding protein, down-regulates TNF-α-induced ICAM-1 gene expression via inhibiting translocation and binding of NF-κB. We demonstrated that Lf reduced TNF-α-induced mRNA and protein levels of ICAM-1 in endothelial cells. ICAM-1 promoter reporter assay indicated that Lf downregulates ICAM-1 at the transcriptional level. TNF-α-induced DNA binding of NF-κB to the variant NF-κB site was significantly inhibited by treatment of Lf. A putative Lf binding site was found to in the ICAM-1 promoter which is overlapped with the NF-κB site. It was demonstrated that exogenous Lf was transported into nucleus in endothelial cells and that Lf alone can bind to the LBS/NF-κB site. ABCD assay demonstrated that Lf competed with NF-κB for the binding to the site. Lf also inhibited TNF-α-induced phosphorylation of IkBα and nuclear translocation of the p65 subunit of NFκB. Furthermore, Lf inhibited U937 monocytoid cell adhesion to HUVECs stimulated with TNF-α. Our results demonstrate that Lf inhibits expression of ICAM-1 via reducing nuclear translocation of NFκB as well as interfering NF-κB binding to the variant NF-κB site, suggesting a protective role of Lf for vascular inflammatory diseases.

Human Plasminogen Kringle 1-5 Reduces Atherosclerosis and Neointima Formation in Mice by Suppressing the Inflammatory Signaling Pathway.
P. Chang1, H. Wu2, G. Shi2; 1Basic Medical Science, National Cheng Kung University, Tainan, Taiwan, 2Department of Biochemistry and Molecular Biology, National Cheng Kung University, Tainan, Taiwan

Background: Activation of vascular endothelial cells (ECs) plays an important role in atherogenesis and plaque instability. Recent research demonstrated that late-stage inhibition of plaque angiogenesis by angiostatin (kringle 1-4) reduces macrophage accumulation and slows the progression of advanced atherosclerosis. Kringle 1-5 (K1-5) is a variant of angiostatin that contains the first five kringle domains of plasminogen. Objective: to investigate whether K1-5 has an inhibitory effect on early-stage atherosclerosis using the apolipoprotein E (ApoE)-deficient mice model and a carotid artery ligation model. Methods: ApoE-deficient mice received K1-5 treatment for 4 weeks, and the severity of aortic atherosclerosis was measured. In the ligation
model, the left common carotid arteries of C57BL/6 mice were ligated near the carotid bifurcation, and the mice received K1-5 for 4 weeks. Human umbilical vein endothelial cells were pretreated with K1-5 before TNF-α treatment to explore the anti-inflammatory effect of K1-5. Results: The areas of the lesion in the aortas of ApoE-deficient mice that received K1-5 treatment were notably decreased, and formation of carotid neointima in the C57BL/6 mice was decreased by treatment with K1-5. Expression of TNF-α-induced intercellular adhesion molecule-1 and vascular cell adhesion molecule-1 was inhibited by K1-5 treatment, possibly via down-regulation of translocation of nuclear factor-κB and expression of reactive oxygen species. Conclusions: K1-5 reduced atherosclerosis and neointima formation in mice, possibly through inhibition of intercellular adhesion molecule-1 and vascular cell adhesion molecule-1 expression in ECs.

**Hepatocyte Hedgehog Pathway Activity in Liver Injury.**

C. A. Grzelak¹, K. Ajami¹, B. Patkunanathan¹, S. R. Calabro³, C. Wicking², G. W. McCaughan¹,³,⁴, N. A. Shackel¹,³,⁴, F. J. Warner¹,⁴, ¹Liver Cell Biology, Centenary Institute, Newtown, NSW, Australia, ²Institute for Molecular Biosciences, The University of Queensland, Brisbane, QLD, Australia, ³A. W. Morrow Gastroenterology and Liver Centre, Royal Prince Alfred Hospital, Sydney, NSW, Australia, ⁴Faculty of Medicine, University of Sydney, Sydney, NSW, Australia

Background and Aims: We have previously identified Hedgehog (Hh) pathway gene expression in human cirrhotic liver. Upregulated Hh pathway activity is also associated with hepatocellular carcinoma development. However, the functional significance is unknown. Therefore, this study aimed to characterise the role of the Hh pathway in an In Vivo mouse model of progressive liver injury. Methods: C57BL/6 mice (n = 5-10) were administered thioacetamide (TAA 300mg/L; drinking water ad lib) for 4, 8 or 20 wks. Hh component expression in whole liver and primary hepatocyte samples was determined using in situ hybridisation (ISH), immunohistochemistry (IHC), reverse-transcriptase PCR (RT-PCR) and quantitative real-time PCR (qPCR). Results: TAA induced a time-dependent progression of liver injury resulting in end stage cirrhosis. Whole liver RT-PCR confirmed expression of Hh components in control and treated groups. qPCR analyses confirmed significant upregulation of Hh pathway activity with progressive liver injury, indicated by upregulation of Gli1 (transcriptional activator) and downregulation of Hhip (Hh inhibitor). RT-PCR analyses also confirmed expression of Hh pathway components in untreated primary hepatocytes. Gli1 expression was induced in primary hepatocytes with progressive liver injury, indicative of Hh pathway activation. In normal liver, ISH revealed specific localisation of Shh (ligand) to cells in the portal tract and diffuse expression across the liver lobule. Expansion of Shh expressing cell populations occurred with TAA-induced liver injury, within the fibrous septae. Shh localised to hepatic stellate cells, immune cells, oval cells, vascular endothelial cells and hepatocytes (IHC). Conclusion: Our studies demonstrate that the Hh signalling pathway is active in normal liver and is upregulated with progressive liver injury. Injured hepatocytes were found to have active Hh pathway signalling, with activity upregulated with progressive liver injury. Hepatocytes were also shown to produce Hh ligand. These results indicate that the hepatocyte may contribute to intrahepatic intercellular interactions involved in progressive liver injury, through Hh mediated paracrine or autocrine mechanisms.

**Preparation of a Controllable RNA Polymerase I-Dependent Expression Vector.**

T. Yoshida¹, M. Ojima¹, M. Kondoh¹, H. Mizuguchi², K. Yagi¹; ¹Laboratory of Bio-functional Molecular Chemistry, Osaka Univ, Osaka, Japan, ²Department of Biochemistry and Molecular Biology, Osaka Univ, Osaka, Japan

Objective: Twenty-million people die from infection diseases in the world a year. Most infectious diseases are caused by RNA virus. The RNA genome transfer system is a powerful tool for basic and clinical research of infection. Mammalian cells have three types of RNA polymerase (pol): RNA pol I, II and III. RNA pol I, II and III transcribe ribosomal RNA, most genes encoding proteins
and various small RNAs, respectively. A variety of non-viral and viral vector systems has been developed with RNA pol II and III promoters; however, vectors with RNA pol I promoters have never been fully developed. We previously prepared RNA pol I-dependent plasmid vector. In the present study, we developed tetracycline (tet)-controllable plasmid and adenovirus (Ad) vectors with RNA pol I promoter. Methods: RNA pol I promoter is composed of enhancer, upstream control element (UCE) and core promoter. To optimize tet-controlled RNA pol I cassette, tet operator (tetO) sequence was inserted into the various sites of RNA pol I promoter. Luciferase was used as a reporter gene. Ad vectors were constructed by an improved In Vitro ligation method (Mizuguchi and Kay, 1998, 1999). Results: TetO sequence was inserted upstream of enhancer, core promoter or UCE in RNA pol I promoter sequence. Co-transfection of the tet-regulated RNA pol I plasmid with plasmid containing a tetracycline repressor or activator resulted in dose-dependent decrease or increase in luciferase expression, respectively. Ad vectors containing the tet-regulated RNA pol I cassette exhibited tet-controllable luciferase expression. We also applied this vector system into evaluation of replication of hepatitis C virus (HCV), and we developed a novel HCV replication system using RNA pol I system. Conclusion: We developed plasmid and viral vector with a tet-controllable RNA pol I promoter. This system will contribute to overcoming infection of RNA viruses.

β3 Integrin Is Involved in Cardiac Fibroblast Proliferation, Pyk2 Signaling and Extracellular Matrix Production.
S. Balasubramanian, M. R. Zile, A. Bradshaw, D. Kuppuswamy; Medicine/Cardiology, Medical University of South Carolina, Charleston, SC

Our recent studies indicate that β3 integrin contributes to hypertrophic growth and survival of cardiomyocytes in response to pressure-overload induced by transverse aortic constriction (TAC). In addition to differences in cardiomyocyte survival after TAC, β3 integrin knockout (β3 KO) animals exhibited reductions in collagen content, fibronectin (FN) levels, and Pyk2 phosphorylation in comparison to wild-type (WT) mice. As collagen and FN are produced primarily by cardiac fibroblasts (Cfb), we sought to assess the relevance of β3 integrin in Cfb in hypertrophic myocardium. Hence, we compared adhesion and platelet-derived growth factor (PDGF-BB) signal transduction, a growth factor with increased expression in hypertrophic myocardium, in isolated primary Cfb from WT and β3 KO mice. In comparison to WT cells, the number of β3 KO Cfb adhered to FN and VN was decreased at 30 min after plating. Similarly, spreading in the initial period (< 30 min after plating) was reduced in β3 KO Cfb when compared to WT Cfb. These data indicate that β3 integrin might play a crucial role in the initial attachment and spreading of Cfb. To understand signaling pathways downstream of β3 integrin, we analyzed the phosphorylation state of nonreceptor tyrosine kinases, the classical components of adhesion signaling. While the phosphorylation of Src and FAK in β3 KO Cfb upon adhesion to FN was similar to that of WT Cfb, there was a marked reduction in Pyk2 (Y402) phosphorylation in β3 KO Cfb. In addition, upon PDGF-BB treatment, while there was no difference in Src and FAK phosphorylation, Pyk2 phosphorylation was markedly reduced. These data suggest that β3 integrin influences Pyk2 signaling in Cfb upon adhesion and growth factor stimulation. Since integrin-Pyk2 signaling is involved in cell proliferation and ECM production, we next analyzed for these changes in WT and β3 KO Cfb. Our results indicate a significant reduction in PDGF-BB-stimulated cell proliferation and collagen production in β3 KO Cfb when compared to WT cells. Together our study demonstrates that, in addition to effects on cardiomyocytes, β3 integrin influences the proliferation and function of Cfb possibly via Pyk2 to affect ECM remodeling in cardiac hypertrophy.

Cytoprotective Effect of P38β MAPK in Astrocytes under Oxidative Stress.
J. Jeong1, J. Shin1, S. Kim1, I. Kim1, Y. Jin1, J. Seo2, M. Kim2, P. Han2, J. Lee1; 1Anatomy, Inha University School of Medicine, Inchon, Korea, South, 2Biological Sciences, Inha University,
Four distinct genes encode the four known members of p38 mitogen-activated protein kinases (MAPKs), that is, p38α, p38β, p38γ, and p38δ in mammals. The activation of p38 MAPKs has been implicated in many cellular processes, such as, inflammation, cell death and survival. Despite the fact that p38α and p38β MAPKs share over 75% homology sequences, increasing evidence indicates that they have distinct, perhaps even opposite roles under stress conditions. We have shown that p38β MAPKs was induced in activated astrocytes, which are enriched in the penumbra after transient focal cerebral ischemia. To investigate the functional significance of p38β MAPK in astrocytes, a C6 astrogloma cell line stably over-expressing p38β MAPK was generated. In these cells, hydrogen peroxide-induced apoptosis was 60% of that compared to parent cells. Interestingly, we found that expression of the small heat shock proteins, αB-crystallin, was significantly increased in these cells, but that the expressions of HSP27 and HSP70 were not. Furthermore repression of αB-crystallin expression by αB-crystallin siRNA transfection suppressed this protective effect indicating that αB-crystallin induction has a crucial role in the protection against H2O2-induced apoptosis in p38β-overexpressing C6 astrogloma cells. In addition, the induction of caspase 3 activity after H2O2-treatment was markedly suppressed in p38β-overexpressing cells, and immunoprecipitation proved binding between αB-crystallin and partially processed caspase-3. These results indicate that p38β confers protection against H2O2-induced astrocytes apoptosis by inducing the small heat shock protein, αB-crystallin, which inhibits caspase-3 activation.

Sophora Flavescens Aiton Inhibits the Production of Pro-Inflammatory Cytokines through Inhibition of the NFκB/IkB Signal Pathway in Human Mast Cell Line (Hmc-1).
S. Kim, M. Hong, J. Kim, J. Kim, Y. Sin, S. Ko; Laboratory of Clinical Biology and Pharmacogenomics, College of Oriental Medicine, Kyunghee University, Seoul, Korea, South

Objective: The dried roots of Sophora flavescens Aiton (SFA) has been used in traditional medicine for treatment of inflammation, gastrointestinal hemorrhage, diarrhea, and asthma. This study investigated the effect of SFA on the inflammatory allergic reaction. Methods and Results: SFA (200 mg/kg) inhibited the mast cell-mediated passive cutaneous anaphylaxis reaction in vivo and the release of histamine from rat peritoneal mast cells by compound 48/80. In addition, the expression levels of phorbol 12-myristate 13-acetate (PMA) and calcium ionophore A23187-stimulated TNF-α, IL-6, and IL-8 were also decreased by SFA treatment. In molecular mechanism level, this study showed that SFA inhibited the nuclear translocation of nuclear factor (NF) κB through inhibition of the phosphorylation and degradation of IκB-α, which is an inhibitor of NF-κB. Moreover, SFA suppressed PMA plus A23187-induced phosphorylation of the mitogen-activated protein kinase p38 and c-jun N-terminal kinase. The inhibited induction of NF-κB promoter by SFA was determined using luciferase activity. Conclusions: These results suggest that SFA could be used as a treatment for mast cell-derived allergic inflammatory diseases.

950/B108
Functional Studies of Primary Hepatocytes: The Relationship between CD147 Expression and Matrix Metalloproteinase (MMP) Activity.
S. R. Calabro1,4, C. A. Grzelak1,4, F. J. Warner1,4, S. V. McLennan2,4, B. Patkunanathan1, N. A. Shackel1,3,4, 1Liver Immunobiology, Centenary Institute, Newtown, NSW, Australia, 2Department of Endocrinology, The University of Sydney, Camperdown, NSW, Australia, 3AW Morrow Gastroenterology and Liver Centre, Royal Prince Alfred Hospital, Camperdown, NSW, Australia, 4The University of Sydney, Camperdown, NSW, Australia

Introduction: CD147, a potent inducer of MMPs (1, 2, 3, 9 & 14) is upregulated in human cirrhotic liver and expressed predominantly on hepatocytes. Additionally, CD147 is the only known receptor for pro-inflammatory extracellular cyclophilin a (CyPA). Progression of liver fibrosis is
characterised by the dysregulation of extracellular matrix (ECM) turnover, mediated by MMPs. Therefore, this study examined expression of CD147 and MMPs in the primary hepatocyte, to determine if the hepatocyte has a role in ECM remodeling. Methods: Cellular localization of CD147 and MMPs (1, 2 & 9) was determined by IHC and confocal microscopy of human cirrhotic liver explants. In-vitro studies were performed on isolated primary mouse hepatocytes from C57Bl6 mice. Cells were cultured on plastic, collagen-1 or matrigel and treated with both CD147 binding [anti-CD147 antibody (5ug/ml) and CyPA (10nM)] and non-binding (TNF-α, TGF-β, HGF) stimuli for 24 hours. An anti-Fc antibody was used to determine the MMP induction specificity of CD147 ligands. CD147 expression was analysed by Western blotting and MMP 2 & 9 activity was determined by gelatin zymography. Results: Localization studies demonstrated that CD147 was expressed on cytokeratin-18 positive hepatocytes as well CD31 positive endothelial cells and CD45 positive inflammatory cells. Further, IHC demonstrated that MMP-1, 2 & 9 were expressed on hepatocytes. In-vitro functional studies of primary hepatocytes demonstrated that CD147 protein expression was most pronounced on matrigel and was induced by anti-CD147 antibody as well as TNF-α, TGF-β, and HGF. Further, MMP-9 expression was also induced by TNF-α. Moreover, either anti-CD147 or IgG control antibody when combined with CyPA, upregulated MMP-2 and -9 dramatically. This induction was blocked by pre-incubation of hepatocytes with an anti-Fc receptor blocking antibody, however anti-CD147 administration was still able to induce MMP-9. Conclusion: The observed upregulation of CD147 and MMP-9 expression in-vitro, suggest that hepatocytes have inducible MMP expression. MMP induction with anti-CD147 administration is consistent with hepatocyte-derived CD147 being actively involved in ECM remodeling associated with liver fibrosis.

Toxicity of Isoproterenol Increases with the Differentiation State of H9c2 Myoblasts.
A. Branco, A. Moreira, S. Pereira, V. Sardão, P. Oliveira; Center for Neuroscience and Cell Biology, Coimbra, Portugal

Cardiomyocyte apoptosis is one consequence of several cardiovascular diseases. During heart failure, larger amounts of catecholamines are released to induce an attempt to restore homeostasis. Over-activation of beta-adrenergic receptors (AR) leads to cardiomyocyte death. Rat H9c2 myoblasts are usually used as an In Vitro model for cardiac cells and are normally used in its undifferentiated state. To investigate the relevance of the differentiation state on drug toxicity, we used three different experimental groups: undifferentiated H9c2 myoblasts, H9c2 differentiated to myotubes in a low serum medium and H9c2 differentiated to a cardiac phenotype by incubation in a low serum media with daily additions of retinoic acid (RA). The objectives of the present work were to characterize the susceptibility of H9c2 myoblasts in different differentiation states to the beta-adrenergic agonist isoproterenol (ISO) and correlate drug effects in terms of alterations in pro-apoptotic proteins and beta-adrenergic receptor density. We observed that by manipulating the differentiation state of H9c2, a different response of cells to ISO was obtained, where differentiated H9c2 cells being more susceptible than non-differentiated cells to ISO for 24 and 48 hours of exposure. Interestingly, differentiated H9c2 cells with RA appear to have a lower amount of beta2-AR (involved in the anti-apoptotic pathway) and beta3-AR than the other two groups of cells. Both the mitochondrial voltage-dependent anion channel (VDAC) and the adenine nucleotide translocator (ANT) were analyzed as both proteins are part of the mitochondrial permeability transition pore. Although no differences regarding the ANT were observed, differentiated cells in the presence of RA contained lower amounts of VDAC. No other differences between groups were found regarding the apoptosis inducing factor (AIF), Bax and Bcl-2, proteins involved in the apoptotic signaling pathway. The present study suggests that the differentiation of H9c2 myoblasts is relevant for the toxicity of isoproterenol, although the molecular mechanism is still under investigation. This work is supported by Fundação para Ciência e Tecnologia, Portugal (FCT PTDC-QUI-64358-2006, SFRH BD/41384/2007).

Bone Morphogenetic Protein Recruits a Peroxisome Proliferator-Activated Receptor Gamma and Beta-Catenin Complex to Regulate Apelin Expression in Pulmonary Endothelial Cells.
T. Alastalo, M. Li, D. Pham, V. de Jesus Perez, H. Sawada, M. Rabinovitch, M. Rabinovitch; Pediatrics, Stanford University, Stanford, CA

In patients with pulmonary arterial hypertension (PAH), mutations in bone morphogenetic protein receptor (BMPR)II signaling result in PA endothelial cell (EC) dysfunction causing reduced EC survival and heightened smooth muscle cell (SMC) proliferation. The down-stream gene targets of BMP signaling important in the pathogenesis of PAH are poorly characterized. Interventions that normalize expression of genes that are targets of BMPRII-mediated signaling could restore PAEC function and reverse PAH. Our data shows that in PAEC BMP signaling can promote physical interaction between nuclear receptor peroxisome proliferator-activated receptor gamma (PPARγ) and beta-catenin (BC), and disruption of this complex with synthetic PPARγ ligands impairs BMP2 mediated survival response. We hypothesized that BMP induced PPAR-BC transcription factor complex regulates genes necessary for PAEC homeostasis and important in PAH. Using whole genome wide ChIP-Chip and gene-expression microarray techniques we have characterized novel targets for BMP-PPAR-BC signaling axis, and identified apelin as an important novel target. The significance of our finding in PAH is shown with BMPRII deficient pulmonary EC from idiopathic PAH (IPAH) patients expressing significantly lower levels of apelin than those from control patients. We further show that deletion of PPARγ from EC in mice, previously shown to cause PAH phenotype, is associated with a significant reduction in apelin expression. Administration of apelin for 2 weeks significantly reverses PAH in these PPARγ deficient mice. Our In Vitro experiments demonstrate that apelin-deficient PAEC are prone to apoptosis and promote PASMC proliferation. We conclude that decreased apelin expression is associated with dysfunctional BMP signaling and contributes to pulmonary vascular remodeling. We further show evidence that apelin could have therapeutic implications in PAH.

S. Hose, C. Zhang, G. Sehrawat, R. Grebe, G. A. Lutty, J. Zigler, D. Sinha; Wilmer Eye Institute, The Johns Hopkins University School of Medicine, Baltimore, MD

The βA3/A1-crystallin gene, which codes for a major structural protein of the lens, is mutated in the Nuc1 rat. We have recently shown that βA3/A1-crystallin is also expressed in astrocytes; however, its function in astrocytes remains elusive. Our studies with Nuc1 suggest that βA3/A1-crystallin may have an important role in maintaining the nuclear architecture of astrocytes, where βA3/A1-crystallin is co-localized with the nuclear membrane protein, Emerin. The mutation causes nuclear membrane fragility, change in nuclear shape and altered disposition of chromatin. In Nuc1 astrocytes, the nucleolus is larger, singular and consistently located at the periphery of the nucleus rather than in the more central location typical of normal astrocytes. In addition, unique perinuclear vacuolar structures containing amorphous and electron-dense material are present in the mutant astrocytes. We suspect that these structures are autophagic in nature. The activation of autophagy is supported by an increase in Beclin 1 in Nuc1 astrocytes compared to normal during early postnatal development. Beclin 1 has been postulated to be important for the initiation of the formation of the autophagosome. This may suggest that autophagy is involved in the rapid repair of the damaged nuclear components of the Nuc1 astrocytes. The autophagic clearance of nuclear wastes in Nuc1 astrocytes appears to diminish as excess degradation of the nuclear components becomes more profound in the aging Nuc1 rats. Indeed, our immunolabeling studies clearly show that Beclin 1 is downregulated in the astrocytes of aging Nuc1 rats. A failure of the programmed cell death process, as we have reported in Nuc1 during ocular development, followed by the failure of autophagy in astrocytes would lead to necrosis and may be the basis for retinal degeneration in aging Nuc1 rats.

Structural and Physiological Studies of Filamin A-CFTR Interaction.
F. Nakamura1, M. P. Playford2, E. Nurminen3, O. T. Pentikäinen3, S. L. Milgram2, J. H. Hartwig1, T. P. Stossel1; 1Medicine, Brigham & Women's Hospital, Boston, MA, 2NHLBI, NIH, Bethesda, MD, 3Biological and Environmental Science & Nanoscience Center, University of Jyväskylä, Jyväskylä, Finland

Cystic fibrosis is caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR), an apical membrane chloride channel expressed in epithelial cells. A previous report has shown that filaminA (FLNa), an actin cross-linking and scaffolding protein, directly interacts with the cytoplasmic N-terminus of CFTR and that this interaction is necessary for stability and confinement of the channel. Here we report that the CFTR N-terminus has sequence similarity to known FLNa-binding partner binding sites. FLNa has 24 Ig (IgFLNa) repeats. A CFTR peptide pulled down repeats 9, 12, 17, 19, 21, and 23, which share sequence similarity but differ from the other FLNa Ig domains defective in CFTR binding. Using known structures of IgFLNa-partner complexes as templates, we generated in silico models of IgFLNa-CFTR peptide complexes. Point and deletion mutants of IgFLNa and CFTR informed by the models, including disease-causing mutations, L15P and W19C, disrupted the binding interaction. The model predicted that a P5L CFTR mutation should not affect binding, but a synthetic P5L mutant peptide had reduced solubility, suggesting a different disease-causing mechanism. Taken together with the fact that FLNa dimers are elongated (~160 nm) strands, whereas CFTR is compact (6~8 nm), we propose that a single FLNa molecule can scaffold multiple CFTR partners. Unlike previously defined dimeric FLNa-partner complexes, the FLNa-monomeric CFTR interaction is relatively weak, presumptively facilitating dynamic clustering of CFTR at cell membranes. Finally, we show in cells that overexpression of FLNa mutants defective in CFTR binding lead to decreased expression of CFTR band C, indicating incomplete processing of the CFTR protein.

Treatment of Wounds with Insulin Followed by SDF1-A Accelerates Wound Healing.
J. Chin, L. Moinet, H. Yuan, M. Martins-Green; Cell Biology & Neuroscience, University of California Riverside, Riverside, CA

Insulin has become a molecule of interest for the treatment of wounds. In 1965-68, insulin was used to speed bone and cutaneous healing in rats and to treat wounds in diabetic mice. By 1998, insulin was used to treat burn wounds in rats and rabbits and in 1999, a clinical trial performed at UCLA found that insulin and zinc accelerate the wound healing process. More recently, we have shown that insulin activates Src, PI3K, Akt and SREBP through interaction with its receptor leading to improved re-epithelialization, angiogenesis and reduced scarring. Our findings point to insulin acting early during wound healing. It is also known that Stromal Derived Factor-1α (SDF1α), a chemokine that plays a key role in stimulating endothelial progenitor cell (EPC) migration from the bone marrow, potentially contributes to neovascularization, a critical step in wound healing. Therefore, we hypothesized that a combination of insulin in the first 4 days after wounding and SDF1α after that, would greatly improve the overall healing process. To test this possibility, we performed excision wounds in mice and applied insulin only, SDF1α only and insulin followed by SDF1α. We collected digital pictures of the wounds over the healing time and determined the wound area as percent of the original wound. In addition, the tissues were collected at 14 days, the time in which the wounds were closed, and prepared for histological sections. We show that in the early days of healing insulin alone accelerates wound closure, but insulin treatment followed by SDF1α accelerated the rate of re-epithelialization. Histological observations show that insulin increases the quality of wound healing, and SDF1α appears to provide more rapid epithelial wound coverage. In conclusion, our data suggest that using insulin followed by SDF1α is potentially a beneficial treatment combination for wound healing, including burn wounds.
Epithelial-to-Mesenchymal Transition: Role of Na,K-ATPase.

Epithelial-mesenchymal transition (EMT) is a process in which polarized epithelial cells undergo multiple biochemical changes and acquire a mesenchymal phenotype. EMT occurs during pathological processes such as cancer progression and fibrosis. Although, it is well recognized that EMT is an important event during cancer progression as well as in fibrotic disease, molecular mechanisms leading to EMT and target molecules affected during this process are poorly understood. A key molecule implicated in EMT is transforming growth factor-β (TGF-β1). This molecule induces EMT by Smad-dependent and independent pathways. Na,K-ATPase is a well-studied molecule for its role in ion homeostasis. We have shown previously that in addition to its epithelial ion transport function, Na,K-ATPase plays a fundamental role in the formation and maintenance of a well-differentiated, polarized epithelial phenotype in mammalian cells and that the Na,K-ATPase β1-subunit functions as a cell-cell adhesion molecule. In this study, using a cell culture model for cancer and fibrosis progression that responds to TGF-β1, we show that Na,K-ATPase is a target molecule of the TGF-β1 signaling pathways. We provide evidence that following treatment with TGF-β1 the surface expression of the β1-subunit of Na,K-ATPase is reduced, prior to well-characterized EMT markers and is associated with the acquisition of a mesenchymal phenotype. RNAi mediated knockdown confirmed the specific involvement of the Na,K-ATPase β1-subunit in the loss of the epithelial phenotype and exogenous over-expression of the Na,K-ATPase β1-subunit attenuates TGF-β1-mediated EMT. We further show that the levels of both the α1- and the β1-subunit of Na,K-ATPase are highly reduced in renal fibrotic tissues. These findings for the first time reveal that Na,K-ATPase is a target of TGF-β1-mediated EMT and is associated with the progression of EMT in both cancer and fibrosis.

Effects of Cellular Stretch on NFkB and STAT3 Activation in Human Intestinal Smooth Muscle Cells.

K. Uray, K. Kislitsyna, C. S. Cox; Pediatric Surgery, University of Texas Medical School at Houston, Houston, TX

Intestinal edema, which often occurs in trauma patients, causes slowed intestinal transit leading to delayed enteral feeding, prolonged hospital stays, and increased complications. Delayed intestinal transit due to intestinal edema has been attributed to decreased myosin light chain (MLC) phosphorylation leading to decreased intestinal contractile activity. Although the mechanism(s) of edema-induced decreases in MLC phosphorylation are unclear, NFkB and STAT3 are both activated and have been shown to play a role. We hypothesize that increased cellular stretch caused by edema development triggers NFkB and STAT3 activation that eventually leads to decreased MLC phosphorylation. Thus, the objective of this study was to determine the effects of cellular stretch on NFkB and STAT3 activation. We subjected primary human intestinal smooth muscle cells (HISMC) to either a control cyclical stretch program (CCS) as during basal intestinal contractile activity or an edema cyclical stretch program (ECS) consisting of an increasing cyclical stretch as observed in edematous intestine. Parameters for the cyclical stretch programs were based on In Vivo data obtained from our intestinal edema animal model. HISMC were also transfected with constitutively active STAT3 (caSTAT3) or IKK (calKK) (IkappaB Kinase). Activation of NFkB and STAT3 were significantly increased in cells subjected to ECS compared to CCS (CCS vs. ECS: P-stat3, 0.20 ± 0.09 vs. 0.34 ± 0.13 U/mg
protein; NFkB, 0.59 ± 0.22 vs. 0.96 ± 0.38). Transfection of unstretched HISMC with caSTAT3 or caIKK decreased carbachol stimulated MLC phosphorylation (MLC-P/MLC: Vector control, 1.76 ± 0.52; caSTAT3, 1.07 ± 0.31; caIKK, 1.05 ± 0.31). Furthermore, transfection with both caIKK and caSTAT3 significantly increased NFkB DNA binding activity. Inhibition of NFkB activation in stretched cells reduced STAT3 activation. These data indicate that increased cellular stretch can initiate the signaling cascades leading to decreased MLC phosphorylation and may be responsible for triggering intestinal edema-induced contractile dysfunction. In addition, the data suggests that NFkB and STAT3 interact to enhance both STAT3 and NFkB signaling.

CD34 Enhances Myogenic Progenitor Cell Proliferation during Adult Skeletal Muscle Regeneration.
L. So, F. Rossi; Biomedical Research Centre, UBC, Richmond, BC, Canada

Upon muscle damage, quiescent satellite cells activate, proliferate, and fuse into damaged myofibers to repair muscle. In chronic degenerative diseases, however, repair eventually fails. Cellular therapy has the potential of curing such diseases, but clinical trials have so far been disappointing. To improve current treatments, regulatory factors and mechanisms governing satellite cell function must be identified and better understood. Here, we focus on CD34, a commonly used satellite cell marker, in muscle regeneration. Although such a role has been proposed based on the tightly regulated expression of CD34 during satellite cell activation, no concrete evidence supporting this notion has yet been provided. Our experiments reveal a clear muscle regeneration defect in CD34KO mice following acute damage. Furthermore, cross-sectional area analysis shows a failure of CD34KO regenerating fibers to undergo hypertrophy. Because CD34 is expressed on a variety of cell types, we have optimized a technique to isolate a population of myogenic progenitor cells (MPCs) from skeletal muscle using flow cytometry. Our data suggests that CD34KO MPCs engraft with significantly less efficiency than WT controls, despite the fact that their differentiation remains normal. Moreover, Bromodeoxyuridine (BrdU) incorporation experiments show that CD34KO MPCs do not proliferate as efficiently as their WT counterparts. Altogether, these results support our hypothesis that CD34 has a role in the early stages of muscle regeneration. Specifically, we hypothesize that although CD34 is not completely necessary for MPC proliferation, CD34 significantly enhances this critical step. Currently, experiments are underway to depict the mechanism in which CD34 enhances proliferation.

Anti-Inflammatory Role of Bone Marrow Stromal Cells Ameliorated the Irradiation-Induced Cell Death in the Cryptic Stem Cells of the Small Intestine.
D. Kim; kyung hee university, Gyeonggi-do, Korea, South

Radiation causes both sudden necrotic cell death and programmed apoptotic cell death. The immediate necrotic cell death may bring up strong inflammatory responses, which may then result in secondary cell death. In order to explore whether mesenchymal stem cells (MSCs) can ameliorate the radiation-induced inflammatory response and its deleterious effect on the tissue or not, mice were irradiated 8 Gy and MSCs were transfused just after the irradiation. Pro-inflammatory cytokines such as IL-1, IL6, and TNF-alpha were elevated by irradiation, which were nullified by MSCs transfusion. on the other hand, MSCs transfusion stimulated anti-inflammatory cytokine IL-10 in the blood. This anti-inflammatory effect was also confirmed by the suppression of neutrophils, eosinophils, and white blood cell counts. When TUNEL assay was performed in the frozen section of small intestine at 4.5 hours post-irradiation, apoptotic cell numbers were markedly decreased by MSCs transfusion, especially at the cryptic zone. Finally, we examined whether the MSCs transfusion in turn affect the regeneration from the radiation damage. The MSCs transfusion resulted in much faster regeneration after the irradiation. In conclusion, MSCs transfusion brings up anti-inflammatory response in the irradiated mice and thus reduce the radiation induced cell death.

**Echovirus 7 Uses a Dynamin- and Clathrin-Dependent Pathway to Infect Polarized Epithelial Cells.**

*C. Kim*, K. P. *Patel*, B. *Narayanan*, J. M. *Bergelson*; ¹Infectious Diseases, Children’s hospital of Philadelphia, Philadelphia, PA, ²University of Pennsylvania School of Medicine, Philadelphia, PA, ³Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA

Enteroviruses such as echoviruses and coxsackieviruses are human pathogens responsible for viral meningitis and myocarditis. They are transmitted via a fecal-oral route and are thought to cross the barrier presented by polarized epithelial cells in the gastrointestinal tract. Polarized cells have distinct apical and basolateral domains divided by tight junctions and these junctions also prevent the free flow of solutes and microbe across the epithelium. Previously, our group found that group B coxsackievirus 3 (CVB3) binds to decay-accelerating factor (DAF) on the apical cellular membrane of polarized epithelial cells (Caco-2), then moves to the tight junction from which it enters the cell by a mechanism that requires caveolin, but not dynamin. In this work, we studied the entry pathway of another DAF-binding enterovirus, echovirus 7 (EV7) by using dominant negative mutants, siRNAs, and drugs to block endocytic pathways. In contrast to what we observed for CVB3, infection by EV7 depends on dynamin and clathrin, but not caveolin. These results show that two related viruses, which bind to the same cell surface receptor, enter cells by different pathways.

**A Role for Actin-Based Motility in Baculovirus Nuclear Translocation and Cell to Cell Spread.**

*T. Ohkawa*, L. E. *Volkman*, M. D. *Welch*; ¹Molecular and Cellular Biology, University of California, Berkeley, CA, ²Department of Plant and Microbial Biology, University of California, Berkeley, CA

Most viruses use the microtubule cytoskeleton for intracellular transport. Baculoviruses, including the type species *Autographa californica* M nucleopolyhedrovirus (AcMNPV), require intracellular transport to reach the nucleus for replication and the cell surface for spread, although previous work indicated that they do not require microtubules. Instead these viruses were shown to associate with actin, suggesting that they use an actin-based mechanism of transport. Using time-lapse microscopy, we observed that AcMNPV nucleocapsids rocketed through the cytoplasm by actin-based motility and were trailed by actin comet-tails. The compartmentalization of baculovirus actin-based motility differs from vaccinia virus, for which an extracellular form moves along the cell surface to promote cell-to-cell spread. AcMNPV actin-based motility depends on the nucleocapsid protein P78/83, an activator of the Arp2/3 complex, as a virus with a mutation in P78/83 showed impaired motility. One key function of actin-based motility is to promote nuclear entry. Moving viruses collided with and stuck to the nucleus, while their actin tails emanated from the point of impact in a corkscrew-like structure. Depolymerizing actin delayed and reduced nuclear entry, whereas depolymerizing microtubules had little effect. Following collisions with the nuclear periphery, nucleocapsids associated with nuclear pores, as revealed by immunofluorescence microscopy. Moreover, blocking nuclear pores by expressing a dominant negative derivative of importin β impeded viral nuclear entry, indicating that the major pathway of entry is through the pore. In addition to playing a role in nuclear translocation, actin-based motility served to translocate nucleocapsids into cell surface spikes, where they accumulated following the onset of viral gene expression. Movement was critical for transport to the surface because the P78/83 mutant shows a severe defect in its ability to localize to the cell periphery. Thus actin-based motility plays a key role in viral transit to the nucleus and the cell surface, and coordination between these transport processes is likely critical for promoting rapid cell-to-cell transmission during infection.

**Respiratory Syncytial Virus Induces a Host Stress Response.**

M. Lindquist\(^1\), J. E. Crowe\(^1\)^2,3; \(^1\)Microbiology/Immunology, Vanderbilt University, Nashville, TN, \(^2\)The Vanderbilt Program in Vaccine Sciences, Vanderbilt University, Nashville, TN, \(^3\)Pediatrics, Vanderbilt University, Nashville, TN

In this study we sought to determine the kinetics and the role of an integrated stress response in host cells during respiratory syncytial virus (RSV) infection. Background: RSV is a leading cause of serious viral lower respiratory tract illness in infants and the elderly worldwide. Unfortunately interactions between viral and host processes during replication have not been well characterized. Cytoplasmic RNA stress granules (SGs) are induced during specific stresses and contain mRNA, translation factors, and RNA binding proteins and have been proposed to selectively regulate host mRNA translation during the stress. Phosphorylation of the translation factor eIF2\(\alpha\) generally triggers SG formation. The host proteins G3BP and HuR are recruited to SGs and have been proposed to be important for SG formation and RNA stability respectively. Methods: Infections were performed using the RSV-A2 strain (MOI=1) for indicated times. SG formation and eIF2\(\alpha\) phosphorylation were determined by immunofluorescence. RNA silencing of G3BP and HuR was performed using shRNA lentiviral vectors. Viral titer and viral RNA levels were determined by plaque assay and RT-PCR respectively. All assays were performed using HEp-2 cells. Results: We observed increasing phosphorylation of eIF2\(\alpha\) and subsequent formation of SGs as RSV infection progressed. We also noted that while SGs were distinct from viral inclusion bodies the SG marker, HuR, was found in both structures. Cells with reduced G3BP expression were impaired for SG formation and regularly showed both a 10-fold reduction in RSV titers and viral RNA levels compared to wild type cells. Cells with reduced levels of HuR showed no difference in titer or viral RNA levels compared to wild type, SG formation was unaffected in these cells. Conclusions: Our findings demonstrate that RSV induces a robust stress response during infection. Inhibition of SG formation via G3BP shRNA results in a decrease of viral titers, indicating pro-viral role for the host response during infection. In addition, although the RNA binding protein HuR is found in RSV inclusion bodies, it does not appear to be essential for SG formation or viral replication.

**Cellular Entry Mechanisms of Vaccinia Virus Extracellular Virions.**

F. I. Schmidt, J. P. Mercer, A. Helenius; Institute of Biochemistry, ETH Zurich, Zuerich, Switzerland

Vaccinia virus (VACV) is the prototypic poxvirus and a close relative of variola, the causative agent of smallpox. Considerable progress in understanding the entry route of its more abundant infectious form, mature virions (MVs), has been made in the last years. Despite their importance for virus spread within infected organisms, the entry mechanism of the less abundant extracellular virions (EVs) remains poorly characterized. Unlike most enveloped viruses, poxvirus EVs are surrounded by two lipid bilayers and therefore require a unique penetration process. EV infection presumably involves the non-fusogenic disruption of the outermost membrane followed by fusion of the inner membrane with cellular lipid bilayers. We used recombinant VACV (strain IHD-J) encoding EGFP or EGFP fusion proteins to characterize the entry process of EV particles into human epithelial cells by a combination of fluorescence microscopy and flow cytometry. Our results indicate that EV particles are endocytosed in the course of the entry process. Infection requires actin dynamics as well as activity of P21/Cdc42/Rac1-activated kinase 1 (PAK1) and Na\(^+\)/H\(^+\) exchangers, suggesting a macropinocytotic mechanism. Furthermore, EV infection is dependent on the acidification of endosomal vesicles. We find that low pH-treatment disrupts the outer EV membrane In Vitro and partly rescues infection in the presence of the vacuolar H\(^+\)-ATPase inhibitor Bafilomycin A1, a potent inhibitor of endosomal acidification. EV particles of the VACV strain Western Reserve are less sensitive to inhibitors of endosomal acidification; a fraction of the EV particles might therefore enter cells by an alternative entry pathway, possibly involving glycosaminoglycan-dependent disruption of the EV wrapper at the plasma membrane.
In conclusion, our data suggest VACV EV particles are internalized by a process that resembles macropinocytosis. Subsequent acidification of endosomal vesicles triggers disruption of the outermost membrane and thus exposes the viral fusion machinery on the inner membrane. Fusion of the inner lipid bilayer with limiting cellular membranes releases the viral core with the genome into the host cell cytoplasm.

From Target Identification to Drug Discovery: The HIV-1 Integrase/Human LEDGF-Case Study.

More than 25 years after its discovery, Human Immunodeficiency Virus 1 (HIV-1) is still one of the major threads of human life. Most anti-HIV drugs currently in use inhibit the catalytic activities of viral enzymes. However, novel mechanisms of action are needed to cope with the increasing resistance against these drugs. A promising alternative is to target the complex interplay between viral proteins and host cells. We used Hybrigenics' ULTImate Y2H™ technology to perform a large-scale yeast two-hybrid study with all HIV-1 proteins as baits, using highly complex cDNA libraries from the CEMC7 T cell line. Analysis of the interaction network led to the selection and functional validation of several protein interactions. We will detail the in-depth characterization and chemical targeting of the interaction between HIV-1 integrase and the human transcriptional co-activator LEGDF (1). siRNA knockdown of LEDGF demonstrated the functional importance of this interaction for targeting integrase to the chromosome. Using a random-primed HIV-1 library, the integrase catalytic core was mapped as the smallest interacting domain in a rebound yeast two-hybrid screen with LEDGF as bait. Moreover, by screening loss-of-affinity mutants in yeast, Q168 of integrase was identified as one of the hot-spots of the interaction. Based on these functional and detailed molecular evidences, we decided to target the HIV-1 integrase / human LEDGF interaction to identify new molecules with therapeutic use in HIV treatment. We set up an assay for High Throughput Screening based on the HTRF® technology by Cisbio International. 77,000 small-molecule compounds were screened for their ability to inhibit the interaction and several profiles of compounds were identified, pointing to different options for hit to lead optimization. This approach highlights the straightforward way from a complex protein interaction network to the functional validation of a selected interaction as therapeutic target, eventually leading to the identification of small molecules as promising new antiviral drug candidates. 965/B123
The Role of Autophagy during Coxsackievirus Infection in Neural Stem Cells.
J. M. Tabor-Godwin, R. Lacharite, G. Tsueng, C. T. Cornell, J. Whitton, R. Sayen, R. Gottlieb, R. Feuer; 1Department of Biology, San Diego State University, San Diego, CA, 2BioScience Center, San Diego State University, San Diego, CA, 3Department of Immunology and Microbial Science, The Scripps Research Institute, San Diego, CA

Recently the process of autophagy has been identified as a crucial step for the replication and survival of viral pathogens following infection of the cell. Some viruses have been shown to manipulate the autophagic process in order to efficiently replicate within the cell, rather than fall prey to this catabolic process and be destroyed in the lysosome. As with other picornaviruses, coxsackievirus B (CVB) has been identified as a virus that utilizes autophagy to its advantage following infection. However, few studies have determined if virus-induced autophagy occurs following infection of stem cells. Therefore, we studied the role of autophagy following CVB infection in neural stem cells, which we previously identified to be highly susceptible to CVB infection, both in culture and in vivo. Neurospheres, or free-floating structures generated by neural stem cells in culture, can remain undifferentiated, but also have the ability to differentiate into all three cell lineages of the central nervous system, including neurons, astrocytes, and
oligodendrocytes. We measured autophagic induction by utilizing LC3-GFP to label autophagosomes following infection with a recombinant dsRED coxsackievirus B3 (dsRED-CVB3). No change in the level of autophagy was seen in undifferentiated neurospheres following infection with dsRED-CVB3. However, a significant decrease in the level of autophagy was observed in differentiated neural stem cells following dsRED-CVB3 infection. In particular, β-tubulin positive differentiated neurospheres underwent the greatest decrease in autophagy of the three cell lineages. In contrast to the results seen with neurospheres, HL-1 cells, a transformed cardiomyocyte cell line, showed an increase in the level of autophagy following dsRED-CVB3 infection. Furthermore, viral titers in HL-1 cells decreased in the presence of an inhibitor of autophagy (3-MA), while viral titers increased in the presence of an inducer of autophagy (CCPA). Hence, we conclude that the role of autophagy in modulating CVB replication appears cell type-specific.

**microRNA Fingerprints in Venezuelan Equine Encephalitis Virus Infection.**  
M. Bhomia$^{1,3}$, N. Balakathiresan$^2$, A. Sharma$^1$, P. Gupta$^{1,3}$, R. Biswas$^5$, R. K. Maheshwari$^4$;  
$^1$Department of Pathology, USUHS, Bethesda, MD, $^2$Graduate School of Nursing, USUHS, Bethesda, MD, $^3$Birla Institute of Technology and Science, Pilani, India

Background: MicroRNAs (miRNA) are small endogenous RNA (~22nts) molecules and play an important role in regulating gene expression, mainly by the mechanism of mRNA degradation or translational repression. MiRNAs are important in normal as well as abnormal cellular processes like development, differentiation, cell proliferation, tumorigenesis, neuronal development and hematopoiesis. Cellular miRNA plays an important role in the pathogenesis of viral infections including hepatitis c virus, human cytomegalovirus and human immunodeficiency virus. Venezuelan equine encephalitis virus (VEEV) is a member of the alphavirus genus in the family Togaviridae. Alphaviruses are mosquito-borne and may cause fatal human diseases. The genome consists of an 11.4kb, positive sense, single stranded RNA. VEEV can be spread by aerosol and has been weaponized making it a potential biothreat agent. Methods: 5-6 week old CD-1 mice were infected with 1000 pfu of V3000 in right footpad. Total RNA was isolated from brains of the infected and uninfected mice using TriZol reagent at different time points post infection (p.i). Brain samples from uninfected mouse were used as an experimental control for basal level expression of miRNA. The miRNA expression profile was generated by quantitative real-time PCR (qRT-PCR) with ABI 7900HT Fast Real time PCR system using a multiplex pool of miRNA stem-loop primers. Statminer software (Integromics Inc) was used for determining the statistically significant differentially miRNAs. Results: Data indicated significant modulation of more than 10 miRNAs. Studies are in progress to analyze miRNA expression profile at different p.i time points. These microRNA are being analyzed for their targets to delineate their role in the regulation of downstream cellular pathways. Conclusions: These results suggest that miRNA may play an important role in the pathogenesis of VEEV infection by affecting downstream gene signaling pathways. This study will help in finding novel biomarkers for VEEV infection and will also allow us to design novel antivirals and miRNA based vaccines for VEEV. These studies were supported by JSTO-CBD/DTRA Contract/ Grant/ Intergovernmental Project Order/ Project # 4.10019_07_US_B.

**Disruption of the Toll-Like Receptor 4 Signaling Pathway by Salmonella Effector SigD.**  
S. Saravia$^1$, M. R. Terebiznik$^2$; $^1$Department of Cell & Systems Biology, University of Toronto at Scarborough, Toronto, ON, Canada, $^2$Department of Biological Sciences, University of Toronto at Scarborough, Toronto, ON, Canada

The enteropathogenic bacteria *Salmonella* are the main cause of food-borne gastroenteritis and typhoid fever worldwide. To evade the host immune response, *Salmonella* invades mammalian cells and survives within an intracellular niche, the *Salmonella* containing vacuole (SCV). The activation of Toll-like receptor 4 (TLR4) by lipopolysaccharide (LPS) triggers an immune response
to counter infection. The stimulation of this pathway requires the recruitment of adaptor proteins, TIR-associated protein (TIRAP) and TRIF-related adaptor molecule (TRAM). Recruitment and activation of these molecules is dependent on the membrane lipid, phosphatidylinositol (4,5) bisphosphate (PI(4,5)P2). The Salmonella effector Salmonella invasion gene D, SigD, is a 4-phosphatase that depletes PI(4,5)P2 from the host cell and plasma membrane during invasion. Thus, in this study, we investigated if SigD could lead to the disruption of the TLR4 pathway. We observed that SigD expression caused the disappearance of TIRAP from the SCVs in HeLa cells. Assessment of the myeloid differentiation primary response gene 88 (MyD88) dependent pathway showed that the expression of SigD attenuates the degradation of IκBα in wild type (wt) Salmonella-infected cells. The TLR4 MyD88 independent pathway requires the adaptor protein TRAM. SigD did not affect the localization of TRAM in the SCV. However, the activation of protein kinase C (PKC) ε, which is required for TRAM activation, is reduced in HeLa cells invaded with wt bacteria in comparison to the SigD deficient Salmonella strain. Taken together, these results suggest that SigD can disrupt both branches of the TLR4 signaling pathway.

Legionella pneumophila Uses β1 Integrins to Adhere to Lung Epithelial Cells.
A. Prashar1, 2, C. Duncan4, D. E. Low1, R. E. Harrison1, 2, C. Guyard1, 3, M. R. Terebiznik1, 2, 1Biological Sciences, University of Toronto at Scarborough, Toronto, ON, Canada, 2Department of Cell and Systems Biology, University of Toronto, Toronto, ON, Canada, 3Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada, 4Ontario Agency for Health Protection and Promotion, Toronto, ON, Canada

Legionella pneumophila, the etiological agent of Legionnaires disease is an intracellular pathogen. The interactions between this respiratory pathogen and host macrophages have been extensively studied but more than 95% of the human lung surface is covered by epithelial cells. Therefore, these cells present an important niche for the intracellular survival of the bacteria. It has been shown that L. pneumophila serogroup 1 (Lp1) invades lung epithelial cells but the mechanisms of adhesion and invasion of these cells are poorly described. Our objective is to investigate the mechanisms used by Lp1 to adhere to lung epithelial cells and the downstream signalling pathways that are activated to initiate bacterial internalization. Using scanning electron microscopy we have characterized that the adhesion of L. pneumophila to lung epithelial cells occurs by the ‘zipper’ mechanism. The host cell membrane wraps around the adhering bacteria, forming a membrane rich structure we are referring to as a ‘pocket’. We have utilized fluorescent chimeras and immunostaining techniques for confocal microscopy to demonstrate that Lp1 adheres to lung epithelial cells (NCI-H292) using the host cell β1 integrin receptors. Engagement of these receptors initiates an adhesion process that is dependent on actin polymerization and the recruitment of actin motor Myosin II. These results have been further confirmed through biochemical assays with pharmacological inhibitors. We have also shown that the adhesion of Lp1 to NCI-H292 cells causes the activation of the focal adhesion signalling pathway and the recruitment of focal adhesion proteins talin and focal adhesion kinase. Based on our results, we conclude that β1 integrin receptors mediate the adhesion of L.pneumophila to lung epithelial cells. Adhesion to these receptors causes bacterial internalization by the ‘zipper’ mechanism through the focal adhesion signalling pathway.

Characterization of the Roles of the LRR Proteins InlJ and InlH in the Virulence of L. monocytogenes.
S. Bruck, N. Personnic, M. Nahori, O. Dussurget, P. Cossart, H. Bieme; Bacteria-Cell interactions, Institut Pasteur, Paris, France

Using comparative genomics, our group identified several potential new virulence factors of Listeria monocytogenes. Subsequent In Vivo assays characterized InJ as a virulent factor. Like the major listerial invasion proteins InlA and InlB, both InlJ and previously identified virulence factor, InlH, are members of the internalin family of proteins characterized by the presence of
leucine-rich repeat domain at the N-terminal. Unlike inlA and inlB, inlJ is only expressed by L. monocytogenes upon infection in vivo. InlH expression is induced by stress stimuli and in the host. To date little is understood about their function in virulence. In order to better understand the listeriosis pathophysiology, we are investigating both InlH and InlJ mechanisms of action. Interestingly, in vivo, InlH down-regulates the IL6 level without affecting the level of neither Tnf nor IL1. Currently, we are working on understanding the role of InlH in the specific regulation of IL6 and the modulation of innate immunity. When expressed on the surface of the avirulent L. innocua InlJ has a high bacterial adherence property. However, the recombinant InlJ protein does not bind cells in vitro. To understand InlJ function, we used comparative DNA Microarray to identify the signaling cascade that InlJ may modulate during infection. Our preliminary data suggest that InlJ alters the phosphoinositide 3-kinase (PI3K) pathway in the host, by down-regulating the PTEN gene. We are also investigating the expression pattern and localization of InlJ in infected organs to decipher its local function.

Tissue-Specific Activities of SARM-ASK1-MKK3 Signaling Coordinate Immunity and Behavior to Pathogenic and Nutritional Bacteria in C. elegans.
R. P. Shivers, T. Kooistra, S. W. Chu, D. J. Pagano, D. H. Kim; Biology, MIT, Cambridge, MA

Microbes represent both an essential source of nutrition and a potential source of lethal infection to the nematode Caenorhabditis elegans. Immunity in C. elegans requires a signaling module comprised of orthologs of the mammalian Toll-Interleukin-1 Receptor (TIR) domain protein SARM, the mitogen-activated protein kinase kinase kinase (MAPKKK) ASK1, and MAPKK MKK3, which activates p38 MAPK. We determined that the SARM-ASK1-MKK3 module has dual tissue-specific roles in the C. elegans response to pathogens—in the cell autonomous regulation of innate immunity, and the neuroendocrine regulation of serotonin-dependent aversive behavior. SARM-ASK1-MKK3 signaling in the sensory nervous system also regulates egg-laying behavior that is dependent on bacteria provided as a nutrient source. Our data demonstrate that these physiological responses to bacteria share a common mechanism of signaling through the SARM-ASK1-MKK3 module and suggest the co-option of ancient immune signaling pathways in the evolution of physiological responses to microbial pathogens and nutrients.

VIP Attenuates Loss of Epithelial Barrier Function Induced by EPEC via VIP/Calmodulin Complex Formation.
V. Conlin1,2, C. Nguyen1,2, X. Wu1, A. Buchan2, K. Jacobson1,2; 1Pediatrics, UBC, Vancouver, BC, Canada, 2Cellular & Physiological Sciences, UBC, Vancouver, BC, Canada

The gastrointestinal tract is lined by a single layer of epithelial cells connected by intercellular junctions located between individual cells, the most apical of which is the tight junction. The tight junction consists of transmembrane proteins (e.g. claudins, occludin, tricellulin and JAM) and cytoplasmic plaque proteins (e.g. ZO 1-3). A healthy epithelium provides a physical barrier between luminal contents and the underlying milieu. Enteric pathogens such as Enteropathogenic E. coli (EPEC) disrupt the colonic epithelial barrier causing diarrhea and intestinal inflammatory disease. The epithelial barrier responds to stimuli from the enteric nervous system; studies have shown that vasoactive intestinal peptide (VIP) ameliorates EPEC-induced barrier disruption. In this study, colonic monolayers were treated with VIP and the mechanisms of action assessed. Transepithelial Resistance: Confluent Caco-2 monolayers were seeded onto Transwell™ filters and basally treated with VIP (10-6M), Forskolin (10-7M), SQ22536 (200μM) and TFP (10-5M) prior to infection. Resistances were monitored for 4 hours post-infection. Immunocytochemistry: Caco-2 monolayers were fixed after 4 hours and labelled with ZO-1, Claudin-3 and tricellulin. Western Blotting/Co-immunoprecipitation: Caco-2 lysates were analysed via SDS-PAGE and probed for MLCK, Calmodulin/MLCK complexes, MLC, MLC-p. EPEC infection disrupts epithelial barrier function by decreasing resistance and disrupting ZO-1, claudin-3 and tricellulin distribution. VIP treatment protects the epithelial barrier, preventing tight junction disruption and
maintaining normal barrier function. Disruption of the epithelial barrier is concomitant with increased MLCK expression (1.5-fold, n=3, p<0.01) and MLC-p phosphorylation (1.4-fold, n=3, p<0.01). Stimulation or inhibition of cAMP had no effect on barrier resistance during infection. Inhibition of calmodulin prevented MLCK-induced barrier disruption (p < 0.01, n=4). VIP/calmodulin complex formation prevents EPEC-induced increase in MLCK activity VIP protects barrier integrity during EPEC infection via a cAMP-independent pathway and prevents MLCK-induced disruption of barrier function via sequestration of calmodulin.

Membrane Protein Dynamics in Mature Phagosomes.
J. DiCiccio, S. Grinstein, W. Trimble; Program in Cell Biology, Hospital for Sick Children, Toronto, ON, Canada

Nascent phagosomes undergo successive fusion and fission events to acquire microbicidal components from endocytic compartments, a process known as maturation. Fully mature phagosomes, or phagolysosomes, have constant levels of lysosomal membrane proteins, and their size appears constant. These observations suggest that phagolysosomes are static compartments. On the other hand, fluid phase markers added to cells after maturation is complete gain access to phagolysosomes, indicating continuous influx of endocytic material. Steady-state maintenance of phagolysosomal size and composition must therefore involve continuous removal of membranous and soluble material. We used fluorescence recovery after photobleaching (FRAP) and photoactivatable GFP (PA-GFP) to study the kinetics of lysosome-associated membrane protein 1 (LAMP-1), a protein characteristic to late endosomes/lysosomes that is acquired by phagosomes following fusion with lysosomes. We have found that LAMP-1 continually enters and exits the mature phagolysosome, suggesting that this compartment is not static but is instead in a dynamic steady state. We are currently investigating the mechanistic details of this process.

Infection and Translocation of Bacillus anthracis across Lung Epithelium.
C. Gu, B. H. Russell, Y. Xu; Texas A&M Health Science Center, Institute of Biosciences and Technology, Houston, TX

Inhalational anthrax is initiated by the entry of Bacillus anthracis spores into the lung. A critical early event to establish the infection is the dissemination of bacteria from the lung. Our In Vitro and In Vivo data suggested that B. anthracis could directly cross the lung epithelium. We found that B. anthracis could adhere to and be internalized by cultured lung epithelial cells. Using a mouse model, we presented evidence that B. anthracis spores were taken up by lung epithelial cells In Vivo soon after spores were delivered into the lung. In transwell assays, B. anthracis were able to translocate across an A549 cell barrier without disruption of the barrier integrity, suggesting a transcellular migration route. To further understand how B. anthracis passages through lung epithelial cells, we further analyzed the intracellular trafficking and fate of internalized spores in lung epithelial cells. Internalized spores were able to survive and persist within lung epithelial cells. In contrast, germinated spores and vegetative bacilli preferentially exited the cells in a process that did not involve cell lysis, suggesting a bifurcation of fate for dormant spores and vegetative bacilli in lung epithelial cells. Investigations to understand the mechanisms underlying the trafficking pathway of spores and vegetative bacilli are currently underway.
